3.4.2. Command-Guided Missiles. A command guided missile is a remotely controlled missile. A cooperating (ground-, ship-, or aircraft-based) control station uses a radar (or two) to acquire the target, track the target, and track the missile. Available computers are used to compute guidance commands (on the basis of ranges, elevations, and bearings) that are transmitted via radio uplink to the missile autopilot. Powerful computers, capable of exploiting complex target models and performance criteria, can provide precision guidance updates in real time. Such systems are limited by the distance from the tracking station to the missile and target. Noise increases, and guidance degrades, as the engagement moves further from the tracking station. Such systems are also more susceptible to electronic countermeasures (ECMs). While command-guided missiles do not require a seeker, one can be included for terminal guidance to maximize the probability of interception at long distances from the tracking station. The Patriot is a command-guided SAM. To significantly increase ECM immunity, some short-range command guided missiles have a wire that unspools at launch, keeping the missile connected to the command station, e.g., the all-weather optically guided antitank Tow missile.

3.4.3. Beam Rider Guidance (BRG). BRG is a specific form of command guidance in which the missile flies along a beam (e.g., radar or laser), which, in principle, points continuously toward the target. If the missile stays within the beam, an intercept will occur. Guidance commands steer the missile back into the beam when it deviates.

BRG causes problems at large ranges because of beam spreading issues.

3.4.4. Command-to-LOS Guidance. Command-to-LOS guidance—used by the Tow missile—is another command guidance method that improves on beam rider guidance by taking beam motion into account.

3.4.5. Energy-Guided Missiles. Radar-guided missiles are guided to the target on the basis of radar energy. Laser-guided missiles are guided on the basis of laser energy. The Hellfire is a laser-guided antitank missile. Heat-seeking missiles are guided on the basis of infrared (IR, heat, or thermal) energy. The AIM-9 Sidewinder is a heat-seeking AAM. Most AAMs employ radar homing or heat-seeking devices and have replaced automatic gunfire as the main armament for fighter aircraft. The shoulder-operated Stinger is a heat-guided fire-and-forget SAM. Such a missile is called a “fire-and-forget missile” because it allows the user to fire, take evasive action, forget, and engage other hostile targets.

3.4.6. Degradation of Electromagnetic Energy-Based Sensors. The performance of many electromagnetic energy-based sensors (e.g., millimeter-wave radars, electrooptical thermal imagers, and laser radar) degrades under adverse weather conditions such as rain, fog, dust, or smoke. This occurs when the size of the weather particles are on the same order as the wavelength of the energy return from the target. Under adverse conditions, microwave radars with wavelengths in centimeters (10 GHz) are not degraded, millimeter radars with millimeter wavelengths (100 GHz) are slightly degraded, and electrooptical systems with micrometer wavelengths (10^5 GHz) are severely degraded. The AIM-120A AMRAAM is a fighter-launched fire-and-forget AAM that uses infrared (IR) sensors to acquire (detect) targets at long range. It uses inertial mid-course guidance without the need for the fighter to illuminate the target. A small active seeker is used for endgame homing.

3.4.7. LOS Guidance. When a missile is near the target, the guidance system may use line-of-sight (LOS) guidance. The guidance system of a LOS guided missile uses target range and LOS information obtained from the target sensor (e.g., a seeker) to generate guidance commands to the missile autopilot.

3.4.8. Radar Terrain Guidance. A radar terrain guided missile uses a radar altimeter, an a priori stored path and terrain profile to navigate and guide the missile over the terrain during the midcourse phase of a flight (typically). The stored path represents a desired path over the terrain. The down-looking radar altimeter is used to measure the altitude with respect to the terrain below. This is used to determine where the missile is with respect to the desired path. Deviations from the path are corrected by adjusting guidance commands to the autopilot. The Tomahawk is an all-weather cruise missile

that uses radar terrain guidance called *terrain contour matching* (TERCOM) [9]. TERCOM terrain profiles—obtained by reconnaissance satellites and other intelligence sources—become finer as the missile approaches the target. Such navigational/guidance systems permit terrain hugging. Terrain echoes (referred to as clutter) then confuse observing radars.

3.4.9. TV Guidance. TV guided missiles use imaging systems that permit a WSO to see the target and remotely guide the missile to the target.

3.4.10. Cruise Missiles. Cruise missiles are typically SSMs that use inertial and terrain following navigation/guidance systems while cruising toward the target. When near the target, endgame guidance is accomplished by either (1) homing in on target emitted/reflected energy, (2) focusing on a target feature by exploiting a forward-looking imaging system and an onboard stored image, or (3) using a more detailed terrain contour with a more accurate downward-looking sensor. Cruise missiles offer the ability to destroy heavily defended targets without risking air crew. Because they are small, they are difficult to detect on radar, particularly when they hug the terrain. Examples of cruise missiles are the AGM-86, Tomahawk [9], and Harpoon. The Tomahawk uses a TERCOM guidance during the cruise phase. For terminal guidance, a conventionally armed Tomahawk uses an electrooptical digital scene matching area correlator (DSMAC) guidance system, which compares measured images with stored images. This technique is often referred to as an *offset navigation or guidance technique*. At no time during the terminal scene matching process does the missile look at the target. Its sensor always looks down. DSMAC makes Tomahawk one of the most accurate weapon systems in service around the world.

3.4.11. Skid-to-Turn and Bank-to-Turn Missiles. Skid-to-turn (STT) missiles, like speedboats, skid to turn. Bank-to-turn (BTT) missiles, like airplanes, bank to turn [5,10–16]. BTT airframe designs offer higher maneuverability than conventional STT designs by use of an asymmetric shape and/or the addition of a wing. BTT missile autopilots are more difficult to design than STT autopilots because of cross-coupling issues. STT missiles achieve velocity vector control by permitting the missile to develop angle-of-attack and side-slip angles [5]. The presence of side-slip imparts a skidding motion to the missile. BTT missiles ideally should have no side-slip. To achieve the desired orientation, a BTT missile is rolled (banked) so that the plane of maximum aerodynamic normal force is oriented to the desired direction. The magnitude of the force is controlled by adjusting the attitude (i.e., angle of attack) in that plane. BTT missile control is made more difficult by the high roll rates required for high performance (i.e., short response time) [4, p. 285]. STT missiles typically require pitch-yaw acceleration guidance commands, whereas BTT missiles require pitch-roll acceleration commands. An overview of tactical missile control design issues and approaches is provided in Ref. 44.

4. GUIDANCE ALGORITHMS

In practice, many guidance algorithms are used [4,8,17–19]. The purpose of a guidance algorithm is to update missile guidance commands that will be issued to the autopilot. This update is to be performed on the basis of missile and target information. The goal of any guidance algorithm is to steer the missile toward the target, resulting in an intercept within an allotted time period (i.e., until the fuel runs out or the target is out of range). The most common algorithms are characterized by the following terms: proportional navigation, augmented proportional navigation, and optimal [8,19]. To simplify the mathematical details of the exposition to follow, suppose that the missile–target engagement is restricted to the two-dimensional pitch plane of the missile. Given this, the engagement dynamics take the following simplified form [20]

$$\dot{R}(t) = V_t \cos(\lambda(t) - \gamma_t(t)) - V_m \cos(\lambda(t) - \gamma_m(t)) \quad (1)$$

$$\dot{\lambda}(t) = \frac{1}{R(t)} [-V_t \sin(\lambda(t) - \gamma_t(t)) + V_m \sin(\lambda(t) - \gamma_m(t))] \quad (2)$$

where (V_m, V_t) , (γ_m, γ_t) denote missile–target speeds (assumed constant) and flight path angles.

4.1. Proportional Navigation Guidance (PNG)

For proportional navigation guidance (PNG) [8,19], the missile is commanded to turn at a rate proportional to the closing velocity V_c (i.e., range rate) and to the angular velocity of the LoS $\dot{\lambda}$. The constant of proportionality N is referred to as the *PNG gain or constant*. For a PNG law, the pitch plane acceleration command $a_{c,\text{PNG}}(t)$ takes the form

$$a_{c,\text{PNG}}(t) = NV_c(t)\dot{\lambda}(t) \quad (3)$$

Typically, N takes on values in the range [3,5].

PNG is relatively easy to implement. For tactical radar homing missiles using PNG, an active seeker provides LOS rate while a Doppler radar provides closing velocity. Traditionally, LOS rate has been obtained by filtering the output of a 2-degree-of-freedom rate gyro mounted to the inner gimbal of the seeker [21]. More recently, ring laser gyros (RLGs) have been used. Unlike conventional spinning gyros, the RLG has no moving parts, no friction, and hence negligible drift. For IR missiles using PNG, the IR system provides LOS rate information, but V_c must be estimated. The Lark was the first missile to use PNG [8].

4.1.1. PNG Optimality and Performance Issues. It can be shown that PNG minimizes the square integral criterion $\int_0^{t_f} a_c^2(\tau) d\tau$ subject to a zero-miss distance at t_f , linearized (small angle) missile–target dynamics, and constant missile–target speeds [22], where t_f denotes the flight time. A missile using PNG is fired not at the target, but at the expected intercept point if the target were to move at constant velocity in a straight line; thus, the missile is fired so that, at least initially, it is on a collision triangle with the

target. The initial angle between the missile velocity vector and the LOS is the missile lead angle. If the missile is not on a collision triangle with the target, then there exists a heading error (HE). It is instructive to understand how PNG missile acceleration requirements vary with (1) initial heading error when the target is not maneuvering, and (2) a constant acceleration target maneuver. These cases are now briefly discussed assuming linearized (small-angle) 2D dynamics with constant missile and target speeds (V_m, V_t), missile autopilot responds instantaneously to guidance acceleration commands (i.e., no lag), and ideal sensor dynamics [8]. We note that the Stinger is an example of a fire-and-forget supersonic SAM that uses PNG with passive IR/UV homing.

4.1.2. PNG Performance: Nonmaneuvering Target, Heading Error. First, consider the impact of a heading error on PNG missile acceleration requirements when the target moves at a constant speed in a straight line. Under the simplifying assumptions given above, the resulting commanded acceleration is as follows:

$$a_{c,PNG}(t) = \frac{-V_m N \text{HE}}{t_f} \left[1 - \frac{t}{t_f} \right]^{N-2} \quad (4)$$

This expression shows that PNG immediately begins removing any heading error (HE) and continues doing so throughout the engagement. The acceleration requirement decreases monotonically to zero as the flight progresses. A larger N results in a larger initial missile acceleration requirement, but a lesser final missile acceleration requirement. The larger the N , the faster the heading error is removed.

4.1.3. PNG Performance: Target Undergoing Constant Acceleration. Now, consider the impact of a constant target acceleration a_t on PNG missile acceleration requirements. Under the simplifying assumptions given above, the resulting commanded acceleration is as follows:

$$a_{c,PNG}(t) = \frac{N}{N-2} \left[1 - \left(1 - \frac{t}{t_f} \right)^{N-2} \right] a_t \quad (5)$$

In sharp contrast to the heading error case examined above, this expression shows that the PNG missile acceleration requirement for a constant target maneuver increases monotonically throughout the flight. As in the heading error case, a higher N results in a greater initial acceleration requirement and a relaxed acceleration requirement near the end of the flight [$a_{c,PNG,max} = a_{c,PNG}(t_f) = (N/(N-2))a_t \leq a_t$].

4.1.4. Zero-Effort Miss (ZEM) Distance. An important concept in guidance law design is that of zero-effort miss distance, denoted $ZEM(t)$ and defined as the miss distance that would result if the target would continue at a constant speed in a straight line and the missile made no further corrective maneuvers. Given this, if one defines the time to go as $t_{go} \stackrel{\text{def}}{=} t_f - t$ and the ZEM distance perpendicular to the LOS as $ZEM_{PLOS}(t)$, then for PNG it can

be shown that

$$a_{c,PNG}(t) = N \left(\frac{ZEM_{PLOS}(t)}{t_{go}^2} \right) \quad (6)$$

where $ZEM_{PLOS}(t) = y + \dot{y}t_{go}$, $y \approx R\lambda$ denotes the relative (small angle) vertical displacement between the missile and target, and $R \approx V_c t_{go}$. The concept of ZEM distance is used to derive more advanced guidance laws [8]. The concept is very powerful since ZEM can be approximated in so many different ways.

4.1.5. PNG Miss Distance Performance: Impact of System Dynamics. For the two cases considered above, the associated relative displacement $y \approx R\lambda$ satisfies

$$\ddot{y} + \frac{N}{t_f - t} \dot{y} + \frac{N}{(t_f - t)^2} y = a_t, \quad y(t_f) = 0$$

and we have zero-miss distance. The preceding discussion on PNG assumes that guidance-control-seeker dynamics are negligible. In practice, this assumption is not satisfied and the inherent lag degrades miss distance performance. When a first order lag with time constant τ is assumed for the combined guidance-control-seeker dynamics, one obtains small miss distances so long as τ is much smaller than t_f (e.g., $t_f > 10\tau$). In practice, of course, high-frequency dynamics impose bandwidth constraints that limit how small τ can be. Despite the above (general) rule of thumb, it is essential that high-frequency system dynamics be carefully modeled or analyzed to obtain reliable performance predictions. Such dynamics include those associated with: control system, computational delays, A/D and D/A conversion, actuators (e.g., thrusters, canards, tailfins), missile structure (e.g., flexible modes), guidance system (e.g., lead-lag compensation), and sensors (e.g., seeker radome, accelerometers, gyros). As one might expect, noise and parasitic effects place a practical upper bound on the achievable guidance system bandwidth. In practice, statistical Monte Carlo simulations (exploiting adjoint methods [8]) are used to evaluate performance prior to flight testing. Such simulations consider the above as well as acceleration/control saturation effects [14,15], typical target maneuvers, and worst-case target maneuvers.

4.1.6. TPNG and PPNG. Shukla and Mahapatra [23] distinguish between true PNG (TPNG) and pure PNG (PPNG). For missile's using TPNG, acceleration commands are issued perpendicular to the LOS (as above). For PPNG, acceleration commands are issued perpendicular to the missile velocity vector. The advantages of PPNG over traditional TPNG are highlighted [23]. In contrast to PPNG, TPNG requires (1) a forward acceleration and deceleration capability (because acceleration command is perpendicular to LOS; not missile velocity), (2) unnecessarily large acceleration requirements, and (3) restrictions on the initial conditions to ensure intercept.

4.2. Tactical Missile Maneuverability

Tactical radar guided missiles use a seeker with a radome. The radome causes a refraction or bending of the incoming radar wave, which in turn, gives a false indication of target location. This phenomenon can cause problems if the missile is highly maneuverable. One parameter that measures maneuverability is the so-called missile (pitch) turning rate frequency (or bandwidth) defined by [2]

$$\omega_x \stackrel{\text{def}}{=} \frac{\dot{\gamma}}{\alpha} \quad (7)$$

where $\dot{\gamma}$ denotes the time rate of change of flight path angle and α denotes angle of attack (AOA). ω_x measures the rate at which the missile rotates (changes flight path) by an equivalent AOA. Assuming that the missile is modeled as a “flying cylinder” [8] with length L and diameter D , it has a lift coefficient

$$C_L = 2\alpha[1 + 0.75(S_{\text{plan}}/S_{\text{ref}})\alpha] \quad (8)$$

where $S_{\text{plan}} \approx LD$, $S_{\text{ref}} = \pi D^2/4$. Noting that $a_m = V_m \dot{\gamma}$ is the missile acceleration, $Q = \frac{1}{2}\rho V_m^2$ the dynamic pressure, $W = mg$ the missile weight, and ρ the density of air, it follows that

$$\omega_x \stackrel{\text{def}}{=} \frac{\dot{\gamma}}{\alpha} = \frac{a_m}{V_m} = \frac{gQS_{\text{ref}}C_L}{W\alpha V_m} = \frac{\rho g V_m S_{\text{ref}} \left[1 + 0.75 \frac{S_{\text{plan}}}{S_{\text{ref}}} \alpha \right]}{W} \quad (9)$$

From this, it follows that ω_x decreases with increasing missile altitude and with decreasing missile speed, i.e., when aerodynamic effectiveness is low.

4.3. Radome Effects: Homing–Robustness Tradeoffs

Let ω denote the guidance–control–seeker bandwidth. If ω is too small, homing is poor and large miss distances result. Typically, we desire $\omega_x < \omega$ so that the closed-loop system “accommodates” the capabilities of the missile. As expected, problems can occur if ω is too large. This, in part, is because of radome–aerodynamic feedback of the missile acceleration a_m into $\dot{\lambda}$. Assuming n -pole dynamics, it can be shown that the missile acceleration a_m takes the form

$$\begin{aligned} a_m &= FG[\dot{\lambda} - R\dot{\theta}] \\ &= FG[\dot{\lambda} - RAa_m] \\ &= [FG/(1 + FGRA)]\dot{\lambda}, \end{aligned} \quad (10)$$

where $G = NV_c$ represents the guidance system, $F = [\omega/(s + \omega)]^n$ represents the flight control system, R is the radome slope (can be positive or negative), and $A = (s + \omega_x)/(\omega_x V_m)$ denotes the missile transfer function from a_m to pitch rate $\dot{\theta}$. For stability robustness, we require the

associated open-loop transfer function

$$L \stackrel{\text{def}}{=} FGRA = NV_c \left(\frac{\omega}{s + \omega} \right)^n R \left(\frac{s + \omega_x}{\omega_x V_m} \right)$$

to satisfy an attenuation specification such as $|L(j\omega)| = NV_c |R| [\omega/\omega_x V_m] < \varepsilon$ for some sufficiently small constant $\varepsilon > 0$. This, however, requires

$$\omega < \varepsilon \left(\frac{V_m}{|R|NV_c} \right) \omega_x \quad (11)$$

for stability robustness. This implies that the bandwidth ω must be small when V_m is small, ($|R|$, N , V_c) are large, or ω_x is small (high altitude and low missile speed). In general, therefore, designers must tradeoff homing performance (bandwidth) and stability robustness properties. Missiles using thrust vectoring (e.g., exoatmospheric missiles) experience similar performance–stability robustness tradeoffs.

4.4. Augmented Proportional Guidance (APNG)

Advanced guidance laws reduce acceleration requirements and miss distance but require more information (time to go, missile–target range, etc.) [18]. In an attempt to take into account a constant target acceleration maneuver a_t , guidance engineers developed augmented proportional guidance (APNG). For APNG, the commanded acceleration is given by

$$a_{c,\text{APNG}}(t) = NV_c \dot{\lambda}(t) + \frac{1}{2} Na_t = a_{c,\text{PNG}}(t) + \frac{1}{2} Na_t \quad (12)$$

or $a_{c,\text{APNG}}(t) = N(ZEM/t_{\text{go}}^2)$, where $ZEM = y + \dot{y}t_{\text{go}} + \frac{1}{2}a_t t_{\text{go}}^2$ is the associated zero-effort miss distance. Equation (10) shows that APNG is essentially PNG with an extra term to account for the maneuvering target. For this guidance law, it can be shown (under the simplifying assumptions given earlier) that

$$a_{c,\text{APNG}}(t) = \frac{1}{2} N \left[1 - \frac{t}{t_f} \right]^{N-2} a_t \quad (13)$$

In contrast with PNG, this expression shows that the resulting APNG acceleration requirements decrease rather than increase with time. From the expression, it follows that increasing N increases the initial acceleration requirement but also reduces the time required for the acceleration requirements to decrease to negligible levels. For $N = 4$, the maximum acceleration requirement for APNG, $a_{c,\text{APNG,max}} = \frac{1}{2} Na_t$, is equal to that for PNG, $a_{c,\text{PNG,max}} = [N/(N - 2)]a_t$. For large $N = 5$, APNG requires a larger maximum acceleration but less acceleration than PNG for $t \geq 0.2632t_f$. Therefore, APNG is more fuel-efficient for exoatmospheric applications than PNG. Finally, it should be noted that APNG minimizes $\int_0^{t_f} a_c^2(\tau) d\tau$ subject to zero-miss distance, linear dynamics, and constant target acceleration [8].

4.5. PNG Command Guidance Implementation

To implement PNG in a command guidance setting (i.e., no seeker), a differentiating filter must be used to estimate the LOS rate. As a result, command guidance is more susceptible to noise than homing guidance. This issue is exacerbated as the engagement takes place further from the tracking station, noise increases, and guidance degrades. Within [24], the authors address command guided SAMs by spreading the acceleration requirements over t_{go} . The method requires estimates for target position, velocity, acceleration, and t_{go} , but takes into account nonlinear engagement geometry.

4.6. Advanced Guidance Algorithms

Classical PNG and APNG were initially based on intuition. Modern or advanced guidance algorithms exploit optimal control theory: optimizing a performance measure subject to dynamic constraints. Even simple optimal control formulations of a missile–target engagement (e.g., quadratic acceleration measures) lead to a nonlinear two-point boundary value problem requiring creative solution techniques, such as, approximate solutions to the associated Hamilton–Jacobi–Bellman equation—a formidable nonlinear partial-differential equation [22]. Such a formulation remains somewhat intractable given today’s computing power—even for command guidance implementations that can exploit powerful remotely situated computers. Given this, researchers have sought alternative approaches to design advanced (near-optimal) guidance laws. Within [19], Nesline and Zarchan present a PNG-like control law that optimizes square-integral acceleration subject to zero-miss distance in the presence of a one-pole guidance–control–seeker system.

Even for advanced guidance algorithms (e.g., optimal guidance methods), the effects of guidance and control system parasitics must be carefully evaluated to ensure nominal performance and robustness [19]. Advanced (optimal) guidance methods typically require additional information such as time-to-go, target acceleration, and target model parameters (e.g., ballistic coefficient). Given this, Kalman filter and extended Kalman filter (EKF) techniques are often used to estimate the required information. For optimal guidance (OG) algorithms to work well, the estimates must be reliable [19]. Cloutier et al. [17] give an overview of guidance and control techniques, including a comprehensive set of references. Other approaches to guidance law design are discussed below.

4.7. Variants of PNG

Nesline and Zarchan [19] compare PNG, APNG, and optimal guidance (OG). The zero-miss distance (stability) properties of PPNG are discussed by Oh [25]. A nonlinear PPNG formulation for maneuvering targets is provided by Yang and Yang [26]. Closed-form expressions for PPNG are presented by Becker [27]. A more complex version of PNG that is “quasi-optimal” for large maneuvers (but requires t_{go} estimates) is discussed by Axelband and Hardy [28]. Park and Kabamba [20] conducted 2D miss distance analysis [20] for a guidance law that combines PNG and

pursuit guidance. White et al. extend PNG by using an outer LOS rate loop to control the terminal geometry of the engagement (e.g. approach angle) [29]. Generalized PNG, in which acceleration commands are issued normal to the LOS with a bias angle, is addressed by Yuan and Hsu [30]. Yang and Yang address 3D generalized PNG [31] using a spherical coordinate system fixed to the missile to better accommodate the spherical nature of seeker measurements. Analytical solutions are presented without linearization. Yang et al. present generalized guidance schemes [32] that result in missile acceleration commands rotating the missile perpendicular to a chosen (generalized) direction. When this direction is appropriately selected, standard laws result. Time–energy performance criteria are also examined. Capturability issues for variants of PNG are addressed in Ref. 33 and the references cited therein. Yang and Yang [34] present a 2D framework showing that many developed guidance laws are special cases of a general law. The 3D case, utilizing polar coordinates, is considered by Tyan [35].

4.8. Optimal Guidance (OG) Laws

Kalman filtering techniques are often combined with OG laws. Such is the case when weaving targets are under consideration. Weaving targets can cause large miss distances when classical and “standard” OG laws are used. Tactical ballistic missiles, for example, can spiral or weave into resonances as they enter the atmosphere as a result of mass or configurational asymmetries. An OG law, based on weaving (variable amplitude) sinusoidal target maneuvers, is developed by Aggarwal [36]. An EKF is used to estimate the target maneuver weave frequency. Methods for intercepting spiraling weaving tactical ballistic targets are also presented in [37]. This includes an optimal weave guidance law incorporating an EKF to estimate relative position, relative velocity, target acceleration, target jerk information, and weave frequency information.

4.9. Differential Game Guidance

Differential game-theoretic concepts have been addressed [22]. In such formulations, a disturbance (e.g., target maneuver) “competes” with a control (e.g., missile acceleration command). The disturbance attempts to maximize a performance index (e.g., miss distance) while the control attempts to minimize the index. Shima and Golan [38] provide an analytical study using a zero-sum pursuit–evade differential game formulation to develop endgame guidance laws assuming that the interceptor has two controls. Linear biproper transfer functions are used to represent the missile’s control systems—a minimum phase transfer function for the canard system and a non-minimum-phase (NMP) transfer function for the tail control system. A first-order strictly proper transfer function is used for the target dynamics. Bounds are assumed for each of the abovementioned transfer function inputs (i.e., reference commands). The optimal strategy is bang-bang in portions of the game space. A switching time exists prior to interception because of the NMP nature of the tail control system. This feature requires good estimates of t_{go} . \mathcal{H}^∞ theory [7] provides a natural differential

game-theoretic framework for developing guidance laws as well as control laws.

4.10. Lyapunov-Based and Other Guidance Laws

Lyapunov methods have been very useful for deriving stabilizing control laws for nonlinear systems [39]. Such methods have been used to obtain guidance laws that require target aspect angle (relative to LOS) rather than LOS rate [40] and that address maneuvering targets in 3D [41]. A new guidance law—referred to as *circular navigation guidance* (CNG)—steers the missile along a circular arc toward the target [42]. Traditionally, the guidance and control systems are designed separately. While this approach has worked well for years, increasing performance requirements affirm the value of an integrated guidance and control system design methodology. Integrated guidance and control issues have been addressed within a polar coordinate framework [43]. New advanced guidance laws may benefit from linear parameter varying (LPV) [44] and state-dependent Riccati equation (SDRE) [45] concepts.

4.11. Nonlinear State Estimation: Extended Kalman Filter

As discussed earlier, OG laws often require missile–target model state/parameter estimates, such as relative position, velocity of target, and acceleration of target t_{go} . An extended Kalman filter (EKF) is often used to obtain the required estimates. This involves using quasilinearized dynamics to solve the associated matrix Riccati differential equation for a covariance matrix that is used with a model based estimator—mimicking the original nonlinear dynamics—to generate quasioptimal estimates. It is well known that poor estimates for t_{go} , for example, can result in large miss distances and significant capture region reduction [19]. Estimating t_{go} as R/V_c is valid only if V_c is nearly constant. A recursive (noniterative) algorithm for t_{go} estimates, which can be used with OG laws, is provided by Tahk et al. [46].

To develop useful estimation techniques, much attention has been placed on modeling the target. Initially, researchers used simple uncorrelated target acceleration models that yielded misleading results. This led to the use of simple dynamical models—point mass and more complex. Both Cartesian and spherical coordinate formulations have been investigated [47]; the latter better reflect the radial nature of an engagement. Single- and multiple-modeled EKFs have been used [48] to address the fact that no single model captures the dynamics that may arise. Low-observability LOS measurements make the problem particularly challenging [48]. Target observability is explored [49] under PNG and noise-free angle-only measurements in 2D. Williams and Friedland present a method for obtaining required estimates for APNG (e.g. y, \dot{y}, a_t, t_{go}) [50]. Since no single (tractable) model and statistics can be used to accurately capture the large set of possible maneuvers by today's modern tactical fighters, adaptive filtering techniques have been employed. Such filters attempt to adjust the filter bandwidth to reflect the target maneuver. Some researchers have used classical Neyman–Pearson hypothesis testing to detect bias in the

innovations to appropriately reinitialize the filter. Threshold levels must be judiciously selected to avoid false detections that result in switching to an inappropriate estimator.

4.12. Long-Range Exoatmospheric Missions: Weight Considerations

For long-range exoatmospheric missions approaching intercontinental ranges, orbital speeds are required (e.g., $\sim 20,000$ ft/s or 13,600 mi/h or 4 mi/s). To study such interceptors, two new concepts are essential. Fuel-specific impulse, denoted I_{sp} , is defined as the ratio of thrust to the time rate of change of total missile weight. It corresponds to the time required to generate a weight equivalent amount of thrust. Fuel-efficient missiles have higher fuel-specific impulses. Typical tactical missile fuel-specific impulses lie in the range of 200–300 s. Fuel mass fraction, denoted mf, is defined as the ratio of propellant weight W_{prop} to total weight $W_T = W_{prop} + W_{structure} + W_{payload}$. SAMs, for example, have a larger fuel mass fraction than do AAMs because SAMs must travel through the denser air at lower altitudes. For fuel-specific impulses less than 300 s, large fuel mass fractions (approaching 0.9) are required for exoatmospheric applications. A consequence of this is that it takes considerable total booster weight to propel even small payloads to near-orbital speeds. More precisely, it can be shown [8, pp. 265–267] that the weight of the propellant required for a single-stage booster to impart a speed change ΔV to a payload weighing $W_{payload}$ is given by

$$W_{prop} = W_{payload} \overline{\text{mf}} \left[\frac{\exp\left(\frac{\Delta V}{g I_{sp}}\right) - 1}{1 - (1 - \overline{\text{mf}}) \exp\left(\frac{\Delta V}{g I_{sp}}\right)} \right] \quad (14)$$

where g denotes the acceleration due to gravity near Earth's surface and $\overline{\text{mf}} \stackrel{\text{def}}{=} W_{prop}/(W_{prop} + W_{structure})$ denotes an (approximate) fuel mass fraction that neglects the weight of the payload $W_{payload}$. Staging can be used to reduce total booster weight for a given fuel-specific impulse I_{sp} and (approximate) fuel mass fraction mf. Efficient propellant expenditure for exoatmospheric intercepts has been addressed [51]. 3D midcourse guidance for SAMs intercepting nonmaneuvering high-altitude ballistic targets has also been addressed [52]. Neural networks are used to approximate (store) optimal vertical guidance commands and estimate t_{go} . Feedback linearization [39] is used for lateral guidance commands.

4.13. Acceleration Limitations

Endoatmospheric missile acceleration is limited by altitude, speed, structural, stall AOAAOA, and drag constraints—stall AOA at high altitudes and structural limitations at low altitudes [see Eq. (8)]. Exoatmospheric interceptor acceleration is limited by thrust-to-weight ratios and flight time; the latter is due to the fact that when the fuel is exhausted, exoatmospheric missiles cannot maneuver.

4.14. THAAD Systems

More recent research efforts have focused on the development of THAAD systems. Calculations show that high-altitude ballistic intercepts are best made head-on so that there is little target deceleration perpendicular to the LOS [8]. This is because such decelerations appears as a target maneuver to the interceptor. EKF methods have been suggested for estimating target ballistic coefficients and state information to be used in OG laws. Estimating ballistic coefficients

$$\beta \stackrel{\text{def}}{=} (W/S_{\text{ref}} C_{D,0}), \quad (15)$$

where $C_{D,0}$ is the zero-lift drag coefficient] is particularly difficult at high altitudes where there is little drag ($\alpha_{\text{drag}} = (1/2\beta)\rho g V_m^2$). Also, the high closing velocity of a ballistic target engagement significantly decreases the maximum permitted guidance system bandwidth for radome slope stability. Noise issues significantly exacerbate the ballistic intercept problem.

5. FUTURE DEVELOPMENTS

Future developments will focus on theater-class ballistic missiles, guided projectiles, miniature kill vehicles, space-based sensors for missile defense, and boost-phase interceptors. The future of missile guidance depends to a large extent on the ongoing reinterpretation of the ABM treaty between the United States and the former Soviet Union. After September 11, 2001, work was initiated on the development of mininukes for underground bunkers. The need for guided missiles that permit precision strikes with minimal collateral damage was also reaffirmed.

MIXED-SIGNAL CMOS RF INTEGRATED CIRCUITS

1. INTRODUCTION

The world of wireless communication and its applications have begun to grow rapidly. The driving force behind this lies in the introduction of digital coding and digital signal processing in wireless communications. This digital revolution is driven by the development of high-performance, low-cost CMOS technologies that allow for the integration of an enormous amount of digital functions on a single die. As CMOS is mainly a digital technology, placing all digital functions on a single die is merely a matter of handling the system complexity. To achieve a truly single-chip solution, the analog part also has to be integrated in CMOS.

The telecommunication market is generally considered to be a business where a single-chip solution in a cheap (CMOS) technology results in a huge cost benefit; the main reason is the high volume of user equipment. Furthermore, in these systems, small size, low board area, low power consumption, and high talktime are crucial, and therefore it is of utmost importance to achieve a high level of integration. This trend toward single-chip, fully integrated systems can clearly be seen in the development of RF systems such as GSM, EDGE, Bluetooth, and wireless LAN. In all these systems, the analog part mainly consists of an RF front end.

Deep submicrometer technologies allow for the operation frequency of CMOS circuits above 1 GHz, which opens the way to fully integrated RF systems. Several research groups have developed high-performance downconverters,

low-phase-noise voltage-controlled oscillators, and dual-modulus prescalers in standard CMOS technologies. The research has already demonstrated fully integrated receivers and synthesizers with no external components, nor tuning or trimming. Further research on low-noise amplifiers, power amplifiers, and synthesizers has resulted in fully integrated CMOS RF transceivers for DCS1800, Bluetooth, and wireless LAN [1–3].

In this article, we will focus on the evolution from the well-known heterodyne receiver topology to the zero- and low-IF topology used in modern receivers. We will also discuss the interaction between the analog part and the digital part regarding substrate noise and decoupling.

2. TECHNOLOGICAL ASPECTS OF MIXED-SIGNAL DESIGN

2.1. Deep Submicrometer MOS Transistors

Because of the never-ending progress in technology down-scaling and the requirement to achieve a higher degree of integration for DSP circuits, deep submicrometer technologies are now considered as standard CMOS technologies. Transistors with f_T values near 100 GHz have been demonstrated in 0.1- μm technologies [4,5]. However, the speed increase of deep submicrometer technologies is reduced by the parasitic capacitance of the transistor, meaning the gate–drain overlap capacitance and the drain–bulk junction capacitance. This can clearly be seen in Fig. 1 in the comparison for different technologies between f_T and the $f_{3\text{dB}}$, the latter is defined as the 3 dB point of a diode connected transistor [6]. The $f_{3\text{dB}}$ is more important for analog design because it reflects the speed limitation of a transistor in a practical configuration, namely, a simple two-stage common-source amplifier. As can be seen in Fig. 1, the f_T rapidly increases, but for real circuit designs ($f_{3\text{dB}}$) the speed improvement is only moderate.

2.2. Integration of Passive Components

In integrated CMOS RF circuits [7,8] it becomes clear that the transistor will not be the limiting factor but rather the passive components and packaging will be. Since the RF signals have to come off the chip sooner or later, and since the RF antenna signal has to get into the chip, any

Figure 1. Comparison between f_T and $f_{3\text{dB}}$.

parasitic PCB, packaging, or bondwire in combination with the ESD (electrostatic discharge) protection network and packaging pin capacitances will strongly affect and degrade the RF signal. Another important aspect in mixed-signal design is the quality factor of the passive elements. High-quality metal–insulator–metal capacitors and low-resistance top-metal layers for inductors are process options that add to the total mask count, and a high amount of passive elements will increase the total die area. An alternative is to separate the processing of the active devices from the processing of the passive components. An example is given in Ref. 9, where a low-cost passive integration and packaging technology is combined with a high-performance CMOS technology. These solutions are feasible as long as the parasitics due to the interconnection of the two dies are small.

3. ARCHITECTURAL ASPECTS

In mixed-signal design, the aim is to integrate both the digital and the analog parts on one single die. However, many analog front-end architectures are not well suited for integration. Therefore, new architectures have been (re)invented that allow a fully integrated solution. The heterodyne receiver, for example, is the best-known and most frequently used receiver topology. In this receiver the desired signal is downconverted to a relatively high intermediate frequency. Very high performances can be achieved with the heterodyne topology. However, the main problem is the poor degree of integration that can be achieved as every stage requires going off chip and requires the use of a discrete bandpass filter.

The zero-IF receiver (see Fig. 2) has been introduced as an alternative that can achieve a much higher degree of integration because this topology uses a direct quadrature downconversion of the desired signal. Theoretically, no discrete high-frequency bandpass filter is required, allowing for the realization of a fully integrated receiver [10]. However the zero-IF receiver is intrinsically very sensitive to parasitic baseband signals such as DC-offset voltages and self-mixing. These drawbacks have kept the zero-IF receiver from being used on large scale in new wireless applications. It has, however, been shown that with the use of dynamic nonlinear correction algorithms,

Figure 2. Zero-IF receiver principle.

Figure 3. Low-IF receiver principle.

implemented in the DSP, the zero-IF topology can be used for high-performance applications such as GSM and DECT [11,12]. In such a system, the performance of the analog architecture is improved by the use of digital algorithms, which clearly demonstrates another benefit of a single-chip mixed-signal approach.

New receiver topologies such as the low-IF receiver [3,13,28] have been introduced. The low-IF receiver performs a downconversion from the antenna frequency directly to—as the term already indicates—a low IF (i.e., in the range of a few 100 kHz; see Fig. 3). Downconversion is done in quadrature and the mirror signal suppression is performed at low frequency, after downconversion, by a polyphase filter. This polyphase filter is a complex filter, consisting of two signal paths: an in-phase path and a quadrature path. This allows for an asymmetric filter characteristic: a passband filter for positive frequencies and a suppression at the same negative frequencies. The polyphase filter can be implemented either as an analog filter [13] or in the DSP, together with the other digital functions. This again demonstrates how the interaction between the analog architecture and the digital part improves the performance of the system. The low-IF receiver is closely related to the zero-IF receiver since it can also be fully integrated and uses a single-stage direct downcon-

version. The difference is that the low-IF receiver does not use baseband operation, resulting in a total immunity to parasitic baseband signals, resolving in this way the main disadvantage of the zero-IF receiver. By the use of a double-quadrature structure, converters requiring neither any external components nor any tuning or trimming have been demonstrated [28].

4. ANALOG CIRCUIT DESIGN IN A DIGITAL CMOS TECHNOLOGY

The general transceiver architecture, depicted in Fig. 4, requires analog functions implemented in a digital technology. As mentioned before, due to the high f_T and $f_{3\text{dB}}$ of current technologies, operating frequencies of 5 GHz and above become possible. The low-noise amplifier, the power amplifier, and the synthesizer are the most critical analog functions since the overall performance of the transceiver will depend mainly on the performance of these analog building blocks.

4.1. The Low-Noise Amplifier

The low-noise amplifier is a very critical building block, since mainly this block will determine the overall noise figure and linearity of the receiver. Furthermore, in deep submicrometer technologies, ESD issues are becoming very important, and this will have a great influence on the LNA design. Most RF CMOS LNA topologies use single-stage inductive degeneration techniques [14,15] to provide resistive input impedance to the antenna. The input of the LNA is usually protected against ESD by two reverse-biased diodes. Care has to be taken since those protection networks increase the noise, capacitive input load, and as such the power drain of the circuit. In Fig. 5, an example of a 0.8-dB noise figure LNA is presented [15]. The LNA has been measured in its nominal 9-mW regime, drawing 6 mA from a 1.5-V power supply. The forward gain (S_{21}) reaches more than 20 dB at 1.23 GHz. At the same time, the reverse isolation is better than 31 dB. The

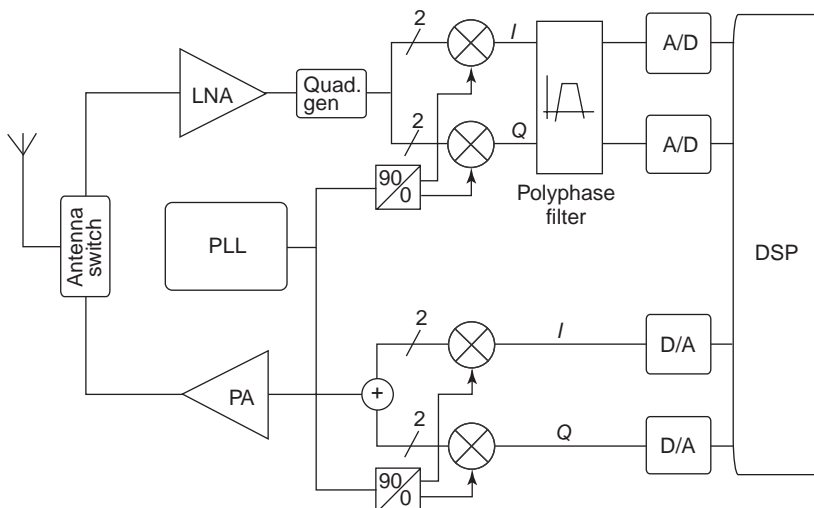

Figure 4. General transceiver architecture.

Figure 5. A 0.8-dB noise figure LNA in 0.25- μm CMOS.

noise figure of the LNA, in nominal operation, reaches a minimum of 0.79 dB at 1.24 GHz. An HBM (human body model) test has shown that the LNA is able to withstand positive ESD pulses up to 0.6 kV and negative ESD pulses up to -1.4 kV, surpassing the 0.5 kV specification.

4.2. The Voltage-Controlled Oscillator

The local oscillator is responsible for the correct frequency selection in up- and downconverters. The signal level of the desired receive channel can be very small, whereas adjacent channels can have very large power levels. Therefore the phase noise specifications for the local-oscillator signal are very critical. Usually, the local oscillator is realized as a phase-locked loop. The very rigid specifications are reflected in the design of the voltage-controlled oscillator (VCO). For the realization of a gigahertz VCO in a submicrometer CMOS technology, two options exist: either ringoscillators or oscillators based on the resonance frequency of an LC tank. The inductor in this LC tank can be implemented as an active inductor or a passive one. It has been shown that for ring oscillators as well as active LC oscillators [16], the phase-noise is inversely related to the power consumption. Therefore, the only viable solution to a low-power, low-phase-noise VCO is an LC oscillator with a passive inductor. As could be expected, the limitation in this oscillator is the integrated passive inductor. For extremely low phase noise requirements, the concept of bondwire inductors has been investigated [16,17]. Since a bondwire has a parasitic inductance of approximately 1 nH/mm and a very low series resistance, very-high- Q inductors can be created. The most elegant solution is the use of a spiral coil on a standard silicon substrate, without any modifications. In combination with fractional- N techniques, low-phase-noise PLL circuits can be obtained. For example, in Fig. 6 a fully integrated synthesizer in a 0.25- μm CMOS technology is presented [18]. The measured phase noise is less than 120 dBc/Hz at 600 kHz, while the reference and fractional spurious signals are respectively 70 dB and 100 dB below the carrier signal.

4.3. A/D Conversion

After downconversion, an analog-to-digital converter is the interface to the DSP. Once the signal is downconverted to DC or low IF, there is the desired signal, along with unwanted blockers that are significantly higher than the signal itself. Digitizing that combination of signals requires a high-dynamic range analog-to-digital converter with excellent noise and spurious-free dynamic range performance. As an example, in the case of Global System for Mobile Communications (GSM), the blocker at 3 MHz offset from the carrier can be 76 dB above the signal, while the blocker at 600 kHz offset is 56 dB above the signal. This sets the upper limit of the A/D converter. Furthermore, at reference sensitivity level, the desired signal at the A/D input would be 1 mV (-60 dBV). Since the quantization noise floor must be low enough not to degrade the noise figure performance, the noise floor required would be -80 dBV. On the other hand, CDMA and wideband code-division multiple access have much lower signal-to-noise requirements, so the tolerable quantization noise floor is relaxed for these application. A trend can be observed to shift the A/D conversion more toward the antenna. This clearly enables the use of multiple standard radio and reduces the chip area of the analog interface. The cost however, is a higher power consumption of the A/D converter.

4.4. The Power Amplifier

In the transmitter path, the power amplifier is the most challenging block for integration in a CMOS technology. Most of the CMOS transceivers reported in open literature deliver power levels in the range of 0 dBm. To achieve a fully integrated CMOS system, the power amplifier also has to be realized in a CMOS technology, on the same die. An alternative is to place the 0-dBm transceiver and the power amplifier in the same package. In this case, one can still benefit from implementing the PA in CMOS, because of the cost reduction and the advantage of a single-technology solution. Another alternative is to use a low-cost technology to integrate the passives [9] and to combine this substrate with the CMOS die.

Figure 6. A fully integrated 0.25- μm CMOS Phase-locked loop.

In a digital CMOS technology, switching-mode power amplifiers are the favored candidates for wireless communications, due to their excellent high efficiency. A simplified presentation of a switching amplifier is an NMOS transistor loaded with a parallel tank, consisting of a power supply inductor, a shunt capacitor, and a load resistor (Fig. 7). Because of the switching LC structure, the maximum voltage at the drain will be higher than the power supply, hence making the transistor sensitive to several failure mechanisms, such as oxide breakdown and hot electrons. The major advantage of a switching topology is that the maximum voltage is present only when the NMOS transistor is switched off. As a consequence, the hot-electron issue is simplified and the main cause of destruction is oxide breakdown, a failure mechanism that is easy to characterize. An important aspect is the integration of the passive components in a CMOS technology. It

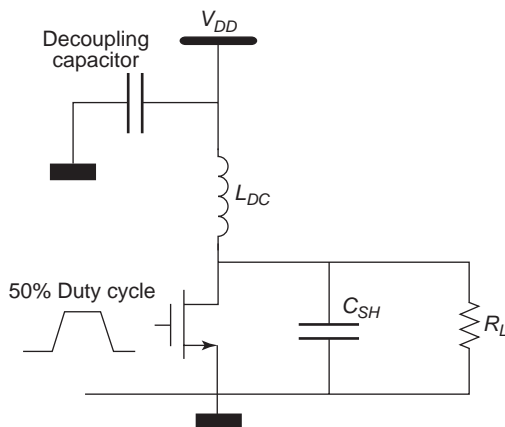

Figure 7. Basic CMOS switching amplifier.

can be shown that a fixed relationship exists between the required inductor L_{DC} , the output power, the operating frequency, and the breakdown voltage [19]. When moving toward GHz frequencies and deep-submicrometer technologies, the value of the inductor L_{DC} becomes very small, as can be seen in Fig. 8. The only way to realize such a small inductance is to integrate it on the same die as the CMOS transistors, since the parasitic inductance and capacitance of bondwires will be too large relative to the required inductance. The decoupling capacitance required for the PA also needs to be integrated on the same die as the power amplifier itself. The resonance frequency of an off-chip decoupling capacitor typically lies around 1 GHz for a 10 pF of decoupling. In order to achieve either more decoupling or a higher frequency, the decoupling has to be

Figure 8. Value of L_{DC} for a lossless Bluetooth power amplifier.

Figure 9. Fully integrated 0.25- μm CMOS Bluetooth power amplifier.

integrated on the same die as the power amplifier, hence justifying the trend toward full integration. Finally, as can be seen in Fig. 4, the power amplifier needs to be driven by the upconversion mixer. Therefore, it is of utmost importance to achieve sufficient power gain in the amplifier. On the other hand, a high power gain will require more driver stages, hence lowering the overall efficiency of the transceiver. Therefore, many tradeoffs are involved in the design of a power amplifier and overall optimization is required [20,21]. In Fig. 9 a fully integrated power amplifier in a 0.25- μm CMOS technology is presented [8]. It can deliver up to +21 dBm, the required input power is only -10 dBm, and the measured power-added efficiency (PAE) is 25.8%.

5. SUBSTRATE COUPLING BETWEEN THE DIGITAL AND ANALOG PARTS

In mixed-signal design, substrate coupling between the analog and the digital parts is an important aspect that needs special attention during design and layout. The issue of substrate coupling is still under research, since a simple and straightforward method is lacking. However, the designer can take some precautions to minimize the influence of the digital switching noise on the sensitive analog blocks [29].

It is a common practice to define the ultimate voltage reference, the ground, off chip. In high-speed applications, various techniques such as separated digital and analog powerlines are used to make an on-chip ground close to the external reference. In this approach all voltages are artificially referred to the external ground, with the on chip ground tied as close to this external reference as possible. As integrated circuits are on chip, however, they are naturally related to the on-chip ground, which will never be exactly equal to the off-chip reference. It is therefore more suitable to define the reference for a circuit on chip. An adequate decoupling will keep the local circuit power constant relative to this local reference. Signal distortion due to limited power supply rejection ratio (PSRR) is thus minimized. As a result of fast current variations in power pads, two analog subcircuits may have a different local reference, even when they share the same analog ground pad [22,23]. Eventually, several local references may be defined for various subsystems and decoupled locally. The transmission of the signal to another subcircuit or to the outside world can be regarded as a separate problem when using a differential approach even for voltages that are single-ended at first sight. A voltage is not an absolute entity, but a difference in electric potential relative to a predetermined reference. For example, the input of a transistor is the voltage difference and the unwanted bulk to

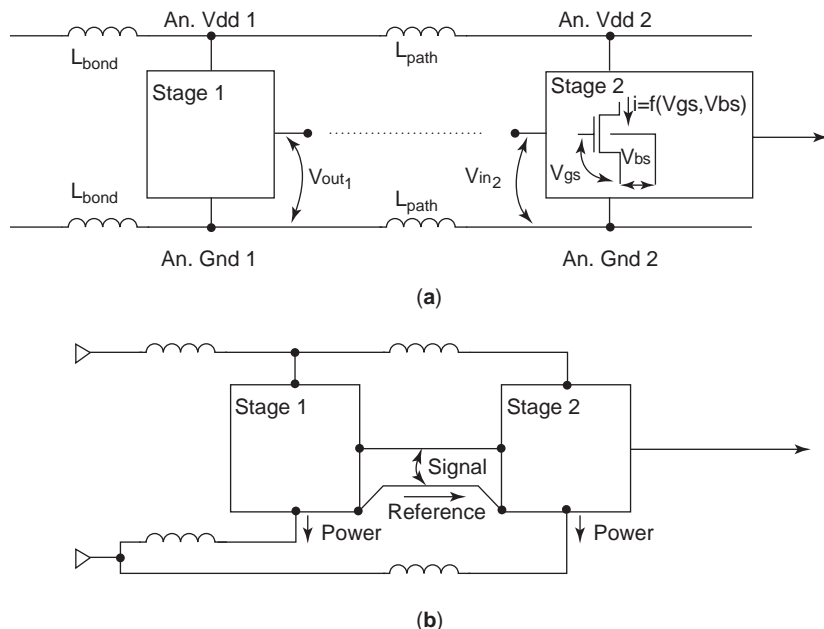

Figure 10. The use of differential circuits in mixed-mode ICs.

Figure 11. Placement and biasing of guard rings.

source voltage (Fig. 10a). To avoid signal disturbance due to reference variations from one place to another, voltages should be transferred concurrently with their reference through a dedicated path (Fig. 10b) rather than rely on a common ground. Similarly, to get the signal off chip, dedicated pins are used for the references.

The relative bondwires' placement requires some attention too. Although coupling between the wires is relatively small [24], it can be sufficient to transfer noise from a noisy path to an adjacent node. Sensitive inputs' bondwires should therefore never be close to noisy wires. Eventually they can be shielded by enclosing them with extra bondwires connected to a quiet ground. Even an optimally decoupled analog circuit can be disturbed by substrate noise injected on some other place on the chip [25]. Guard rings can limit this effect when used correctly. Figure 11 summarizes the correct placement and biasing of the rings. The first step in reducing substrate coupling is the limitation of the injected noise. A guard ring close to the digital transistors and biased with a dedicated pin will provide a return path for injected currents (Fig. 11A). This ring may not be biased with either of the on-chip grounds. Biasing with the digital ground would inject extra noise into the substrate, while using the analog ground would couple substrate noise directly into it. To reduce the effect of the current that reaches the bulk, a low-impedance return path is of utmost importance [26,27]. For heavily doped substrates, the best result is obtained by mounting the die with conductive epoxy to the leadframe using several bondwires to connect it to the external ground (Fig. 11B). Eventually, large substrate contacts with a dedicated pin filling spare places on the chip can be an alternative (Fig. 11C). In lightly doped substrates, where most currents flow just underneath the chip surface, a guard ring with dedicated pin surrounding the digital block is an effective return pad. In these substrates, physical separation of noise source and sensitive circuit is also very effective as the resistance in the noise path continuously increases with the distance. For heavily doped material, a separation of more than 4 times the epilayer thickness is useless as most of the disturbing current then just passes through the low ohmic bulk [26]. Substrate noise disturbs the analog circuits through their bulk to source voltage. To reduce this bulk effect, bulk source

voltage variations of analog MOS transistors should be minimized. The bulk must thus be tied locally to the analog reference rather than to the (slightly different) external one. This is achieved with bulk contacts close to the analog transistors and biased with the local analog ground (Fig. 11D), which results in an optimal output voltage relative to the local on-chip analog reference. A guard ring with dedicated pin around the analog circuits eventually enhances the noise immunity even further (Fig. 11E) [26], but does not eliminate the need of the good bulk contacts to the local analog ground.

6. CONCLUSIONS

The trend toward deep-submicrometer technologies has enabled the use of CMOS for the integration of high-performance analog functions. First, the analog architecture needs to be adjusted to allow a fully integrated solution. The next step is to place both the digital and the analog functions on a single die, which allows. For an interaction between the analog architecture and the digital DSP, which enables one to achieve a higher performance of the analog part. This results in highly reconfigurable mixed-circuit systems in the cheapest technology available. The trend toward deep-submicrometer technologies will allow achieving those goals as long as the short-channel effects will not limit the performance concerning linearity and intermodulation problems. Furthermore, substrate noise coupling between the digital part of the system and the sensitive analog blocks can degrade the analog performance, hence demanding some precautions regarding bulk contacts, guard rings, and packaging.

MIXER CIRCUITS

KATSUJI KIMURA
NEC Corporation

A frequency mixer inputs two frequencies—a radiofrequency (RF) and a local-oscillator (LO) frequency—mixes them, and produces their difference frequency and sum frequency. The output signal is tuned by a filter, and one of the two output frequencies is selected: the difference or the sum. When the output difference frequency is an intermediate frequency (IF), the mixer is usually called a down-conversion frequency mixer, and when the output sum frequency is a high frequency, it is usually called an up-conversion frequency mixer.

A frequency mixer is fundamentally a multiplier, because the analog multiplier outputs a signal proportional to the product of the two input signals. Therefore, a frequency mixer is represented by the symbol for the multiplier, as shown in Fig. 1.

The transfer function of a nonlinear element is expressed as

$$f(u) = a_0 + a_1u + a_2u^2 + a_3u^3 + \dots + a_nu^n + \dots \quad (1)$$

The product xy of the two input signals x and y can be derived from only the second-order term: a_2u^2 , where $u = x + y$,

Figure 1. A symbol for a frequency mixer. The symbol for a multiplier is used.

and x and y are the two input signals. The product of the two input signals is produced by a nonlinear element, such as a diode or transistor. For example, single-diode mixers, singly balanced diode mixers, doubly balanced diode mixers, single-transistor mixers, singly balanced transistor mixers, and doubly balanced transistor mixers are usually used as frequency mixers.

1. APPLICATION TO RECEIVERS

Mixers are used to shift the received signal to an intermediate frequency, where it can be amplified with good selectivity, high gain, and low noise, and finally demodulated in a receiver. Mixers have important applications in ordinary low-frequency and microwave receivers, where they are used to shift signals to frequencies where they can be amplified and demodulated most efficiently. Mixers can also be used as phase detectors and in demodulators, and must perform these functions while adding minimal noise and distortion.

Figure 2 shows, for example, the block diagram of a VHF or UHF communication receiver. The receiver has a single stage input amplifier; this preamp, which is usually called an RF amplifier, increases the strength of the received signal so that it exceeds the noise level of the following stage; therefore, this preamp is also called a low-noise amplifier (LNA). The first IF is relatively high (in a VHF or UHF receiver, the widely accepted standard has been 10.7 MHz); this high IF moves the image frequency well away from the RF, thus allowing the image to be rejected effectively by the input filter. The second conversion occurs after considerable amplification, and is used to select some particular signal within the input band and to shift it to the second IF. Because narrow bandwidths are generally easier to achieve at this lower frequency, the selectivity of the filter used before the detector is much better than that of the first IF. The frequency synthesizer generates the variable-frequency LO signal for the first mixer, and the fixed-frequency LO for the second mixer.

Figure 3 illustrates an ideal analog multiplier with two sinusoids applied to it. The signal applied to the RF port has a carrier frequency ω_s and a modulation waveform $A(t)$. The other, the LO, is a pure, unmodulated sinusoid at frequency ω_p .

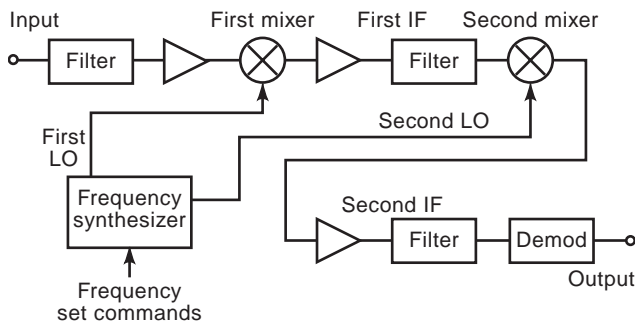

Figure 2. Double-superheterodyne VHF or UHF communication receiver.

Figure 3. A mixer is fundamentally a multiplier. The difference frequency in the IF results from the product of sinusoids.

Applying some basic trigonometry to the output is found to consist of modulated components at the sum and difference frequencies. The sum frequency is rejected by the IF filter, leaving only the difference.

Fortunately, an ideal multiplier is not the only device that can realize a mixer. Any nonlinear device can perform the multiplying function. The use of a nonideal multiplier results in the generation of LO harmonics and in mixing products other than the desired one. The desired output frequency component must be filtered from the resulting chaos.

Another way to view the operation of a mixer is as a switch. Indeed, in the past, diodes used in mixers have been idealized as switches operated at the LO frequency. Figure 4a shows a mixer modeled as a switch; the switch interrupts the RF voltage waveform periodically at the LO frequency. The IF voltage is the product of the RF voltage and the switching waveform.

Another switching mixer is shown in Fig. 4b. Instead of simply interrupting the current between the RF and IF ports, the switch changes the polarity of the RF voltage periodically. The advantage of this mixer over the one in Fig. 4a is that the LO waveform has no DC component, so the product of the RF voltage and switching waveform does not include any voltage at the RF frequency. Thus,

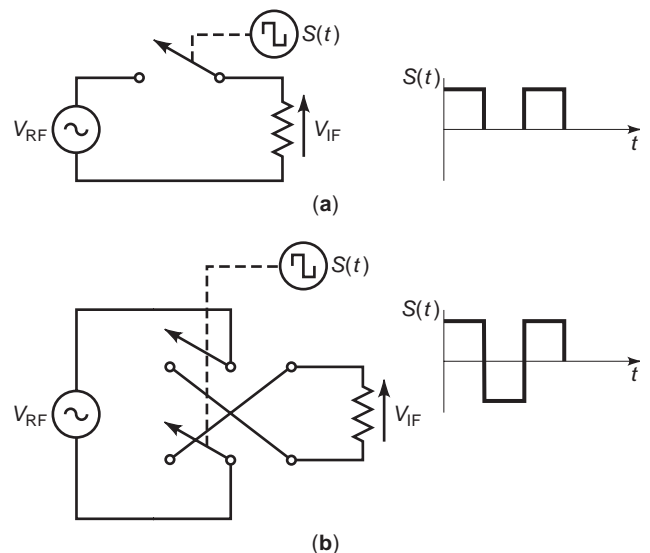

Figure 4. Two switching mixers: (a) a simple switching mixer; (b) a polarity-switching mixer. The IF is the product of the switching waveform $s(t)$ and the RF input, making these mixers a type of multiplier.

even though no filters are used, the RF and LO ports of this mixer are inherently isolated. Doubly balanced mixers are realizations of the polarity-switching mixer.

2. SEMICONDUCTOR DEVICES FOR MIXERS

Only a few devices satisfy the practical requirements of mixer operation. Any device used as a mixer must have strong nonlinearity, electrical properties that are uniform between individual devices, low noise, low distortion, and adequate frequency response. The primary devices used for mixers are Schottky barrier diodes and field-effect transistors (FETs). Bipolar junction transistors (BJT) are also used occasionally, primarily in Gilbert cell multiplier circuits (see Fig. 6d), but because of their superior large-signal-handling ability, higher frequency range, and low noise, FET devices such as metal-oxide-semiconductor FETs (MOSFET), gallium arsenide (GaAs) metal-semiconductor FETs (MESFET), and high-electron-mobility transistors (HEMTs) have been usually preferred.

The Schottky barrier diode is the dominant device used in mixers. Because Schottky barrier diodes are inherently capable of fast switching, have very small reactive parasitics, and do not need DC bias, they can be used in very broadband mixers. Schottky barrier diode mixers usually do not require matching circuits, so no tuning or adjustment is needed.

Although mixers using Schottky barrier diodes always exhibit conversion loss, transistor mixers are capable of conversion gain. This helps simplify the architecture of a system, often allowing the use of fewer amplifier stages than necessary in diode mixer receivers.

Since the 1950s, bipolar transistors have dominated mixer applications as single-transistor mixers in AM radio and communication receivers. In particular, an analog multiplier consisting of a doubly balanced differential amplifier, called the *Gilbert cell*, was invented in the 1960s. Since then, the Gilbert cell mixer has been used as a monolithic integrated circuit (IC) for AM radio receivers and communication equipment. Silicon BJTs are used in mixers because of their low cost and ease of implementation with monolithic ICs. These bipolar devices are used as mixers when necessary for process compatibility, although FETs generally provide better overall performance. Silicon BJTs are usually used in conventional single-device or singly and doubly balanced mixers. Progress in the development of heterojunction bipolar transistors (HBT), which use a heterojunction for the emitter-to-base junction, may bring about a resurgence in the use of bipolar devices as mixers. HBTs are often used as analog multipliers operating at frequencies approaching the microwave range; the most common form is a Gilbert cell. Silicon-germanium (Si-Ge) HBTs are a new technology that offers high performance at costs close to that of silicon BJTs.

A variety of types of FETs are used in mixers. Since the 1960s, silicon MOSFETs (often dual-gate devices) have dominated mixer applications in communication receivers up to approximately 1 GHz. At higher frequency, GaAs MESFETs are often used. The LO and RF signals can be applied to separate gates of dual-gate FETs, allowing good

RF-to-LO isolation to be achieved in a single-device mixer. Dual-gate devices can be used to realize self-oscillating mixers, in which a single device provides both the LO and mixer functions.

Although silicon devices have distinctly lower transconductance than GaAs, they are useful up to at least the lower microwave frequencies. In spite of the inherent inferiority of silicon to GaAs, silicon MOSFETs do have some advantages. The primary one is low cost, and the performance of silicon MOSFET mixers is not significantly worse than GaAs in the VHF and UHF range. The high drain-to-source resistance of silicon MOSFETs gives them higher voltage gain than GaAs devices; in many applications this is a distinct advantage. Additionally, the positive threshold voltage (in an n-channel enhancement MOSFET), in comparison with the negative threshold voltage of a GaAs FET, is very helpful in realizing low-voltage circuits and circuits requiring only a single DC supply. Mixers using enhancement-mode silicon MOSFETs often do not require gate bias, and dual-gate MOSFETs offer convenient LO-to-RF isolation when the LO and RF are applied to different gates.

A MESFET is a junction FET having a Schottky barrier gate. Although silicon MESFETs have been made, they are now obsolete, and all modern MESFETs are fabricated on GaAs. GaAs is decidedly superior to silicon for high-frequency mixers because of its higher electron mobility and saturation velocity. The gate length is usually less than 0.5 μm , and may be as short as 0.1 μm ; this short gate length, in conjunction with the high electron mobility and saturation velocity of GaAs, results in a high-frequency, low-noise device.

HEMTs are used for mixers in the same way as conventional GaAs FETs. Because the gate I - V characteristic of a HEMT is generally more strongly nonlinear than that of a MESFET, HEMT mixers usually have greater intermodulation (IM) distortion than FETs. However the noise figure (NF) of an HEMT mixer usually is not significantly lower than that of a GaAs FET. An HEMT is a junction FET that uses a heterojunction (a junction between two dissimilar semiconductors), instead of a simple epitaxial layer, for the channel. The discontinuity of the bandgaps of the materials used for the heterojunction creates a layer of charge at the surface of the junction; the charge density can be controlled by the gate voltage. Because the charge in this layer has very high mobility, high-frequency operation and very low noise are possible. It is not unusual for HEMTs to operate successfully as low-noise amplifiers above 100 GHz. HEMTs require specialized fabrication techniques, such as molecular beam epitaxy, and thus are very expensive to manufacture. HEMT heterojunctions are invariably realized with III-V semiconductors; AlGaAs and InGaAs are common.

2.1. Passive Diode Mixers

Figure 5 shows the most common form of the three diode mixer types: a single-device diode mixer, a singly balanced diode mixer, and a doubly balanced diode mixer. Conversion loss of 6–8 dB is usually accepted in these passive mixers.

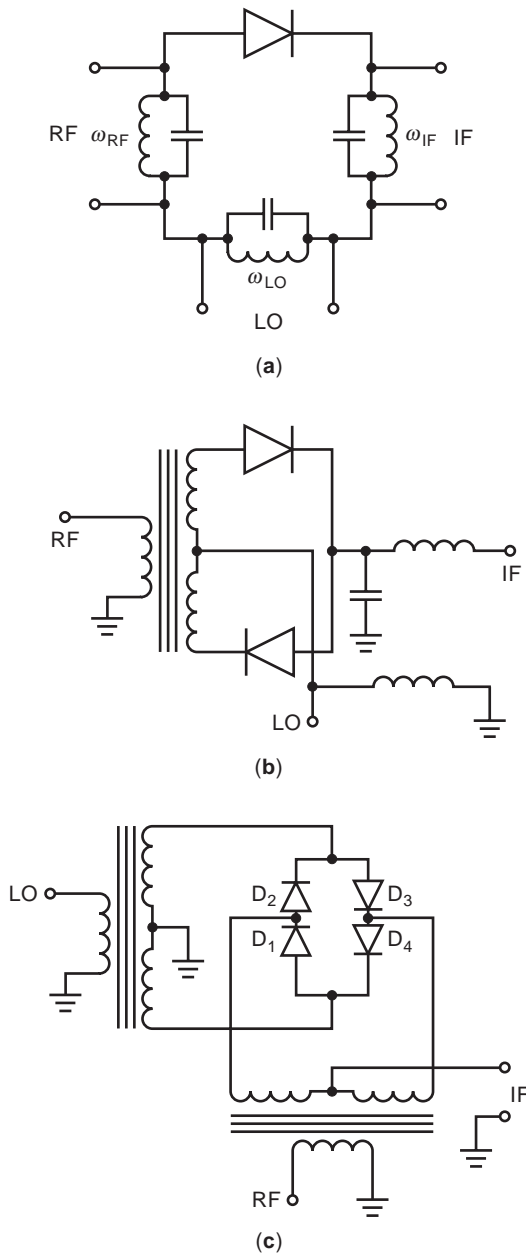

Figure 5. The three most common diode mixer types: (a) single-device; (b) singly balanced; (c) doubly balanced.

2.2. Active Transistor Mixers

Active transistor mixers have several advantages, and some disadvantages, in comparison with diode mixers. Most significantly, an active mixer can achieve conversion gain, while diode and other passive mixers always exhibit loss. This allows a system using an active mixer to have one or two fewer stages of amplification; the resulting simplification is especially valuable in circuits where small size and low cost are vital. A precise comparison of distortion in diode and active transistor mixers is difficult to make because the comparison depends on the details of the system. Generally, however, it is fair to say that distortion levels of well-designed active mixers are usually comparable to those of diode mixers.

It is usually easy to achieve good conversion efficiency in active mixers. Thus, active transistor mixers have gained a reputation for low performance. Nevertheless, achieving good overall performance in active transistor mixers is not difficult.

Because transistors cannot be reversed, as can diodes, balanced transistor mixers invariably require an extra hybrid at the IF. This can be avoided only by using a p-channel device instead of an n-channel device, or vice versa, however, this is possible only in silicon circuits, and even then the characteristics of p- and n-channel devices are likely to be significantly different.

2.2.1. Bipolar Junction Transistor Mixers. Figure 6 shows BJT mixers, a single-device BJT mixer, a singly balanced BJT mixer, a differential BJT mixer, and a doubly balanced BJT mixer.

In a single-device BJT mixer (Fig. 6a), the input signals are introduced into the device through the RF and LO diplexer, which consists of an RF bandpass filter, an LO bandpass filter, and two strips, $\lambda/4$ long at the center of the RF and LO frequency ranges; the square-law term of the device's characteristic provides the multiplication action. A single-device BJT mixer achieves a conversion gain of typically 20–24 dB, a noise figure of typically 4–5 dB (which is about 3 dB more than that of the device in the amplifier at the RF), and a third intercept point near 0 dBm. The IM product from this type of single-device BJT mixer usually depends on its collector current, but when the supplied collector-to-emitter voltage V_{CE} is not enough (typically below 1.2 V), the IM product increases as V_{CE} decreases.

A singly balanced BJT upconversion mixer (Fig. 6b) consists of two BJTs interconnected by a balun or hybrid. The two collectors are connected through a strip, $\lambda/2$ long at the center of the LO frequency range, for reducing the LO leakage. This upconversion mixer exhibits 16 dB conversion gain and 12 dB LO leakage suppression versus the wanted RF output level at 900 MHz.

A singly balanced BJT differential mixer (Fig. 6c) consists of an emitter-coupled differential pair. The RF is superposed on the tail current by AC coupling through capacitor C_2 , and the LO is applied to the upper transistor pair, where capacitive degeneration and AC coupling substantially reduce the gain at low frequencies. Note that the circuit following C_2 is differential and hence much less susceptible to even order distortion.

A multiplier circuit (Fig. 6d) conceived in 1967 by Barrie Gilbert and widely known as the Gilbert cell (although Gilbert himself was not responsible for his eponym; indeed, he has noted that a prior art search at the time found that essentially the same idea—used as a “synchronous detector” and not as true mixer—had already been patented by H. Jones) is usually used as an RF mixer and sometimes as a microwave mixer.

Ignoring the basewidth modulation, the relationship between the collector current I_C and the base-to-emitter voltage V_{BE} for a BJT is

$$I_C = I_S \exp\left(\frac{V_{BE}}{V_T}\right) \quad (2)$$

Figure 6. BJT mixers: (a) a single-device BJT mixer; (b) a singly balanced BJT upconversion mixer; (c) a singly balanced BJT differential mixer; (d) a doubly balanced BJT mixer consisting of a Gilbert cell.

where $V_T = kT/q$ is the thermal voltage, k is Boltzmann’s constant, T is absolute temperature in Kelvin, and q is the charge of an electron. I_S is the saturation current for a graded-base transistor.

Assuming matched devices, the differential output voltage of the Gilbert cell is

$$V_{IF} = -R_L I_{EE} \tanh\left(\frac{V_{RF}}{2V_T}\right) \tanh\left(\frac{V_{LO}}{2V_T}\right) \quad (3)$$

For small inputs

$$V_{IF} \approx -\frac{R_L I_{EE}}{4V_T^2} V_{RF} V_{LO} \quad (4)$$

The product $V_{RF} V_{LO}$ is obtained by the Gilbert cell at small signals.

2.2.2. FET Mixers. Figure 7 shows FET mixers: a single-device FET mixer, a dual-gate FET mixer, a singly

balanced FET mixer, a differential FET mixer, and a doubly balanced FET mixer.

In a single-device FET mixer (Fig. 7a), the RF–LO diplexer must combine the RF and LO and also provide matching between the FET’s gate and both ports. The IF filter must provide an appropriate impedance to the drain of the FET at the IF and must short-circuit the drain at the RVF and especially at the LO frequency and its harmonics.

The configuration of a dual-gate mixer (Fig. 7b) provides the best performance in most receiver applications. In this circuit, the LO is connected to the gate closest to the drain (gate 2), while the RF is connected to the gate closest to the source (gate 1). An IF bypass filter is used at gate 2, and an LO–RF filter is used at the drain. A dual-gate mixer is usually realized as two single-gate FETs in a cascade connection.

A singly balanced FET mixer (Fig. 7c) uses a transformer hybrid for the LO and RF; any appropriate type of hybrid can be used. A matching circuit is needed at the gates of both FETs. The IF filters provide the requisite short circuits to the drains at the LO and RF frequencies, and additionally provide IF load impedance transformations.

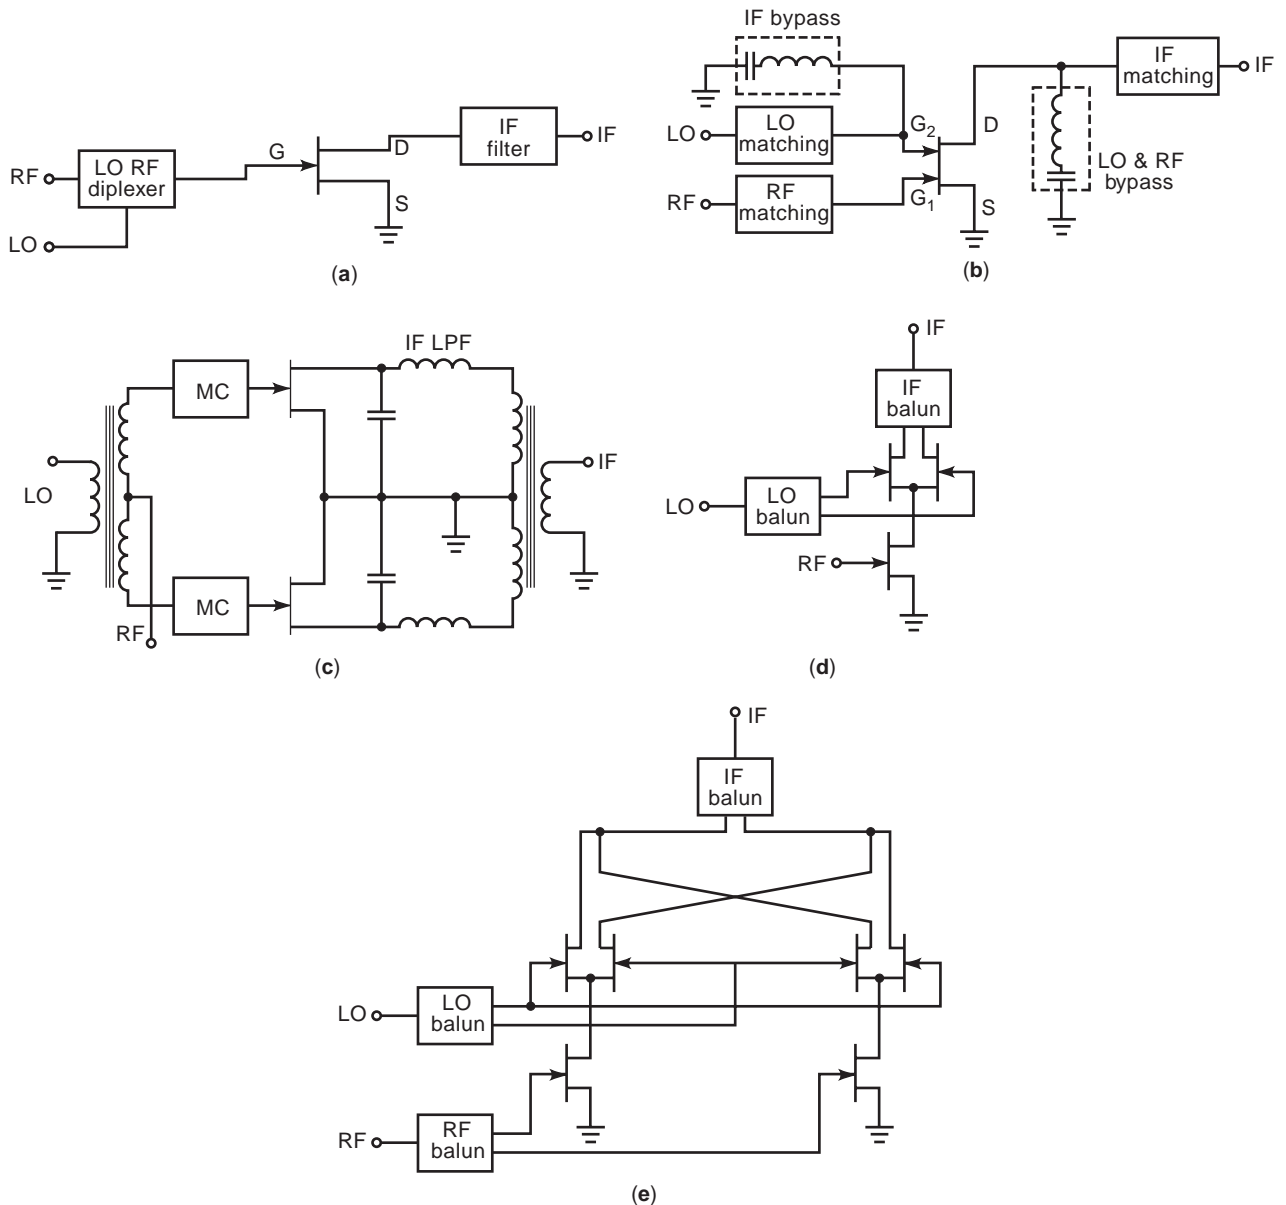

Figure 7. FET mixers: (a) a single-device FET mixer; (b) a dual-gate FET mixer; (c) a singly balanced FET mixer; (d) a differential mixer; (e) a doubly balanced mixer.

The singly balanced mixer of Fig. 7c is effectively two single-device mixers interconnected by hybrids.

In a differential FET mixer (Fig. 7d), the RF is applied to the lower FET, and the LO is applied through a balun or hybrid to the upper FETs. This mixer operates as an alternating switch, connecting the drain of the lower FET alternately to the inputs of the IF balun. An LO matching circuit may be needed. Because the RF and LO circuits are separate, the gates of the upper FETs can be matched at the LO frequency, and there is no tradeoff between effective LO and RF matching. Similarly, the lower FET can be matched effectively at the RF. An IF filter is necessary to reject LO current.

A doubly balanced FET mixer (Fig. 7e) is frequently used as an RF or microwave mixer. Like many doubly balanced mixers, this mixer consists of two of the singly

balanced mixers shown in Fig. 7d. Each half of the mixer operates in the same manner as that of Fig. 7d. The interconnection of the outputs, however, causes the drains of the upper four FETs to be virtual grounds for both LO and RF, as well as for even order spurious responses and IM products.

3. IMAGE-REJECTION MIXERS

The image-rejection mixer (Fig. 8) is realized as the interconnection of a pair of balanced mixers. It is especially useful for applications where the image and RF bands overlap, or the image is too close to the RF to be rejected by a filter. The LO ports of the balanced mixers are driven in phase, but the signals applied to the RF ports have 90°

Figure 8. Image-rejection mixer.

phase difference. A 90° IF hybrid is used to separate the RF and image bands. A full discussion of the operation of such mixers is a little complicated.

The most difficult part of the design of an image-rejection mixer is the IF hybrid. If the IF is fairly high, a conventional RF or microwave hybrid can be used. However, if the mixer requires a baseband IF, the designer is placed in the problematical position of trying to create a Hilbert transforming filter, a theoretical impossibility. Fortunately, it is possible to approximate the operation of such a filter over a limited bandwidth.

4. MIXING

A mixer is fundamentally a multiplier. An ideal mixer multiplies a signal by a sinusoid, shifting it to both a higher and a lower frequency, and selects one of the resulting sidebands. A modulated narrowband signal, usually called the RF signal, represented by

$$S_{RF}(t) = a(t) \sin(\omega_s t) + b(t) \cos(\omega_s t) \tag{5}$$

is multiplied by the LO signal function

$$f_{LO}(t) = \cos(\omega_p t) \tag{6}$$

to obtain the IF signal

$$S_{IF}(t) = \frac{1}{2} a(t) \sin[(\omega_s + \omega_p)t] + \sin[(\omega_s - \omega_p)t] + \frac{1}{2} b(t) \cos[(\omega_s + \omega_p)t] + \cos[(\omega_s - \omega_p)t] \tag{7}$$

In the ideal mixer, two sinusoidal IF components, called *mixing products*, result from each sinusoid in $s(t)$. In receivers, the difference-frequency component is usually desired, and the sum-frequency component is rejected by filters.

Even if the LO voltage applied to the mixer’s LO port is a clean sinusoid, the nonlinearities of the mixing device distort it, causing the LO function to have harmonics. Those nonlinearities can also distort the RF signal, resulting in RF harmonics. The IF is, in general, the combination of all possible mixing products of the RF and LO harmonics. Filters are usually used to select the appropriate response and eliminate the other (so-called spurious) responses.

Every mixer, even an ideal one, has a second RF that can create a response at the IF. This is a type of spurious response, and is called the image; it occurs at the

frequency $2f_{LO} - f_{RF}$. For example, if a mixer is designed to convert 10 GHz to 1 GHz with a 9-GHz LO, the mixer will also convert 8 GHz to 1 GHz at the same LO frequency. Although none of the types of mixers we shall examine inherently reject images, it is possible to create combinations of mixers and hybrids that do reject the image response.

It is important to note that the process of frequency shifting, which is the fundamental purpose of a mixer, is a linear phenomenon. Although nonlinear devices are invariably used for realizing mixers, there is nothing in the process of frequency shifting that requires nonlinearity. Distortion and spurious response other than the sum and difference frequency, though often severe in mixers, are not fundamentally required by the frequency-shifting operation that a mixer performs.

4.1. Conversion Efficiency

Mixers using Schottky barrier diodes are passive components and consequently exhibit conversion loss. This loss has a number of consequences: the greater the loss, the higher the noise of the system and the more amplification is needed. High loss contributes indirectly to distortion because of high signal levels that result from the additional preamplifier gain required to compensate for this loss. It also contributes to the cost of the system, since the necessary low-noise amplifier stages are usually expensive.

Mixers using active devices often (but not always) exhibit conversion gain. The conversion gain (CG) is defined as

$$CG = \frac{\text{IF power available at mixer output}}{\text{RF power available to mixer input}} \tag{8}$$

High mixer gain is not necessarily desirable, because it reduces stability margins and can increase distortion. Usually, a mixer gain of unity, or at most a few decibels, is best.

4.2. Noise

In a passive mixer whose image response has been eliminated by filters, the noise figure is usually equal to, or only a few tenths of a decibel above, the conversion loss. In this sense, the mixer behaves as if it were an attenuator having a temperature equal to or slightly above the ambient.

In active mixers, the noise figure cannot be related easily to the conversion efficiency; in general, it cannot even be related qualitatively to the device’s noise figure when used as an amplifier. The noise figure (NF) is defined by the equation

$$NF = \frac{\text{input signal-to-noise power ratio}}{\text{output signal-to-noise power ratio}} \tag{9}$$

The sensitivity of a receiver is usually limited by its internally generated noise. However, other phenomena sometimes affect the performance of a mixer front end

more severely than does noise. One of these is the AM noise, or *amplitude noise*, from the LO source, which is injected into the mixer along with the LO signal. This noise may be especially severe in a single-ended mixer (balanced mixers reject AM LO noise to some degree) or when the LO signal is generated at a low level and amplified.

Phase noise is also a concern in systems using mixers. LO sources always have a certain amount of phase jitter, or phase noise, which is transferred degree for degree via the mixer to the received signal. This noise may be very serious in communications systems using either digital or analog phase modulation. Spurious signals may also be present, along with the desired LO signal, especially if a phase-locked-loop frequency synthesizer is used in the LO source. Spurious signals are usually phase modulation sidebands of the LO signal, and, like phase noise, are transferred to the received signal. Finally, the mixer may generate a wide variety of intermodulation products, which allow input signals—even if they are not within the input passband—to generate spurious output at the IF. These problems must be circumvented if a successful receiver design is to be achieved.

An ideal amplifier would amplify the incoming signal and incoming noise equally and would introduce no additional noise. From Eq. (9) such an amplifier would have a noise figure equal to unity (0 dB).

The noise figure of several cascaded amplifier stages is

$$NF = NF_1 + \frac{NG_2 - 1}{G_1} + \frac{NF_3 - 1}{G_1 G_2} + \dots + \frac{NF_n - 1}{\prod_1^n G_n} \quad (10)$$

where NF is the total noise figure, NF_n is the noise figure of the n th stage, and G_n is the available gain of the n th stage.

From Eq. (10), the gain and noise figure of the first stage of a cascaded chain will largely determine the total noise figure. For example, the system noise figure (on a linear scale) for the downconverter shown in Fig. 9 is

$$NF = \frac{1}{L_{RF}} + \frac{NF_{LNA} - 1}{L_{RF}} + \frac{1}{L_{RF} G_{LNA}} \left(\frac{1}{L_{IM}} - 1 \right) + \frac{NF_M - 1}{L_{RF} G_{LNA} L_I} + \dots = \frac{1}{L_{RF}} \left(NF_{LNA} + \frac{NF_M - L_I}{G_{LNA} L_I} + \dots \right) \quad (11)$$

where L_{RF} and L_I are the insertion losses of the RF filter and the image-rejection filter, respectively, NF_{LNA} and NF_M are the noise figures of the LNA and the mixer, respectively, and G_{LNA} is the power gain of the LNA. This equation assumes that the noise figures of the filters are the same as their insertion losses.

Figure 9. RF front end.

4.3. Bandwidth

The bandwidth of a diode mixer is limited by the external circuit, especially by the hybrids or baluns used to couple the RF and LO signals to the diodes. In active mixers, bandwidth can be limited either by the device or by hybrids or matching circuits that constitute the external circuit; much the same factors are involved in establishing active mixers' bandwidths as amplifiers' bandwidths.

4.4. Distortion

It is a truism that everything is nonlinear to some degree and generates distortion. Unlike amplifiers or passive components, however, mixers often employ strongly nonlinear devices to provide mixing. Because of these strong nonlinearities, mixers generate high levels of distortion. A mixer is usually the dominant distortion-generating component in a receiver.

Distortion in mixers, as with other components, is manifested as IM distortion (IMD), which involves mixing between multiple RF tones and harmonics of those tones. If two RF excitations f_1 and f_2 are applied to a mixer, the nonlinearities in the mixer will generate a number of new frequencies, resulting in the IF spectrum shown in Fig. 10. Figure 10 shows all intermodulation products up to third order; by n th order, we mean all n -fold combinations of the excitation tones (not including the LO frequency). In general, an n th-order nonlinearity gives rise to distortion products of n th (and lower) order.

An important property of IMD is that the level of the n th order IM product changes by n decibels for every decibel of change in the levels of the RF excitations. The extrapolated point at which the excitation and IMD levels are equal is called the n th-order IM intercept point, abbreviated IP_n . This dependence is illustrated in Fig. 11. In most components, the intercept point is defined as an output power; in mixers it is traditionally an input power.

Given the intercept point IP_n and input power level in decibels, the IM input level P_1 in decibels can be found from

$$P_1 = \frac{1}{n} P_1 + \left(1 - \frac{1}{n} \right) IP_n \quad (12)$$

where P_1 is the input level of each of the linear RF tones (which are assumed to be equal) in decibels. By convention, P_1 and P_1 are the input powers of a single frequency component where the linear output level and the level of the n th order IM product are equal; They are not the total

Figure 10. IF spectrum of intermodulation products up to third order. The frequencies f_1 and f_2 are the excitation.

Figure 11. The output level of each n th-order IM product varies n decibels for every decibel change in input level. The intercept point is the extrapolated point at which the curves intersect.

power of all components. For example, P_1 is the threshold level for the receiver. The fluctuation of the IMD level is rather small in spite of the fluctuations of P_1 and IP_n .

4.5. Spurious Responses

A mixer converts an RF signal to an IF signal. The most common transformation is

$$f_{IF} = f_{RF} - f_{LO} \tag{13}$$

although others are frequently used. The discussion of frequency mixing indicated that harmonics of both the RF and LO could mix. The resulting set of frequencies is

$$f_{IF} = mf_{RF} - nf_{LO} \tag{14}$$

where m and n are integers. If an RF signal creates an in-band IF response other than the desired one, it is called a *spurious response*. Usually the RF, IF, and LO frequency ranges are selected carefully to avoid spurious responses, and filters are used to reject out-of-band RF signals that may cause in-band IF responses. IF filters are used to select only the desired response.

Many types of balanced mixers reject certain spurious responses where m or n is even. Most singly balanced mixers reject some, but not all, products where m or n (or both) are even.

4.6. Harmonic Mixer

A mixer is sensitive to many frequencies besides those at which it is designed to operate. The best known of these is the image frequency, which is found at the LO sideband opposite the input, of the RF frequency. The mixer is also sensitive to similar sidebands on either side of each LO harmonic. These responses are usually undesired; the

Figure 12. Small-signal mixing frequencies ω_n and LO harmonics $n\omega_p$. Voltage and current components exist in the diode at these frequencies.

exception is the harmonic mixer, which is designed to operate at one or more of these sidebands.

When a small-signal voltage is applied to the pumped diode at any one of these frequencies, currents and voltages are generated in the junction at all other sideband frequencies. These frequencies are called the small-signal mixing frequencies ω_n and are given by the relation

$$\omega_n = \omega_0 + n\omega_p \tag{15}$$

where ω_p is the LO frequency and

$$n = \dots, -3, -2, -1, 0, 1, 2, 3, \dots \tag{16}$$

These frequencies are shown in Fig. 12. The frequencies are separated from each LO harmonic by ω_0 , the difference between the LO frequency and the RF.

5. MODULATION AND FREQUENCY TRANSLATION

5.1. Modulation

Modulation is the process by which the information content of an audio, video, or data signal is transferred to an RF carrier before transmission. Commonly, the signal being modulated is a sine wave of constant amplitude and is referred to as the carrier. The signal that varies some parameter of the carrier is known as the modulation signal. The parameters of a sine wave that may be varied are the amplitude, the frequency, and the phase. Other types of modulation may be applied to special signals, such as pulsewidth and pulse position modulation of recurrent pulses. The inverse process—recovering the information from an RF signal—is called *demodulation* or *detection*. In its simpler forms a modulator may cause some characteristic of an RF signal to vary in direct proportion to the modulating waveform: this is termed analog modulation. More complex modulators digitize and encode the modulating signal before modulation. For many applications digital modulation is preferred to analog modulation.

A complete communication system (Fig. 13) consists of an information source, an RF source, a modulator, an RF channel (including both transmitter and receiver RF stages, the antennas, the transmission path, etc.), a demodulator, and an information user. The system works if the information user receives the source information with acceptable reliability. The designer’s goal is to create a low-cost working system that complies with the legal restrictions on such things as transmitter power, antenna

Figure 13. Conceptual diagram of a communication system.

height, and signal bandwidth. Since modulation demodulation schemes differ in cost, bandwidth, interference rejection, power consumption, and so forth, the choice of the modulation type is an important part of communication system design.

Modulation, demodulation (detection), and heterodyne action are very closely related processes. Each process involves generating the sum and/or difference frequencies of two or more sinusoids by causing one signal to vary as a direct function (product) of the other signal or signals. The multiplication of one signal by another can only be accomplished in a nonlinear device. This is readily seen by considering any network where the output signal is some function of the input signal e_1 , for example

$$e_0 = f(e_1) \quad (17)$$

In any perfectly linear network, this requires that

$$e_0 = ke_1 \quad (18)$$

and, assuming two different input signals

$$e_0 = k(E_a \cos \omega_a t + E_b \cos \omega_b t) \quad (19)$$

where k is a constant. In this case the output signal contains only the two input-signal frequencies. However, if the output is a nonlinear function of the input, it can, in general, be represented by a series expansion of the input signal. For example, let

$$e_0 = k_1 e_1 + k_2 e_1^2 + k_3 e_1^3 + \cdots + k_n e_1^n \quad (20)$$

When e_1 contains two frequencies, e_0 will contain the input frequencies and their harmonics plus the products of these frequencies. These frequency products can be expressed as sum and difference frequencies. Thus, all modulators, detectors, and mixers are of necessity nonlinear devices. The principal distinction between these devices is the frequency differences between the input signals and the desired output signal or signals. For example, amplitude modulation in general involves the multiplication of a high-frequency carrier by low-frequency modulation signals to produce sideband signals near the carrier frequency. In a mixer, two high-frequency signals are multiplied to produce an output signal at a frequency that is the difference between the input-signal frequencies. In a detector for amplitude modulation, the carrier is multiplied by the sideband signals to produce their different frequencies at the output.

To understand the modulation process, it is helpful to visualize a modulator as a blackbox (Fig. 14) with two

inputs and one output connected to a carrier oscillator producing a sinusoidal voltage with constant amplitude and frequency f_{RF} . The output is a modulated waveform

$$F(t) = A(t) \cos[\omega_s t + \Theta(t)] = A(t) \cos \Phi(t) \quad (21)$$

whose amplitude $A(t)$ or angle $\Phi(t)$, or both, are controlled by $v_m(t)$. In amplitude modulation (AM) the carrier envelope $A(t)$ is varied while $\Theta(t)$ remains constant; in angle modulation $A(t)$ is fixed and the modulating signal controls $\Phi(t)$. Angle modulation may be either frequency modulation (FM) or phase modulation (PM), depending upon the relationship between the angle $\Phi(t)$ and the modulation signal.

Although the waveform [21] might be called a modulated cosine wave, it is not a single-frequency sinusoid when modulation is present. If either $A(t)$ or $\Theta(t)$ varies with time, the spectrum of $F(t)$ will occupy a bandwidth determined by both the modulating signal and the type of modulation used.

5.1.1. Amplitude Modulation. Amplitude modulation in the form of ON-OFF keying of radio-telegraph transmitters is the oldest type of modulation. Today, amplitude modulation is widely used for those analog voice applications that require simple receivers (e.g., commercial broadcasting) and require narrow bandwidths.

In amplitude modulation the instantaneous amplitude of the carrier is varied in proportion to the modulating signal. The modulating signal may be a single frequency, or, more often, it may consist of many frequencies of various amplitudes and phases, e.g., the signals constituting speech. For a carrier modulated by a single-frequency sine wave of constant amplitude, the instantaneous signal $e(t)$ is given by

$$e(t) = E(1 + m \cos \omega_m t) \cos(\omega_c t + \phi) \quad (22)$$

where E is the peak amplitude of unmodulated carrier, m is the modulation factor as defined below, ω_m is the frequency of the modulating voltage (radians per second), ω_c

Figure 14. Blackbox view of a modulator.

Figure 15. Amplitude-modulated carrier.

is the carrier frequency (radians per second), and ϕ is the phase angle of the carrier (radians).

The instantaneous carrier amplitude is plotted as a function of time in Fig. 15. The modulation factor m is defined for asymmetrical modulation in the following manner:

$$m = \frac{E_{\max} - E}{E} \quad (\text{upward or positive modulation}) \quad (23)$$

$$m = \frac{E - E_{\min}}{E} \quad (\text{downward or negative modulation}) \quad (24)$$

The maximum downward modulation factor, 1.0, is reached when the modulation peak reduces the instantaneous carrier envelope to zero. The upward modulation factor is unlimited.

The modulation carrier described by Eq. (22) can be rewritten as follows:

$$\begin{aligned} e(t) &= E(1 + m \cos \omega_m t) \cos(\omega_c t + \phi) \\ &= E \cos(\omega_c t + \phi) + \frac{mE}{2} \cos[(\omega_c + \omega_m)t + \phi] \\ &\quad + \frac{mE}{2} \cos[(\omega_c - \omega_m)t + \phi] \end{aligned} \quad (25)$$

Thus, the amplitude modulation of a carrier by a cosine wave has the effect of adding two new sinusoidal signals displaced in frequency from the carrier by the modulating frequency. The spectrum of the modulated carrier is shown in Fig. 16.

5.1.2. Angle Modulation. Information can be transmitted on a carrier by varying any of the parameters of the sinusoid in accordance with the modulating voltage. Thus, a carrier is described by

$$e(t) = E_c \cos \theta \quad (26)$$

where $\theta = \omega_c t + \phi$.

This carrier can be made to convey information by modulating the peak amplitude E_c or by varying the instantaneous phase angle θ of the carrier. This type of modulation is known as *angle modulation*. The two types of angle modulation that have practical application are phase modulation (PM) and frequency modulation (FM).

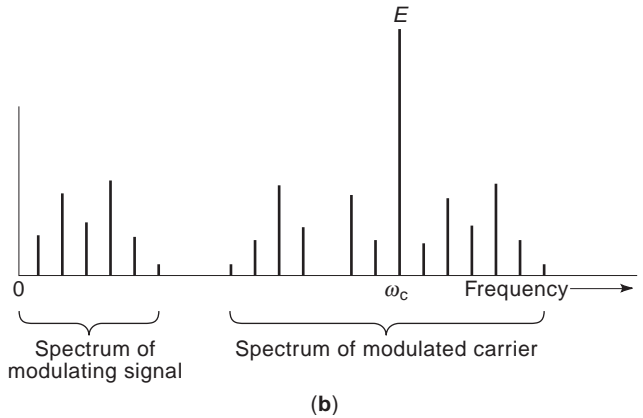

Figure 16. Frequency spectrum of an amplitude-modulated carrier: (a) carrier modulated by a sinusoid of frequency ω_m ; (b) carrier modulated by a complex signal composed of several sinusoids.

In phase modulation, the instantaneous phase angle θ of the carrier is varied by the amplitude of the modulating signal. The principal application of phase modulation is in the utilization of modified phase modulators in systems that transmit frequency modulation. The expression for a carrier phase-modulated by a single sinusoid is given by

$$e(t) = E_c \cos(\omega_c t + \phi + \Delta\phi \cos \omega_m t) \quad (27)$$

where $\Delta\phi$ is the peak value of phase variation introduced by modulation and is called the phase deviation, and ω_m is the modulation frequency (radians per second).

In frequency modulation, the instantaneous frequency of the carrier, that is, the time derivative of the phase angle θ , is made to vary in accordance with the amplitude of the modulating signal. Thus

$$f = \frac{1}{2\pi} \frac{d\theta}{dt} \quad (28)$$

When the carrier is frequency-modulated by a single sinusoid

$$f = f_{\text{RF}} + \Delta f \cos \omega_m t \quad (29)$$

where Δf is the peak frequency deviation introduced by modulation. The instantaneous total phase angle θ is

given by

$$\theta = 2\pi \int f dt + \theta_0 \tag{30}$$

$$\theta = 2\pi f_{RF}t + \frac{\Delta f}{f_m} \sin 2\pi f_m t + \theta_0 \tag{31}$$

The complete expression for a carrier that is frequency-modulated by a single sinusoid is

$$e(t) = E_c \cos \left(\omega_c t + \frac{\Delta f}{f_m} \sin 2\pi f_m t + \theta_0 \right) \tag{32}$$

The maximum frequency difference between the modulated carrier and the unmodulated carrier is the frequency deviation Δf . The ratio of Δf to the modulation frequency f_m is known as the modulation index or the deviation ratio. The degree of modulation in an FM system is usually defined as the ratio of Δf to the maximum frequency deviation of which the system is capable. Degree of modulation in an FM system is therefore not a property of the signal itself.

In digital wireless communication systems, Gaussian-filtered minimum-shift keying (GMSK) is the most popular, and four-level frequency-shift keying (4-FSK) and $\pi/4$ -shifted differential encoded quadriphase (or quadrature) phase-shift keying ($\pi/4$ -DQPSK) are also used. GMSK and 4-FSK are both frequency modulation, but $\pi/4$ -DQPSK is phase modulation.

5.1.3. Pulse Modulation. In pulse-modulated systems, one or more parameters of the pulse are varied in accordance with a modulating signal to transmit the desired information. The modulated pulse train may in turn be used to modulate a carrier in either angle or amplitude. Pulse modulation provides a method of time duplexing, since the entire modulation information of a signal channel can be contained in a single pulsetrain having a low duty cycle, i.e., ratio of pulse width to interpulse period, and therefore the time interval between successive pulses of a particular channel can be used to transmit pulse information from other channels.

Pulse modulation systems can be divided into two basic types: pulse modulation proper, where the pulse parameter which is varied in accordance with the modulating signal is a continuous function of the modulating signal; and quantized pulse modulation, where the continuous information to be transmitted is approximated by a finite number of discrete values, one of which is transmitted by each single pulse or group of pulses. The two methods are illustrated in Fig. 17. In quantized pulse modulation systems, the input function can be approximated with arbitrary accuracy by increase of the number of discrete values available to describe the input function. An example of a quantized pulse modulation system is shown in Fig. 18; the information is transmitted in pulse code groups, the sequence of pulses sent each period indicating a discrete value of the modulating signal at that instant. Typically, the pulse group might employ a binary number code, the presence of each pulse in the group

Figure 17. Input–output relationships of quantized and unquantized pulse modulation systems: (a) unquantized modulation system; (b) quantized modulation system.

indicating a 1 or 0 in the binary representation of the modulating signal.

The principal methods for transmitting information by means of unquantized pulse modulation are pulse-amplitude modulation (PAM; see Fig. 19), pulsewidth modulation (PWM), and pulse position modulation (PPM).

5.2. Frequency Translation

The most common form of radio receiver is the superheterodyne configuration shown in Fig. 20a. The signal input,

Figure 18. Example of a quantized pulse modulation system.

Figure 19. Pulse amplitude modulation: (a) amplitude-modulated pulsetrain; (b) frequency spectrum of the modulated pulse-train.

with a frequency ω_s , is usually first amplified in a tunable bandpass amplifier, called the *RF amplifier*, and is then fed into a circuit called the *mixer* along with an oscillator signal, which is local to the receiver, having a frequency ω_p . The LO is also tunable and is ganged with the input bandpass amplifier so that the difference between the input signal frequency and that of the LO is constant.

In operation, the mixer must achieve analog multiplication. With multiplication, sum and difference frequency components at $\omega_s \pm \omega_p$ are produced at the output of the mixer. Usually, the sum frequency is rejected by sharply tuned circuits and the difference frequency component is subsequently amplified in a fixed-tuned bandpass amplifier. The difference frequency is called the intermediate frequency (IF), and the fixed-tuned amplifier is called the *IF amplifier*. The advantage of this superheterodyne configuration is that most amplification and outband rejection occurs with fixed-tuned circuits, which can be optimized

for gain level and rejection. Another advantage is that the fixed-tuned amplifier can provide a voltage-controlled gain to achieve automatic gain control (AGC) with input signal level. In high-performance and/or small-size receivers, the filtering in the IF amplifier is obtained with electromechanical crystal filters.

To formalize the mixer operation, assume that both the input signal and the local oscillator output are unmodulated, single-tone sinusoids:

$$V_s = E_s \cos(\omega_s t) \tag{33}$$

$$V_p = E_p \cos(\omega_p t) \tag{34}$$

If the multiplier (mixer) has a gain constant K , the output is

$$V_0 = \frac{K}{2} E_s E_p [\cos(\omega_s - \omega_p)t + \cos(\omega_s + \omega_p)t] \tag{35}$$

The difference frequency, $\omega_s - \omega_p$, is denoted by ω_{if} .

If the input is a modulated signal, the modulation also is translated to a band about the new carrier frequency, ω_{if} . For example, if the input is amplitude-modulated,

$$\begin{aligned} V_s &= E_s(1 + m \cos \omega_m t) \cos \omega_s t \\ &= E_s \cos(\omega_s t) + \frac{m}{2} E_s \cos(\omega_s - \omega_m)t \\ &\quad + \frac{m}{2} E_p \cos(\omega_s + \omega_m)t \end{aligned} \tag{36}$$

The input can be represented as in Fig. 20b, with the carrier frequency term and an upper sideband and a lower sideband, each containing the modulation information.

For a linear multiplier, each of the input components is multiplied by the LO input, and the output of the multiplier contains six terms, as shown in Fig. 20c: the difference-frequency carrier with two sidebands and the sum-frequency carrier with two sidebands. The latter combination is usually rejected by the bandpass of the IF amplifier.

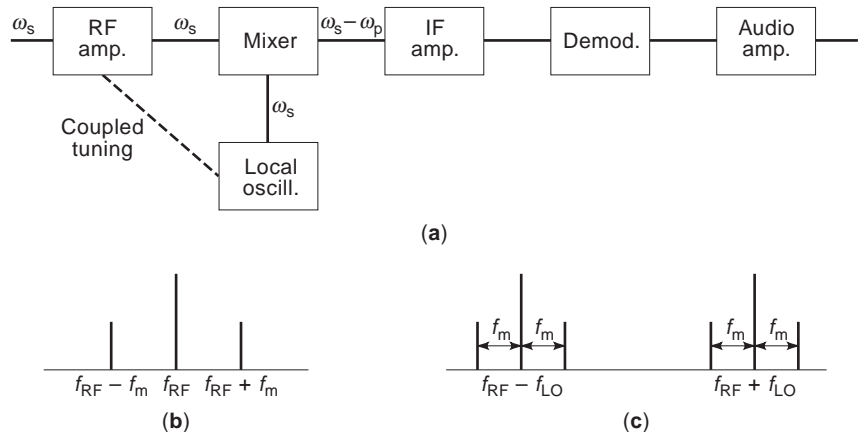

Figure 20. (a) The superheterodyne configuration; frequency spectra of (b) the input and (c) the multiplier output.

The series connection of the two cross-coupled, emitter-coupled pairs with a third emitter-coupled pair requires a high supply voltage, more than 2.0V. Therefore, many circuit design techniques for linearizing the low-voltage Gilbert cell have also been discussed.

6.1.2. Modified Gilbert Cell with a Linear Transconductance Amplifier. The modified Gilbert cell with a linear transconductance amplifier in Fig. 23 possesses a linear transconductance characteristic only with regard to the second input voltage V_y , because it utilizes a linear transconductance amplifier for the lower stage. Low-voltage operation is also achieved using the differential current source output system of two emitter-follower-augmented current mirrors. The general structure of the mixer is a Gilbert cell with a linear transconductance amplifier, since the cross-coupled emitter-coupled pairs that input the LO signal possess a limiting characteristic. To achieve the desired low distortion, the differential pair normally used as the lower stage of the cell is replaced with a superlinear transconductance amplifier. In practice, the linear input voltage range of the superlinear transconductance amplifier at a 1.9V supply voltage is 0.9V peak to peak for less than 1% total harmonic distortion (THD) or 0.8V for less than 0.1% THD.

The differential output current of the modified Gilbert cell with a linear transconductance amplifier is

$$\begin{aligned} \Delta I &= I^+ - I^- = (I_{C1} + I_{C3}) - (I_{C2} + I_{C4}) \\ &= 2G_y V_y \tanh\left(\frac{V_x}{2V_T}\right) \end{aligned} \tag{38}$$

where $G_y = 1/R_y$ and the DC common-base current gain factor α_F is taken as equal to one for simplification, since its value is 0.98 or 0.99 in current popular bipolar technology.

The product of the hyperbolic tangent function of the first input voltage and the second input voltage of the linear transconductance amplifier is obtained.

6.2. Quarter-Square Multipliers Consisting of Two Cross-Coupled Squaring Circuits

To realize a multiplier using squaring circuits the basic idea is based on the identity $(x + y)^2 - (x - y)^2 = 4xy$ or $(x + y)^2 - x^2 - y^2 = 2xy$. The former identity is usually expressed as

$$\frac{1}{4} [(x + y)^2 - (x - y)^2] = xy \tag{39}$$

The quarter-square technique based on the above identity has been well known for a long time.

The two input voltage ranges and the linearity of the transconductances of the quarter-square multiplier usually depend on the square-law characteristics of the squaring circuits and sometimes depend on the linearities of the adder and subtractor in the input stage. A quarter-square multiplier does not usually possess limiting characteristics with regard to both inputs.

6.3. Four-Quadrant Analog Multipliers with a Multiplier Core

The multiplier core can be considered as four properly combined square circuits. The multiplication is based on the identity

$$\begin{aligned} (ax + by)^2 + \left[(a - c)x + \left(b - \frac{1}{c} \right) y \right]^2 \\ - [(a - c)x + by]^2 - \left[ax + \left(b - \frac{1}{c} \right) y \right]^2 = 2xy \end{aligned} \tag{40}$$

where a , b , and c are constants.

Figure 23. Modified Gilbert cell with a linear transconductance amplifier.

If each squaring circuit is a square-law element with another parameter z , the identity becomes

$$\begin{aligned} &(ax + by + z)^2 + \left[(a - c)x + \left(b - \frac{1}{c} \right) y + z \right]^2 \\ &- [(a - c)x + by + z]^2 \\ &- \left[ax + \left(b - \frac{1}{c} \right) y + z \right]^2 = 4xy \end{aligned} \tag{41}$$

In Eqs. (40) and (41), the parameters a , b , c , and z can be canceled out.

MOS transistors operating in the saturation region can be used as square-law elements. Four properly arranged MOS transistors with two properly combined inputs produce the product of the hyperbolic functions of the inputs. A cell consisting of four emitter- or source-common transistors biased by a single cell tail current can be used as a multiplier core.

6.3.1. Bipolar Multiplier Core. Figure 24a shows a bipolar multiplier core. The individual input voltages applied to the bases of the four transistors in the core can be expressed as $V_1 = aV_x + bV_y + V_R$, $V_2 = (a - 1)V_x + (b - 1)V_y + V_R$, $V_3 = (a - 1)V_x + bV_y + V_R$, $V_4 = aV_x +$

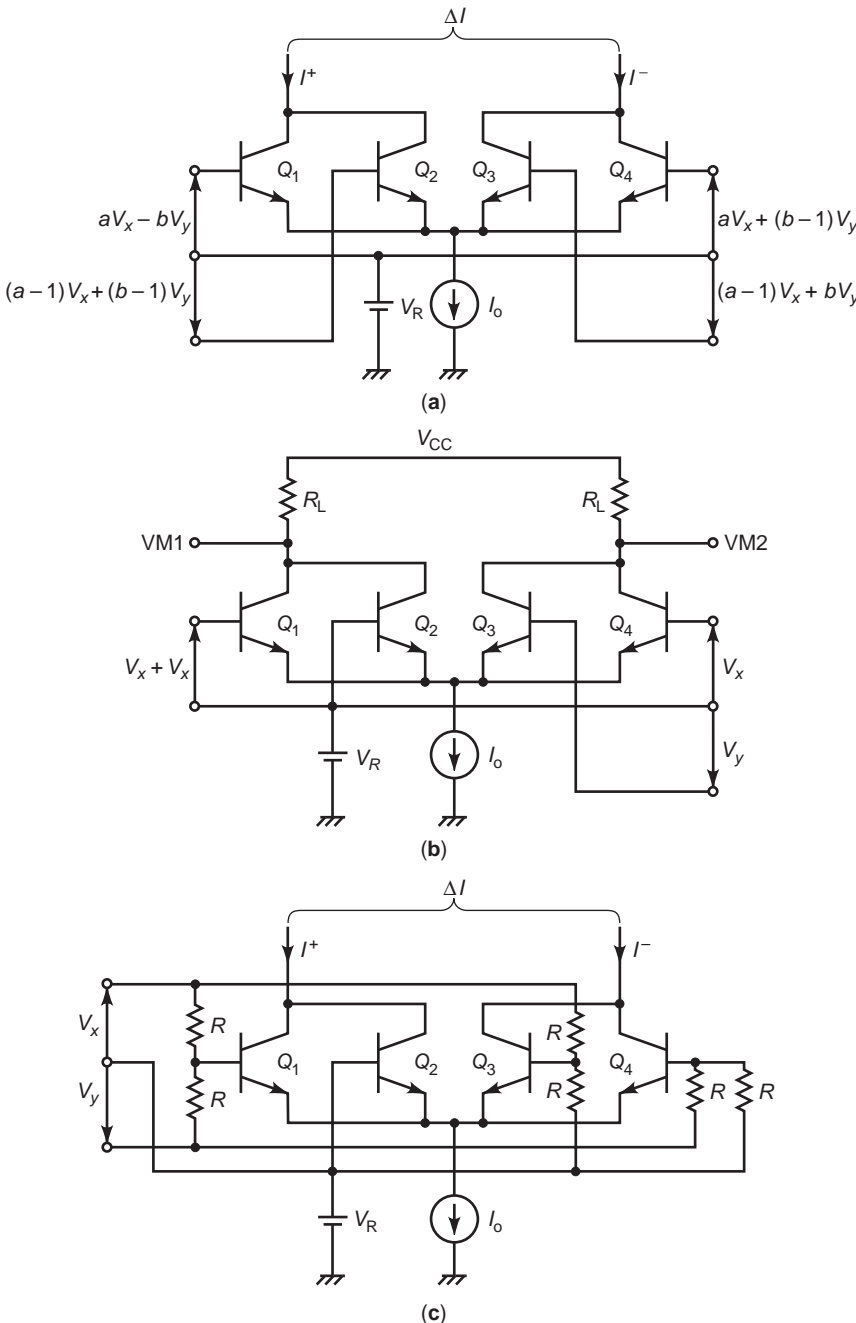

Figure 24. Bipolar multiplier: (a) general circuit diagram of core; (b) the core with the simplest combination of the two input voltages; (c) the bipolar multiplier consisting of a multiplier core and resistive dividers.

$(b-1)V_y + V_R$. The differential output current is expressed as

$$\begin{aligned} \Delta I &= I^+ - I^- = (I_{C1} + I_{C2}) - (I_{C3} + I_{C4}) \\ &= \alpha_F I_0 \tanh\left(\frac{V_x}{2V_T}\right) \tanh\left(\frac{V_y}{2V_T}\right) \end{aligned} \quad (42)$$

The parameters a and b are canceled out. The transfer function of the bipolar multiplier core is expressed as the product of the two transfer functions of the emitter-coupled pairs. The difference between Eqs. (42) and (38) is only in whether the tail current value is multiplied by the parameter α_F or by its square. Therefore, a bipolar multiplier core consisting of a quadritail cell is a low-voltage version of the Gilbert cell.

Simple combinations of two inputs are obtained when $a = b = \frac{1}{2}$, $a = \frac{1}{2}$, and $b = 1$, and $a = b = 1$ as shown in Fig. 24b. In particular, when $a = b = 1$, resistive voltage adders are applicable because no inversion of the signals V_x and v_y is needed (Fig. 24c).

6.3.2. MOS Multiplier Core. Figure 25a shows the MOS four-quadrant analog multiplier consisting of a multiplier core. Individual input voltages applied to the gates of the four MOS transistors in the core are expressed as $V_1 = aV_x + bV_y + V_R$, $V_2 = (a-c)V_x + (b-1/c)V_y + V_R$, $V_3 = (a-c)V_x + bV_y + V_R$, $V_4 = aV_x + (b-1/c)V_y + V_R$. The multiplication is based on the identity of Eq. (41).

Ignoring the body effect and channel-length modulation, the equations for drain current versus drain-to-source voltage can be expressed in terms of three regions of operation as

$$I_D = 0 \quad (43a)$$

for $V_{GS} \leq V_T$, the OFF region,

$$I_D = 2\beta \left(V_{GS} - V_T - \frac{V_{DS}}{2} \right) V_{DS} \quad (43b)$$

for $V_{DS} \leq V_{GS} - V_T$, the triode region, and

$$I_D = \beta (V_{GS} - V_T)^2 \quad (43c)$$

for $V_{GS} \geq V_T$ and $V_{DS} \geq V_{GS} - V_T$, the saturation region, where $\beta = \mu (C_o/2)(W/L)$ is the transconductance parameter, μ is the effective surface carrier mobility, C_o is the gate oxide capacitance per unit area, W and L are the channel width and length, and V_T is the threshold voltage.

The differential output current is expressed as

$$\begin{aligned} \Delta I &= I^+ - I^- = (I_{D1} + I_{D2}) - (I_{D3} + I_{D4}) \\ &= 2\beta V_x V_y (V_x^2 + V_y^2 + |V_x V_y| \leq I_0/2\beta) \end{aligned} \quad (44)$$

The parameters a , b , and c are canceled out. Four properly arranged MOS transistor with two properly combined inputs produce the product of two input voltages. Simple combinations of two inputs are obtained when $a = b = \frac{1}{2}$ and $c = 1$, $a = \frac{1}{2}$ and $b = c = 1$, and $(a = b = c = 1)$ as shown in Fig. 25b.

Figure 25c shows a CMOS four-quadrant analog multiplier consisting of only a multiplier core and an active voltage adder.

In addition, a multiplier consisting of the multiplier core in Fig. 25a and a voltage adder and subtractor has been implemented with a GaAs MESFET IC, and a useful frequency range from dc to UHF bands of 3 GHz was obtained for a frequency mixer operating on a supply voltage of 2 or 3 V.

7. RADIOFREQUENCY SIGNAL AND LOCAL OSCILLATOR

Figure 26 shows a block diagram of a communication system, showing modulation and demodulation. A wireless communication system will usually consists of an information source, which is modulated up to RF or microwave frequencies and then transmitted. A receiver will take the modulated signal from the antenna, demodulate it, and send it to an information “sink,” as illustrated in Fig. 26. The rate at which information can be sent over the channel is determined by the available bandwidth, the modulation scheme, and the integrity of the modulation-demodulation process.

Frequency synthesizers are ubiquitous building blocks in wireless communication systems, since they produce the precise reference frequencies for modulation and demodulation of baseband signals up to the transmit and/or receive frequencies.

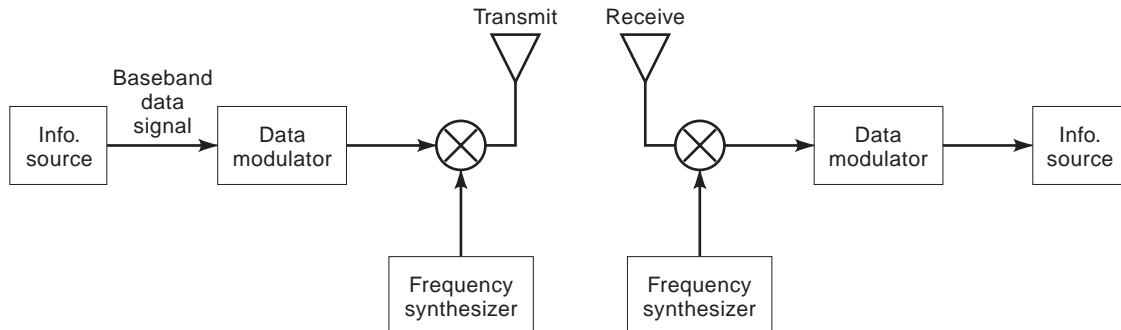

Figure 26. Block diagram of communications system, showing modulation and demodulation.

Figure 27. Block diagram of frequency synthesizer producing single-tone sinusoidal output.

A simple frequency synthesizer might consist of a transistor oscillator operating at a single frequency determined by a precise crystal circuit. Tunable transistor frequency sources rely on variations in the characteristics of a resonant circuit to set the frequency. These circuits can then be embedded in phase-locked loops (PLLs) to broaden their range of operation and further enhance their performance.

A representative view of a frequency synthesizer is given in Fig. 27 which shows a generic synthesizer producing a single tone of a given amplitude that has a delta-function-like characteristic in the frequency domain.

Indirect frequency synthesizers rely in feedback, usually in the form of the PLL, to synthesize the frequency. A block diagram of a representative PLL frequency synthesizer is shown in Fig. 28. Most PLLs contain three basic building blocks: a phase detector, an amplifier loop filter, and a voltage-controlled oscillator (VCO). During operation, the loop will acquire (or lock onto) an input signal, track it, and exhibit a fixed phase relationship with respect to the input. The output frequency of the loop can be varied by altering the division ratio (N) within the loop, or by tuning the input frequency with an input frequency divider (Q). Thus, the PLL can act as a broadband frequency synthesizer.

8. FREQUENCY SYNTHESIZER FIGURES OF MERIT

An ideal frequency synthesizer would produce a perfectly pure sinusoidal signal, which would be tunable over some specified bandwidth. The amplitude, phase, and frequency of the source would not change under varying loading, bias, or temperature conditions. Of course, such an ideal circuit is impossible to realize in practice, and a variety of performance measures have been defined over the years to characterize the deviation from the ideal.

8.1. Noise

The output power of the synthesizer is not concentrated exclusively at the carrier frequency. Instead, it is distrib-

Figure 29. Phase noise specification of frequency source. The noise is contained in the sidebands around the signal frequency at f_0 .

uted around it, and the spectral distribution on either side of the carrier is known as the *spectral sideband*. This is illustrated schematically in Fig. 29. This noise can be represented as modulation of the carrier signal, and resolved into AM and FM components. The AM portion of the signal is typically smaller than the FM portion.

FM noise power is represented as a ratio of the power in some specified bandwidth (usually 1 Hz) in one sideband to the power in the carrier signal itself. These ratios are usually specified in “dBc/Hz” at some frequency offset from the carrier. The entire noise power can be integrated over a specified bandwidth to realize a total angular error in the output of the oscillator, and oscillators are often specified this way.

8.2. Tuning Range

The tuning range of an oscillator specifies the variation in output frequency with input voltage or current (usually voltage). The slope of this variation is usually expressed in megahertz per volt. In particular, the key requirements of oscillator or synthesizer tuning are that the slope of the frequency variation remain relatively consistent over the entire range of tuning and that the total frequency variation achieve some minimum specified value.

8.3. Frequency Stability

Frequency stability of an oscillator is typically specified in parts per million per degree centigrade (ppm/°C). This parameter is related to the Q of the resonator and the frequency variation of the resonator with temperature. In a free-running system this parameter is particularly important, whereas in a PLL it is less so, since an oscillator that drifts may be locked to a more stable oscillator source.

Figure 28. Indirect frequency synthesizer using a phase-locked loop.

8.4. Harmonics

Harmonics are output from the oscillator synthesizer that occur at integral multiples of the fundamental frequencies. They are typically caused by nonlinearities on the transistor or other active devices used to produce the signal. They can be minimized by proper biasing of the active device and design of the output matching network to filter out the harmonics. Harmonics are typically specified in “dBc” below the carrier.

8.5. Spurious Outputs

Spurious outputs are outputs of the oscillator synthesizer that are not necessarily harmonically related to the fundamental output signal. As with harmonics, they are typically specified in “dBc” below the carrier.

The desire for mobility and for communication with others is deeply ingrained in human nature. The need to develop an efficient public mobile communication system has been driving a lot of researchers since the late nineteenth century. It is generally accepted that mobile communication (precisely speaking, mobile radiocommunication) was born in 1897, when Guglielmo Marconi gained a patent for his wireless telegraph. Since then, mobile communications have gone from the early stages at the beginning of the twentieth century, when mobile communication was widely used in navigation and in maintaining contacts with remotely traveling ships and airplanes, through

infancy of the 1950s and the 1960s, to maturity at the end of the twentieth century, when public mobile telephony, paging, and other mobile services are common place. There are several comprehensive readings available on each of those specific services [1–4], and this article does not pretend to cover all topics related to mobile communication. Rather, we concentrate on some specific issues that, in our opinion, allow the reader to understand major differences between mobile and stationary or fixed communications.

1. HISTORY

Mobile communication has always been used by people, particularly during military struggles, when commanders needed to pass their orders to remote troops in the middle of a battle. Several methods have been used, with horns and drums among the most popular. Different optical “mobile communication” systems based on so-called signal flags have also been used for maritime applications. All of those methods have been, however, of a limited range and small capacity. There were no major improvements in mobile communication until the birth of electromagnetic theory.

In the late nineteenth century, after the theoretical predictions made by Maxwell in his treatise on electricity and magnetism and Rudolf Hertz’s experimental work on the transmission and reception of electromagnetic waves, Guglielmo Marconi and some other researchers started to look into possible applications of electromagnetic radiation for communication purposes. Since then, radio communications have been used to save lives, win battles, generate new businesses, maximize opportunities, and so forth. From the introduction of public mobile cellular telephony in the 1980s, mobile communications have become elements of mass communication with the objective of providing a broad range of services similar to, and in some instances exceeding, those offered by the public switched telephone network (PSTN). The level of penetration for mobile phones varies among different countries, but in some countries it is already high.

Before the 1970s, numerous private mobile radio networks—citizen band (CB) radio, ham operator mobile radio, and portable home radio telephones—used different types of equipment utilizing diverse fragments of radio spectrum located in the frequency band from about 30 MHz to 3 GHz. Standardization started to take place in the 1970s with the development of the Nordic Mobile Telephone (NMT) system by Ericsson and the Advanced Mobile Phone Services (AMPS) by AT&T. Both systems have become *de facto* and *de jure* the technical standards for the analog mobile telephony as the so-called first-generation systems. Soon after the deployment of those first-generation systems, second generation, fully digital mobile cellular systems appeared on drawing boards throughout the world. The Groupe Spécial Mobile (GSM), pan-European, fully digital cellular telephony standard was developed in late 1980s. After its successful deployment, it began to be accepted as a standard for the second-generation mobile radio not only in Europe but

also in other parts of the world. The main competition for the GSM monopoly in digital mobile telephony has come from code-division multiple-access (CDMA) spread-spectrum technology, developed primarily for military applications. The CDMA-based IS-95 systems, and time-division multiple-access (TDMA)-based GSM systems have their powerful supporters and vigorous opponents, and it is not clear yet which approach is going to be adopted in the development of the third generation of mobile telephony or the future public land mobile telecommunication system (FPLMTS), which recently has been re-named International Mobile Telecommunications—2000 (IMT-2000).

2. OVERVIEW OF CONCEPTS

A typical mobile communication system consists of mobile terminals, base stations, mobile switching centers, and telecommunication channels. Those telecommunication channels are either of a fixed nature (cables or dedicated radiolinks), to provide connections between base stations and the mobile switching center, or mobile radio channels between mobile terminals and base stations servicing those terminals.

Unlike fixed telecommunication channels, the mobile radio channels are nonstationary and exhibit a high level of unpredictability with regard to channel characteristics. In addition, due to the nature of radiocommunication and low directivity of antennas used, there is always a possibility of strong interference from other users of the radio spectrum. All these factors need to be carefully taken into account while calculating a power budget for a mobile radio channel.

One of the specific features of mobile communication systems is the need to assign a free radio channel to the user requiring the connection. This is done during setup of the connection. This setup, combined with the limited frequency spectrum available for mobile services, means that the number of simultaneous calls within the coverage area of a single base station is highly limited. Therefore, before introduction of the cellular concept (which is explained later in the section on spectrum management), the number of simultaneous calls within a system covering sometimes a huge area was very low. For example, the single-base-station mobile system in New York City in the 1970s could only support a maximum of 12 simultaneous calls over one thousand square miles [5]. The concept of such a cellular system is illustrated in Fig. 1.

There are generally four different types of channels that are used for communication between the base station and mobiles: (1) forward voice channels (FVCs), used for voice transmission from the base station to mobiles; (2) reverse voice channels (RVCs), used for voice transmission from mobiles to the base station; (3) forward control channels (FCC), used for transmission of signaling data from the base station to mobiles; and (4) reverse control channels (RCC), used for transmission of signaling data from mobiles to the base station. The control channels transmit and receive data necessary to set up a call, moving it to an unused voice channel, and to manage the

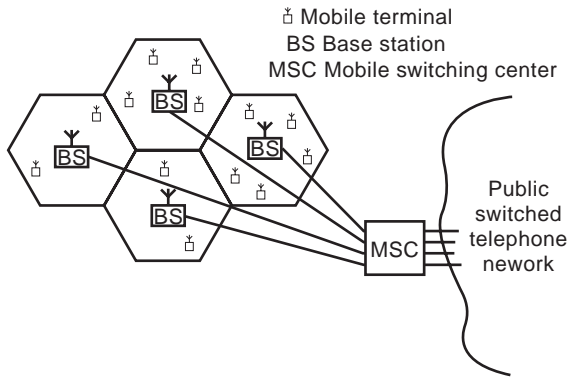

Figure 1. Configuration of a cellular system.

handovers between base stations. They are also used for constant monitoring of the system and for synchronization purposes.

The base station serves as a bridge between all mobile users in its coverage area and the mobile switching center (MSC). The MSC acts as a central switching point, closing the traffic among the connected base stations, and serves as a gateway to the PSTN. It also coordinates all activities of the base stations and accommodates all billing and maintenance functions. A typical MSC handles 100,000 cellular subscribers and 5000 simultaneous conversations [6].

3. CLASSIFICATION

Mobile communication systems are classified into generations in accordance with evolution of systems in time. Indicators for a generation are involved transmission techniques, supported services, and status of unification. First-generation systems were introduced in the early 1980s and used analog techniques basically for speech services. Second generation systems evolved in the late 1980s and are now in a mature form. They utilize digital techniques, and, apart from speech, they support some

low-rate data services. Second-generation systems may be further classified into cellular, cordless, and professional radio systems. Due to the wide range of second-generation systems and their immense complexity, we only summarize some air interface parameters of selected digital cellular systems in Table 1. Standards for third-generation systems are currently being developed to provide mobile multimedia telecommunications and universal coverage. In the following subsections, we will give a concise overview of mobile communication systems and refer to the literature for details.

3.1. First-Generation Systems

The first-generation cellular systems use analog frequency modulation (FM) for traffic channels, digital frequency shift keying (FSK) for signaling channels, and a frequency division duplex (FDD) method. In addition, frequency-division multiple access (FDMA) is employed to share the transmission medium. In the beginning, businesspeople were the main customers, but later acceptance in residential markets started to increase immensely. In 1981, the Scandinavian countries introduced the Nordic Mobile Telephone standard NMT-450 [7] and in 1986 the NMT-900 standard, where the numbers in the acronyms indicate the utilized frequency band in MHz. The AMPS system [8] was developed in the United States, and service opened in 1983. AMPS has been adapted by many countries, such as Canada and Australia. A variant of AMPS is the Total Access Communication system (TACS) deployed in 1985 in the United Kingdom, which basically uses a smaller channel spacing than AMPS. In 1986, the C-450 system [9] opened its service in Germany.

3.2. Second-Generation Systems

3.2.1. Cellular Systems

3.2.1.1. Global System for Mobile Communication.

Although mobile communication in most European countries was well covered by their individual analog cellular systems, incompatible standards made it impossible to

Table 1. Characteristics of Selected Second-Generation Systems

Mobile System	GSM	DCS-1800	DECT	IS-95
Frequency band				
MS → BS	890–915 MHz	1710–1785 MHz	1880–1990 MHz	824–849 MHz
BS → MS	935–960 MHz	1805–1880 MHz	1880–1900 MHz	869–894 MHz
Carrier spacing	200 kHz	200 kHz	1728 kHz	1250 kHz
Duplex spacing	45 MHz	95 MHz	0 Hz	45 MHz
No. of carriers	125	375	10	20
System bandwidth	2 × 25 MHz	2 × 75 MHz	20 MHz	2 × 25 MHz
Speech coder				
Full rate	13 kb/s RPE-LTP	13 kb/s RPE-LTP	32 kb/s ADPCM	8, 4, 2, 1 kb/s QCELP
Half rate	5.6 kb/s VSELP	4.5 kb/s VSELP		
Multiple access	TDMA	TDMA	TDMA	CDMA
Duplexing method	FDD	FDD	TDD	FDD
Modulation	GMSK ($BT^{\alpha} = 0.3$)	GMSK ($BT^{\alpha} = 0.3$)	GMSK ($BT^{\alpha} = 0.5$)	QPSK/BPSK
Frame bit rate	271 kbps	271 kbps	1.152 Mbps	1.288 Mbps
Frame length	4.615 ms	4.615 ms	10 ms	20 ms

interwork among systems or share equipment. To overcome this deficiency, the Conférence Européenne des Postes et Télécommunications (CEPT) established in 1982 the Groupe Spécial Mobile to develop a pan-European standard. The outcome was the GSM system [10], which now stands for global system for mobile communication. The standard specifies a digital cellular system on the basis of a dedicated pan-European frequency band allocated at 900 MHz. GSM supports a variety of speech and low-rate data services. In 1991, the first GSM system opened and since then it has experienced tremendous popularity worldwide, as indicated by the more than 65 countries that have already adopted GSM. An extension of GSM is the Digital Cellular System—1800 (DCS-1800) standard allocated in the 1.8-GHz band. DCS-1800 has been designed to meet the requirements of personal communication networks (PCN).

3.2.1.2. Interim Standard 54 (IS-54). During the 1980s, increasing demand on cellular services was observed in the United States, approaching traffic capacity limits of analog AMPS. To satisfy the enormous capacity requirements, the Cellular Telecommunication Industry Association asked for a digital standard. As a result, IS-54 [11] has been developed and is also known as United States Digital Cellular (USDC). IS-54 is designed to coexist with analog AMPS in the same frequency band but to replace the analog system step by step. For that reason, IS-54 has to be upward compatible to AMPS and hence is sometimes referred to as digital AMPS (D-AMPS). With the used digital techniques and planned employment of a half-rate codec, IS-54 is expected to provide six times the traffic capacity than AMPS.

3.2.1.3. Interim Standard 95 (IS-95). Development of IS-95 was launched in 1991 after Qualcomm successfully demonstrated a CDMA digital cellular validation system. The IS-95 standard [12] specifies a direct-sequence CDMA digital cellular system. This wideband digital cellular standard employs a set of spreading sequences that are assigned to users. All users in the cellular system transmit in the same radio channel but using different sequences. Therefore, frequency planning is not required and can be thought of as replaced by planning how to allocate spreading sequences in different cells.

3.2.1.4. Personal Digital Cellular (PDC). The Japanese effort to increase capacity over analog systems is documented in a PDC air interface standard [13], which was issued in 1991. This digital cellular system has been allocated a different frequency band than the analog system. It supports speech, data, and short message services.

3.2.2. Cordless Systems

3.2.2.1. Cordless Telephony (CT2). The initial goal of cordless telephony was to provide wireless pay phone services with low-cost equipment but no support of incoming calls. These systems cover only a single cell with a radius of about 300 m outdoor and 50 m indoor. Most manufacturers in Europe agreed on a common air interface (CAI), which become the CT2/CAI standard [14]. It uses digital

techniques and replaces analog cordless telephony, which offered only a small number of channels. In Canada, CT2 + was developed to support incoming calls as well. By dedicating more carriers for signaling purposes, location management was practicable.

3.2.2.2. Digital European Cordless Telecommunications (DECT). The DECT standard [14] was developed by the European Telecommunications Standards Institute (ETSI) and has been allocated a guaranteed pan-European frequency. It is designed as a flexible interface based on open system interconnection (OSI) and was finalized in 1992. The system provides mobility in picocells with very high capacity. Speech and data services are supported where incoming and outgoing calls can be managed. Initially, DECT was intended for interworking with private automatic branch exchange (PABX) to provide mobility within the area of a PABX. Its application-independent interface allows also interworking with PSTN, integrated services digital network (ISDN), or even GSM. For operators of public networks, DECT can be employed to span the last mile to subscribers by radio local loop (RLL).

3.2.2.3. Personal Handy Phone Systems (PHS). In 1989, the Japanese Ministry of Posts and Telecommunications initiated the standardization process for another cordless system, which become the PHS standard [15]. Among other things, the standard defines the air interface, voice services, and data services. The system is designed for small cells, and it maintains incoming as well as outgoing calls. A special feature of PHS is that mobiles that are close enough may bypass the base station and communicate directly with each other.

3.2.3. Professional Mobile Radio. Besides cellular and cordless systems, a variety of professional mobile radio (PMR) systems have been designed for professional and private users. In 1988, the European Commission and ETSI initiated standardization of a PMR system known as trans-European trunked radio (TETRA). Applications include group calls within a fleet of users and fleet management as required by police, safety organizations, or taxi companies. Similarly, in the United States the so-called Associated Public Safety Communications Officers Project 25 (APCO 25) is specifically concerned with public safety radio services. There are a number of other PMR systems, such as European radio message (ERMES), digital short-range radio (DSSR), and terrestrial flight telephone system (TFTS), to mention only a few.

3.3. Third-Generation Systems

At present, mobile communications is realized by many kinds of competitive and incompatible standards, systems, and services. On the other hand, unification of cellular, paging, cordless, and professional mobile radio is desirable to manage limited physical resources, improve system quality, and keep up with the great demand for mobile services. Third-generation systems aim to provide unification and worldwide coverage.

3.3.1. Universal Mobile Telecommunication System. The European effort to support the same type of services anywhere and anytime is known as the Universal Mobile Telecommunication System (UMTS) and is described in Ref. 16. It is based on GSM, DCS-1800, and DECT. Standardization is concerned with air interface and protocol issues aiming for global coverage for speech, low-to-medium bit rate services, and multimedia capabilities. A major challenge is to achieve higher data rates, up to 2 mbps. In 1987, the European Union launched a program called Research and Development in Advanced Communications Technologies in Europe (RACE). RACE was supposed to investigate advanced options for mobile communications and in that way assist ETSI in standardization of UMTS. Several subprojects within RACE were concerned with advanced topics, as the following examples indicate. The advanced TDMA (ATDMA) project investigated antenna systems and equalization issues. An approach to increase data rate was undertaken in the Code Division Testbed (CODIT) project. Recently, an agreement was reached among European companies on the radio interface for UMTS based on wideband CDMA (W-CDMA) and time division CDMA (TD-CDMA) technologies [17]. Operation of UMTS is expected to commence in the beginning of the twenty-first century.

3.3.2. International Mobile Telecommunications—2000. In the mid-1980s, the International Telecommunications Union (ITU) began its studies of future public land mobile telecommunication systems, the goal of which is to support mobile communication anywhere, anytime. The goals are similar to those intended to be reached by UMTS, but under a worldwide perspective. The ITU approach is now called International Mobile Telecommunications—2000 (IMT-2000) [18], the former FPLMTS (the attached 2000 indicates the frequency band of operation in MHz as well as the year in which service is planned to open). At the World Administrative Radio Conference in 1992 (WARC-92), a bandwidth of 230 MHz in the 2 GHz frequency band was allocated worldwide to IMT-2000. A major objective of IMT-2000 is to offer users a small, inexpensive pocket communicator and provide for seamless roaming of a mobile terminal across various networks. Services range from voice to data and mobile multimedia applications or even Internet access. These services will be offered for a wide range of operating environments, such as indoor, outdoor, terrestrial, and satellite networks. ITM-2000 will utilize technologies like the asynchronous transfer mode (ATM) to provide broadband transport services.

3.3.3. Other Systems

3.3.3.1. Wireless Local Area Networks (WLANs). Mobile data of second-generation systems offers only low bit rate wireless data transmission but with wide-area mobility and roaming. UMTS and IMT-2000 are supposed to increase the bit rate to some 2 Mbps. On the other hand, for in-house and on-premises networking there is substantial demand for higher bit rates in the range of 20 Mbps, whereas mobility is required only in a restricted area. WLAN systems for such local networking are planned to complement third-generation systems and are considered a flexible and cost-

effective alternative to cable-based LANs. Since proprietary solutions are typically customized and rely on products of a particular equipment supplier, standardization of WLAN systems has been undertaken as follows. The high-performance radio local-area network (HIPERLAN) standard [19] was developed by ETSI. HIPERLAN achieves a bit rate of 20 Mbps and can be used to extend wired LANs such as Ethernet. Spectrum has been recommended in the 5- and 17-GHz bands. Access to the shared transmission channel is gained by a contention-based and collision avoidance strategy. All time-critical services are supported by best effort and, in principle, may achieve the same access priority. The Institute of Electrical and Electronics Engineers (IEEE) 802.11 standard [20] represents the first approach for WLAN products from an internationally recognized, independent organization. It defines the protocol for two types of networks—namely, adhoc and client/server networks. IEEE 802.11 operates in the industrial, scientific, and medical (ISM) band at 2.4 GHz using spread-spectrum modulation. The medium access control (MAC) uses a collision avoidance mechanism. The third major effort in the area of WLANs is known as wireless ATM (WATM) [21,22]. With ATM being a widely accepted standard for broadband networking, it is natural to extend this technology into the wireless domain. Accordingly, the ATM Forum is working toward a WATM standard. A WATM system will provide bandwidth on demand for low- and high-priority services, hence providing real support of time critical multimedia services. Furthermore, a WATM system will interwork seamlessly with wired ATM networks and can be expected to cooperate very well with IMT-2000.

3.3.3.2. Satellite Systems. Further improvement of coverage can be provided by satellite systems [23], which are a component of future-generation mobile systems. Low-Earth-orbit (LEO) satellite systems typically operate on orbits at an altitude of 700–1400 km, whereas medium-Earth-orbit (MEO) satellite systems have their orbits at about 10,000 km. Compared to geostationary satellite systems, LEO and MEO systems allow low-power handhelds and smaller antennas and offer a smaller round-trip delay between Earth and satellite. Both LEO and MEO systems employ a number of satellites that form a satellite network and offer worldwide coverage. Satellite systems can be used to cover remote areas that are out of range of a terrestrial cellular system or where a telephony system does not exist. The first generation of satellite personal communications networks (S-PCN) will basically support voice, data, facsimile, and paging. Promising candidates of LEO/MEO systems are Intermediate Circular Orbit (ICO) satellite cellular telephone systems, formerly known as Inmarsat-P, Odyssey, Globalstar, and Iridium. The second generation of S-PCN systems, such as the Teledesic approach, will evolve toward multimedia services and employ ATM technology as well.

4. MOBILE RADIO CHANNELS

Mobile radio channels considered to be a complex and severe transmission medium. Path loss often exceeds that of

Figure 2. Illustration of multipath propagation typically experienced in a mobile radio environment. Signals between transmitter and receiver propagate along a line-of-sight (LOS) path and are scattered through several echo paths.

free space by several tens of decibels. Reflection, diffraction, scattering, and shadowing lead to fading and multipath reception (Fig. 2). Mobile radio channels are time variant, where signals fluctuate randomly as the receiver moves over irregular terrain and among buildings. Understanding channel behavior and development of channel models for a specific band is always vital for efficient system design.

4.1. Large-Scale Propagation Models

Propagation models that predict the average signal strength of a received signal at a given distance from the transmitter are called large-scale propagation models. These models are concerned with loss along the wave propagation path between the mobile and base stations. Extensive measurement campaigns have been undertaken to develop models for some typical environments. We distinguish roughly between rural, sub-urban, and urban environments.

4.1.1. Free-Space Model. The ideal large-scale model is free-space propagation, assuming that no objects or obstacles influence propagation. Free-space path loss is given by [24]

$$L_F = 10 \log G_t + 10 \log G_r - 20 \log f_c - 20 \log d - 32.44 \text{ dB} \quad (1)$$

where G_t and G_r are the transmitter and receiver antenna gain compared to an isotropic antenna, f_c is the carrier frequency in MHz, and d is the distance between the transmitter and receiver in km.

4.1.2. Okumura–Hata Model. Okumura [25] presented a graphical method to predict the median attenuation relative to free space for a quasismooth terrain. The model consists of a set of curves developed from measurements and is valid for a particular set of system parameters in terms of carrier frequency, antenna height, and so forth. After the free-space path loss has been computed, the median attenuation, as given by Okumura's curves, has to be added. Additional correction factors apply for different terrains. Later, Hata [26] transformed Okumura's graphical method into an analytical framework. The Hata model

for urban areas is given by the empirical formula

$$L_{50, \text{urban}} = 69.55 \text{ dB} + 26.16 \log f_c - 13.82 \log h_t - a(h_r) + (44.9 - 6.55 \log h_t) \log d \quad (2)$$

where $L_{50, \text{urban}}$ is the median path loss in dB. Equation (2) is valid for carrier frequencies f_c in the range from 150 to 1500 MHz, mobile antenna height h_r from 1 to 10 m, and base station antenna height ranging from 30 to 200 m. The distance d between mobile and base is supposed to be within 1–20 km. The correction factor $a(h_r)$ for mobile antenna height h_r for a small- or medium-sized city is given by

$$a(h_r) = (1.1 \log f_c - 0.7)h_r - (1.56 \log f_c) - 0.8 \text{ dB} \quad (3)$$

and for a large city it is given by

$$a(h_r) = \begin{cases} 8.29 [\log(1.54h_r)]^2 - 1.1 \text{ dB} & \text{for } f_c \leq 300 \text{ MHz} \\ 3.2 [\log(11.75h_r)]^2 - 4.97 \text{ dB} & \text{for } f_c \geq 300 \text{ MHz} \end{cases} \quad (4)$$

Equation (2) serves as the standard formula in urban areas and has to be modified for suburban areas:

$$L_{50, \text{suburban}} = L_{50, \text{urban}} - 2[\log(f_c/28)]^2 - 5.4 \text{ dB} \quad (5)$$

For rural areas, we have to use

$$L_{50, \text{rural}} = L_{50, \text{urban}} - 4.78(\log f_c)^2 - 18.33 \log f_c - 40.94 \text{ dB} \quad (6)$$

A uniform extension of these formulas for carrier the frequency range $1500 \text{ MHz} \leq f_c \leq 2000 \text{ MHz}$ and small cells, such as those of personal communications systems, is specified by the European Co-operative for Scientific and Technical research (COST-231) recommendation [27].

4.2. Wideband Characterization

To model the time and frequency dispersion of a mobile radio channel with respect to wideband transmission, a system theory approach can be utilized [28]. This approach is concerned with fading and multipath in the vicinity of a small area. A set of system functions provides a description in either the time or frequency domain. Due to the random nature of the radio channel, system functions describe stochastic processes.

4.2.1. Time-Variant Impulse Response and Autocorrelation Function. Bello [28] showed that a radio channel may be regarded as a linear time-variant systems. He introduced a set of continuous-time and continuous-frequency

system functions, each of which completely describes the channel and can be transformed into any of the remaining functions. For the sake of clarity, we assume hereinafter that signal spectra are narrow compared with carrier frequency and channel bandwidth. Thus, we can use a complex lowpass equivalent to represent a bandpass system [29]. In doing so, let us focus on the time domain and consider the input delay spread function $h(t, \tau)$, defined by

$$y(t) = \int_{-\infty}^{\infty} x(t - \tau)h(t, \tau) d\tau \quad (7)$$

where $x(t)$ and $y(t)$ denote the complex envelope of the transmitted and received signals, respectively. The input delay spread function $h(t, \tau)$ can be thought of as time-variant impulse response of the lowpass equivalent channel at time t due to unit input impulse applied in the past at time $t - \tau$.

Correlation functions provide significant insight into stochastic processes and are often used to avoid specification of multidimensional probability density functions. In this context, the autocorrelation function of the channel impulse response is given by [28]

$$R_h(t_1, t_2; \tau_1, \tau_2) = \overline{h(t_1, \tau_1)h^*(t_2, \tau_2)} \quad (8)$$

where $h(t, \tau)$ is assumed to be a random process without deterministic component, $\overline{h(\cdot)}$ denotes the ensemble average of $h(\cdot)$, and $*$ indicated a conjugate complex. Variables t_1 and t_2 denote time instants, whereas τ_1 and τ_2 denote delays. For many mobile radio channels Eq. (8) does not depend on absolute time but on time difference. In addition, scatterers may be regarded as uncorrelated. Such a channel is called a *wide-sense stationary uncorrelated scattering* (WSSUS) channel, and its autocorrelation function simplifies to [28]

$$R_h(t_1, t_2; \tau_1, \tau_2) = P_h(\Delta t; \tau_2)\delta(\tau_2 - \tau_1) \quad (9)$$

where $P_h(\Delta t; \tau_2)$ is a cross-power spectral density, $\Delta t = t_2 - t_1$ indicates time difference, and $\delta(\tau)$ denotes a unit impulse at time $\tau = \tau_2 - \tau_1$.

4.2.2. Time and Frequency Dispersion Parameters. In practice, a set of typical channel parameters is used to characterize the dispersive behavior of a mobile radio channel in the time and frequency domain. Similar to Bello's system approach of corresponding functions, time and frequency dispersion parameters possess dual representations in the frequency and time domain, respectively. These parameters can be obtained from measurements and employed for channel classification.

4.2.2.1. Delay Spread and Coherence Bandwidth. Because of multipath propagation, the impulse response of a mobile radio channel appears as a series of pulses rather than a single delayed pulse. A received signal suffers spreading in time compared to the transmitted signal. Delay spread can range from a few hundred nanoseconds inside buildings up to some microseconds in urban areas.

Delay-related parameters can be obtained from the power delay profile $P_h(\tau)$ [29], which is defined as the power spectral density for $\Delta t = 0$:

$$P_h(\tau) = P_h(\Delta t, \tau)|_{\Delta t=0} \quad (10)$$

Maximum excess delay is defined as the period between the time of the first arriving signal and the maximum time at which a multipath signal exceeds a given threshold. The first moment of a power delay profile is called mean excess delay m_τ and is defined by

$$m_\tau = \frac{\int_0^{\infty} \tau P_h(\tau) d\tau}{\int_0^{\infty} P_h(\tau) d\tau} \quad (11)$$

The square root of the second central moment of the power delay profile is referred to as root-mean-square (RMS) delay spread, σ_τ , and is defined by

$$\sigma_\tau = \sqrt{\frac{\int_0^{\infty} [\tau - m_\tau]^2 P_h(\tau) d\tau}{\int_0^{\infty} P_h(\tau) d\tau}} \quad (12)$$

The coherence bandwidth B_c translates time dispersion into the language of the frequency domain. It specifies the frequency range over which a channel affects the signal spectrum nearly in the same way, causing an approximately constant attenuation and linear change in phase. Coherence bandwidth is inversely proportional to rms delay spread:

$$B_c \propto \frac{1}{\sigma_\tau} \quad (13)$$

4.2.2.2. Doppler Spread and Coherence Time. Movement of a mobile station relative to a base station or movement of objects within the channel causes the received frequency at the mobile station to differ from the transmitted frequency due to Doppler shift. In a multipath environment, a mobile station receives signals from different paths. Its relative movement with respect to each path differs, which results in a range of Doppler shifts. The bandwidth over which dispersion of the transmitted frequency occurs is referred to as the Doppler spread, B_d . The time domain equivalent to Doppler spread B_d is called coherence time, T_c . It specifies a period over which the channel impulse response $h(t, \tau)$ is nearly time invariant. Coherence time is inversely proportional to Doppler spread:

$$T_c \propto \frac{1}{B_d} \quad (14)$$

4.2.3. Classification of Multipath Channels

4.2.3.1. Flat Fading. This type of fading is related to delay spread. It occurs when the signal symbol period is

much larger than rms delay spread. As a result, intersymbol interference (ISI) almost vanishes. In the dual domain, the signal bandwidth is narrow compared to the coherence bandwidth. The channel has a flat transfer function with almost linear phase, thus affecting all spectral components of the signal similarly.

4.2.3.2. Frequency Selective Fading. If the signal symbol period is much lower than rms delay spread, the receiver is able to resolve multipath components, and ISI impairs transmission. In that case, the bandwidth of the signal exceeds the coherence bandwidth, and various spectrum components may be affected differently. Frequency selective fading is also caused by delay spread.

4.2.3.3. Fast Fading. This type of fading is caused by motion in a mobile environment and hence relates to Doppler spread. Fast fading can be observed when significant changes in the channel impulse response occur within the signal symbol period. In other words, the bandwidth of the Doppler spectrum is wide compared with the signal bandwidth, which then causes significant signal distortion.

4.2.3.4. Slow Fading. In the case when the channel impulse response is almost time invariant for the duration of a signal symbol period, we observe a slow fading and only a minor signal distortion. The Doppler spread is then narrow compared to the signal bandwidth.

4.3. Narrowband Characteristics

We consider an unmodulated sinusoidal waveform being transmitted at carrier frequency f_c and described in complex notation by $x(t) = \exp(j2\pi f_c t)$, where $j = \sqrt{-1}$. The equivalent lowpass signal at the receiver can be written as [29]

$$\begin{aligned} y(t) &= y_I(t) + jy_Q(t) \\ &= \sum_{i=-\infty}^{\infty} a_i(t) \cdot \exp[j2\pi f_{d,i}t - j2\pi f_c \tau_i(t)] \end{aligned} \quad (15)$$

where $y_I(t)$ and $y_Q(t)$ denote, respectively, in-phase and quadrature components of the complex-valued signal $y(t)$, $a_i(t)$ is complex amplitude, $f_{d,i}$ is Doppler frequency, and $\tau_i(t)$ is delay of the i th multipath component.

4.3.1. Fading Distributions

4.3.1.1. Rayleigh Fading. Suppose there is no dominant path between transmitter and receiver, and all multipath components are multiply reflected to build a diffuse received signal. In that case, complex amplitude $a_i(t)$, Doppler frequency $f_{d,i}$, and delay $\tau_i(t)$ can be considered statistically independent of each other. The probability density function of the received signal envelope $r(t) = |y(t)| = \sqrt{y_I^2(t) + y_Q^2(t)}$ leads to a Rayleigh distribution

given by [24]

$$p_{\text{Rayleigh}}(r) = \frac{r}{\sigma_y^2} \exp\left(-\frac{r^2}{2\sigma_y^2}\right) \quad (16)$$

where $r \geq 0$ is the received signal envelope and $\sigma_y^2 = E\{y_I^2(t)\} = E\{y_Q^2(t)\}$ is the variance of the zero-mean and normally distributed processes, describing $y_I(t)$ and $y_Q(t)$. Mean m_r and variance σ_r of $r(t)$ are given by $m_r = E\{r(t)\} = \sqrt{\pi/2} \cdot \sigma_y$ and $\sigma_r^2 = (2 - \pi/2) \cdot \sigma_y^2$, respectively.

4.3.1.2. Rice Fading. Let the received signal contain a dominant component that might be caused by a line-of-sight (LOS) path or single reflected multipath components. In terms of an equivalent lowpass signal, we have to add a constant r_0 to the real part of $y(t)$ and thus $y(t) = [r_0 + y_I(t)] + jy_Q(t)$. The corresponding probability distribution function of the signal envelope $r(t) = \sqrt{[r_0 + y_I(t)]^2 + y_Q^2(t)}$ leads to a Rician distribution [24]

$$p_{\text{Rice}}(r) = \frac{r}{\sigma_y^2} \exp\left(-\frac{r^2 + r_0^2}{2\sigma_y^2}\right) I_0\left(\frac{r \cdot r_0}{\sigma_y^2}\right) \quad (17)$$

where $r_0 \geq 0$ is the peak amplitude of the dominant component and $I_0(\cdot)$ is the zero-order modified Bessel function of the first kind.

4.3.1.3. Lognormal Fading. When a mobile station moves within an area about the base station, the local-mean power P_r of the received signal varies about the area-mean power P_s due to shadowing effects. Measurements have shown that the logarithmic value $L_r = 10 \log(P_r)$ in dB of the local-mean power P_r is normal distributed about the logarithmic value $L_s = 10 \log(P_s)$ in dB of the area-mean power P_s . This gives rise to the call P_r being lognormal distributed, and the corresponding probability density function is given by [30]

$$\begin{aligned} p_{\text{lognormal}}(P_r) &= \frac{10 \log(e)}{P_r} \cdot \frac{1}{\sqrt{2\pi}\sigma_s} \\ &\times \exp\left\{-\frac{[10 \log(P_r) - L_s]^2}{2\sigma_s^2}\right\} \end{aligned} \quad (18)$$

where standard deviation σ_s in dB characterizes the shadowing effect.

5. SPECTRUM MANAGEMENT

The radiofrequency spectrum is a limited resource that has to be shared in some way among the communication community. With the increasing demand for mobile radio communication, regulations and methods for efficient spectrum usage are required. Frequency authorities such as the ITU and the Federal Communications Commission (FCC) play a vital part in allocating frequency bands to new systems and in worldwide coordination of the radio spectrum. Once a frequency band has been

licensed, the cellular concept enables spectrum efficiency by reusing frequency in spatial by distant areas. Bandwidth-efficient modulation schemes can be used to increase further the total number of available channels in a system.

5.1. Frequency Licensing

Spectrum planning is a hierarchical process that starts at the highest international level at the ITU and is covered by the WARC. This international framework is a base for national frequency planning and allocation. From the start of a licensing process to actual frequency allocation with specified services, often several years elapse. On the other hand, today's main requirements of licensing procedures are speed, transparency, fairness, efficiency, and conformity with government objectives. As a response, several national regulatory methods for licensing of frequency bands have been applied and are still used, depending on the local situation [31].

5.1.1. Over-the-Counter Allocation. This is the traditional method, which can be regarded as a first come, first served principle. Obviously, with this method there will be unsatisfied demand. In addition, there is no guarantee that those who apply first will be those who value the spectrum most highly or whose service is of greatest importance to the community. In cases where demand does not exceed supply (e.g., for many military applications), this approach is still favored.

5.1.2. Comparative Assessment. In this approach governments and regulators assess the relative merits of different applicants for a frequency band. The criteria are varied—for example, anticipated consumer benefits, the technology applied, or the perceived overall social worth of the service to be supplied. A regulator must be able to make judgments about the most valued use of a frequency band. Apparently, comparative assessment is neither transparent nor fast or even fair and should only be used when a decision can be easily reached (e.g., if there is no competition between providers due to a monopolistic market).

5.1.3. Lotteries. Lotteries involve a random distribution of licenses to different applicants of the same frequency band. Lotteries are quick and fair as long as all participants have the same weight and do not circumvent this by submitting multiple entries under different names. Even then lotteries might not be effective because the value of the service cannot be accounted for.

5.1.4. Tenders. Applicants provide sealed bid tenders for a desired frequency band. The advantages of this method are its fairness and transparency. The problem is that it is not effective in the sense that the most valued service will be gained by the company with the highest financial resources. This may lead to proprietary services if the final service in that band is not completely defined in advance. Otherwise, if the service is already defined, this approach is better than those previously mentioned. One

major disadvantage still remains: the high possibility of overvaluing the asset because the bids of others are not known.

5.1.5. Auctions. Auctioning of frequency bands combines the advantages of the tender approach with information about the bids of the applicants. In addition, government interests concerning enhanced competition can be taken into account by restricting the occupied amount of frequency bands for an applicant to a certain percentage. Sometimes the fairness of this approach is criticized because similar lots could be sold for very different prices. Furthermore, collisions may happen at auctions. To offer multiple frequency bands at the same time, the simultaneous multiple-round auction was developed. It seems that the latter method is one of the best for efficient and fair spectrum management. It fulfills most of the requirements mentioned previously and returns the pressure from the regulators back to the applicants. Thus, it is going to be applied in future licensing procedures in which an excess of demand over supply can be forecast (e.g., for third-generation mobile systems).

5.2. Frequency Reuse

The concept of frequency reuse is a core element of all cellular mobile radio systems [1,6]. It significantly increases system capacity, which may be indicated by the total number of available duplex channels. The frequency band allocated to a cellular system is organized into a finite number of frequency channels, each of which can be simultaneously reused in different geographic locations (so-called cells). In that way, a cellular system can serve more customers compared with the case when the whole system area is covered by just a single base station. On the other hand, reuse of frequency channels causes interference between those cells that use the same channel (this is called *cochannel interference*). It is a major task of cellular system design to maximize capacity and to minimize interference. Since capacity can be increased by using smaller cells and interference decreases with larger cells, a compromise is required.

In cellular system design, some idealized assumptions are made that ease the complex task of capacity and interference analysis. First, a hexagonal cell shape is normally proposed as a model to approximate the actual footprint of a base station. Thus, the whole coverage area of a cellular system can be represented by a homogeneous grid of hexagons. Because of this geometry, the number of cells in a cluster or cluster size can only take certain values and is given by

$$N = I^2 + IJ + J^2 \quad (19)$$

where the shift parameters I and J are nonnegative integers. Figure 3 shows the frequency reuse concept for a seven-cell cluster in which each letter denotes a set of frequencies. A certain cell is surrounded by adjacent channel neighbors. The nearest co-channel neighbor (say, to cell G) can be found by moving along a chain of $I = 2$ hexagons,

Figure 3. Illustration of the cellular concept by means of a seven-cell cluster. The seven frequencies reused in the system are labeled A through G. Shift parameters are $I = 2$ and $J = 1$.

turning 60° counter-clockwise, and finally moving in that new direction along $J = 1$ cells.

Here, we consider a homogeneous hexagonal cellular system in which cells are roughly of equal size. It turns out that cochannel interference does not depend on transmission power but on the ratio between distance D of a cell to the center of the nearest cochannel cell and radius R of a cell (Fig. 4). This parameter is called the *cochannel reuse ratio* and is given by

$$Q = D/R = \sqrt{3N} \tag{20}$$

A large cochannel reuse ratio means that transmission quality is high, since cochannel interference is kept low because of a reasonable spatial separation of cochannel neighbors. Large capacity can be obtained when the cluster size and correspondingly the cochannel reuse ratio is small.

Usually, cochannel interference can be quantified by computing the signal-to-interference ratio (SIR). For that purpose, let γ denote the path loss exponent and assume γ to be constant over the whole coverage area of the cellular system. In a mobile radio environment, γ typically ranges between two and four. In addition, assume that all base stations transmit the same power. Then the SIR at a mobile station can be estimated by

$$\frac{S}{I} = \frac{R^{-\gamma}}{\sum_{i=1}^{i_0} D_i^{-\gamma}} \tag{21}$$

where i_0 is the number of cochannel interfering cells. Let us now consider cochannel interfering cells from the first

Figure 4. Interference geometry between two co-channel cells used to compute the signal-to-interference ratio assuming an idealized hexagonal cell shape. Cells are of radius R and have distance D from each other.

Table 2. Signal-to-Interference Ratio for Various Cluster Sizes

I	J	N	Q	S/I in dB	
				Eq. (22)	Eq. (23)
1	1	3	3.00	11.30	8.03
2	1	7	4.58	18.65	17.26
3	0	9	5.19	20.84	19.74
2	2	12	6.00	23.34	22.57

tier only and assume that all those base stations are at a distance D from the desired base station. Then the SIR can be approximated as

$$\frac{S}{I} = \frac{Q^\gamma}{i_0} = \frac{(D/R)^\gamma}{i_0} = \frac{(\sqrt{3N})^\gamma}{i_0} \tag{22}$$

Finally, in the worst-case scenario, in which the mobile station is located at the cell boundaries, the SIR can be approximated as

$$\frac{S}{I} = \frac{1}{2(Q-1)^{-\gamma} + 2Q^{-\gamma} + 2(Q+1)^{-\gamma}} \tag{23}$$

Table 2 shows SIR values for some typical cluster sizes. The pass loss exponent is taken as $\gamma = 4$, and the number i_0 of cochannel interfering cells in a fully developed system is about six. Subjective tests undertaken for voice services have shown that an $S/I = 18$ dB gives satisfactory quality. In a homogeneous hexagonal system, this requires a cluster size of at least seven.

Apart from frequency reuse, there are some other techniques to improve the capacity of a cellular system. Improved capacity is often required to adapt the initial system to an increasing demand on services or to better cover congested areas. Sectoring is such a technique and replaces omnidirectional antennas at a base station by several sector antennas. Most common is an arrangement of three or six sectors whereby a 120° or 60° directional antenna radiates within a certain sector. Due to less cochannel interferers in the first tier of a sectorized system, this approach decreases the signal-to-interference ratio and thus allows for a smaller cluster size (i.e., higher capacity). A second technique is called cell splitting, which basically reduces the cell sizes. In that way, more cells fit within an area, resulting in more available channels per area.

5.3. Digital Modulation Techniques for Mobile Communication

A modulation scheme for a mobile communication system should utilize the allocated frequency band and power as efficiently as possible. With regard to second-generation systems and the intended application of data services in future wireless systems, digital modulation techniques are a natural choice. Selection of an appropriate digital modulation scheme can be made on the basis of the following characteristics. The power density spectrum is defined as the relative power in a modulated signal versus

Table 3. Spectral Efficiency of Second-Generation Systems

System	Modulation Technique	Data Rate (kbps/s)	Channel Spacing (kHz)	Efficiency (bps/Hz)
GSM	GMSK ($BT^a = 0.3$)	270.8	200	1.35
IS-54	$\pi/4$ -DQPSK	48.6	30	1.62
IS-95	QPSK/BPSK	1288	1250	1.03
PDC	$\pi/4$ -DQPSK	42	25	1.68
CT-2	GMSK ($BT^a = 0.5$)	72	100	0.72
DECT	GMSK ($BT^a = 0.5$)	1152	1728	0.67
PHPS	$\pi/4$ -DQPSK	384	300	1.28
TETRA	$\pi/4$ -DQPSK	36	25	1.44

^a $BT = 3$ dB-bandwidth and bit duration product of the Gaussian filter.

frequency. It consists of a main lobe and several sidelobes, which indicate interference into adjacent channels. A modulation scheme can be further assessed by its robustness against interference and channel impairments, which is indicated by a low bit error rate. Bandwidth efficiency measures the bit rate that can be transmitted per unit of frequency bandwidth and is expressed as the number of bits per second per hertz (bps/Hz). Apart from that, implementation complexity and costs have to be considered as well. A desirable modulation scheme should achieve high bandwidth efficiency at a given bit error rate and simultaneously offer a narrow power density spectrum. Digital modulation schemes currently being used in second generation systems can be classified into phase shift keying (PSK) and continuous phase modulation (CPM).

The family of PSK schemes belongs to the class of linear modulation techniques [29]; that is, a modulating digital signal is used to vary linearly the amplitude of a transmitted signal. The most popular schemes within this family include quaternary phase shift keying (QPSK), offset QPSK (OQPSK), $\pi/4$ phase shift QPSK ($\pi/4$ -QPSK), and differentially encoded $\pi/4$ -QPSK, called $\pi/4$ -DQPSK. QPSK splits the baseband data signal into two pulsestreams (namely, in-phase and quadrature components), which reduces the data rate to half that of the baseband signal. The phase of the carrier takes one of four values (say, 0° , 90° , 180° , or 270° or an equally spaced but rotated constellation of these). Side lobes in the power density spectrum of a QPSK-modulated signal are usually suppressed by passing the signal through a front-end filter, but then the signal envelope will no longer have a constant envelope. When the filtered signal experiences a 180° shift in carrier phase, the envelope fluctuates significantly and even goes through zero. Such an envelope fluctuation will cause reappearance of sidelobes every time the filtered QPSK modulated signal passes a nonlinearity (e.g., a nonlinear amplifier). An improvement over QPSK offers the OQPSK modulation scheme, in which a shift of one bit delay is introduced to the quadrature component. As a result, in-phase and quadrature components have signal transitions at separate time instants, and thus shifts in carrier phase are limited to a maximum of $\pm 90^\circ$. Because 180° phase shifts have been removed, the envelope cannot go through zero any longer. Envelope fluctuations are less severe, and nonlinear amplification can be applied. Finally, $\pi/4$ -QPSK can be regarded as a compromise between

QPSK and OQPSK, which limits the maximum phase shift to $\pm 135^\circ$. $\pi/4$ -QPSK can be differentially encoded and is then called $\pi/4$ -DQPSK. The $\pi/4$ -DQPSK technique uses the phase shifts in the carrier instead of the phase to transmit information. It can be noncoherently detected, which is one of the reasons that $\pi/4$ -DQPSK has been employed in many digital mobile communication systems, such as IS-54, PDC, and PHS.

Improvement of OQPSK in terms of out-of-band radiation can be obtained from the CPM technique [32], which continuously varies the carrier phase and thus completely avoids discontinuous phase transitions. Further, all CPM schemes have constant carrier envelopes and hence allow for nonlinear amplification. Among the most popular CPM schemes are minimum shift keying (MSK) and Gaussian minimum shift keying (GMSK). MSK can be regarded as a special case of OQPSK in which the baseband signal uses half-sinusoidal pulses instead of a rectangular pulse shape (this produces the desired smooth phase transitions). Unfortunately, MSK does not have a power density spectrum as compact as desirable for mobile radio. A tighter spectrum can be achieved by passing the modulating signal through a premodulating pulse shaping filter. Following this concept, GMSK uses a filter with a Gaussian or bell-shaped transfer function. The compact power density spectrum of GMSK is gained at the expense of an increased irreducible bit error rate due to intersymbol interference. GMSK has been adopted for GSM, DECT, and CT-2.

Table 3 summarizes modulation techniques used in second-generation systems along with the achieved bandwidth efficiency. The most popular schemes are $\pi/4$ -DQPSK and GMSK. Note that the employed GMSK schemes differ in the 3 dB bandwidth and bit duration product BT of the Gaussian filter.

6. CONCLUSION

Mobile communication has already become an integral part of modern life and is one of the driving forces of telecommunications. Wireless access to global telecommunication can be expected to change the face of telecommunication even further. Apart from traditional voice services and low-rate data, future mobile communication will provide for multimedia services that are a mixture of voice, data, text, graphic, and video. Land mobile,

maritime, aeronautic, and satellite systems will not just coexist but will establish a global mobile system allowing users to communicate at any time and from anywhere in the world. Before this vision of a global mobile system can become reality, several technical challenges have to be resolved. Such resolution will require support from all areas of communication engineering, such as source and channel coding, bandwidth-efficient modulation, multiple access control, and protocol and security issues.

MOBILE RADIO CHANNELS

RODNEY G. VAUGHAN

1. INTRODUCTION

The term *mobile channel* refers to the transfer function of a radio link when one or both of the terminals are moving. The moving terminal is typically in a vehicle such as a car, or a personal communications terminal such as a cell-phone. Normally one end of the radio link is fixed, and this is referred to as the *base station*. In the link, there is usually multipath radiowave propagation, which is changing with time, or as a function of position of the moving terminal. The effects of this multipath propagation dominate the behavior and characterization of the mobile channel.

The radiofrequency of the link ranges from hundreds of kilohertz, as in broadcast AM radio, to microwave frequencies, as in cellphone communications. Indeed, even optical frequencies are used, as in an infrared link used for indoor computer communications. The kind of channel most often referred to as “mobile,” however, is that using microwave frequencies, and this article concentrates on the characteristics of a mobile microwave radio link. Much of the dynamic channel behavior can be scaled by the carrier frequency and by the speed of the mobile terminal.

Current spectral usage is a result of many different historical developments, so the bands used by mobile radio channels have evolved to be at many frequencies. For example, current vehicular and personal communications terminals mostly use frequencies around 900 MHz and 1.8 GHz. In the future, higher frequencies will be used. The frequency has a definitive bearing on the rate at which the channel changes.

Some examples of mobile channels include domestic cordless telephones; cellular telephones and radiotelephones; pagers; satellite communication terminals, including navigational services such as Global Positioning System (GPS) reception; and radio networks for local data communications. Finally, the reception by portable receivers of broadcast radio, at frequencies of a few hundred kilohertz (AM radio), are common forms of the mobile radio channel.

The use of mobile channels has grown very quickly since the early 1990s. This growth will continue. It is driven by a combination of consumer demand for mobile voice and data services and advances in electronic technology. A limiting factor to the growth is that many users

must share the radio spectrum, which is a finite resource. The spectral sharing is not only local; it is also international, and so spectral regulatory issues have also become formidable. The increasing pressure to use the spectrum more efficiently is also a driving force in regulatory and technical developments.

To a user, a mobile or personal communications system is simple: it is a terminal, such as a telephone, that uses a radio link instead of a wire link. The conspicuous result is that the terminal is compact for portability, and it has an antenna, although for personal communications the antenna is often no longer visible. To the communication engineer, however, the mobile terminal can be viewed as a component in an electrical circuit. The mobile channel is one link in the circuit, but this link is the most complex, owing to its use of radiowaves in complicated propagation environments and of radio signal-processing technology needed to facilitate wireless transmission among multiple users.

In mobile channels, efficient spectral utilization is a function of the basic limitations on controlling radiowave behavior in complicated physical environments, including the launching and gathering of the waves. Thus antennas and propagation are key topics, and their roles characterize the channel behavior.

2. THE MOBILE CHANNEL

The mobile channel covers many different transfer functions that have different properties. Figure 1 illustrates individual channels [1]. The figure shows half of a link,

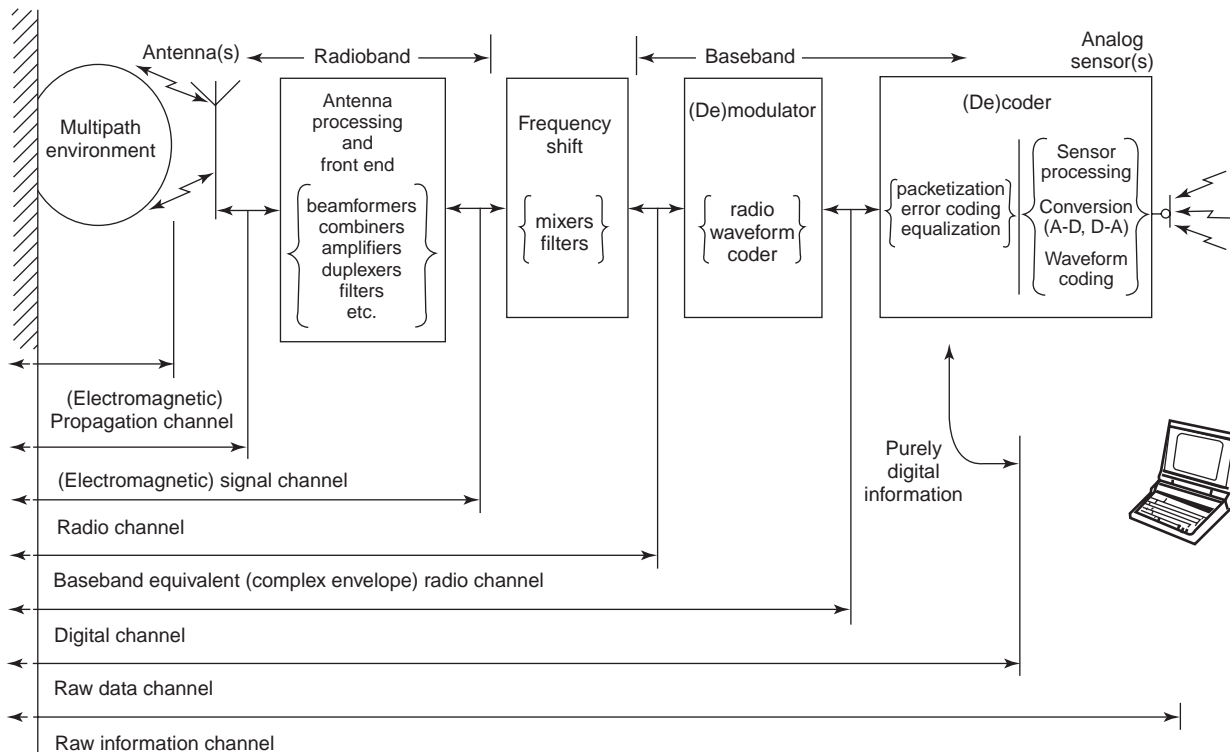

Figure 1. Various channels in a mobile communications link. The term “mobile channel” refers to the analog aspects of the channel, excluding modulation and coding.

with the other half essentially an inverse process. The multipath propagation environment represents the physical environment of the radio waves in the mobile channel. The flow of information is described here for transmission, but the description adapts readily to reception. A *raw information channel* refers to the transfer function that separates the transmitted and received raw information. For speech, for example, degradations of the immediate acoustical environment from reverberation and acoustic noise form part of the channel “seen” by the user at the receiving end. The quality of the information channel may be subjective, although standard metrics of distortion and signal-to-noise ratio can be applied for characterization. The electrical signal is often digitized for efficient transmission, and the *digital channel* is nonlinear, but its channel quality can be measured directly as a *bit error ratio* (BER). This digital form is sometimes rearranged by encoding techniques for more robust transmission of the information. The digital information is coded into analog waveforms and then mixed, or *heterodyned*, to the radio carrier frequency and transmitted via the antenna.

The distinguishing feature of the mobile channel is the changing multipath propagation between transmitter and receiver. The receiving antenna gathers the many incident electromagnetic waves from the multipath environment. These multipath contributions mutually interfere in a random, time-varying manner, and so statistical techniques are needed to characterize the channel. In the physical transmission media, the waves that bear the information are the signals of the *electromagnetic propagation channel*. The antenna reduces the signals from a vector form of orthogonal polarizations to a scalar voltage. The signal at the open-circuited receiving antenna terminal is the output of the *electromagnetic signal channel*. The antenna needs to be terminated in order to maximize the power received by the front end. The signal-to-noise ratio (SNR) is established at this point in the link, and the resulting signal is the output of the *radio channel*. The antenna is a critical part of the mobile channel, and it can control much of the channel behavior. The baseband equivalent form of the radio channel, which is the radio channel shifted in frequency to a lowpass spectral position, is the signal that engineers use for mathematical characterization and most electronic (including digital) signal processing. The analog form of the radio channel is what will be referred to from here on as the mobile channel.

2.1. Multiple Access for Mobile Channels

Most mobile communications systems are for multiple users, and a *multiple access* technique is required to allow the spectrum to be shared. In cellular systems, for example, the frequencies are reused at geographically spaced locations. For indoor systems, the frequency reuse spacing may be between floors. In a system design, the multiple access technique interacts with the choice of channel modulation and signal coding. The three basic techniques are frequency-division multiple access (FDMA), which has channels occupying different narrow bandwidths simultaneously; code-division multiple access (CDMA), in which

multiple users share wider band-widths simultaneously by using differently coded waveforms; and time-division multiple access (TDMA), in which users share a bandwidth by occupying it at multiplexed times. Some systems employ a combination of these techniques.

Multiple access is not a part of the mobile channel as such. However, the reader should remain aware that multiple access is part of the communications system and the choice of technique has an influence on the mobile channel bandwidth, its usage, and the type of signaling employed. Multiple access also brings in co- and adjacent-channel interference, in which the unwanted signals at a receiver may not be noiselike, but in fact be signals with very similar characteristics to the wanted signal. In systems with densely packed users, the system capacity is interference-limited.

3. MULTIPATH PROPAGATION EFFECTS

Multipath radiowave propagation is the dominant feature of the mobile channel. More often than not, the transmitted signal has no line-of-sight path to the receiver, so that only indirect radiowave paths reach the receiving antenna. For micro-wave frequencies, the propagation mechanisms are a mixture of specular (i.e., mirrorlike) reflection from electrically smooth surfaces such as the ground, walls of buildings, and sides of vehicles; diffraction from edges of buildings, hills, and other structures or formations; scattering from posts, cables, furniture, and other components; and diffuse scattering from electrically rough surfaces such as some walls, trees, and grounds.

Some multipath propagation occurs in nearly all communications links. The basic phenomenon is that several replicas of the signal are received, instead of one clean version. The result can be seen as television ghosts, for example. On transmission lines, reflections from mismatches on the line give the same effect, for example, echoes on telephone lines. On a long distance point-to-point radio link, a direct line-of-sight wave, a single ground bounce, and atmospherically refracted waves can all contribute to the received signal. When signal replicas are too close together to be discriminated and processed as discrete contributions, the received signal becomes distorted. This distortion limits the capacity of the channel. The phenomena is akin to the severe acoustic distortion known as the *railway station effect*, where increasing power output (volume) does not increase the intelligibility of the message. In digital communications, the distortion caused by multipath propagation creates an analogous effect; an increase in transmitted power does not decrease the BER as a simplistic implication of Shannon’s theorem might suggest. The amount and nature of the multipath propagation sets the level of power at which the BER becomes essentially independent of the SNR. The effect has often been referred to as the “irreducible BER,” but the use of signal processing, in particular equalization, can in fact reduce the BER further. Experimental examples of the irreducible BER in the digital channel are given below, but this article otherwise concerns the analog mechanisms and the statistical nature of the mobile channel.

3.1. Fading in the Mobile Channel

3.1.1. Fast Fading. The interference, or phase mixing, of the multipath contributions causes time- and frequency-dependent fading in the gain of the channel. The time dependence is normally from the changing position of the mobile terminal, and so is also referred to as *space dependence*. At a given frequency, the power of the received signal, and thus the gain of the mobile channel, changes with time. This changing SNR is called *signal fading* and is often experienced as audible “swooshing” or “picket fencing” when an FM station (with a radio frequency of about 100 MHz) is received by the antenna on a moving car. If the mobile terminal is stationary, the signal may continue to experience some fading, and this is caused by changes in the multipath environment, which may include moving vehicles and other objects.

In nearly all situations the changing mobile position dominates the time variation of the mobile channel. Usually, the multipath environment is taken, or at least modeled, as unchanging. This is called the *static multipath* assumption. In this case, a static mobile experiences an unchanging channel. If now the radiofrequency is swept, then the gain of the transfer function experiences fading similar to that due to changes in position, because the electrical path distances of the multipath components are frequency-dependent. For a continuous-wave (CW) signal, the time- and frequency-dependent fades can be some 40 dB below the mean power level, and up to 10 dB above the mean. This indicates the large dynamic range required of the receiver just to handle the multipath interference. This fading is variously called the *fast fading*, *short-term fading*, or *Rayleigh fading* after the Rayleigh distribution of the signal magnitude. The maximum density of fading is a fade about every half-wavelength on average, and this occurs typically in urban outdoor and indoor environments. The fast fading dominates the mobile channel characteristics and usage. For example, traditional amplitude modulation at microwave frequencies is not feasible, because for a fast-moving mobile terminal the fading interferes directly with the modulation.

3.1.2. Slow Fading. The dynamic range of the received signal is also affected by *slow fading*, also called *long-term fading* or *shadow fading*. This is superimposed on the fast fading. It is caused by shadowing of the radio signal to the scatterers as the mobile terminal moves behind large obstacles such as hills and buildings. The rate of the slow fading therefore depends on the large-scale nature of the physical environment. The basic short-term multipath mechanism remains unchanged. The dynamic range of the slow fading is typically less than that of the fast fading, being confined to about ± 10 dB for most of the time in urban and suburban environments. The total dynamic range for the fading therefore becomes about 70 dB. The distance-based path loss, as a mobile terminal roams near to and far from a base station, adds to this range.

3.2. Narrowband and Wideband

In a typical mobile microwave signal link, the *relative bandwidth* is small. This means that the spectral extent of

the signal is less than a few percent of the nominal carrier frequency. The fading within the frequency response of the transfer function is referred to as *frequency-selective fading*. If the bandwidth is sufficiently small so that all the frequency components fade together, then this is called a *flat fading* channel.

In the mobile channel context, a *narrowband* channel has flat fading and a *wideband* channel has frequency-selective fading. The use of a single frequency, or CW, for channel characterization is the limiting case of the narrowband channel. Historically, fading has been the principal observed characteristic of the mobile channel. Fast fading is merely one manifestation of the reception of several replica signals.

3.3. The Effect of Fading on the Digital Channel: Irreducible Bit Error Ratio

3.3.1. Timing Errors from Random Frequency Modulation. The digital channel in Fig. 1 is in principle the simplest channel to characterize experimentally, since it concerns a BER measure. The fading in the mobile channel has a particular effect on the BER curves, namely, the “irreducible BER” mentioned above. The example in Fig. 2 [2] shows curves of BER against carrier-to-noise ratio (CNR) from simulations of the narrowband mobile channel with carrier frequency 920 MHz. The static (no fading)

Figure 2. The irreducible BER for a digital mobile channel is attained when an increase of SNR does not improve the BER. The static (no fading) channel shows the classical waterfall shape of the Gaussian noise-limited channel, but as the fading rate increases, the form of the curve alters drastically. (From Ref. 2.)

curve shows the classical waterfall shape of the Gaussian channel. But the fading channel curves, shown with fading rate f_D , feature irreducible BERs, which occur at lower CNRs with increasing fading rate. The fading rate of 40 Hz corresponds to a mobile speed of about 40 km/h and a carrier frequency of 900 MHz. This corresponds approximately with using a cellphone from a moving car. The curves hold their basic form independently of the type of angle modulation used. The mechanism for the bit errors is timing error caused by the random FM, discussed below, imposed on the signal by the fading channel. The random FM causes jitter on the symbols after they have passed through the mobile channel.

3.3.2. Intersymbol Interference from Multiple Time Delays. As the signaling rate increases, an analogous irreducible BER effect occurs as a result of the several signal replicas arriving at different times. This spread of delays causes intersymbol interference when one dispersed symbol overlaps with other, similarly dispersed symbols. In analog parlance, this is called *dispersive distortion*. In the mobile channel the situation is complicated by the dispersion changing with time. The effect is depicted in the experimental example of Fig. 3 [3], where for a fixed fading rate of $f_D = 40$ Hz the increasing digital transmission rate experiences an increasing irreducible BER. As in Fig. 2, the effect is that the capacity of a given link cannot be increased by simply increasing the CNR, for example, by increasing the transmitted power. Signal processing is required.

Figure 3. The irreducible BER caused by intersymbol interference. As the signaling rate increases relative to the spread of multipath propagation delay times, the irreducible BER increases. (From Ref. 3.)

Figure 4. The static mobile channel transfer function. $x(\tau)$ and $y(\tau)$ are electronic signals before the transmitting antenna and after the receiving antenna, respectively. The impulse response can be found by Fourier transformation of a swept frequency measurement, for example.

3.4. Signal Processing for Mitigation of the Multipath Effect

Several signal-processing techniques can be applied to the mobile channel to reduce distortion and recover the capacity relative to the static channel. *Equalization* and *rake* systems basically attempt to gather the delayed signal replicas and recombine them into a single signal, which, ideally, is no longer distorted or faded. *Antenna diversity* uses multiple antenna elements to receive the same signal but with different multipath degradations, and combines the signals so that the resultant channel has better capacity than any of the channels from the individual antenna elements. A combination of the equalization, or rake, and antenna diversity methods is called *space-time processing*. All these techniques can be effective in improving the mobile channel. In fact, the use of antenna diversity offers very large potential capacities by effectively reusing the frequency at different positions in space.

3.5. The Mobile Channel as a Transfer Function

Figure 4 depicts a static mobile channel, which is taken as the baseband equivalent radio channel of Fig. 1. Recall that the effect of the antennas is included in the transfer function. The impulse response $h(\tau)$ and the transfer function $H(\omega)$ are related by Fourier transformation in the usual way, denoted $h(\tau) \leftrightarrow H(\omega)$. Here τ is the delay time and ω is the angular baseband equivalent frequency. The impulse response indicates the dispersive nature of the

channel, which causes distortion of the signals which are transmitted through it. This impulse response is modeled as a series of discrete delta functions below.

The example of Fig. 4 is for an instant in time t . As the mobile terminal moves, the delays and phases of the individual multipath contributions become functions of time. The impulse response and transfer function therefore become expressed mathematically as functions of time, that is, $h(\tau, t)$ and $H(\omega, t)$. If the scatterers in the multipath environment can be considered to be essentially stationary, then the time t and position z are related by the velocity V of the mobile: $z = Vt$. From now on the spatial variable z will be mostly used.

The following sections will develop, through the use of several assumptions about the channel, a double Fourier transform relation between the impulse response as a function of delay time and time (i.e., position) and the transfer function as a function of baseband angular frequency and Doppler frequency. Because of the variation of the transfer functions, the statistical parameters of the channel are relevant, and these also can be couched in terms of Fourier relations.

3.6. The Receiving Antenna in Multipath Transmission

The moving antenna combines the radiowave contributions, which have continuously changing delays, amplitudes, and polarizations. Deterministic analysis is not feasible except in simplistic situations, and to be able to interpret the statistical description requires an appreciation of multipath phenomena.

A base station transmitter is taken to emit power in a fixed radiation pattern. After multiple scattering, for example from many reflections, the polarization is changed in a random way and the electric (and magnetic) field has all three Cartesian components, independent of the transmitted polarization. These components can be independent functions of frequency and position. So the total incident electric field, at a point in space, can be written in baseband equivalent form [i.e., with a complex envelope, in which a factor of $\exp(j\omega_C t)$ is suppressed, where ω_C is the carrier frequency] as the complex vector

$$\begin{aligned} \mathbf{E}_1(\omega; x, y, z) = & E_x(\omega; x, y, z)\hat{x} + E_y(\omega; x, z)\hat{y} \\ & + E_z(\omega; x, y, z)\hat{z} \end{aligned} \quad (1)$$

in which the components, such as E_x , are complex scalars.

The introduction of an antenna promotes a change to spherical coordinates referred to the antenna orientation and position. The position is denoted with the single spatial variable z . The incident fields are now written as

$$\mathbf{E}_1(\omega, z; \theta, \phi) = E_\theta(\omega, z; \theta, \phi)\hat{\theta} + E_\phi(\omega, z; \theta, \phi)\hat{\phi} \quad (2)$$

The open circuit voltage of an antenna depends on both the incident field and the receiving pattern, $\mathbf{h}_a(\omega; \theta, \phi) = h_\theta(\omega; \theta, \phi)\hat{\theta} + h_\phi(\omega; \theta, \phi)\hat{\phi}$. This notation for the receiving pattern should not be confused with the symbol for the impulse response, $h(\tau, z)$. The open circuit

voltage is defined by

$$V_O(\omega, z) = \int_0^{2\pi} \int_0^\pi \mathbf{E}_1(\omega, z; \theta, \phi) \cdot \mathbf{h}_a(\omega; \theta, \phi) \sin \theta \, d\theta \, d\phi \quad (3)$$

and represents the transfer function of the electromagnetic signal channel.

By expanding the dot product, this transfer function is written in terms of the incident field components, which are now collectively detected as *standing waves*, and the receiving pattern components, as

$$\begin{aligned} H(\omega, z) = & \int_0^{2\pi} \int_0^\pi [E_\theta(\omega, z; \theta, \phi)h_\theta(\omega; \theta, \phi) \\ & + E_\phi(\omega, z; \theta, \phi)h_\phi(\omega; \theta, \phi)] \sin \theta \, d\theta \, d\phi \end{aligned} \quad (4)$$

This formula shows the inseparability of the antenna pattern and the incident fields in the definition of the mobile channel.

The antenna pattern is recognized as a filter in the spatial (including polarization) domain. The frequency dependence of the antenna pattern also represents a filter in the more familiar frequency domain. The space–frequency filter of the antenna is the difference between the vector electromagnetic propagation channel and the scalar electromagnetic signal channel of Fig. 1. If terminating (i.e., matching) the antenna has a negligible effect over the band of interest, then Eq. (4) represents the mobile channel.

4. CHANNEL MODEL USING DISCRETE EFFECTIVE SCATTERERS

Modeling the incident waves as emanating from discrete directions allows the convenience of using effective point sources. These are referred to as *effective scatterers*, because their scalar contribution is the physical incident wave weighted by the receiving pattern. The transfer function is written as the sum of effective scatterers, which have an amplitude a , a phase ψ , and a delay time τ for the information carried:

$$H(\omega, z) = \sum_i a_i \exp(j\psi_i) \exp(-j\omega_R \tau_i) \quad (5)$$

Here the radiofrequency is the sum of the carrier frequency (the center frequency of the radio band) and baseband equivalent frequency:

$$\omega_R = \omega_C + \omega \quad (6)$$

In the static situation, the terms in the transfer function containing the delays are constant and can be incorporated into the phases of the effective scatterers.

The effect of the moving terminal on the transfer function can be seen by considering an effective scatterer at a relatively large distance r_0 from it. The geometry is shown in Fig. 5. The mobile terminal moves a distance z along the spatial axis in the positive direction. The electrical

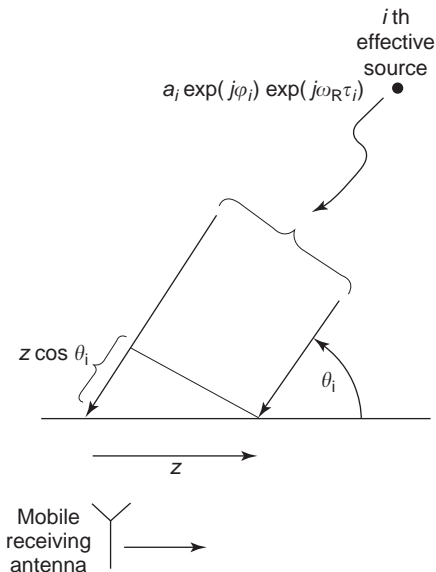

Figure 5. Point source with moving receiver. In a model of the channel, Eq. (5), the point source is not necessarily a physical scatterer, but can rather be considered as a point representation (an “effective scatterer”) that produces the waves received from a given angular direction.

distance to the i th effective scatterer changes from $k_R r_{0i}$, where k_R is the radiofrequency wavenumber, to

$$\begin{aligned} k_R r_i &\approx k_R r_{0i} - k_R z \cos \theta_i \\ &= \omega_R \tau_i - \frac{\omega_R}{c} \cos \theta_i z \\ &= \omega_R \tau_i - u_i z \end{aligned} \tag{7}$$

where

$$u_i = k_R \cos \theta_i \tag{8}$$

is the *spatial Doppler frequency* in radians per meter. The Doppler frequency in radians per second is

$$\omega_{Di} = u_i V = k_R V \cos \theta_i \tag{9}$$

Here u_i is a scaled directional cosine to the i th effective scatterer, and a receiver movement z produces a phase shift $u_i z$ in the signal from the scatterer.

The changing phase term of an effective scatterer at position z in Eq. (5) is

$$\omega_R \tau_i = \omega_C \tau_i + \omega \tau_i - \frac{\omega_C}{c} \cos \theta_i z - \frac{\omega}{c} \cos \theta_i z \tag{10}$$

The first term is independent of the position and baseband frequency, and can be incorporated in the phase of the scatterer. The last term is negligible, because in microwave communications we normally have a small relative bandwidth (i.e., $\omega/\omega_C \ll 1$). So within the approximations

above, the transfer function is

$$H(\omega, z) = \sum_i a_i \exp(j\psi_i) \exp[j(-\omega\tau_i + zu_i)] \tag{11}$$

Fourier transformation with respect to the baseband frequency ω gives the position-dependent impulse response as a function of the delay time and position,

$$h(\tau, z) = \sum_i a_i \exp(j\psi_i) \delta(\tau - \tau_i) \exp(ju_i z) \tag{12}$$

A further Fourier transformation, this time with respect to the position z , gives a function of delay time and spatial Doppler frequency, denoted

$$a(\tau, u) = \sum_i a_i \exp(j\psi_i) \delta(\tau - \tau_i) 2\pi \delta(u - u_i) \tag{13}$$

4.1. Fourier Transform Relations with Continuous Transfer Functions

The Fourier pair $a(\tau, u) \Leftrightarrow H(\omega, z)$ have the continuous form

$$H(\omega, z) = \frac{1}{2\pi} \int_0^\infty \int_{-k_C}^{k_C} a(\tau, u) \exp[j(-\omega\tau + zu)] du d\tau \tag{14}$$

$$a(\tau, u) = \frac{1}{2\pi} \int_{-\infty}^\infty \int_{-\infty}^\infty H(\omega, z) \exp[j(\omega\tau - zu)] d\omega dz \tag{15}$$

Note the mixed signs of the exponents. Moving in the negative z direction instead of the positive z direction, for example, changes the sign of the exponent zu in Eqs. (14) and (15).

From the double Fourier transform relation, there can be four complex functions that carry the same information for characterization of the mobile channel. These are denoted:

- $a(\tau, u)$, the scattering function in the time delay–spatial Doppler domain (referred to as the effective scattering distribution)
- $h(\tau, z)$, the impulse response in the delay–space domain (spatial spectrum)
- $A(\omega, u)$, the transfer function in the baseband frequency–spatial Doppler domain (frequency spectrum)
- $H(\omega, z)$, the transfer function in the baseband frequency–space domain (space–frequency spectrum)

The functions are related by the following single-dimensional Fourier transforms of the mobile channel:

$$\begin{aligned} a(\tau, u) &= \frac{1}{2\pi} \int A(\omega, u) e^{j\omega\tau} d\omega \\ A(\omega, u) &= \int a(\tau, u) e^{-j\omega\tau} d\tau \end{aligned} \tag{16}$$

$$h(\tau, z) = \frac{1}{2\pi} \int H(\omega, z) e^{j\omega\tau} d\omega \quad (17)$$

$$H(\omega, z) = \int h(\tau, z) e^{-j\omega\tau} d\tau$$

$$a(\tau, u) = \int h(\tau, z) e^{-jzu} dz \quad (18)$$

$$h(\tau, z) = \frac{1}{2\pi} \int a(\tau, u) e^{jzu} du$$

$$A(\omega, u) = \int H(\omega, z) e^{-jzu} dz \quad (19)$$

$$H(\omega, z) = \frac{1}{2\pi} \int A(\omega, u) e^{jzu} du$$

The amplitudes, phases, delays, and directions of the effective sources are randomly distributed, and the transfer function consequently behaves randomly, so a statistical approach is called for their characterization.

4.2. Averaging across a Transfer Function for Channel Gain

In terms of an individual channel transfer function, the total power, or *channel gain*, is given by

$$P^{(i)} = \frac{1}{L\omega_B} \int_L \int_{\omega_B} |H(\omega, z)|^2 d\omega dz \quad (20)$$

where L is an averaging distance or locus covering the positional averaging, and ω_B is an averaging bandwidth. Any of the abovementioned channel functions can be used to get the power in this way (Parseval's theorem). Integrating single variables gives the frequency-dependent power transfer function averaged over position

$$|H(\omega)|^2 = \frac{1}{L} \int_L |H(\omega, z)|^2 dz \quad (21)$$

and the position-dependent- (time-dependent) power transfer function averaged over the frequency band:

$$|H(z)|^2 = \frac{1}{\omega_B} \int_{\omega_B} |H(\omega, z)|^2 d\omega \quad (22)$$

This quantity is approximated in a receiver by the position-varying (or time-varying) received-signal strength indicator (RSSI) signal. However, in practice, the RSSI voltage is normally proportional to the logarithm of the channel power.

On averaging the power across a wideband channel, the total received power fades less than a narrowband component. This is the advantage of wideband modulation systems. Analogously, antenna diversity is used to reduce the fading by averaging the channel over samples of the spatial variable.

5. STATISTICAL BASIS OF A MOBILE CHANNEL

5.1. Power Spectra and Channel Correlation Functions

Assuming ergodicity so that the statistics remain second order, the *autocorrelation function*, denoted by R , of the effective scatterer distribution with respect to the delay times is written

$$R_a(\tau_1, \tau_2; u) = \langle a(\tau_1, u) a^*(\tau_2, u) \rangle \quad (23)$$

where the angular brackets denote averaging over all relevant realizations of the effective scattering distribution. This contrasts with the averaging over frequency or space for a single channel realization as in the previous section. The average power in the effective scattering distribution is

$$P(\tau, u) = R_a(\tau, \tau; u) = \langle |a(\tau, u)|^2 \rangle \quad (24)$$

Note that the averaging is of the powers, not of the complex values, of the $a(\tau, u)$.

This averaged power distribution can be expressed in several different statistical forms as seen below. Substituting Eq. (16) into Eq. (23) gives the Fourier transform

$$\begin{aligned} R_a(\tau_1, \tau_2; u) &= \frac{1}{4\pi^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_A(\omega_1, \omega_2; u) \exp[j(\omega_1\tau_1 - \omega_2\tau_2)] d\omega_1 d\omega_2 \end{aligned} \quad (25)$$

The inverse relation is

$$\begin{aligned} R_A(\omega_1, \omega_2; u) &= \int_0^{\infty} \int_0^{\infty} R_a(\tau_1, \tau_2; u) \exp[-j(\omega_1\tau_1 - \omega_2\tau_2)] d\tau_1 d\tau_2 \end{aligned} \quad (26)$$

Major simplifications are possible under certain assumptions, as follows.

5.1.1. Wide-Sense Stationarity in Frequency. The channel is now assumed to be *wide sense stationary in the frequency domain*. This means that the mean and correlation of $A(\omega, u)$ do not depend on the choice of frequency, ω , but on only the frequency difference, $\Delta\omega = \omega_2 - \omega_1$. This is a reasonable assumption for the frequencies within the small relative bandwidths of most mobile communications systems. Denote the autocorrelation of a wide-sense stationary (WSS) process using S , for example, by

$$\begin{aligned} R_A(\omega_1, \omega_2; u) &= R_A(\omega, \omega + \Delta\omega; u) \\ &= S_A(\Delta\omega; u) \quad (\text{WSS in } \omega) \end{aligned} \quad (27)$$

that is, the autocorrelation of the transfer function in the frequency-spatial Doppler domain is a power spectrum whose argument is the frequency difference. The symbols S and R are used to represent the correspondence of the power spectra S and the autocorrelation R of a process

that is WSS. As a result of the wide sense stationarity in ω , we can write Eq. (25) as

$$\begin{aligned} R_a(\tau_1, \tau_2; u) &= \frac{1}{4\pi^2} \int \int S_A(\Delta\omega; u) \exp(-j\Delta\omega\tau_2) \\ &\quad \times \exp[-j\omega_1(\tau_2 - \tau_1)] d\omega_1 d\Delta\omega \\ &= P(\tau_2, u) \delta(\tau_2 - \tau_1) \end{aligned} \quad (28)$$

where

$$P(\tau, u) = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_A(\Delta\omega, u) \exp(j\Delta\omega\tau) d\Delta\omega \quad (29)$$

is the averaged power delay–Doppler frequency distribution of Eq. (24). The delta function in the autocorrelation of Eq. (28) is referred to as the *uncorrelated scattering* (US), and here means that a fading signal received at a given delay time is uncorrelated (when averaged over the relevant realizations) with a fading signal received at any other delay time. The wide-sense stationarity (via the $\Delta\omega$ factor) in the baseband frequency domain and the uncorrelated scattering in the delay time domain [the $\delta(\Delta\tau)$ factor] are equivalent characteristics.

5.1.2. Wide-Sense Stationarity in Space. Similarly, *wide-sense stationarity in the spatial domain* corresponds to uncorrelated scattering in the Doppler domain. This means that the fading signal at one spatial Doppler frequency u [or angle $\theta = \cos^{-1}(u/k_C)$] is uncorrelated with a fading signal received from any other spatial Doppler frequency. Denoting the spatial difference $\Delta z = z_2 - z_1$, we have

$$\begin{aligned} R_a(\tau; u_1, u_2) &= \iint S_h(\tau; \Delta z) \exp[j(z_2 u_2 - z_1 u_1)] dz_1 dz_2 \\ &= P(\tau, u_2) 2\pi \delta(u_2 - u_1) \end{aligned} \quad (30)$$

where the averaged power of the effective scattering distribution is expressed as

$$P(\tau, u) = \int S_h(\tau, \Delta z) \exp(-j\Delta z u) d\Delta z \quad (31)$$

5.1.3. Wide-Sense Stationary Uncorrelated Scattering Channel. Combining the space and frequency wide-sense stationary conditions, we have

$$\begin{aligned} R_a(\tau_1, \tau_2; u_1, u_2) &= \frac{1}{2\pi} \iint S_H(\Delta\omega, \Delta z) \exp[j(-\Delta\omega\tau_2 + \Delta z u_2)] \\ &\quad d\Delta\omega d\Delta z \delta(\tau_2 - \tau_1) 2\pi \delta(u_2 - u_1) \\ &= P(\tau_2, u_2) \delta(\tau_2 - \tau_1) 2\pi \delta(u_2 - u_1) \end{aligned} \quad (32)$$

where now

$$P(\tau, u) = \frac{1}{2\pi} \iint S_H(\Delta\omega, \Delta z) \exp[-j(\Delta\omega\tau - \Delta z u)] d\Delta\omega d\Delta z \quad (33)$$

The inverse Fourier transform is

$$S_H(\Delta\omega, \Delta z) = \frac{1}{2\pi} \iint P(\tau, u) \exp[j(\Delta\omega\tau - \Delta z u)] d\tau du \quad (34)$$

Thus the wide-sense stationarity conditions presented above result in the frequency–space correlation function being the double Fourier transform of the average power density of the effective scatterer distribution.

The term WSSUS was used by Bello [4] to describe tropospheric multipath channels containing scintillating scatterers being illuminated by static antennas. In the context of the mobile channel, the WSS refers to wide-sense stationarity in position, which implies uncorrelated scattering in the spatial Doppler frequency. The US refers to the delta function in delay time (effective sources at different delays are mutually uncorrelated), which implies WSS in the frequency domain.

The assumption of the WSSUS conditions in the channel allows the convenience of the double Fourier transform relations. However, in applying the Fourier relations for a given situation, the validity of the WSSUS model should always be questioned. The channel can often be arranged to be “sufficiently valid” for gaining useful insight and inferring channel behavior, by appropriately arranging the averaging. This averaging, denoted with the angular brackets, is often taken as several sampled records over short distances (tens of carrier wavelengths or several tens of fades) in order to stay within a given physical environment, followed by the power distribution averaging. Statistically, ensemble averaging implies many “realizations.” We can interpret this as several sampled records that should have uncorrelated data (e.g., well-separated spatial paths) within the same physical environment, or else as several records in different (i.e., independent) physical environments. The two cases are different. One case averages within a single environment; the other case averages over many different environments. Strictly speaking, the presence of multiple uncorrelated records in the same immediate environment does not truly satisfy the hypothesis of statistically independent records, because the scattering distribution is the same, that is, the signal sources constituting the physical scatterers are common to all the data records.

5.2. Key Relations for a Mobile Channel

Equations (14), (15) and, (33), (34) are key results for the mobile channel. They relate, respectively, by double Fourier transformation, a baseband channel transfer function $H(\omega, z)$ to an effective source distribution $a(\tau, u)$ that provides the incident multipath signals, and the average power spectral density of the channel $S_H(\Delta\omega, \Delta z)$ to the average power distribution of the effective scatterers,

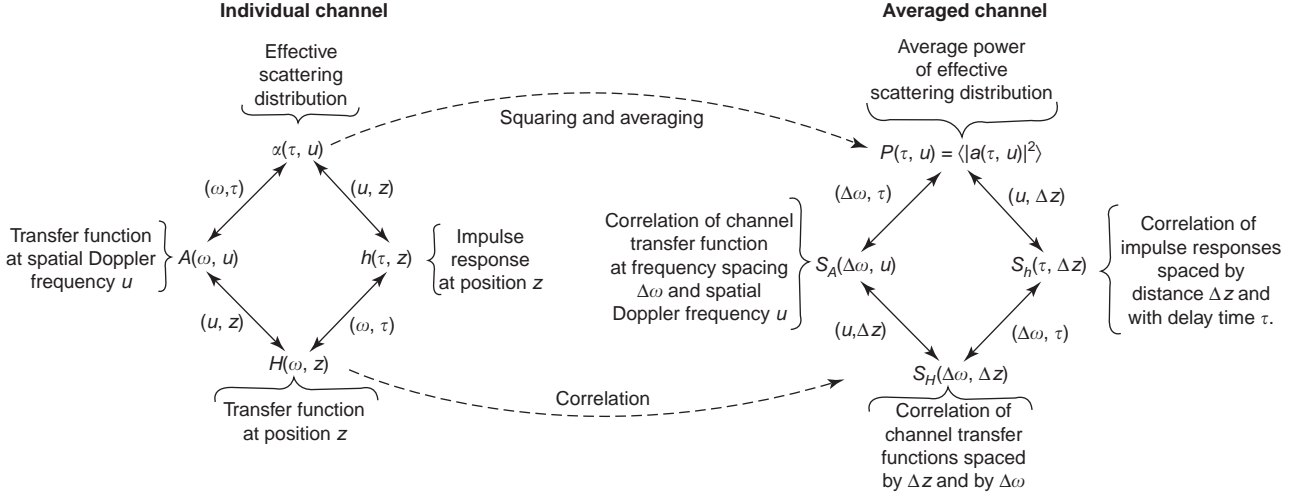

Figure 6. Fourier transform relations for the mobile channel functions and for their statistical representations under wide sense stationarity in frequency and position, $u = k_C \cos \theta$ is the spatial Doppler frequency, with θ the zenith angle with respect to the direction of motion z , and k_C the wavenumber of the radio carrier frequency. (From Ref. 1.)

$P(\tau, u)$. Figure 6 [1] depicts the relations between the functions.

5.3. Averaged Power Profiles

The more familiar single transformations also are of interest. Mathematically, we can put $\Delta z = 0$ in the frequency correlation

$$S_H(\Delta\omega) = S_H(\Delta\omega, \Delta z = 0) = \langle H(\omega, z_0) H^*(\omega + \Delta\omega, z_0) \rangle \quad (35)$$

from which Eq. (34) reduces to

$$S_H(\Delta\omega) = \int P(\tau) \exp(-j\Delta\omega\tau) d\tau \quad (36)$$

where the average power delay profile

$$P(\tau) = \int P(\tau, u) du \quad (37)$$

is the average power at delay τ , found by integrating over all spatial Doppler frequencies ($u = k_C$ to $u = -k_C$), that is, in all directions over the averaged power of the effective scattering distribution. In practice, the antenna performs this integration [recall that the effective scattering distribution $P(\tau, u)$ already includes the effect of the antenna]; for example, an omnidirectional antenna will gather the waves from all the directions. However, a single measurement from an antenna only accounts for a single realization of the effective scattering distribution—that is, for one point in the space of one environment. To estimate $P(\tau)$ from measurements, the averaging of the profile needs to be done over several different positions [i.e., several z_0 values in Eq. (35)], either in the same physical environment or in many different physical environments, as discussed above.

The frequency correlation function $S_H(\Delta\omega)$ is the Fourier transform of the average power delay profile $P(\tau)$

for the WSS channel with uncorrelated scattering. The inverse relation is

$$P(\tau) = \frac{1}{2\pi} \int S_H(\Delta\omega) \exp(j\Delta\omega\tau) d\Delta\omega \quad (38)$$

The Fourier relation in Eqs. (36) and (38) is identical to the relation between the transfer function and its impulse response, as in Fig. 4.

Similarly to the average delay profile, *the average spatial Doppler profile* is averaged over all delays:

$$P(u) = \int P(\tau, u) d\tau \quad (39)$$

$P(\tau)$ and $P(u)$ are sometimes called the *delay spectrum* and *Doppler spectrum*, respectively. Finally, the total power of the effective scatterers is given by

$$P = \iint P(\tau, u) d\tau du \quad (40)$$

Many details, extending to situations outside the mobile channel, may be found in Ref. 3.

5.3.1. Spreads. The *spread*, or second centralized moment, of a distribution is a standard characterizing parameter. For an instantaneous (i.e., snapshot, or unaveraged) channel distribution function, the instantaneous spread is the standard deviation of that function. For example, for a channel with a snapshot transfer function $h(\tau)$, the definition of the *instantaneous delay spread* is

$$\sigma_\tau^{(i)} = \sqrt{\frac{\int \tau^2 |h(\tau)|^2 d\tau}{\int |h(\tau)|^2 d\tau} - \left(\frac{\int \tau |h(\tau)|^2 d\tau}{\int |h(\tau)|^2 d\tau} \right)^2} \quad (41)$$

The (average) *delay spread*, denoted σ_τ , follows the same definition but uses the averaged distribution $P(\tau) = \langle |h(\tau)|^2 \rangle$ instead of $|h(\tau)|^2$. The analogous definition for the *Doppler spread* is

$$\sigma_u = \sqrt{\frac{\int u^2 P(u) du}{\int P(u) du} - \left(\frac{\int u P(u) du}{\int P(u) du}\right)^2} \quad (42)$$

It is important to note that it is the individual power distributions that are averaged to produce the power profiles, which are then used to produce the spreads. Statistically, it is wrong to calculate the spreads of individual channels, average these, and call the result the average spread.

5.3.2. Power Profile Examples. Two power profiles that are commonly used for modeling because of their simplicity, are the one-sided exponential

$$P(\tau) = \frac{1}{\sigma_\tau} \exp\left(-\frac{\tau}{\sigma_\tau}\right) \Leftrightarrow S_H(\Delta\omega) = \frac{1}{1 + j2\pi \Delta\omega \sigma_\tau} \quad (\tau \geq 0) \quad (43)$$

and the two-path

$$P(\tau) = \delta(\tau) + |a_2 \exp(j\alpha_2)|^2 \delta(\tau - \tau_2) \Leftrightarrow S_H(\Delta\omega) = 1 + |a_2 \exp(j\alpha_2)|^2 \exp(j\Delta\omega\tau_2) \quad (44)$$

which are shown in Fig. 7. The exponential is the most commonly used model.

The two-path model offers much insight into the mechanisms of the channel and is used in the following sections to develop the basic characteristics and parameters of

Figure 7. Examples of the exponential and the two-path models for the power delay profile. The two-path model comprises idealized discrete multipath contributions, whereas the exponential profile has a continuum of multipath contributions.

interest of the mobile channel’s behavior. It is later extended to the many-path situation. Liberties are taken with the mathematical use of the delta functions to allow convenient modeling.

6. THE TWO-PATH MODEL

The two-path model and its “statistics” (the model is treated statistically despite the situation being deterministic) produce and explain nearly all of the behavior that can be found in real-world mobile channels. Such a model is also used in point-to-point communications where there can be a direct wave with a single ground bounce. The term “two-path” refers to two effective sources. However, the introduction of the directions of the effective sources is delayed until later, since the directions have no bearing on the received signal while the receiver is static. The moving receiver introduces a changing frequency dependence, and the rate of change is determined by the directions. Understanding the behavior of the static model allows a smooth transition to understanding the many-path channel behavior.

6.1. Static Model for Frequency-Selective Fading

The two-path scenario is shown with its variation with frequency in Fig. 8. The impulse response, on setting $\tau_1 = 0$ and $\alpha_1 = 0$ for the first path, is

$$h^{(2)}(\tau) = \delta(\tau) + a_2 \exp(j\alpha_2) \delta(\tau - \tau_2) \quad (45)$$

and so represents a signal arriving with zero delay with normalized magnitude and zero phase, and a signal arriving at a delay of τ_2 with magnitude a_2 and phase α_2 . The transfer function is minimum phase when $a_2 \leq 1$, and is maximum phase (or in the general case, non-minimum phase) when $a_2 > 1$.

This model, which is static in the sense that the two effective scatterers are constant in amplitude and phase, needs no averaging to obtain the power profile. So $P(\tau) = \langle |h(\tau)|^2 \rangle = |h(\tau)|^2$ for the static case. The delay spread is thus the same as the instantaneous delay spread, and from Eqs. (44) and (41), is $\sigma_\tau^{(2)} = a_2 \tau_2 / (1 + a_2^2)$. The delay spread is not affected by time reversal or magnitude scaling of the power profile. In the two-path case, this means that a_2 can be replaced by $1/a_2$ (i.e., a

Figure 8. The impulse response of the static two-path model amplitudes 1 and a_2 , and a complex plane representation of the transfer function for the case $a_2 > 1$.

change from a minimum- to a maximum-phase channel) and the delay spread stays the same.

6.1.1. Transfer Function. The transfer function is obtained by Fourier transformation of Eq. (45), and is (the factor $1/2\pi$ is omitted for brevity)

$$H^{(2)}(\omega) = 1 + a_2 \exp[j(\alpha_2 - \omega\tau_2)] \quad (46)$$

where the delay difference is $\Delta\tau = \tau_2 - \tau_1 = \tau_2$. The in-phase component is the real part of the transfer function, $I(\omega) = 1 + a_2 \cos(\omega\tau_2 - \alpha_2)$, and similarly the quadrature part is $Q(\omega) = a_2 \sin(\omega\tau_2 - \alpha_2)$. Apart from the DC term, these are simply quadrature sinusoids. The phase of the second effective scatterer, α_2 , is now set to zero for brevity. The power transfer function is $|H(\omega)|^2 = 1 + a_2^2 + 2a_2 \cos(\omega\tau_2)$, and so the frequency fading behavior is periodic with period $1/\tau_2$ (Hz). The phase of the transfer function is

$$\phi^{(2)}(\omega) = \tan^{-1} \left(\frac{-a_2 \sin \omega\tau_2}{1 + a_2 \cos \omega\tau_2} \right) \quad (47)$$

which has a maximum rate of change when the power is a minimum. For the case $a_2 \leq 1$, the maximum and minimum values of the phase are $\pm \sin^{-1} a_2$. When $a_2 = 1$ and $\omega\tau_2 = n\pi$ (n is an integer), the phase changes by π over an infinitesimally small change in ω .

6.1.2. Group Delay. The group delay of a transfer function is the negative derivative of the phase with respect to frequency, $\tau_g(\omega) = -\partial\phi(\omega)/\partial\omega$. It approximates the time delay of the envelope of a narrowband signal after it has passed through a transfer function with phase $\phi(\omega)$ [5]. Changes in the group delay mean changes in the expected arrival times of information, such as symbols, at the receiver.

For a channel that contains many delay values, the received signal becomes distorted owing to the dispersion. For the two-path model, the group delay is found by differentiating Eq. (47) to be

$$\tau_g^{(2)}(\omega) = \frac{a_2\tau_2(a_2 + \cos \omega\tau_2)}{1 + a_2^2 + 2a_2 \cos \omega\tau_2} \quad (48)$$

For the minimum-phase case, this varies between $a_2\tau_2/(a_2 - 1)$ and $a_2\tau_2/(a_2 + 1)$. If different frequencies were sent through the channel, then these values are the extrema of the group delays that would be experienced. Figure 9 shows the in-phase and quadrature signals, the envelope and phase, and the group delay for the transfer function of a static two-path model.

6.1.3. Features of the Static Two-Path Model. The features from this deterministic model are frequency dependence with

- Smoothly varying in-phase and quadrature components
- Fading envelope

Figure 9. The periodic frequency selective channel behavior for the static two-path model. The receiver is at a fixed position. The magnitude shows fading, the phase is changing quickly at the fade frequencies, and the group delay is correspondingly large (and negative for $a_2 \leq 1$) at the fade frequencies.

- Sharp transitions of the phase of the transfer function, occurring when the envelope is at a minimum
- Possibility of both minimum-phase fades ($a_2 \leq 1$) and non-minimum-phase fades ($a_2 > 1$)
- Dispersive channel with sharp spikes in the group delay at the envelope minima

These transfer function variations are all periodic in the two-path model, but as seen below, the same effects occur also in the real-world channel, but with a random frequency and space dependence.

The reason for the phase behavior coinciding with the envelope is best seen from the locus of the signal in Fig. 8, where the envelope minima occur as the locus is passing closest to the origin, which is also when the phase is changing the quickest. For deep fades, the phase change is always nearly $\pm\pi$ (the sign depends on whether a_2 is less than or greater than one), and such phase jumps are also a characteristic of the many-path channel.

6.2. Moving Receiver

In a moving receiver, we can fix the frequency to a CW for simplicity and get behavior as in the static channel of Fig. 8, but with spatial (i.e., time, for a given mobile speed), instead of frequency, dependence. For a CW channel, the transfer function is

$$H^{(2)}(z) = 1 + a_2 \exp[j(\alpha_2 + \Delta u z)] \quad (49)$$

where $\Delta u = k_C(\cos\theta_2 - \cos\theta_1)$ is the spatial Doppler frequency difference between the two effective sources. The transfer function now has spatial periodicity with a period (in meters) of $2\pi/\Delta u$. For example, with sources exactly in front of ($\theta_1 = 0$) and behind ($\theta_2 = \pi$) the moving receiver, the periodicity is given by a spacing of exactly $z = \lambda_C/2$, that is, half the carrier wavelength.

6.3. Random Frequency Modulation

The spatial analogy to the group delay is the random FM, given in radians per meter by the derivative of the phase with respect to position as $\omega_R(z) = 2\pi\partial\phi(z)/\partial z$. The random FM is an angle modulation in the channel and will be applied to a signal borne by the channel. It means that angle modulation systems are affected as the receiver moves. In practice, the random FM is often too small to be noticed in a working system, but as carrier frequencies increase, the fading rate and the spectrum of random FM increasingly invades the signal band. In summary, the CW spatial mobile channel follows the same behavior as that in the frequency-dependent static channel, the transfer function signals shown in Fig. 9 apply with the abscissa $\omega\tau_2$ replaced with $z\Delta u$, and the group delay becomes the random FM (with the opposite polarity).

6.3.1. Two-Dimensional Transfer Function. The frequency and spatial dependences can be combined to give the two-dimensional transfer function, again with $\alpha_2 = 0$

$$H^{(2)}(\omega, z) = 1 + a_2 \exp[j(\Delta u z - \omega\tau_2)] \quad (50)$$

which explicitly indicates the two-dimensional nature of the fading. The range of angles Δu determines the spatial fading rate, and the range of delay times, $\Delta\tau = \tau_2$, determines the rate of fading in the frequency domain. The statistical equivalents of these quantities, the Doppler spread and the delay spread, are used for describing the average fading rates found in the real world many-path situation.

7. STATISTICAL APPROACH USING TWO-PATH MODEL

The statistical approach is required when there are too many paths to determine the channel, which is normally the case in mobile communications. The statistical approach to the two-path model also offers insight into the statistical behavior of the many-path case. In the static case, the transfer function of the two-path model assumes all its possible values as the relative amplitude a_2 and phase α_2 are varied. In practice, averaging is over the phase-mixing process, so here we fix the amplitude and average over the changing phase only. In the static case, the phase of the frequency-dependent transfer function can be changed by changing the frequency. In a mobile channel, the fixed-frequency transfer function is averaged over the varying phase by averaging over many positions.

Since the two-path transfer function has a symmetric, periodic envelope with half period π/τ_2 (rad), equally likely frequencies are expressed by a uniform probability density function (pdf) over one of the periods:

$$p_\omega(\omega) = \frac{\tau_2}{\pi}, n \frac{\pi}{\tau_2} \leq \omega \leq (2n + 1) \frac{\pi}{\tau_2} \quad (n \text{ any integer}) \quad (51)$$

The analogous expression for the moving receiver holds for equally likely positions (viz., $p_z(z) = \Delta u/\pi$). These pdfs allow the pdfs of the channel function to be calculated below.

7.1. Probability Density Function of Channel Power

For $a_2 < 1$ and equally likely frequencies, the pdf for the power $\gamma(\omega) = |H(\omega)|^2$ is, from function transformation of p_ω

$$Pr^2(\gamma) = p_\omega(\omega) \left| \frac{\partial\omega}{\partial\gamma(\omega)} \right| = \frac{1}{\pi\sqrt{(2a_2)^2 - [\gamma - (1 + a_2^2)]^2}} \quad (52)$$

where $1 + a_2^2$ and $(2a_2)^2$ are the mean and variance, respectively, of the power in the two-path channel.

7.2. Cumulative Density Function of Channel Power

The cumulative density function (cdf) is the integral of the pdf over its range values $(1 - a_2)^2$ to $(1 + a_2)^2$, and is written

$$\text{Prob}(\gamma^{(2)}(\omega) \leq \gamma_0) = 1 - \frac{1}{\pi} \cos^{-1} \left(\frac{\gamma_0 - (1 + a_2^2)}{2a_2} \right) \quad (53)$$

This probability approach is an alternative to the deterministic form $H^{(2)}(\omega)$ for characterizing the two-path channel. The approach is needed when a deterministic form is not available. The cdfs for the n -path model with all the $a_n = 1$ are given in Fig. 10 for $n = 2, 3, 8$. The eight-path case is very close, except at the tails of the distribution, to the Rayleigh distribution, which corresponds to the limiting case $n \rightarrow \infty$, discussed further below.

The pdf for the two-path case is centered at its mean, $1 + a_2^2$, and is confined to its limits, that is, between $(1 - a_2)^2$ and $(1 + a_2)^2$. At these limits, the pdf $p_\gamma^{(2)}$ goes to infinity. The many-path pdfs can behave the same way. This does not cause interpretation problems, however, since the probability of the power being at these limits is infinitesimal and the integral of the function of course maintains its unity value. For example, for $a_2 = 1$, the

Figure 10. The cdf for the power of the $n = 2, 3, 4, 8$ channels, where all the multipath amplitudes are the same. The $n = 8$ model is essentially the same, for the cdf range displayed, as Rayleigh ($n \rightarrow \infty$) distribution, given in Fig. 14.

fades go exactly to zero in the transfer function. In the cdf of Fig. 10, the interpretation is that there is an infinitesimally small probability of the power being zero:

$$\text{Prob}(\gamma(\omega) \leq \gamma_0) \rightarrow 0 \text{ as } \gamma_0 \rightarrow 0, a_2 = 1 \quad (54)$$

A similar situation holds for the power approaching its maximum value $(1 + a_2)^2$:

$$\text{Prob}(\gamma(\omega) \leq \gamma_0) \rightarrow 1 \text{ as } \gamma_0 \rightarrow (1 + a_2)^2 \quad (55)$$

In the $a_2=1$ two-path example, the cdf diagram shows that for 10% of the frequencies the power transfer function is more than 13 dB below its mean value. The cdf curves are arranged so that the mean power always corresponds to 0 dB. A flat channel ($a_2 = 0$) would be represented by a line at $\gamma_0 = 0$ dB.

In summary, it is the phase difference between the source contributions that is the generic random variable for the statistical approach to the short-term variation of the power or envelope. In the static scenario, the averaging over the phase difference is implemented by varying the frequency. For the moving-receiver case, the CW transfer function is averaged over space. In the general case, the transfer function is a two-dimensional distribution with phase mixing causing fading in both frequency and position.

7.3. Coherence Bandwidth

An important parameter in a frequency-selective fading channel is the frequency separation for which the fading becomes effectively independent in the statistical sense. This frequency separation is determined by the auto-correlation of the channel transfer function. It is presented here as independent of frequency, that is, the channel is assumed to be WSS. The frequency correlation coefficient function, sometimes referred to as the *coherence function*, is

$$C(\Delta\omega) = \frac{S_H(\Delta\omega) - \langle H(\omega) \rangle \langle H^*(\omega) \rangle}{S_H(0) - \langle H(\omega) \rangle \langle H^*(\omega) \rangle} \quad (56)$$

and for the static two-path model with $a_2 = 1$, the magnitude of this is

$$|C^{(2)}(\Delta\omega)| = \left| \cos \frac{\Delta\omega\tau_2}{2} \right|, \quad a_2 = 1 \quad (57)$$

The coherence bandwidth Ω_C (rad/s) is defined as the frequency span from the maximum (unity) of the frequency correlation coefficient function to where the magnitude of the function first drops to a value C_C

$$|C(\Delta\omega = \Omega_C)| = C_C \quad (58)$$

as illustrated in Fig. 11.

C_C is taken by various authors from $1/e = 0.37$ to 0.9 [6–8]. A change of C_C scales the coherence bandwidth nonlinearly, so any results derived from some value of C_C

Figure 11. The definition of a coherence bandwidth Ω_C in terms of the frequency correlation coefficient function, or coherence function, and a correlation value of C_C . Narrowband channels, separated by a minimum frequency Ω_C , will display mutually uncorrelated fading in the sense that the correlation coefficient is $C_C < \sim 0.75$.

are also scaled in some way. The coherence function is periodic in $\Delta\omega$ for the two-path channel, since $H^{(2)}(\omega)$ is periodic. $\Omega_C^{(2)}$ is minimum for $a_2 = 1$, and for this case, the coherence bandwidth in hertz, $\Omega_C^{(2)}/2\pi$, can be written directly from Eqs. (57) and (58) as

$$B_{C,\text{Hz}}^{(2)} = \frac{1}{\pi\tau_2} \cos^{-1} C_C, \quad a_2 = 1 \quad (59)$$

The coherence bandwidth decreases with increasing delay difference between the two-path contributions, τ_2 . Also, the coherence bandwidth decreases with increasing relative amplitude a_2 . When a_2 is small, the coherence bandwidth becomes undefined, as the coherence function does not drop down to C_C .

7.4. Product of Coherence Bandwidth and Delay Spread

While the delay spread is a measure of the channel time dispersion, the coherence bandwidth is a measure of the fading rate with changing frequency. The ideal communications channel has a zero delay spread and infinite coherence bandwidth. For the two-path model, the delay spread increases while the coherence bandwidth decreases for increasing relative delay τ_2 and increasing relative amplitude a_2 . The coherence bandwidth and the delay spread are thus inversely related, but the exact relationship is not simple in the many-path case.

The product of these two parameters was taken for experimental channels using $C_C = 0.75$ [7], and an empirical law was found that $B\sigma_\tau$ was constant and approximately equal to $\frac{1}{8}$ (Gans' law). The constancy of the product can also be viewed as an uncertainty principle [5,9]. It gives a lower bound for the many-path channel as

$$B_{C,\text{Hz}}(C_C) \cdot \sigma_\tau \geq \frac{1}{2\pi} \cos^{-1} C_C \quad (60)$$

The equality holds for the two-path case with equal powers, as in Eq. (59), which corresponds to maximum delay spread.

For the two-path channel, the product $B_C^{(2)} \sigma_\tau^{(2)}$ does not exist for small a_2 , since $B_C^{(2)}$ does not exist. The dependence of this product on a_2 , is weaker than its dependence on the choice of C_C . The product $B_C^{(2)} \sigma_\tau^{(2)}$ is a minimum when a_2 is 1, that is, when the frequency fades are the deepest. In this case and for the value $C_C = 0.75$, the two-path product is in close agreement with Gans's law, $B_{C,Hz}^{(2)} \sigma_\tau^{(2)} = (1/2\pi) \cos^{-1} 0.75 \approx \frac{1}{8}$.

In the two-path model, then, the virtually constant value of the product allows the delay spread to be calculated from a measured correlation bandwidth, or vice versa. However, in a general many-path case, the expression for the coherence-bandwidth–delay-spread product must be heeded as a lower limit. It should always be borne in mind that the choice of C_C for the coherence bandwidth affects the value of the product. Because the delay spread is mathematically unbounded in the model (no limit is placed on τ_2), there is no theoretical upper limit for $B\sigma_\tau$ in the many-path case, even though the coherence bandwidth can simultaneously remain essentially constant. In practice, physical and practical considerations such as the space loss described below are imposed on the model and the delay spread and the product become bounded through these.

7.5. Correlation Distance

The correlation distance is the spatial counterpart of the coherence bandwidth. It is traditionally defined as the spatial displacement $d_d = \Delta z$ corresponding to when the spatial correlation coefficient, defined at a given frequency, decreases to some value. Instead of using the complex transfer function $H(z)$, analogously to using $H(\omega)$ for the coherence function, the envelope correlation coefficient function

$$\rho_r(\Delta z) = \frac{R_r(\Delta z) - \langle r \rangle^2}{R_r(0) - \langle r \rangle^2} \quad (61)$$

has been used traditionally, and the coefficient value is taken as $\rho_r(d_d) = 0.7$. The correlation distance is a measure of the spatial fading rate and therefore depends inversely on the spatial Doppler spread σ_u . The product of these, $d_d \sigma_u$, is lower bounded, but not with the same relationships as $B\sigma_\tau$.

8. MANY-PATH MODEL

The preceding discussion has touched several times on the many-path model. Many channel parameters for the three-path model can be derived deterministically. The three-path model has been of interest in point-to-point links because it matches the physical situation of a direct, a ground bounce, and a single atmospherically diffracted ray. It has been also used to help “randomize,” relative to the two-path model, a transfer function for a more realistic-looking (over two or three fades), but tractable, model. However, it otherwise offers little more insight into the channel behavior than does the two-path model. The statistics for the few-path (less than about 10) model are

rather complicated. When there are more than about 10 components of similar amplitude, however, the statistics follow, to a good approximation, the limiting case of a very large number of paths. The phase-mixing process of adding many random phasors gives, from the central limit theorem, the classical Rayleigh channel. The distribution functions are given below.

8.1. Phase Mixing with Many Random Contributions

Equations (11) and (12) describe the model. For a narrow band channel, the in-phase and quadrature components are Gaussian-distributed from the central limit theorem. It follows that: the distribution of the power is chi-square with 2 degrees of freedom (i.e., exponential), the envelope is Rayleigh-distributed, and the phase is uniformly distributed. The transfer function signals, as a function of position, are depicted in Fig. 12. The incident power is from all directions for this example. The figure can be compared with the signals from the two-path model, shown as a function of frequency in Fig. 9. The features of the channel are essentially the same as those in the two-path model, although the process is random. There are both minimum-phase and maximum-phase deep fades. Similarly, the random FM spikes have an associated polarity that is random.

8.1.1. Rayleigh Envelope and Uniform Phase. The signal representing the channel transfer function is represented as a complex Gaussian process. The in-phase component and quadrature components are denoted x and y , the envelope r , and the phase θ , and these are related as

$$x + jy = r e^{j\theta} \quad (62)$$

Here x and y are independent, zero mean Gaussians, so the pdf for each is (here for x)

$$p_x(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{x^2}{2\sigma^2}\right) \quad (63)$$

where σ is the standard deviation of each component. The envelope and phase pdfs are established as independent with Rayleigh and uniform distributions respectively, through the steps

$$\begin{aligned} p_{r,\theta}(r, \theta) &= p_{x,y}(x, y) \left| \frac{\partial(x, y)}{\partial(r, \theta)} \right| \\ &= \frac{r}{\sigma^2} \exp\left(-\frac{r^2}{2\sigma^2}\right) \cdot \frac{1}{2\pi} \quad (r \geq 0) \\ &= p_r(r) \cdot p_\theta(\theta) \end{aligned} \quad (64)$$

The pdf of the phase is $1/(2\pi)$, so the mean phase is π and the standard deviation is $\pi/\sqrt{3}$. The averaged power is

$$\langle r^2 \rangle = \langle x^2 \rangle + \langle y^2 \rangle = 2\sigma^2 \quad (65)$$

Figure 12. The signals of a many-path, narrow-band channel as a function of position. As the mobile receiver moves, the narrowband signal quantities vary in a way similar to the behavior of the plots. The in-phase and quadrature components comprise complex Gaussians, the magnitude or envelope is Rayleigh-distributed, the phase is uniformly distributed, and the random FM is Student- t -distributed.

and r^2 is recognized as having a chi-square distribution with 2 degrees of freedom,

$$p_{r^2}(r^2) = \frac{1}{2\sigma^2} \exp\left(-\frac{r^2}{2\sigma^2}\right) \quad (66)$$

The Rayleigh statistics are included in the more general Rice statistics, below.

8.1.2. Rice Envelope and Phase. Sometimes there is a single dominant effective source. This usually corresponds to a line-of-sight situation, which gives a single dominant effective scatterer. Multipath transmission still occurs, and the Rice distribution describes the statistics of the narrowband envelope. The Rice distribution results from one or both of the Gaussian processes having nonzero mean. These phase processes become

$$x_{\text{Ri}} = x + x_s, \quad y_{\text{Ri}} = y + y_s \quad (67)$$

where the x and y are zero-mean Gaussian and x_s and y_s are the respective means representing the dominant component (sometimes called the *specular*, or *coherent*, component, with x and y representing the *diffuse*, or *incoherent* component) of the signal. The phasor combination is shown in Fig. 13 in which $\phi = \tan^{-1}(y_{\text{Ri}}/x_{\text{Ri}})$ is the absolute phase of the Rice envelope r_{Ri} , and θ is the phase difference between r_{Ri} (Rayleigh component plus dominant component) and the dominant component r_s . The mean of the absolute phase of the process is $E(\theta + \phi)$. A coordinate rotation allows the phase to be defined as just θ .

From

$$(x_{\text{Ri}} - x_s)^2 + (y_{\text{Ri}} - y_s)^2 = r^2 = r_{\text{Ri}}^2 + r_s^2 - 2r_{\text{Ri}}r_s \cos \theta \quad (68)$$

the Rice pdf is

$$p_{r_{\text{Ri}},\theta}(r_{\text{Ri}}, \theta) = \frac{r_{\text{Ri}}}{2\pi\sigma^2} \exp\left(-\frac{r_{\text{Ri}}^2 + r_s^2 - 2r_{\text{Ri}}r_s \cos \theta}{2\sigma^2}\right) \quad (69)$$

The envelope and phase are thus statistically dependent, unlike the Rayleigh case. The $+\pi$ and $-\pi$ transitions that occur in the phase of the Rayleigh signal as the locus passes near the origin are now reduced to smaller values, which depend on the length of the envelope phasor component r_{Ri} . The Rice channel can be purely minimum phase when the dominant component is large enough.

The Rice k factor is the ratio of powers of the dominant component and the Rayleigh component:

$$k_{\text{Ri}} = \frac{r_s^2}{2\sigma^2} \quad (70)$$

When the dominant component r_s approaches zero, k_{Ri} approaches 0, and the distribution reduces to Rayleigh.

Figure 13. The Rice process has envelope r_{Ri} comprising the additive constant r_s and the Rayleigh envelope r . The phase of the Rice signal is θ .

Similarly, when the dominant component becomes very large, the Rice distribution for the envelope approaches Gaussian with mean r_s .

8.1.3. Rice Envelope. For convenience, the envelope is normalized by the Gaussian standard deviation:

$$r_{\text{Ri}}^{(n)} = \frac{r_{\text{Ri}}}{\sigma} \tag{71}$$

The envelope pdf is

$$\begin{aligned} p_{r_{\text{Ri}}}(r_{\text{Ri}}) &= \frac{r_{\text{Ri}}}{2\pi\sigma^2} \exp\left(-\frac{r_{\text{Ri}}^2 + r_s^2}{2\sigma^2}\right) \int_0^{2\pi} \exp\left(\frac{r_{\text{Ri}}r_s \cos \theta}{\sigma^2}\right) d\theta \\ &= \frac{r_{\text{Ri}}}{\sigma^2} \exp\left(-\frac{r_{\text{Ri}}^2 + r_s^2}{2\sigma^2}\right) I_0\left(\frac{r_{\text{Ri}}r_s}{\sigma^2}\right), r_{\text{Ri}} \geq 0 \end{aligned} \tag{72}$$

or in terms of $r_{\text{Ri}}^{(n)}$ and k_{Ri} ,

$$\begin{aligned} p_{r_{\text{Ri}}^{(n)}}(r_{\text{Ri}}^{(n)}) &= \frac{1}{\sigma} r_{\text{Ri}}^{(n)} \exp\left\{-\left[\frac{1}{2}\left(r_{\text{Ri}}^{(n)}\right)^2 + k_{\text{Ri}}\right]\right\} I_0\left(r_{\text{Ri}}^{(n)} \sqrt{2k_{\text{Ri}}}\right), r_{\text{Ri}}^{(n)} \geq 0 \end{aligned} \tag{73}$$

As k_{Ri} approaches infinity, the Rice pdf becomes a deltalike function, being a Gaussian with a variance approaching zero.

The Rice distribution is sometimes called Nakagami-Rice, in recognition of its independent development by Rice [10] and by Nakagami [11], who reported it in English at a later time. Because of its physical justification for many situations, the Rice distribution is the preferred one for short-term fading. Review material covering aspects of Rice’s work is presented in Refs. 12 and 13. The distribution for the random FM and group delay for the Rice channel is given by the Student t distribution [1,14].

The Rice envelope cumulative density function (cdf) is expressed as

$$\text{Prob}(r_{\text{Ri}} \leq r_0) = 1 - Q_1\left(\frac{r_s}{\sigma}, \frac{r_0}{\sigma}\right) \tag{74}$$

where Q is the Marcum Q function [15]. Further worthwhile discussion on the Q function is given in Refs. 1, 16, and 17. The Rice envelope cdf is sketched in Fig. 14 for values of the Rice k factor, including the Rayleigh case.

8.2. Lognormal Shadow Fading

Shadow fading has been found experimentally to be well described by the lognormal distribution. Whereas the Gaussian distribution results from the addition of many random variables, the lognormal distribution results from the product of many positive random variables. It follows that when Gaussian variables are expressed in logarithmic units, they then follow a lognormal distribution. The transformation of variables between the distributions is $z = e^x$, or $\ln z = x$. (z here is a variable, not distance.) If x is

Figure 14. The Rice envelope cdf. For zero specular component, the distribution is Rayleigh, and approaches Gaussian (vertical line at 0 dB) for an asymptotically large specular component.

Gaussian, then z is lognormal. Alternatively stated, if z is lognormal, then $\ln z$ is Gaussian. The pdf of the lognormal distribution is found from the Gaussian pdf

$$p_1(z) = p_x(x) \left| \frac{\partial x}{\partial z} \right| = \frac{1}{\sqrt{2\pi}\sigma_{\ln z}} \exp\left(-\frac{(\ln z - m_{\ln z})^2}{2\sigma_{\ln z}^2}\right) \tag{75}$$

where $m_{\ln z}$ and $\sigma_{\ln z}^2$ are the mean and variance respectively of $\ln z$. The lognormal signal representing the local mean of the envelope looks like one of the phase components of Fig. 14, except that the scale would be in decibels rather than linear. Typically $\sigma_{\ln z}$ is 3–8 dB in urban environments.

8.3. Suzuki: Lognormal and Rayleigh

Combining the short-term Rayleigh and long-term lognormal distributions provides a model for the stochastic component of the path loss of a narrowband signal in mobile communications.

The lognormal distribution is over the mean of the envelope. This can be interpreted as Gaussian for the envelope mean in decibels. The Rayleigh envelope mean is linearly related to the Gaussian standard deviation, viz., $\langle r \rangle = \sqrt{\pi/2}\sigma$, so the lognormal distribution can be applied to the σ [18]. The distribution can be written

$$\begin{aligned} p_{\text{Su}}(r) &= \int_0^\infty \frac{r}{\sigma^2} \exp\left(-\frac{r^2}{2\sigma^2}\right) \cdot \frac{1}{\sqrt{2\pi}\sigma_l} \exp\left(-\frac{(\ln \sigma - m_l)^2}{2\sigma_l^2}\right) d\sigma \end{aligned} \tag{76}$$

No closed form has been found for the integral, which is a practical inconvenience when applying the Suzuki distribution. However, the distribution has the advantage of being based on a physical model for the envelope, and thus

offers good agreement with experimental results on large-scale records of envelopes of narrowband signals.

Many other distributions have been used to fit mobile channel fading [19]. Some have various advantages for mathematical manipulations or for the fitting of experimental data. Two are noteworthy because of their versatility. The Nakagami m [11] distribution has a single parameter that allows the shape of the distribution to be altered, in particular for small values of r . The generalized gamma distribution [20] has effectively two parameters that can independently adjust the shape of the small and large values of r .

9. PATH LOSS AND THE MOBILE CHANNEL

Much of the preceding discussion has been a statistical description of the behavior of the mobile channel. The interest in the envelope or power of the mobile transfer function is because this dominates the SNR of the received signal. The power is also referred to as the *channel gain*. How this ties in with the path loss is addressed in this section. In so doing, the discussion returns to the electromagnetic propagation and antenna issues of the opening sections.

Path loss is a well-defined concept originating from point-to-point radio links. It comes from the Friis transmission equation, which relates the transmitted and received powers (P_T, P_R respectively), the antenna gains (G_T, G_R respectively), and the path loss L :

$$\frac{P_R}{P_T} = G_T G_R \frac{1}{L} \quad (77)$$

Path loss is seen from this equation to be the reciprocal of the path gain. For frequency-independent antenna gains, the free space path loss for a separation distance d and wavelength $\lambda = c/f$ is

$$L_F = \left(\frac{4\pi d}{\lambda}\right)^2 = \left(\frac{4\pi f d}{c}\right)^2 \quad (78)$$

so that it varies as the frequency squared and the distance squared. The incident field strength is not dependent on frequency. In Eq. (77), the antennas are considered impedance- and polarization-matched.

9.1. Mean Path Loss and Mean Antenna Gain

In a mobile channel, the classical point-to-point situation does not apply. The received power and the receiving antenna gain become statistical quantities. The antenna's *mean gain* can be defined by the average gain into a well-defined distributed direction. The mean received power can be defined from a time average. The path loss is the time-varying quantity (because of the spatially dependent phase mixture of multipath propagation signals), and so the mean received power with Eq. (77) defines a *mean path loss*. Sometimes the term *mean effective gain* is used when comparing antennas by measuring their time-averaged received powers in the same environment. In this

context, it must be assumed that the transmitting power and the mean path loss are both common to each measurement record used for the averaging. The mean effective gains are then proportional to the mean received powers and include polarization mismatches. What is being measured is how well, on average, the vector antenna pattern is directed toward the vector distribution of incoming power from the measurement environments.

9.2. Scenario Models

Model distributions are used to approximate the average incident power incident power directions for various applications. For a mobile vehicle, for example, the Clarke scenario [21,22], given by

$$S^{(C)}(\theta, \phi) = S^{(C)}(\theta) = \delta(\theta - \pi/2) \quad (79)$$

is often used. This corresponds to a uniform source distribution at the horizon, surrounding the antenna. Transforming to the spatial Doppler variable results in the pdf

$$p_u^{(C)}(u) = \frac{1}{\pi \sqrt{k_C^2 - u^2}} \quad (80)$$

and this spatial Doppler spectrum is for the incident fields or the electromagnetic propagation channel (for one polarization), and also for the mobile channel if an omnidirectional (in the $\theta = \pi/2$ plane) antenna is used. The spatial Doppler spread is $\sigma_u^{(C)} = k_C/\sqrt{2}$ (rad/m). The spatial correlation coefficient for the envelope is $\rho_r^{(C)}(\Delta z) \approx J_0^2(k_C \Delta z)$, giving a 0.7 correlation distance of about 0.13 wavelengths and an average distance between fades of about 0.5 wavelength.

For a directional antenna, the spatial Doppler distribution corresponding to the pattern must be multiplied with Eq. (80) to get the spatial Doppler spectrum of the mobile channel. This is how the antenna pattern can control the mobile channel behavior. A single-lobed, directional pattern acts as a spatial Doppler bandpass filter and results in a decreased (relative to an omnidirectional pattern) Doppler spread, and therefore a decreased spatial fading rate. This effect can be seen with laser speckle, where the dark areas are the deep fades of energy, and the interspeckle distance, even though the frequency is optical, is sufficiently large to be visible to the eye because the spatial Doppler spread of the illuminating beam is so small.

MOBILE SATELLITE COMMUNICATIONS

JOHN LODGE
 Communications Research
 Centre
 Ottawa, Ontario, Canada

Mobile satellite (MSAT) systems provide communications services to mobile and portable terminals using a radio-transmission path between the terminal and the satellite. An example of such a system, illustrating its typical components, is shown in Fig. 1. The mobile terminal may be installed in any one of a number of platforms including cars, trucks, railcars, aircraft, and ships. Alternatively, it could be a portable terminal with a size ranging from that of a handheld unit up to that of a briefcase, depending on the system and the service provided. Yet a third class could be small but fixed remote terminals serving functions such as seismic data collection and pipeline monitoring and control. A mobile satellite system requires one or more satellites with connectivity to the terrestrial infrastructure (e.g., to the public switched telephone network and to the various digital networks) supplied by one or more Earth stations. Typically, most of the communications traffic is between the mobile terminal and another terminal or application outside the mobile satellite system. However, most mobile satellite systems allow for mobile-to-mobile communications within the system. The Earth stations are coordinated by a control center in a way that shares the satellite transmission resources efficiently. Also, the control center may issue commands to the satellites via the Earth stations.

A number of radiolinks are required for such a system. Communication from the Earth station to the mobile terminal is said to be in the forward direction, whereas communication from the mobile terminal to the Earth station is said to be in the return direction. In both the forward and return directions, an uplink to the satellite and a downlink from the satellite are required, for a total of four radiolinks. The links between the Earth station and the satellite are sometimes referred to as *feeder links*, whereas

MOBILE SATELLITE COMMUNICATIONS

JOHN LODGE
 Communications Research
 Centre
 Ottawa, Ontario, Canada

Mobile satellite (MSAT) systems provide communications services to mobile and portable terminals using a radio-transmission path between the terminal and the satellite. An example of such a system, illustrating its typical components, is shown in Fig. 1. The mobile terminal may be installed in any one of a number of platforms including cars, trucks, railcars, aircraft, and ships. Alternatively, it could be a portable terminal with a size ranging from that of a handheld unit up to that of a briefcase, depending on the system and the service provided. Yet a third class could be small but fixed remote terminals serving functions such as seismic data collection and pipeline monitoring and control. A mobile satellite system requires one or more satellites with connectivity to the terrestrial infrastructure (e.g., to the public switched telephone network and to the various digital networks) supplied by one or more Earth stations. Typically, most of the communications traffic is between the mobile terminal and another terminal or application outside the mobile satellite system. However, most mobile satellite systems allow for mobile-to-mobile communications within the system. The Earth stations are coordinated by a control center in a way that shares the satellite transmission resources efficiently. Also, the control center may issue commands to the satellites via the Earth stations.

A number of radiolinks are required for such a system. Communication from the Earth station to the mobile terminal is said to be in the forward direction, whereas communication from the mobile terminal to the Earth station is said to be in the return direction. In both the forward and return directions, an uplink to the satellite and a downlink from the satellite are required, for a total of four radiolinks. The links between the Earth station and the satellite are sometimes referred to as *feeder links*, whereas

the links between the mobile terminal and the satellite are typically referred to as *service links* or *mobile links*. In some of the more advanced satellite systems with multiple satellites, there are radiolinks between adjacent satellites called *intersatellite links*.

A wide variety of services and applications are supported by mobile satellite systems, with many more proposed. First- and second-generation systems are limited to data rates ranging from a few hundred bits per second (bps) to several tens of kilobits per second (kbps) and have concentrated their efforts on providing services that fall within categories such as telephone-quality speech, packet data communications, facsimile, generic asynchronous stream data, and paging. Third-generation systems are expected to be capable of transmission at rates up to several hundred kilobits per second and will be capable of delivering moderate-quality video and high-quality audio services. Increasingly, the services delivered by these systems will appear to be an extension of those available to users over the converging terrestrial systems.

Many satellites isolate selected frequency bands from the composite uplink signal using filtering, translate these selected bands to their downlink frequency band, amplify them, and then transmit them toward the Earth in the appropriate antenna beam. The term *transparent* satellite is used in this case. As an extension of this concept, some of the newer satellites use digital processing to select the uplink signal in a given frequency band, timeslot, and antenna beam, and then “switch” it to the desired downlink frequency band, timeslot, and antenna beam. The most sophisticated satellites demodulate the uplink transmissions and then process the resulting data signals in the same manner as a digital switch prior to modulation for downlink transmission. This type of satellite is sometimes referred to as a *regenerative satellite*.

A wide variety of mobile satellite terminals is commercially available. Here, we give only a few examples. Figure 2 shows a receive-only unit, manufactured by Skywave Mobile Communications Inc., that can be used to receive alphanumeric messages sent to a personal computer-based terminal, over the Inmarsat-D system. This system

is a high-penetration system and can receive messages even when moderate blockage of the satellite signal is occurring. The receiver is the small black rectangular object beside the laptop computer. The white disk-shaped object is the antenna, which has a magnetic base allowing it to be temporarily mounted on the roof of a vehicle. At other times, any flat surface will suffice.

A Mitsubishi MSAT telephone transceiver, mounted on the front wall of the trunk of a car, is shown in Fig. 3. The corresponding antenna subsystem, mounted on the car’s roof, is shown in Fig. 4. A third subsystem, which is not shown, is the user’s interface unit in the passenger compartment, including the telephone handset.

The major subsystems of the CAL Corporation’s satellite telephone terminal, for telephone communications to aircraft via MSAT, are shown in Fig. 5. Most of the terminal’s electronics are contained in the blackbox on the right-hand side. This box would normally be mounted

inside the pressurized cabin of the aircraft. The antenna subsystem is shown on the left-hand side, with its radome placed behind it. For this particular antenna, two short helices are used as the transducing elements in order to achieve the required amount of antenna gain while keeping the profile of the antenna low. The antenna is often mounted on the top of the fuselage, as is shown in Fig. 6. However, on some aircraft the top of the tail fin is a preferred location for antenna mounting.

1. MOBILE SATELLITE LINKS

We will start by considering the path of the radio signal as it travels from the satellite to the mobile terminal, that is, the downlink in the forward direction. A detailed discussion of this link will introduce the concepts necessary to understand more concise discussions pertaining to the

other links of interest in a mobile satellite system. Radio-frequency bandwidth and electrical power are two scarce resources that tend to constrain the design of mobile satellite systems. In this section, the focus is primarily on power; efficient bandwidth utilization is partially addressed in subsequent sections. Clearly, downlink power will be limited because most satellites use solar power as their primary source of electrical power. Also, uplink power from the mobile terminal tends to be limited because such a terminal receives electrical power from either its own battery or that of the vehicle.

1.1. Line-of-Sight Transmission

At the satellite, the signal is amplified so that its average signal power is P_t dBW, at the input to the transmitting

Figure 6. A Cessna Citation jet aircraft, operated by the Ontario Air Ambulance Service, equipped with a mobile satellite communications terminal. The antenna subsystem can be seen mounted on top of the fuselage.

antenna. It is the transmitting antenna's function to spread that signal power as uniformly as possible over the desired coverage area on Earth's surface, while wasting as little power as possible outside this coverage area. This is directly analogous to the ability of the reflecting surface of a flashlight to focus the light from the bulb into a beam of light. A measure of the ability of the antenna to focus the radiation is its gain, which is the ratio of the flux density at the center of the coverage area to that value that would occur if the power had been radiated equally in all directions (i.e., isotropic radiation). This gain is a function of the size of the antenna, and for a circular parabolic antenna it is given by

$$G = 10 \log_{10} \frac{\Omega \pi^2 D^2}{\lambda^2} \text{dBi} \quad (1)$$

where Ω is the efficiency of the antenna (typically between 50% and 70%), D is the diameter in meters, and λ is the wavelength of the radiofrequency signal in meters. Other types of antennas will have differing gains, but Eq. (1) provides an order-of-magnitude estimate of the required antenna size to achieve a prescribed gain. This discussion assumes that a single beam is used to cover the desired area. For reasons that will be discussed later, it may be advantageous to cover the desired area with multiple overlapping beams, but using the same antenna superstructure. An example of one way to achieve this is to use a single large reflector with multiple feeds (i.e., source transducers) in different locations near the focal point of the reflector. Of course, increasing the number of beams increases the complexity of the satellite. The size and weight of the satellite's antennas are constrained by the need to maintain reasonable costs for the satellite and its launch. Nevertheless, advanced technology allows for surprisingly large antennas to be deployed in space. For example, the North American MSAT satellites have two elliptical antennas, measuring 6×5 m, and provide five beams covering all continental North America, the Caribbean Sea, and Hawaii. Some later systems have significantly larger antennas and can support more than 100 beams.

As the signal travels from the satellite to Earth, its flux density decreases as the square of the distance traveled. This power loss is referred to as the *free-space path loss* and is given by

$$L_p = 10 \log_{10} \frac{(4\pi d)^2}{\lambda^2} \text{dB} \quad (2)$$

where d is the distance traveled between the satellite and the mobile terminal. A geostationary orbit is a circular orbit for which the orbital radius, position, and velocity are such that the satellite remains in approximately the same location above the equator as Earth rotates. For a geostationary orbit, like that of MSAT, the radius is about 42,163 km, resulting in a typical propagation delay of greater than an eighth of a second to traverse from the satellite to the surface of Earth. At MSAT frequencies, the corresponding path loss is about 188 dB! The great

altitude of a geostationary satellite allows it to view about a third of the surface of the planet. Consequently, global coverage (with the exception of the polar regions) is possible with only three satellites. A larger number of satellites, in circular orbits at lower altitudes, can be used to provide global service with the advantages of lower path loss, shorter propagation delay, and lower launch costs on a per satellite basis. For reasons of satellite longevity, altitudes that avoid the Van Allen radiation belts are usually selected. The low-Earth orbits (LEOs) are located beneath the primary belt and have altitudes between 500 and 2000 km. Similarly, the medium-Earth orbits (MEOs) are located between the primary and secondary belts and have altitudes between 9000 and 14,000 km. The medium-Earth orbits are sometimes referred to as *intermediate circular orbits* (ICOs). Unlike systems that use geostationary orbits, these other systems typically use several distinct orbital planes, each of which is inclined with respect to the equator. A number of proposed systems have planned to use highly elliptical orbits (HEOs) instead of circular ones. The potential advantage of a HEO-based system is that it can provide high angle-of-elevation coverage to selected areas in the temperate zones (i.e., those parts of the world for which the demand for communications services is the greatest) with a moderate number of satellites. Despite this advantage, it does not appear that HEO systems will play a significant role in mobile satellite communications.

On reaching the terminal, the signal energy is collected by the receiving antenna and is converted by a transducer to an electrical signal. A typical example of a mobile satellite antenna designed for the MSAT system is shown in Fig. 7. Here, the transducing element is a short helical structure, similar to the element used for the land mobile satellite terminal and to each of the two elements for the aircraft mobile satellite terminal shown previously in this article. The white dome is a radome that is placed over the antenna to protect it. This antenna must be steered in azimuth but has a wide enough beam that steering in elevation is not necessary. Many mobile terminals use closed-loop antenna steering mechanisms, based on the received signal strength. The graybox shown in Fig. 7 contains a self-calibrating electronic compass that can be used to improve the antenna steering achievable using signal strength alone. Because of the fact that the physical rules describing the propagation of transmitting and receiving display a reciprocal relationship, an appropriate measure of the antenna's ability to collect the energy is the antenna gain, as described in the text near Eq. (1). Therefore, the average power of the received signal from the line-of-sight propagation path at the output of the receiving antenna is given by

$$P_r = 10 \log_{10} C = P_t + G_t - L_p + G_r \text{dBW} \quad (3)$$

where G_t is the gain of the transmitting antenna and G_r is the gain of the receiving antenna.

The signal's radiofrequency plays a major role in Eq. (3), with G_t , L_p , and G_r increasing with the square of the frequency. The net result is that the received power

Figure 7. A prototype antenna system designed for the North American MSAT system. On the right-hand side of the foreground is the short helical antenna element. It can be steered in azimuth but is fixed in elevation. The box on the left-hand side is the antenna steering unit, and the radome is shown in the background.

also increases with the square of the frequency. Alternatively, if the received power is treated as the fixed parameter, smaller antennas could be used at higher frequencies. Some of this benefit for higher frequencies is offset by other propagation effects. For example, the lower frequencies (i.e., longer wavelengths) are more robust in the presence of blockage by collections of small obstacles such as foliage and rain. A second factor that is very important is the availability of an otherwise unused radio spectrum. At the international level, spectrum usage is determined by the International Telecommunications Union (ITU) at an ongoing series of World Administrative Radio Conferences (WARC). Then national bodies, such as the Federal Communications Commission (FCC) in the United States, license-specific service providers to offer the corresponding services within each country. A wide variety of frequency bands have been allocated for mobile satellite systems, typically with the larger allocations being at the higher carrier frequencies as a result of availability. Consequently, the systems that offer low-data-rate services are generally allocated lower frequency bands than do those offering high data rate services. For example, a number of systems offering low-rate store-and-forward messaging services communicate between the satellite and the mobile terminal in frequency bands between 100 and 400 MHz, although most of the systems offering medium-rate mobile satellite telephone services

use bands between 1.5 and 2.5 GHz, and many of the proposed systems for providing high-rate multimedia services plan to operate in bands between 20 and 30 GHz.

Because of the large path loss that is typical of satellite transmissions, the received power is very low. In fact, it is so low that the thermal noise in the receiving antenna and front end of the receiver must be accounted for. The resulting carrier-to-noise-spectral-density ratio is given by

$$10 \log_{10} \frac{C}{N_0} = P_r - T_r - k \text{dB} \cdot \text{Hz} \quad (4)$$

where T_r is the composite noise temperature of the receiver expressed (dBK) and k is Boltzmann's constant ($-228.6 \text{ dBW/K} \cdot \text{Hz}$). If the transmission is digital with a rate of R bps, the energy-per-bit-to-noise-spectral-density ratio is given by

$$\frac{E_b}{N_0} = \frac{C}{N_0 \cdot R} \quad (5)$$

Of course, thermal noise is not the only impairment that needs to be considered. Some of the other common impairments that are encountered by mobile satellite transmissions will be addressed in the following sections.

1.2. Multipath Propagation and Shadowing

In addition to the line-of-sight path, the signal can reach the receiving antenna by reflected paths from objects that are usually located nearby. Often, several distinct reflecting objects are in the field of view of the receiving antenna. If the differences in the propagation times for the various propagation paths (reflected and line of sight) are much less than the reciprocal of the bandwidth of the transmitted signal, the effect of the multipath propagation can be viewed as non-time-dispersive. This type of multipath propagation will affect the power and carrier phase of the received signal according to the nature of the superposition of the paths, but it will not distort its frequency content or introduce intersymbol interference in the case of a digital transmission. For land mobile satellite applications, measurements [1] taken in a frequency band near 1.8 GHz indicate that the difference in propagation times rarely exceeds 600 ns. Consequently, for signal bandwidths up to several hundred kilohertz, the multipath propagation can be considered non-time-dispersive. The following discussion is based on this assumption being valid. If the geometry of the paths change with time as a result of terminal motion, satellite motion, or motion of the reflecting objects, the power and carrier phase of the received signal will vary with time. This time-varying phenomenon is referred to as *fading*, or more specifically as *flat fading* for the non-time-dispersive case.

For the purpose of evaluating the performance of candidate transmission techniques, it is frequently desirable to model the propagation environment in a way that is suitable for numerical analysis and simulation. An approximation that is often made is to assume that the reflecting objects are adequately numerous and independent in

nature for the central-limit theorem to apply. Consequently the fading can be represented by a Gaussian process that is completely statistically characterized by its power spectral density. The power spectral density will be nonzero only over a bandwidth equal to the difference in frequency between the path with the greatest Doppler frequency shift and that with the least [2]. This type of fading model is referred to as *Rayleigh fading*. The combination of the line-of-sight path with the Rayleigh fading reflected path is referred to as *Rician fading*, which has the additional parameter called the carrier-to-multipath ratio (C/M), defined to be the ratio of the average signal power received over the line-of-sight path to that received over the reflected paths.

Another effect that can greatly affect the availability and performance of a mobile communication link is shadowing, the term given to blockage of the line-of-sight path. Such blockage occurs naturally in terrestrial mobile satellite environments as the moving vehicle passes by obstacles such as buildings, trees, and bridges. Many obstacles result in such severe attenuation of the line-of-sight signal that it is weaker than the reflected paths and can be ignored. A useful but simple model for shadowing is to switch between a good state (unshadowed) and a bad state (shadowed) with the typical time period for enduring each state being determined by the parameters of a two-state Markov model [3,4]. A transmission model corresponding to this discussion is shown in Fig. 8. A simple shadowing model is to apply a fixed attenuation selected on a shadowing event by shadowing event basis, using a lognormal distribution. If the shadowing is caused predominantly by foliage, the line-of-sight path may also be included with being subjected to attenuation according to another lognormal distribution [5]. Of course the values selected for the model's parameters depend on many issues, including angle of elevation to the satellite, type of terminal (e.g., land mobile, aircraft, marine, handheld), antenna gain pattern, vehicular velocity, satellite velocity, environment (e.g. urban, suburban, highway), and terrain.

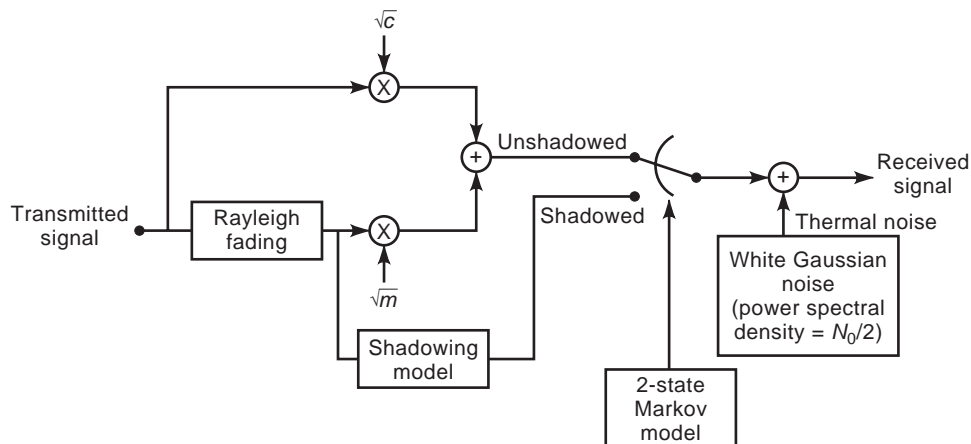

Figure 8. A useful model of fading and shadowing for the evaluation of mobile satellite transmission schemes. Here, c is the average power for the line-of-sight path and m is the average power for the reflected paths.

1.3. Other Sources of Degradation

Degradation to the received signal caused by thermal noise, multipath propagation, and shadowing have already been discussed. In many systems, these are the dominant sources of degradation, but there are a number of other ones that should be appreciated. Perhaps the next most important source of degradation is interference to the desired signal from other signals within the same system. If the interference is caused by another signal that is located in the same frequency channel as the desired signal, the interference is referred to as *cochannel interference*. For narrowband signals, cochannel interference is generally caused by interferers in other antenna beams for which the out-of-beam attenuation provided by the satellite antenna is not sufficiently great to render the interfering signal negligible. For spread spectrum signals, some of the cochannel interference may be due to other signals within the same beam. Interference to the desired signal can occur from signals in the adjacent frequency channels as a result of the fact that some of their transmitted energy falls outside of their allotted frequency channel. This type of interference is known as *adjacent-channel interference*.

For some mobile satellite systems, the ratio of the carrier frequency to the bit rate is many orders of magnitude. When this is the case, a nonnegligible amount of degradation can occur because the phase of the radiofrequency carrier differs significantly from its ideal value in a time-varying nature, which is the result of the electronic components in the system. This phenomenon is called *phase noise*. Common sources of phase noise include imperfect oscillators and frequency synthesizers, vibration of the mobile terminal's electronic circuitry (known as microphonics), and electronic steering of the mobile terminal's phased-array antenna.

Nonlinear power amplification, at several locations in a mobile satellite system, can cause degradation. In the case of the transmitting power amplifier in the mobile terminal, typically only a single carrier (signal) is present, and

the distortion of that signal by the amplifier's nonlinear behavior has two effects: (1) there will be a small reduction in the power efficiency of the desired transmission—for example, if the signal is digital, a little more transmit power will be necessary to achieve the required bit-error rate; and (2) the distortion will often broaden the power spectrum of the transmitted signal, resulting in increased interference in the adjacent channels.

Nonlinear distortion will also occur in the transmit power amplifiers of Earth stations and the satellites. Usually, many carriers will be amplified simultaneously. In this case, the result is a broadband noiselike signal caused by the intermodulation of the many carriers present in the amplifier.

Depending on the frequency band used by the given mobile satellite system, it may be necessary to account for effects such as ionospheric scintillation, tropospheric scintillation, gaseous absorption, and rain attenuation. In general, these effects become more severe for lower angles of elevation.

2. THE SIGNAL-PROCESSING PATH

In this section we discuss some of the signal-processing techniques that can be used to increase the efficiency with which the scarce resources of the radiofrequency spectrum and electrical power are used. Figure 9 shows a high-level block diagram of the processing stages for the transmitting side of the communication chain. The inverse operations are performed on the receiving side to recover the transmitted information. Here, we will discuss the blocks in this processing chain only to the level necessary for understanding their role in a mobile satellite context. More detailed treatment of many of these processing stages can be found elsewhere in this encyclopedia.

The first block in the chain is the information source. Examples include telephone-quality speech, data representing text, and multimedia signals representing a composite of audio, video, and data components. Regardless of the type of information that is to be transmitted, it is important to minimize the number of bits required to represent the information subject to constraints such as delay, processing complexity, and quality of the representation. This is the objective of the second block in the chain, entitled "source coding." Using telephone-quality speech as an example, the analog waveform can be accurately represented using a 64-kbps stream of data, by sampling the waveform at 8 kps (8000 samples per second) and giving each sample 8 bits of precision. However, using more recently developed speech-coding standardized techniques, the bit rate can be reduced a full order of

magnitude to 6.4 kbps without a significant reduction in speech quality [6]. Very efficient standardized low-rate videocoding techniques also exist [7]. Of course, the same techniques as are used for computer storage can be used to reduce the size of data and text files for mobile satellite transmission.

2.1. Error Control Coding

Error control coding introduces redundancy into the bitstream by increasing the total number of bits in such a way that each original bit influences several bits in the error-control-coded bitstream. This redundancy can then be used to correct (forward error correction coding) or detect (error detection coding) transmission errors at the receiver. We will consider forward error correction first. Even though the additional bits do result in an increase in the required number of bits to be transmitted, appropriate coding and decoding schemes will generally result in a net reduction in the transmitted power required to meet a given bit error rate. For first-generation mobile satellite systems, rate- $\frac{1}{2}$ constraint length 7 convolutional coding has been a fairly standard choice. Note that the rate is the ratio of the number of bits into the coder to those out of the coder. In some cases, punctured versions of this code have been used to achieve a higher coding rate, thereby improving bandwidth efficiency at the expense of power efficiency. A predominant reason for the popularity of this code is that it was one of the first fairly powerful error correction codes for which decoder integrated circuits, capable of processing soft decisions, were commercially available. For decoding in fast fading and shadowing conditions, the soft decision should incorporate channel state information so that the decoder assigns relatively less importance to bits that were received when the signal was faded or blocked.

The achievable coding gain is a strong function of the block length over which coding is performed, with larger blocks allowing for greater gains. For applications for which the packet or frame length is quite short (e.g., most packet data and low-rate speech applications) convolutional coding is still a good choice, although constraint lengths greater than 7 can be implemented now. Tail biting (i.e., encoding the input data in a circular buffer) can be performed to eliminate the overhead of transmitting extra bits to terminate the code's decoding trellis [8].

For applications for which the frame length is longer than a couple of hundred bits, turbo coding will be a strong candidate for future systems [9]. The performance of turbo coding improves as the block length increases; however, the end-to-end delay of the transmission system

Figure 9. A high-level block diagram of the processing stages for the transmitting side of the communication chain.

increases with increasing block lengths. Consequently, only services that are tolerant of fairly large delays can benefit from the most power efficient error control coding. For rate- $\frac{1}{2}$ coding, Fig. 10 shows the performance for constraint length 9 convolutional coding (80-bit block) and turbo coding (512-bit block and 10,000-bit block). This turbo code uses 16-state recursive systematic convolutional codes as its component codes. These performance results assume antipodal signaling (e.g., ideal coherent binary phase shift keying); the only channel impairment is Gaussian noise.

In general, the benefit that can be achieved by error correction coding increases with increasing decoding complexity and block (i.e., codeword) size, and with decreasing code rate. One way to achieve a higher code rate, for a fixed decoding complexity, is to use puncturing [10]. Puncturing increases the code rate by selectively deleting some of the coded bits prior to transmission. In order to increase the code rate beyond 1 bit per symbol, it is necessary for the coder to map the input sequence of bits into a sequence of symbols for which the size of the symbol alphabet is greater than 2. A well-known technique for doing this is trellis-coded modulation [11,12]. Some forms of trellis-coded modulations are designed in such a way that standard convolutional decoder integrated circuits can be used to perform the decoding. These forms are referred to as *pragmatic trellis-coded modulations* [13]. An example of the tradeoff between power and bandwidth efficiency can be seen in Fig. 11. Here, all three codes are based upon the same convolutional code, where the rate- $\frac{1}{2}$ code is a constraint length 9 code, the rate- $\frac{3}{4}$ code is a punctured version of the rate- $\frac{1}{2}$ code, and the rate-1 code is a pragmatic trellis-coded modulation with the rate- $\frac{1}{2}$ code mapped into a four-level constellation.

Figure 10. The performance of various rate- $\frac{1}{2}$ codes in an additive white Gaussian noise environment. Shown are simulation results for a constraint length 9 convolutional code with tail biting and a block size of 80 bits, and turbo coding with block sizes of 512 bits and 10,000 bits.

Figure 11. The performance of codes of differing rates in an additive white Gaussian noise environment. Shown are simulation results for the constraint length 9 rate- $\frac{1}{2}$ code; the rate- $\frac{3}{4}$ code, which is a punctured version of the rate- $\frac{1}{2}$ code; and the rate-1 code, which is a pragmatic trellis-coded modulation with the rate- $\frac{1}{2}$ code mapped into a four-level constellation.

Error detection coding is useful for services that are message- or frame-based, and it is important to know whether a given message or frame has been received correctly. In these cases a small field of parity bits (e.g., 16 parity bits) is appended to the message, with the parity bits generated using a cyclic redundancy code. At the receiver, if the parity bits computed from the received data bits do not agree with the received parity bits, the message is known to be in error. In some systems, a request will then be sent to the transmitter to retransmit the message.

Returning to error correction coding, many forward error correction codes are much better suited to correcting randomly distributed single errors than long bursts of errors, assuming that the average bit error rate is fixed. However, some impairments such as multipath fading cause error patterns that are bursty in nature. To the extent allowed by constraints such as message length and delay restrictions for the service, interleaving can be used between the coder and the modulator in an attempt to eliminate error bursts prior to decoding. Interleaving permutes the order of the coded symbols according to a rule that is known at both the transmitter and the receiver. After demodulation at the receiver, the deinterleaver performs the inverse permutation prior to passing the soft decisions to the decoder. By so doing, sequences of soft decisions corresponding to poor bursts of signal are broken up and mixed with soft decisions that were received under more favorable conditions.

2.2. Modulation

After interleaving, the sequence of coded symbols is modulated. Here, we restrict our consideration to linear modulation schemes. For a linear modulation scheme, the

transmitted signal is given by

$$\begin{aligned}
 s(t) &= \operatorname{Re} \left\{ \left[\sum_{i=0}^{N-1} a_i g(t - iT) \right] e^{j\omega_0 t} \right\} \\
 &= \left[\sum_{i=0}^{N-1} g(t - iT) \operatorname{Re}(a_i) \right] \cos(\omega_0 t) \\
 &\quad - \left[\sum_{i=0}^{N-1} g(t - iT) \operatorname{Im}(a_i) \right] \sin(\omega_0 t)
 \end{aligned} \quad (6)$$

where a_i ; $i=0, \dots, N-1$ is the sequence of complex modulation symbols, T is the symbol period, $g(t)$ is the unit pulse response of the pulse shaping filter and is assumed to be real, and ω_0 is the radian carrier frequency. In the second line of Eq. (6), the term inside the square brackets prior to “cos” is referred to as the in-phase component of the signal and the term inside the square brackets prior to “sin” is referred to as the quadrature component of the signal. For M -ary signaling, each a_i is selected from an alphabet of M complex numbers, with the modulus of each complex number representing the amplitude of the given symbol and the phase of each complex number representing the phase of the given symbol. The majority of mobile satellite communication systems use one or more forms of phase modulation. In the case of phase modulation, each a_i is selected from a symbol alphabet for which all elements have a modulus of 1. Therefore, only the phase of the symbol varies. Binary phase shift keying (BPSK) is popular for low-rate systems because of its robustness. For BPSK, each a_i is selected from the alphabet $\{1, -1\}$ which is purely real, and consequently a BPSK waveform has no quadrature component. A variation of BPSK, that is used in aeronautical satellite communications, is $\pi/2$ -BPSK for which subsequent symbols experience a relative phase shift of $\pi/2$ radians. For example, each a_i is selected from the alphabet $\{1, -1\}$ when i is even and from $\{j, -j\}$ when i is odd. When used with an appropriate choice of pulse shaping filter, such as a 40% square-root raised-cosine filter, the result is a waveform that suffers less spectral spreading when passed through a nonlinear amplifier, but enjoys all the robustness of standard BPSK. For systems requiring some additional spectral efficiency, some form of quadrature phase shift keying (QPSK) is usually selected. Standard QPSK can be thought of as two BPSK signals transmitted in parallel: one as the in-phase component and the other as the quadrature component. A variation of QPSK that is of some interest is $\pi/4$ -QPSK, for which subsequent symbols experience a relative phase shift of $\pi/4$ radians. The advantages of selecting $\pi/4$ -QPSK are similar to those described previously for $\pi/2$ -BPSK. Another variation of QPSK that is even more robust to nonlinear amplification is offset QPSK for which the symbol timing for the in-phase component is offset by half a symbol period relative to that of the quadrature component.

2.3. Multiple Access

Next we consider how the satellite resources of bandwidth and power can be efficiently shared between many users.

The sharing of the transmission medium between several users is referred to as multiple access (see MULTIPLE ACCESS MOBILE COMMUNICATIONS). We start from a highly idealized point of view, considering the case where there is only a single beam, perfect synchronization in both time and frequency have been achieved, and no interference is permitted between users.

First, let power be the only constraint. Each user can have as much bandwidth as desired but cannot exceed some fixed maximum value of transmit power. Under this constraint, each user attempts to maximize throughput (i.e., bit rate) subject to the requirement that the average bit error rate is better than some specified value. In general, lowering the coding rate allows for greater power efficiency and consequently a higher throughput for a given amount of power. The achievable region is illustrated by the area under the curve labeled “Power constraint” in Fig. 12. Note that the coding rate is expressed in bits per dimension, which takes into account the modulation and error control coding. This is the ratio of the number of bits into the error correction coder to the number of dimensions out of the modulator, over a fixed period of time. In Eq. (6), $\operatorname{Re}\{a_i\}$ and $\operatorname{Im}\{a_i\}$ can be considered as examples of dimensions in the signal space. It is well known that for a bandwidth of B and a time duration of T_s the number of available dimensions is $2BT_s$ [14].

Now let bandwidth be the only constraint considered. Clearly, the composite bit rate will increase linearly as the users increase their coding rate. The achievable region is illustrated by the area under the curve labeled “Bandwidth constraint” in Fig. 12. If both the power and bandwidth constraints are taken into account, there is an optimal code rate (assuming block size and decoding complexity are fixed) R_{opt} that maximizes the throughput of the system. If the system is operating at a lower rate, it is said to be bandwidth-limited, and if it is operating at a higher rate, it is said to be power-limited. With most of the early mobile satellite systems, the satellites were comparably weak, the demand for spectrum was low, and few devices were available to support coding rates below rate $\frac{1}{2}$. Consequently, most early systems were operating in the power-limited region. With newer systems, much more

Figure 12. The tradeoff between capacity and coding rate subject to a power constraint and bandwidth constraint. R_{opt} is the coding rate that maximizes the capacity.

emphasis is now placed on achieving nearly optimum capacity in the system design.

One example of a set of dimensions (i.e., a basis) for the signal space is the time sample representation of the composite signal, with sampling being performed at the Nyquist rate. If sequential groups of these time samples are apportioned between the users, the sharing arrangement is called *time-division multiple access* (TDMA). Here, the mobile terminals must be fairly accurately synchronized in time so that bursts arriving at the satellite from different terminals can be tightly packed without interfering with each other. Typically, the required timing accuracy is achieved when the terminal requests to initiate communication by sending a short burst on a random access channel, for which accurate timing is not necessary. Then along with an assignment of a set of timeslots, the system sends the terminal an accurate clock correction that was calculated by the Earth station based on the measured time-of-arrival of the burst. Of course many other potentially useful bases exist. If nonoverlapping portions of the total bandwidth are apportioned between the users the arrangement is called *frequency-division multiple access* (FDMA). In this case, timing accuracy is no longer important, but narrower-band filtering is necessary and the lower data rates present on each carrier tend to make the system more susceptible to phase noise. If orthogonal codes are used to form the basis of the signal space, the sharing is called *code-division multiple access* (CDMA). In a synchronous CDMA system, the carriers must be synchronized in time to within a small fraction of a chip period so that orthogonality is maintained. In the forward direction, this is fairly straightforward to achieve if all the signals are originating from a single Earth station. In an asynchronous CDMA system, time synchronization is not required with the result that the signals are no longer truly orthogonal, resulting in some interference. In the return direction, achieving sufficiently accurate time synchronization among all the mobile terminals is quite challenging so asynchronous CDMA could be preferred over synchronous CDMA. Of course, combinations of these approaches are possible. Most of the mobile satellite systems to date have used FDMA. However, systems based on narrowband TDMA, which is a combination of FDMA and TDMA, are beginning to appear, even though CDMA is a strong candidate for systems with many beams or where there are severe power spectral density limitations.

More efficient use of both bandwidth and power can be achieved if the satellite's antenna system covers the desired area of Earth's surface with several smaller beams instead of one large one. The power efficiency of the link is improved as a result of the higher antenna gain associated with the smaller beams. With respect to frequency, the total allocated system bandwidth is divided into a number of distinct subbands, which need not be of equal bandwidth. As illustrated in Fig. 13, each beam is assigned a subband in such a manner that some desired minimum distance between beams with the same subband is maintained. The frequency reuse factor is the ratio of the number of beams to the number of distinct frequency subbands.

For most of the preceding discussion, it was assumed that no interference between users is permitted. In reality,

Figure 13. Total coverage area, consisting of multiple beams. In this case, there are 14 beams and the total frequency band is subdivided into three subbands. Two of the subbands are used in five beams, whereas the remaining subband is used in four. The resulting frequency reuse factor is 4.667.

some interference is unavoidable and may even be desirable to decrease system complexity and possibly to improve system capacity. For example, some CDMA systems allow each transmission to be completely asynchronous in chip timing and carrier phase relative to that of other users occupying the same frequency band and period in time. In this case, each transmission appears to be low-level broadband noise to the other users. Unlike the FDMA and TDMA systems for which the interference tends to be dominated by a small number of dominant interferers, the interference experienced by a user is the result of a very large number of other users resulting in a level of interference that is much less variable. Full statistical advantage can be taken of voice activation without the need for sophisticated dynamic channel assignment strategies. Powerful error correction coding allows for high levels of both intra- and interbeam interference. This results in the ability to reuse the same frequency bands in every beam and a corresponding high level of capacity in a multibeam satellite system [15].

Because interference is unavoidable, interference mitigation techniques are of interest. One example of such a technique is power control, for which the power of each user terminal is dynamically adjusted with the goal of providing it with just enough power to meet the required grade of service. Allowing terminals additional power would only serve to exacerbate the interference levels experienced in the system. A second example is the use of multiuser detection schemes (16).

3. PRESENT AND PLANNED SYSTEMS

Here the intent is to provide some examples of systems that are presently offering mobile satellite communications services and of those that are planned for the future. The systems discussed represent only a sampling and not an exhaustive summary.

Global mobile satellite communications got its start in 1976 when 3 Marisat satellites were launched and positioned at approximately equal intervals in geostationary orbits. In 1979, Inmarsat was formed to offer global

maritime satellite communications services. Inmarsat is a multinational organization that was created by the United Nations affiliated International Maritime Organization. Even though its original charter restricted its operation to maritime services, its charter was later extended to include aeronautical as well as land mobile and portable services. The nature of the Inmarsat organization continued to evolve with the goal of allowing it to offer an increasing array of mobile satellite services in a commercially competitive environment.

Inmarsat-A was the first system to offer commercial service on a global basis. Its terminals are relatively large and expensive; the typical antenna is a 1-m-diameter parabolic dish, and a terminal weight of around 35 kg is representative. Consequently, the majority of customers are large commercial users with most of the marine terminals installed on ocean-going ships and most of the portable terminals belonging to governments or news gathering organizations. Voice transmission was accomplished using analog frequency modulation, which is neither bandwidth nor power efficient by today's standards. Inmarsat has introduced several new voice and data systems that are based on more recent digital technologies. All Inmarsat's systems operate over geostationary satellites. The first of these new systems is the Inmarsat aeronautical system, which is based on the work of the International Civil Aviation Organization and the Airlines Electronic Engineering Committee.

The purpose of the aeronautical system is to provide comprehensive aeronautical communications services, including basic air traffic services, aeronautical operational control, and cabin telephone. Inmarsat began by providing the cabin telephone service, with other services to be phased in later. This system is unique in that it is the only mobile satellite system that has been designed in a manner consistent with Open System Interconnect (OSI) principles.

The Inmarsat-M and -B systems were developed in parallel and share a common protocol. The M system offers lower-cost and reduced weight (typically about 10 kg) terminals, which provide communications-quality voice (4.2 kbps voice coding rate with the addition of error control coding bringing the rate up to 6.4 kbps), low-speed data (2.4 kbps), and facsimile services. In addition to marine and land mobile terminals, portable terminals the size of a small briefcase (including the antenna) are available. Telephone booths based on Inmarsat-M technology, which are powered using solar panels, are used in underdeveloped parts of the world.

Inmarsat-B is the designated successor to Inmarsat-A for providing high-quality professional communications services. For operation within the global beam of a satellite, the mobile antenna requirements for the A and B systems are identical, with a typical gain of 20 dBi. Inmarsat-M terminals have smaller antennas, with gains of 14 and 12 dBi for marine and land mobile terminals, respectively. Also available are still smaller "mini-M" terminals that operate only in the higher gain beams provided by the Inmarsat-3 series of satellites, launched in 1996 and 1997.

Inmarsat-C was introduced in 1990 to support store-and-forward packet data services such as telex, electronic

mail, messaging, and position reporting. Even though only low-bit rates (600 bps) are supported, the terminals are small and inexpensive relative to those for the other Inmarsat systems. An antenna with a gain as low as 1 dBi will suffice.

A number of regional systems offer terminals and services similar to those of the mini-M system. One example is the North American MSAT system, for which Canada and the United States each launched a geostationary satellite. A number of future regional systems are planned for Asia and the Middle East, using extremely large geostationary satellites, which should be capable of delivering these services to handheld terminals, or higher data rate services to larger terminals.

These systems are alike in that they all use geostationary satellites, and the mobile terminals receive their signals in a band around 1550 MHz and transmit their signals in a band around 1650 MHz. Systems exist that use completely different frequency bands and in some cases orbits. We will begin with brief discussions of two systems that offer two-way messaging and position determination. These systems have targeted truck fleet management and cargo position reporting as primary application areas.

In 1990, the OmniTRACS system began full operation, providing two-way communications and position reporting services. It was licensed to operate on a secondary basis, which implies that it must not interfere with primary users, in the 12/14 GHz bands using existing geostationary satellites. The early start of service has allowed the OmniTRACS system to build up a large customer base. A number of novel spread-spectrum techniques are employed to safeguard against interfering with other systems.

The Orbcomm system plans to operate with a full constellation of 36 LEO satellites. The mobile terminals will receive their signals at about 138 MHz and transmit their signals at about 150 MHz. The system operators hope to achieve a competitive cost advantage by having small inexpensive satellites, low launch costs (as a result of the small satellites and low orbits), and lower terminal costs caused by the lower-frequency electronics.

A number of planned systems expect to offer handheld telephone services on a global basis. Three systems that deserve particularly close attention are Globalstar, Iridium, and ICO. Globalstar and Iridium are LEO systems with 48 and 66 active satellites in a full constellation, respectively. The ICO system will use 10 active MEO satellites. The multiple-access technique selected for ICO and Iridium is narrowband TDMA, whereas Globalstar will use CDMA. Iridium and Globalstar should be offering global services before the turn of the century, whereas ICO is expected to be a couple of years later.

Early in the next century, a number of satellite systems are planned to offer a broad range of services, including higher rate services that should effectively extend the digital network capabilities that will be available terrestrially. The highest profile of these is the Teledesic system. Originally, this system planned to use 840 LEO satellites! This has now been scaled back to a planned initial constellation of 288 LEO satellites.

For a number of reasons, position determination can be very important for a mobile satellite communication user. In fact, position determination is an integral part of many of the services such as vehicle fleet management and cargo tracking. Some terminals may use position information for antenna steering and to aid in the satellite and antenna beam handoff algorithms. Also, accurate position information is required for obtaining a license to offer service in some countries because the national authority insists on knowing if a call is being made within its territory. Some mobile satellite communications systems are capable of providing fairly coarse position estimation using the signals and satellites within the systems itself. However, accurate position determination is usually done by taking advantage of the Navstar global positioning system (GPS) (17).

The GPS system employs 24 satellites distributed in 6 orbital planes, each inclined by 55° with respect to the equator. These satellites are in 12h medium earth orbits. Even though the system is financed by the US Department of Defense, it is used globally for both civilian and military applications. In addition to the signals generated aboard the Navstar satellites, the Inmarsat-3 satellites have transponders that can relay ground-generated GPS-type signals. These additional signals can be used to improve the accuracy and reliability of the position estimates. A GPS receiver estimates the range to several satellites and then uses these estimates to determine its position by triangulation. Range estimates to Earth's three satellites are sufficient to provide two-dimensional position (i.e., on the Earth's surface or if the altitude is known) plus accurate time, whereas four satellites are required to provide three-dimensional position plus accurate time. Each Navstar satellite transmits in two frequency bands; the L_1 carrier is centered at 1575.42 MHz, and the L_2 carrier is centered at 1227.60 MHz. Frequency-dependent range estimates can be used to compensate for the effect of the ionosphere. The L_1 carrier is modulated with a short coarse/acquisition code (C/A code) at a chip rate of about 1 MHz and a longer precision code (P code) at a chip rate of about 10 MHz. The L_2 carrier is modulated with the P code only. The P code is dithered in a pseudorandom fashion so that precision is limited for users other than those in the U.S. military. In addition to the previously mentioned ranging codes, the carriers are modulated by a low-rate datastream carrying a navigation message that includes satellite position and satellite clock correction information. Typical civilian GPS receiver sets achieve a position accuracy of about 100 m and a time accuracy of about 10 ns. It is expected that the dithering of the P code will be eliminated within several years, allowing the accuracy for civilian sets to improve to better than 30 m.

4. TRENDS IN MOBILE SATELLITE SYSTEMS

Increasingly a broader range of services is being offered, with many of the new services requiring data rates that are higher than those currently available. Ultimately the services offered to mobile satellite users will be an extension of those that are available from terrestrial systems,

with the result that mobile satellite service offerings will be pulled along by the expansion and convergence that is occurring terrestrially. The upward trend in the data rates will necessitate increased use of the higher-frequency bands by mobile satellite systems.

In order to achieve the large numbers of users predicted by market studies, the trend toward smaller and less expensive terminals will need to continue. Small and simple antennas for the mobile terminals will be essential to achieve this goal. New systems must find ways to provide the extra power needed to offer the combination of higher data rates to smaller terminals. For systems based on geostationary satellites, this will require very powerful satellites with extremely large antennas. Because of reduced path loss, for systems using satellites in lower orbits, the size and power of the satellite can be traded off with the altitude of the orbit. Of course, as the altitude of the orbit decreases, the number of satellites needed to provide global coverage increases.

A large number of systems are in the planning stage, and one can expect fierce competition based on cost to the user, range of services, quality of services, and availability. Because it is usually not feasible to overcome blockage, satellite diversity to offer improved availability may become an important issue. Systems based on geostationary satellites will have an advantage for services requiring broad area coverage, such as point-to-multipoint communications, broadcasting, and wide-area paging. On the other hand, systems based on lower-Earth orbits will have an advantage for global point-to-point communications services, particularly if large transmission delays are undesirable. An example of such a service is global handheld telephony.

From the wide range of technologies and service offerings that characterize planned systems, it is clear that the field of mobile satellite communications is far from being mature.

MODE-MATCHING METHODS

F. ARNDT
University of Bremen
Bremen, Germany

1. INTRODUCTION

Due to its high efficiency, the mode-matching (MM) method has been applied for the calculation of waveguide structures already for a very long time. It is one of the oldest electromagnetics (EM)-based methods for the rigorous solution of waveguide discontinuity problems. In their historical papers 1944, Whinnery, Jamieson [1,2] and Robbins [2] calculated parallel-plate and coaxial transmission-line discontinuities, such as step junctions and diaphragms, already utilizing the typical character-

istic features of the method, which later was called the “mode-matching method”: expansion of the tangential electromagnetic field at the plane of discontinuity in terms of the corresponding waveguide modes, application of the (mode) matching conditions for tangential fields at the discontinuity, and utilization of the orthogonal properties of the waveguide modes for determination of the corresponding expansion coefficients.

Like nearly all important developments concerning the solution of electromagnetic problems, the work in Refs. 1 and 2 was—besides the original contributions of the authors—however, also a result of already available broad knowledge on the solution of waveguide problems contributed by many researchers. These included (to name only a few of them) Hahn’s analysis of cavity resonators [3] using a modal expansion method, Courant and Hilbert’s eigenfunction expansion and eigenfunction orthogonality theorem [4] (the general case of the well-known Fourier series expansion method), Stratton’s general waveguide modes solution approach constructed from superposition of elementary wavefunctions [5], the network formulation of microwave field theory and scattering matrix description of waveguide discontinuities during the 1940s at MIT, summarized by Marcuvitz et al. in [6,7], and the comprehensive contributions on integral equation formulations of the field problem of discontinuities and obstacles and its solutions by Schwinger at MIT, put together in Ref. 10. A compendious historical review of these early microwave field theory developments is given by Oliner [45].

The MM technique has been applied by Clarricoats and Slinn [13] and Wexler [14] to waveguide discontinuities using matrix notations and including the consideration of higher-order mode effects between discontinuities. Wexler called the method *modal analysis*, a notation that is also used in literature when referring to the MM technique. A MM technique utilizing an intermediate section for offset discontinuities has been introduced by Piefke [15] and Knetsch [17,18]. Convergence investigations have been carried out by Mastermann and Clarricoats [20], Lee et al. [22], Mittra et al. [23], and Chu et al. [58]. Lee et al. [22] used the term *mode-matching*, a term that is now widely adopted in the literature for this method, and is also used in the present article.

In 1960, Collin [11] applied the eigenfunctions expansion principle for the solution of the transverse cross section eigenvalue problem of inhomogeneous waveguides. Such applications are later referred to as “field matching” [91,92]. Field matching has found considerable applications during the 1980s for solving in particular microstrip and finline cross section eigenvalue problems, e.g., Kowalski, Pregla [21], Bornemann, Arndt [59,96]. For field matching, also special techniques have been applied, such as the transverse resonance method, Sorrentino [91], Sorrentino, Itoh [48], Bornemann, Arndt [96]. Hybrid combinations of the field-matching and MM methods have been applied for solving discontinuities at inhomogeneous waveguide structures by Arndt et al., Omar et al. [29,52,70,107]. The field-matching method, however, leads to numerically often inefficient indirect eigenvalue problems (e.g., to the necessity of search algorithms for the zeros of a determinant). For waveguide discontinuities

involving nonanalytical eigenvalue problems, therefore, other hybrid combinations, such as the MM/finite-element (MM/FE) method, Beyer, Arndt [123,129], Montejo-Garai, Zarpata [132], are preferred, where the FE cross section solution leads to a numerically more convenient standard explicit eigenvalue problem.

Arndt, Bornemann, Vahldiek applied 1981 [31] the MM method has been applied [131] for the rigorous analysis and optimization of E-plane metal-insert filters. A detailed description of the MM technique in terms of full-wave scattering matrix parameters for cascaded waveguide structures applied for optimized filters and transformers has been presented by Patzelt and Arndt [34]. The direct application of the full-wave scattering matrix (generalized scattering matrix, GSM) formalism [31,34] for cascaded waveguide discontinuities including evanescent modes leads to a numerically stable description of composed waveguide components and circuits also applicable to all higher-order modes.

Besides the GSM combination of discontinuities, the generalized admittance, e.g., [79] and generalized impedance matrices e.g., [121,146] (GAM, GIM) have been applied. Although there were initially some discussions regarding advantages and disadvantages with preference for GSM, GAM, or GIM combinations, all three formulations lead to nearly the same order of efficiency [142]. It is also worth mentioning that many new terms and formulations, introduced in many publications basically for the MM method, mostly describe the same (MM) approach with—at best—some only marginal modifications. This phenomenon obviously also results from the fact that the MM method can be interpreted [102] as a special case of Harrington's method of moments, [16] when using orthogonal eigenfunctions as basis functions.

Waveguide discontinuity problems for different port planes, with applications such as T-, X-, and six-port junctions, and magic tees, — have been solved by the MM method mostly either utilizing Kühn's resonator method [26] [e.g., 35,42,49,64,78,103,110,115] or Sharp's Green function technique [12] [e.g., 104,105]. A three-plane [7] MM method has been applied [101,140] by Zaki et al.

For scattering problems at the waveguide discontinuity to open space, the MM method has been used in conjunction with the method of moments [32,39,68,82,87] by Kühn, Hombach, James, and Arndt et al. The plane-wave spectrum in half-space combination is applied in [65] by Encinar, Rebolgar.

Although analytic solutions of the waveguide cross section eigenvalue problem for the application of the MM method, in addition to rectangular, circular, coaxial waveguides, have also been presented for elliptic waveguide discontinuities by Matras, Bungler, Arndt, Mongiardo, et al. [135,141,149], the applicability of the efficient MM method is greatly extended by using the MM/FE technique mentioned above [123,129,132]. In this way, for instance, the inclusion of waffle-iron, dual-mode, ridged waveguide, and combine filters is possible [142,143,148,154,160].

To extend the flexibility of the MM technique for applications to arbitrarily shaped planar waveguide structures, Reiter and Arndt introduced 1992 the boundary contour MM (BCMM) method [108,130]. A wideband modeling of planar waveguide structures is also possible

by the efficient boundary integral resonant-mode expansion (BIRME) method [138,139,153] (Conciauro et al., 1996). Arbitrarily shaped 3D waveguide structures can be included by a hybrid MM/method-of-moment (MM/MoM) technique, which was been introduced by Bungler, Arndt, 2000 [150].

Oliner stated in his overview [43] that the “network formulation of microwave field theory has been fundamental to the rapid progress made by the microwave community.” In view of the extremely high efficiency of the MM technique combined with the elegant completeness of the rigorous full-wave generalized scattering matrix formulations of waveguide circuits, I would like to append: MM techniques and their hybrid combinations are about to realize a microwave engineers' dream of achieving CAD tools for rigorous, optimized waveguide component designs within extremely short response times on a PC.

In this article, we will describe some basic relations of the MM method, and discuss some advanced aspects. Representative application examples will demonstrate the versatility and computational speed of the MM method.

2. THEORY

2.1. Mode Matching at a Step Discontinuity

Step discontinuities between two homogeneous waveguides (Fig. 1) are basic key building blocks, by which many other elements and components can be composed, including irises, transitions, bifurcations, iris filters, diplexers, and transformers. Moreover, the basic principles of the MM technique can be well elucidated at a step discontinuity.

At the plane of discontinuity $z=0$, the tangential electromagnetic field components E_{ti} , H_{ti} at the plane of discontinuity $z=0$ can either be described using Maxwell's equations directly (e.g., see Refs. 91 and 119 where explicit mode-matching formulations for some simple step discontinuities are given), or one can apply the more elegant description via vector potentials or Hertzian potentials (e.g. [11]). Matching of the tangential field components ultimately leads to a relation of forward (a_i)- and backward (b_i)-traveling or evanescent modes (also designated as incident or scattered modes) described by their amplitude coefficients a_i , b_i , respectively, which are advantageously normalized to the complex apparent power transmitted through the common aperture A of the discontinuity

$$a^2, b^2 = \iint_A \underline{\underline{E}}_{tp,r} \times \underline{\underline{H}}_{tp,r} dA \quad (1)$$

such that a mode amplitude of $a_i = 1\sqrt{W}$, $b_i = 1\sqrt{W}$, at $z=0$ transports an apparent power of amount 1 W through the cross-section A of the waveguide in forward (p) or backward (r) direction, respectively.

In this way, a more general description when matching the tangential field components along the transverse surface of the general step discontinuity from region I to II (Fig. 1) is possible, yielding directly the relation between

Figure 1. Some step discontinuity key building blocks between two homogeneous waveguides.

incident and scattered mode amplitude coefficients **a** and **b**, e.g. [34,142]

$$\sqrt{Z_i^I}(a_i^I + b_i^I) = \sum_{j=1}^{\infty} C_{ij} \sqrt{Z_j^{II}}(a_j^{II} + b_j^{II}) \quad i=1 \dots \infty \quad (2)$$

$$\sum_{i=1}^{\infty} C_{ij} \sqrt{Y_i^I}(a_i^I - b_i^I) = \sqrt{Y_j^{II}}(a_j^{II} - b_j^{II}) \quad j=1 \dots \infty,$$

where $Z = 1/Y$ are the modal wave impedances

$$Z_i = \frac{1}{Y_i} = \begin{cases} \frac{\omega\mu}{\beta_i} & \text{TE modes} \\ \frac{\beta_i}{\omega\epsilon} & \text{TM modes} \\ \sqrt{\frac{\mu}{\epsilon}} & \text{TEM modes} \end{cases} \quad (3)$$

with $j\beta = \gamma$, the propagation factor determined by the separation equation (7). The mode amplitude coefficients in (2) are related to the normalized voltages U and currents I introduced by Marcuvitz [7] by

$$\frac{U_i}{\sqrt{Z_i}} = u_i = a_i + b_i \quad (4)$$

$$I_i \sqrt{Z_i} = i_i = a_i - b_i$$

Figure 2. Scattering matrix combination of two cascaded structures.

C_{ij} in (2) are the elements of the frequency independent¹ coupling matrix

$$C_{ij} = \int_{S_{II}} \int \mathbf{e}_i^T \mathbf{e}_j^{II} dS = \int_{S_{II}} \int \mathbf{h}_i^{I*} \mathbf{h}_j^{II} dS \quad (5)$$

where \mathbf{e} and \mathbf{h} are the transversal eigenvectors

$$\mathbf{e} = \begin{cases} \mathbf{u}_z \times \nabla_t \Psi & \text{TE modes} \\ -\nabla_t \Psi & \text{TM and TEM modes} \end{cases} \quad (6)$$

$$\mathbf{h} = \mathbf{u}_z \times \mathbf{e}$$

¹Note that this holds only for this kind of structures like step discontinuities in z direction. For cavities, for instance, Fig. 3, C_{ij} relating to different planes are frequency dependent.

with \mathbf{u}_z is the unit vector in the z direction, and \mathbf{T} denotes the transposed. The potentials Ψ are for TE- and/or TM-mode solutions of the 2D Helmholtz equation

$$\nabla_t^2 \Psi + k_c^2 = 0 \quad (7)$$

with the separation condition

$$k_c^2 + \beta^2 = k^2 \quad (8)$$

where k is the free-space wavenumber, and $\nabla_t^2 = \nabla^2 - (\partial^2/\partial z^2)$ denotes the transversal Laplace operator. For TEM modes, Ψ are solutions of the Laplacian equation

$$\nabla_t^2 \Psi = 0 \quad (9)$$

The potentials Ψ are suitably normalized:

$$\iint_{S_j} \nabla_t^T \Psi_i \nabla_t \Psi_i dS = 1 \quad (10)$$

The Dirichlet and Neumann boundary conditions are

$$\begin{aligned} \Psi^{TM} = 0 \quad \Gamma_E & \quad \frac{\partial \Psi^{TM}}{\partial n} = 0 \quad \Gamma_M \quad (\text{TM modes}) \\ \frac{\partial \Psi^{TE}}{\partial n} = 0 \quad \Gamma_E & \quad \Psi^{TE} = 0 \quad \Gamma_M \quad (\text{TE modes}) \\ \Psi_i^{\text{TEM}} = \begin{cases} \text{const} \neq 0 & \Gamma_{Ei} \\ 0 \text{ else} & \Gamma_E \end{cases} & \quad \frac{\partial \Psi_i^{\text{TEM}}}{\partial n} = 0 \quad \Gamma_M \quad (i\text{th TEM mode}) \end{aligned} \quad (11)$$

where Γ denotes an electric (E) or magnetic (M) wall.

2.2. Generalized Scattering Matrix

Equation (2) can be represented in the form of a matrix equation by using either the incident and scattered mode amplitude coefficients \mathbf{a} and \mathbf{b}

$$\begin{aligned} \mathbf{a}^I + \mathbf{b}^I &= \mathbf{V}(\mathbf{a}^{II} + \mathbf{b}^{II}) \\ \mathbf{V}^T(\mathbf{a}^I - \mathbf{b}^I) &= \mathbf{a}^{II} - \mathbf{b}^{II} \end{aligned} \quad (12)$$

or by using the normalized voltages \mathbf{u} and currents \mathbf{i} (4)

$$\begin{aligned} \mathbf{u}^I &= \mathbf{V}\mathbf{u}^{II} \\ \mathbf{V}^T\mathbf{i}^I &= \mathbf{i}^{II} \end{aligned} \quad (13)$$

with

$$\begin{aligned} \mathbf{V} &= [\sqrt{\mathbf{Y}^I}] [\mathbf{C}] [\sqrt{\mathbf{Z}^I}] \\ \sqrt{\mathbf{Y}^I} &= \text{diag}(\sqrt{Y^I}) \\ \sqrt{\mathbf{Z}^I} &= \text{diag}(\sqrt{Z^I}) \end{aligned} \quad (14)$$

The formulation in terms of \mathbf{a} and \mathbf{b} (12) leads after rearranging the relations in terms of scattered and incident mode amplitude coefficients directly to the modal generalized scattering matrix (GSM)

$$\mathbf{b} = \mathbf{S}\mathbf{a} = \begin{bmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} \\ \mathbf{S}_{21} & \mathbf{S}_{22} \end{bmatrix} \mathbf{a} \quad (15)$$

with the submatrices and $\mathbf{1}$ the unit matrix

$$\begin{aligned} \mathbf{S}_{11} &= -\mathbf{1} + \mathbf{V}\mathbf{S}_{21} \\ \mathbf{S}_{12} &= \mathbf{V}[\mathbf{1} + \mathbf{S}_{22}] \\ \mathbf{S}_{21} &= 2\mathbf{T}^{-1}\mathbf{V}^T \\ \mathbf{S}_{22} &= \mathbf{T}^{-1}[\mathbf{1} - \mathbf{V}^T\mathbf{V}] \\ \mathbf{T} &= \mathbf{1} + \mathbf{V}^T\mathbf{V} \end{aligned} \quad (16)$$

Note that only the inversion of submatrix \mathbf{T} is required.

From (12)–(16) it can be shown that the GSM \mathbf{S} has the interesting properties being symmetric and self-inverting:

$$\mathbf{S} = \mathbf{S}^T = \mathbf{S}^{-1}. \quad (17)$$

The generalized \mathbf{S} -matrix \mathbf{S} , which includes evanescent modes does not show the familiar unitarity relation for passive circuits. The unitarity holds only if relating to purely propagating waves. It can be shown, however, that the coupling matrix (5) is unitary also for the general case.

$$\mathbf{C}^T\mathbf{C} = \mathbf{1} \quad (17a)$$

Some of these rather well-known relations [18] are put together in Ref. 127, where it is also shown that other matching criteria, such as the conservation of the complex power used e.g., in Ref. 36, lead to identical mode-matching expressions similar to those of (12) and (13), see also Ref. 56. This follows finally from the general orthogonal properties relations for different E , H modes already given in Ref. 11.

In case of rectangular, circular, circular coaxial, and elliptical waveguide discontinuities, the cross section eigenvectors required for the MM technique are given analytically [7,9,11,13–122,141]. For more general cross sections, the corresponding eigenvalue problem can be solved numerically, where formulations by a 2D finite-element (FE) method [123,129,132] are preferred, leading to a fast convergent direct solution without requiring search algorithms that are usually necessary for cross section field matching, e.g., [29,96], or boundary integral approaches [137]. The powerful MM/FE method significantly extends the applicability of the MM method to a wide class of waveguide discontinuities and components, including waveguide structures with ridged, waffle-iron, arbitrarily shaped iris, combine cross-sections [142,143, 148,154,160].

For fastest convergence, it is shown [20,22,23,58] that for a step discontinuity, the ratio of the number of expansion modes used on both sides should be chosen according to the size of the different waveguide cross section areas. This ‘fastest convergence ratio’ [58] is conveniently given automatically when selecting a fixed cutoff frequency up to which all higher-order modes are included on both sides [142]. For usual step discontinuities, a cutoff frequency of about 10–40 times the highest analysis frequency has given excellent convergence and agreement with measurements [142].

For industrial microwave component design optimizations using rigorous EM methods, losses are commonly neglected, since an optimum solution for the lossless case leads also to the optimum solution for the lossy case. Moreover, finite measured insertion losses are due mainly to parameters that are often of a rather more statistical nature, such as ohmic contacts between halves of fabricated waveguide housings or surface roughness influences, than of a finite metal conductivity nature. Nevertheless, the MM method offers the possibility to include losses due to finite metallic conductivity, if required, by appropriate MM in a rather straightforward manner [145].

The complete required information for a multiport discontinuity (e.g., step-to-multiaperture waveguide; see Fig. 1) is inherently involved in the corresponding single discontinuity [83,85]. Hence, multiport discontinuities such as *n* furcations can be formulated by merely using corresponding matrix schemes utilizing the *S* matrix of a single step as submatrix [77,83,85].

2.3. Line Integral Formulation of Coupling Integrals

The frequency-independent coupling area integrals (5) can be formulated in terms of numerically somewhat more convenient line integrals by using the common definitions of the transversal eigenvectors (6) [142,156]:

$$\begin{aligned}
 & \frac{k^2 c_{II}}{k_{cII}^2 - k_{cI}^2} \oint_{\Gamma_{II}} \Psi^{II} \frac{\partial \Psi^I}{\partial n} dc && \text{TE-TE} \\
 & 0 && \text{TE-TE and TEM-TE} \\
 & - \oint_{\Gamma_{II}} \Psi^{II} \frac{\partial \Psi^I}{\partial \tau} dc && \text{TE-TE and TEM-TE} \\
 & \frac{k_{cI}^2}{k_{cI}^2 - k_{cII}^2} \oint_{\Gamma_{II}} \Psi^I \frac{\partial \Psi^{II}}{\partial n} dc && \text{TM-TM} \\
 & \oint_{\Gamma_{II}} \Psi^I \frac{\partial \Psi^{II}}{\partial n} dc && \text{TE-TE and TEM-TE} \\
 & 0 && \text{TEM-TM}
 \end{aligned} \tag{18}$$

In case of degenerate modes ($k_{cI} = k_{cII}$), an adequate expression for the limiting case $k_{cI} \rightarrow k_{cII}$ has to be taken into account [157].

2.4. Orthogonality of Eigenmodes

An important property of the transversal eigenvectors \mathbf{e} and \mathbf{h} (6) is their orthogonality [11]. In case of degenerate eigenmodes, that is, modes as a solution of (9) of same

cutoff frequency, namely, same eigenvalue ($k_{ci} = k_{cj}$), the orthogonality has to be enforced.

The scalar product of two eigenvectors be defined as follows:

$$\begin{aligned}
 \langle \mathbf{e}_i, \mathbf{e}_j \rangle &= \int_{\Omega} \int \mathbf{e}_i^T \mathbf{e}_j d\Omega = \int_{\Omega} \int \mathbf{h}_i^T \mathbf{h}_j d\Omega \\
 &= \int_{\Omega} \int \mathbf{u}_z^T (\mathbf{e}_i^T \times \mathbf{h}_j) d\Omega
 \end{aligned} \tag{19}$$

For orthogonal eigenvectors their scalar product is zero [11]. With (6), (7), and (11), we obtain after partial integration

$$\langle \mathbf{e}_i, \mathbf{e}_j \rangle = \begin{cases} \int_{\Gamma} \psi_i \frac{\partial \psi_j}{\partial n} d\Gamma + k_{cj}^2 \int_{\Omega} \psi_i \psi_j d\Omega \\ = \int_{\Gamma} \psi_j \frac{\partial \psi_i}{\partial n} d\Gamma + k_{ci}^2 \int_{\Omega} \psi_i \psi_j d\Omega \\ i, j \text{ of same mode type} \\ - \int_{\Gamma} \psi_i \frac{\partial \psi_j}{\partial t} d\Gamma = 0, \quad i \text{ TE}, j \text{ TM or TEM} \\ \int_{\Gamma} \psi_i \frac{\partial \psi_j}{\partial n} d\Gamma = 0, \quad i \text{ TM}, j \text{ TEM} \end{cases} \tag{20}$$

where “*t*” designates the tangential direction.

For the first case, the contour integrals are zero if *i* and *j* are of type TE or TM:

$$\langle \mathbf{e}_i, \mathbf{e}_j \rangle = 0, \quad k_{ci}^2 \neq k_{cj}^2 \quad \text{and} \quad i, j \text{ same mode type} \tag{21}$$

That is: Two eigenvectors are orthogonal if they are of different mode types or if they are of same mode type and have different cutoff frequencies. These features are summarized in Ref. 11.

For degenerate eigenmodes, two or more eigenvectors of the same type have the same eigenvalue (same cutoff frequency) and hence the same propagation factor (8). Therefore, any linear combination of degenerate eigenmodes is also a degenerate eigenmode [11]. As there are only a finite number of degenerate eigenmodes \tilde{e}_i , their orthogonality can be enforced by using the Gram–Schmidt orthogonalization [165], where e_i is the recursively determined new orthogonal eigenvector:

$$\begin{aligned}
 e_1 &= \tilde{e}_1 \\
 e_i &= \tilde{e}_i - \sum_j^{i-1} \langle \tilde{e}_i, e_j \rangle e_j
 \end{aligned} \tag{22}$$

$$\langle e_i, e_i \rangle = 1$$

2.5. Cascaded Elements

The generalized scattering matrix (GSM) of a cascaded microwave circuit *C* (Fig. 2) consisting of two partial components *A* and *B* is given by a straight-forward

numerically stable matrix combination, where $[1]$ is the unit matrix:

$$\begin{aligned} [S_{11}^C] &= [S_{11}^A] + [S_{12}^A][S_{11}^B][Q][S_{21}^A] \\ [S_{12}^C] &= [S_{12}^A]([1] + [S_{11}^B][Q][S_{22}^A])[S_{12}^B] \\ [S_{21}^C] &= [S_{21}^B][Q][S_{21}^A] \\ [S_{22}^C] &= [S_{22}^B] + [S_{21}^B][Q][S_{22}^A][S_{12}^B] \\ [Q] &= ([1] - [S_{22}^A][S_{11}^B])^{-1}. \end{aligned} \quad (23)$$

The GSM \mathbf{S}_e of a structure described by a GSM \mathbf{S} containing at all ports i homogeneous waveguide sections of lengths l_i is

$$\begin{aligned} [S_e] &= [D][S][D] \\ [D] &= [\text{diag}(\exp(-j\beta l_i))] \end{aligned} \quad (24)$$

In this way, based on the single-step discontinuity, a complete class of waveguide structures can conveniently be described, including transformers, irises, filters, diplexers, and polarizers. Typical examples can be found in the literature [31,33–35,37,38,42,46,47,49–51,53–55,60,63,64,66,67,74,78–106,109–126] an overview is also given in Refs. 119,142 and 153.

For modes below their cutoff frequencies, the propagation factor $\gamma = j\beta$ is real. It is therefore obvious that the numerical effort can be significantly reduced by considering only modes in the cascading process for which the amount of $\exp(-\gamma l)$ is higher than a defined limiting value. These modes, which contribute significantly, are called *accessible modes* [27]. The set of modes of higher number applied at the immediate discontinuity is called *localized modes*.

2.6. Generalized Admittance, Impedance Matrices

Besides the generalized scattering matrix GSM \mathbf{S} (15), the generalized admittance matrix (GAM) \mathbf{Y} , the generalized impedance matrix (GIM) \mathbf{Z} and the transmission matrix \mathbf{W} have been applied in the literature [57,79,104,105,121,122]. The GAM and GIM descriptions of a step discontinuity require additional waveguide sections of finite length at the ports. Based on normalized voltages and currents (4) and the relations (12), the corresponding expressions can be derived [57,79,104,105,121,122]. The relationships between \mathbf{S} , \mathbf{Y} , and \mathbf{Z} are given by

$$\begin{aligned} [Y] &= ([1] - [S])([1] + [S])^{-1} \\ [S] &= ([1] - [Y])([1] - [Y])^{-1} \\ [S] &= ([Z] - [1])([Z] - [1])^{-1} \end{aligned} \quad (25)$$

The transmission matrix \mathbf{W} is only applicable for same number of modes of the ports. Moreover, \mathbf{W} is numerically instable as the implied $\exp(-\gamma l)$ and $\exp(+\gamma l)$ expressions can exceed the available numerical range of the corre-

sponding computer for large γl . The \mathbf{S} , \mathbf{Y} , \mathbf{Z} formulations have their advantages and disadvantages. By selecting appropriate reference planes and applying adequate segmentation techniques [166,167], \mathbf{Y} , \mathbf{Z} can be set up for boundary enlargement and boundary reduction structures, respectively, without requiring the solution of an equation system [79,104,105,121,122,153]. On the other hand, for cascaded structures when taking the reduction according to accessible modes into account, \mathbf{Y} , \mathbf{Z} representations require the solution of an entire equation system of the form

$$(i_a) = ((y_{aa}) - (y_{al})(y_{ll}) - (\mathbf{1}))^{-1}(y_{la})(u_a) \quad (26)$$

where the subscripts “ a ” and “ l ” denote the corresponding accessible and localized terms, respectively. For the reduced \mathbf{Z} matrix, we obtain an identical expression. This is in contrast to the \mathbf{S} -matrix description, where we need only deleting the corresponding submatrix elements in (23).

The combination of \mathbf{Y} , \mathbf{Z} with an empty waveguide requires higher computational effort than the multiplication with diagonal matrices (24) for \mathbf{S} . Hence, a simple variation of the intermediate lengths, such as during optimization, is more time-consuming. Moreover, if a section length falls in the vicinity of half a wavelength of a propagating mode, there is the possibility of numerical instability in the expressions for \mathbf{Y} , \mathbf{Z} . Finally, as the generalized S matrix for describing the behavior of a microwave structure is usually desired, \mathbf{Y} - and \mathbf{Z} -matrix formulations have to be converted to the S matrix according to (25), which requires an additional matrix inversion. To sum up, it is meanwhile commonly adopted that the criterion of the computational effort, as seen on a global average, does not justify the exclusive preference for a specific matrix representation.

2.7. T-, X-, and Six-Port Junctions

Many waveguide components include structures with apertures in different planes (Fig. 3), such as corners and T and X junctions. Kühn’s resonator method [26] applied for the calculation of the S parameters of a waveguide corner leads, for instance, via superposition

Figure 3. Rectangular cavity with port apertures in different planes.

of the two standing-wave solutions of short-circuited 90° degree waveguides of the two ports I and II in a common “resonator” region, to an equation system of the form [83,103]

$$\begin{pmatrix} \mathbf{a}^I - \mathbf{b}^I \\ \mathbf{a}^{II} - \mathbf{b}^{II} \end{pmatrix} = \begin{bmatrix} [D^I][Q] \\ [Q^T][D^{II}] \end{bmatrix} \begin{pmatrix} \mathbf{a}^I + \mathbf{b}^I \\ \mathbf{a}^{II} + \mathbf{b}^{II} \end{pmatrix} \quad (27)$$

where $[D]$ are diagonal matrices and $[Q]$ is a frequency-dependent matrix, which describes the coupling between the ports. Analog expressions can be derived for T-, X-, and six-port junctions [78,83,85,99,103,110,115].

Sharp’s [12] cavity method leads directly to generalized admittance expressions of the form

$$Y_{mn}^{eh(i,j)} = j\omega \iint_{S_j/S_i} \mathbf{n} \times \mathbf{e}_n^{h(j)}(\mathbf{r}) \underline{G}(\mathbf{r}, \mathbf{r}') \mathbf{h}_m^{h(i)}(\mathbf{r}') dr' \quad (28)$$

with the aperture eigenvectors (6), and the Green function G of the cavity. The corresponding descriptions for T-, X-, and six-port structures can be found in the literature [12,79,88,100,104,153].

Both formulations are nearly equivalent in terms of efficiency with the condition that for Sharp’s method both eigenfunctions of the apertures and the cavity Green function are given analytically.

2.8. Arbitrarily Shaped Planar Structures

Many waveguide components include arbitrarily shaped planar waveguide structures (Fig. 4), such as mitred bends, cylindrical posts, Y-junctions, steps or irises with finite radii, and shaped cavities. For such structures, the boundary contour MM method (BCMM) is applied [108,130]. The basic idea is to describe the arbitrarily shaped contour between the k -port apertures by a complete set of cylindrical mode functions, which leads to a set of linear equations

$$\mathbf{T}\boldsymbol{\alpha} = \mathbf{E}(\mathbf{a} + \mathbf{b}) \quad (29)$$

where the elements of the matrix \mathbf{T} are the coupling integrals of the field vectors of the cavity region. Because of the nonorthogonality of these field vectors at the

Figure 4. Arbitrarily shaped planar waveguide structure.

boundary, the matrix is not diagonal. The matrix \mathbf{E} describes the expansion of the electric field in the waveguide ports by cylindrical wavefunctions in the cavity region.

The excitation coefficients $\boldsymbol{\alpha}$ can be eliminated, which yields the generalized S -matrix at the k -port junction in the form

$$\mathbf{S} = (\mathbf{I} - \mathbf{C})^{-1}(\mathbf{I} + \mathbf{C}) \quad (30)$$

with

$$\mathbf{C} = \frac{1}{j\eta} \mathbf{E}^T \mathbf{T}^{-1} \mathbf{E} \quad (31)$$

η is the free space characteristic impedance. A second method for such structures is the hybrid MM/transfinite-element method [157], which has the advantage over the BCMM of higher flexibility, for example, as it is not restricted by possibly shaded regions in the description of the boundary region. In this way, septated T junctions, for instance, can also be efficiently calculated.

The boundary integral resonant-mode expansion (BIRME) method [138,139,153] is a third method, which applies a wideband pole expansion representation of the admittance matrix expressions. This method has been described [138,139,153] mainly for H -plane- or E -plane-type of modes, so far.

2.9. Arbitrarily Shaped Cross Sections

For arbitrarily shaped cross sections, such as for cross irises and ridged waveguide structures, the hybrid MM/finite-element (MM/FE) method is advantageously applied. This hybrid combination extends the applicability of the MM method to the inclusion of a comprehensive class of components [142], such as waffle-iron filters, dual-mode filters with coupling screws, and cross-irises.

Figure 5. Optimized C-band satellite diplexer. Photograph and measured results by courtesy of MBB (now EADS), Prof. Fasold, Germany. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

2.10. Radiating Apertures and Arbitrarily Shaped 3D-Structures

Radiating apertures can be included in the MM method by applying a hybrid MM/method-of-moments (MoM) technique. The same is true for arbitrarily shaped 3D waveguide structures, such as partial-height posts within a partially open circular cavity (e.g., suitable for combline filter elements) [142,150,157,164].

3. SOME TYPICAL APPLICATION EXAMPLES

A classical satellite industry component example [90], illustrating the current state of the art design of advanced

microwave components by fast MM techniques and direct full-wave optimization, is the C-band diplexer shown in Fig. 5. The compact component (silver-plated aluminum housing) without tuning screws has been fabricated by a computer-controlled milling technique. For the optimization of such components, the evolution strategy [64] is advantageously applied. Typical MM method CPU speeds on standard PCs for such components showing excellent accuracy with measurements are in the order of merely fractions of a second per frequency point. This may illustrate the high computational power of the MM technique for the CAD and optimization of advanced waveguide components.

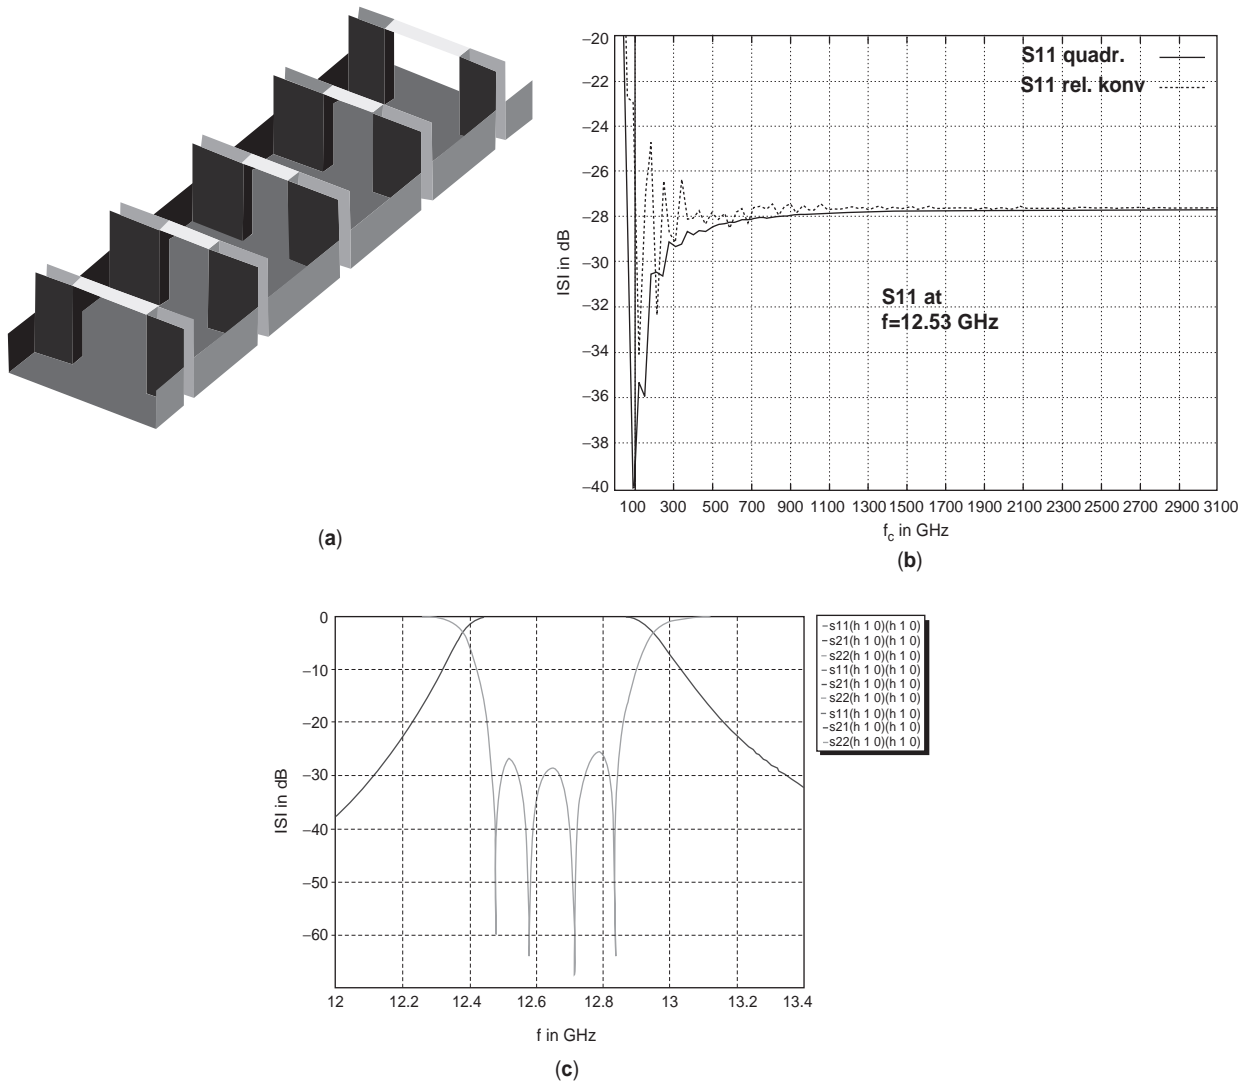

Figure 6. WR-75 H-plane iris filter example. Dimensions (mm): $a = 19.05$, $b = 9.525$, iris widths $a_1 = 9.600$, $a_2 = 6.385$, $a_3 = 5.860$, iris thickness $z_1 = 2$, resonator lengths $l_1 = 12.030$, $l_2 = 13.600$: (a) structure; (b) convergence behavior. Solid line—fastest convergence, localized modes at step discontinuity sides chosen according to given cutoff frequency f_c ; dashed line—number of localized modes identical on both sides. (c) S parameters: (1) for $f_c = 1100$ GHz, two accessible modes in resonator; (2) for $f_c = 3100$ GHz, two accessible modes in resonator; (3) for $f_c = 3100$ GHz, all localized modes in resonator (the results are identical within drawing accuracy). MM CPU speed for case 1:5 s, 500 frequency points (i.e., 10 ms/frequency point). PC: 3 GHz P4. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The next example is a simple *H*-plane iris-coupled WR-75 waveguide filter (Fig. 6a), illustrating some basic features of the MM technique outlined in the previous section. Figure 6b shows the convergence behavior S_{11} as a function of cutoff frequency up to which all higher-order modes are taken into account. The fastest convergence (solid line) is achieved for choosing the number of modes at the discontinuity side according to given cutoff frequency f_c . In Fig. 6c, complete identity for the *S* parameters within drawing accuracy is demonstrated for the cases (1) $f_c = 1100$ GHz (70 localized modes, 2 accessible modes),

(2) $f_c = 3100$ (197 localized modes, 2 accessible modes), (3) $f_c = 3100$ (197 localized modes, 197 accessible modes). The MM CPU speed for this example (case 1) is ~ 10 ms per frequency point (3 GHz P4 PC) for the *S*-matrix formulation. The *Y*-matrix formulation leads to nearly identical speed (factor 1.2 slower), while for this example the *Z*-matrix formulation is about factor 4.2 slower.

On the basis of the MM techniques described above, many examples have been published in the literature showing the broad application potential of this efficient CAD technique. Typical waveguide components, which

Figure 7. WR-75 diplexer with stub-loaded waveguide sections and post compensated T junction. Result of direct full-wave optimization by applying the MM technique. CPU speed: 0.5 s/frequency point, 3 GHz P4 PC, 19 modes. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

have been successfully designed by direct MM full-wave optimization, include many kinds of waveguide filters [31, 33, 34, 37, 38, 41, 46, 50, 61–63, 66, 67, 75, 76, 84, 89, 93, 96, 98, 99, 106, 109, 113, 117, 119, 123, 129, 132, 138, 139, 142, 143, 148, 153–155, 158, 160], mode sensors/converters [42, 55, 87, 113], transformers [47, 74, 95], couplers [35, 49, 64, 79, 88, 94, 97, 100, 104, 111, 119, 162, 163], polarizers [44, 53, 60], phase shifters [43, 51, 73, 80, 97, 105, 119, 145], diplexers [54, 83, 90, 119], multiplexers [81, 85, 124, 134, 143, 161] power dividers [77, 78, 142], and orthomode transducers [114, 119].

A typical WR-75 diplexer example, which includes some advanced MM elements, such as postcompensated T-junction and stub-loaded waveguides with rounded corners for convenient milling fabrication, is shown in Fig. 7. Because of the high CPU speed also for more complicated structures when applying the MM method (in this example ~ 0.5 s per frequency point; 3 GHz P4 PC), the direct full-wave optimization toward the given specifications is a straightforward task. The stubs are (instead of steps) modeled by X junctions; hence a rather low number of modes (19 higher-order modes in this example) has proved to be sufficient for convergence and excellent agreement with measurements.

The applicability of the MM method for waveguide components with arbitrarily shaped cross sections, for radiating structures, and for arbitrarily shaped 3D waveguide structures, is extended by hybrid techniques.

Because of the importance of these more recent extensions of the MM method [155, 157], CAD techniques based on hybrid methods are described in a separate article in this encyclopedia.

4. CONCLUSION

The mode-matching (MM) method is one of the oldest electromagnetics (EM)-based methods for the rigorous solution of waveguide discontinuity problems. The technical importance of the MM technique is its extremely high computational efficiency together with high accuracy and dynamic range. MM techniques and their hybrid combinations achieve CAD tools for rigorous, optimized waveguide component designs within extremely short response times on a PC. The article has presented an overview of the state of the art of MM techniques and described some more recent advances. The versatility and high calculation speed of the MM techniques is well documented in the literature in many examples, which have found widespread application in the microwave industry.

MODULATION-DOPED FETs

1. INTRODUCTION

To some extent, the MODFET is the compound semiconductor analog of the ubiquitous MOSFET (metal oxide semiconductor field-effect transistor), which utilizes a pseudo-two-dimensional carrier gas, the concentration of which is modulated by a gate potential. In a MODFET, a higher-bandgap material with a high doping concentration (assumed to be n-type in this discussion) is grown on a lower-bandgap intrinsic material [1]. In practice, growth of a thin intrinsic layer of the high-bandgap material, known as the *intrinsic layer*, *setback layer*, or *spacer*, precedes growth of the rest of the high-bandgap material. Electrons diffuse from the doped higher-bandgap material to the lower-bandgap material where they are confined and form a conducting sheet, a two-dimensional electron

gas (2DEG). When the gate voltage is adequately high so that the source–drain channel is no longer depleted, the 2DEG is free to conduct in the intrinsic material. Because the undoped low-bandgap material has no donor atoms cluttered about, impurity scattering no longer inhibits the carrier mobility and saturation velocity. The spacer mentioned above serves to increase the channel mobility further by shielding the 2DEG from ionized impurities, although at the cost of decreased sheet carrier density.

Major refinements of the MODFET following its introduction have concentrated on improving the sheet carrier concentration through increased band discontinuity ΔE_c by adding and/or increasing the InAs mole fraction in the channel. The conventional MODFET uses AlGaAs and GaAs for the high-bandgap and low-bandgap materials, respectively, denoted as AlGaAs/GaAs, on a GaAs buffer. Carrier density and its confinement in the GaAs improve with increasing ΔE_c , induced by a larger Al mole fraction in $\text{Al}_x\text{Ga}_{1-x}\text{As}$. A technical problem, encountered in MODFETs, is the presence of DX centers whose concentration can be of the same order of magnitude with that of donors in the AlGaAs donor layer. Unfortunately, increased AlAs compositions exacerbate the DX center problem. Typically, DX center traps are mitigated by choosing an Al mole fraction less than 22% at the expense of reducing the conduction band discontinuity and thus the sheet electron concentration [2].

The PMODFET, or pseudomorphic MODFET, alleviates the DX center problem as well as providing a channel in InGaN with superior transport properties over GaAs. The structure is achieved by inserting a thin InGaAs layer between the GaAs buffer and the AlGaAs setback layer in otherwise conventional MODFET. The higher the In mole fraction in $\text{In}_x\text{Ga}_{1-x}\text{As}$, the higher the electron mobility within the 2DEG. Additionally, greater carrier confinement can be achieved with pseudomorphic systems because large conduction band discontinuities can be obtained between InGaAs and low-AlAs-mole-fraction AlGaAs. However, the thickness of the lattice mismatched InGaAs must be below the critical thickness beyond which misfit dislocations occur. The lattice constant, lattice mismatch, and the critical thickness are functions of the In mole fraction of the strained InGaAs layer; this limits the In mole fraction content to about 30% on GaAs. There are also the lattice-matched and pseudomorphic MODFETs based on InP substrates, which take advantage of the superior mobility and confinement properties of the AlInAs/InGaAs. Devices based on InP have exhibited the lowest noise figures yet achieved.

2. SYNOPSIS OF ANALYTICAL DESCRIPTION OF MODFETs

In MODFETs the carriers that form the channel in the lower-bandgap material are donated by the larger higher-bandgap material and/or provided by metal contacts. Since the mobile carriers and their parent donors are spatially separated, ionized impurity scattering is nearly eliminated, which leads to mobilities that are characteristic of nearly pure semiconductor. A Schottky barrier is then used to modulate the mobile charge that in turn

causes a change in the drain current. By virtue of the heterolayer construction, the gate can be placed very close to the conducting channel, which results in large transconductances [1]. A simplified analytical description of MOD-FET operation that shows quantitatively the effect of charge stored at the heterointerface on mobility and carrier velocity follows here. For its simplicity, while making the important points, the model of Drummond et al. [3] will be utilized. Simultaneous solutions of Poisson's and Schrödinger's expressions in the presence of bias must be numerically solved for a more accurate description.

The treatment will begin by stipulating that the amount of charge depleted from the barrier donor layer is equal to the charge accumulated at the interface while the Fermi level is kept constant across the heterointerface. For a visual description, refer to Fig. 1. The electron charge (or hole charge in the case of p-channel MODFET) depleted from the barrier layer is given by

$$n_s = \sqrt{\frac{2eN_d}{q}(\Delta E_c - E_{F2} - E_{F1}) + N_d^2 d_1^2} - N_d d_1 \quad (1)$$

where E_{F2} is the separation between the conduction band in the barrier layer and the Fermi level, N_d is the donor concentration in the barrier layer, ε is the dielectric permittivity of the barrier layer, ΔE_c is the conduction band discontinuity, E_{F1} is the Fermi level with respect to the conduction band edge in the channel layer, and d_1 is the thickness of the undoped layer in the barrier layer at the heterointerface. The electron charge stored at the heterointerface is given by

$$n_s = \frac{\rho kT}{q} \ln \left[(1 + e^{q/kT(E_{F1} - E_0)})(1 + e^{q/kT(E_{F1} - E_1)}) \right] \quad (2)$$

where $E_0 = \gamma_0 n_s^{2/3}$ and $E_1 = \gamma_1 n_s^{2/3}$ are the positions of the first and the second quantum states at the interface, a triangular well formed by the interfacial stored charge. The energy reference is the bottom of the conduction band edge in the smaller bandgap material.

Figure 1. Equilibrium band diagram of a modulation-doped structure with Fermi level, quantum states, and the band discontinuity indicated.

We are assuming here that these lowest energy states are the only ones that are either filled or partially filled. The constants γ_0 and γ_1 , which are dependent on the effective mass of the channel material used, and ρ (density of states = $qm^*/\pi\hbar^2$) are derived in the triangular well. Depending on the value of the voltage applied, the gate on the surface of the barrier layer depletes some or all the stored charge at the interface. Simultaneously solving Eqs. (1) and (2) results in the determination of the Fermi level in case the interface sheet charge concentration is known, or the determination of the sheet charge concentration when the Fermi level is known. With a gate present, Eq. (1), which depicts the equilibrium situation, must be replaced with

$$n_s = \frac{\varepsilon}{qd} [V_g - (q\phi_b - qV_{p2} + E_{F1} - \Delta E_c)] \quad (3)$$

where ϕ_b is the Schottky barrier height of the gate metal deposited on the barrier layer, V_g is the gate to channel voltage, and $V_{p2} = qN_d d_d^2 / 2\varepsilon$. Here d_d is the thickness of the doped barrier layer, and $d = d_d + d_1$. Simultaneous solutions of Eqs. (2) and (3) give the interface charge concentration in the presence of a gate bias. Equation (3) can be conveniently reduced and expressed as

$$n_s = \frac{\varepsilon}{q(d + \Delta d)} (V_g - V_{\text{off}}) \quad (4)$$

with $V_{\text{off}} = \phi_b - \Delta E_c - V_{p2} + \Delta E_{F0}$ and $\Delta d = (\varepsilon a / q)$ ($= 80 \text{ \AA}$ for GaAs). Here the terms ΔE_{F0} and a are determined from the extrapolations. For example, ΔE_{F0} , which is a temperature-dependent quantity, is the residual value of the Fermi level and can be obtained from the extrapolation of the calculated Fermi level values versus the interface sheet charge to the zero sheet charge. The term a is slope of the curve, which is reasonably linear for a wide range of sheet charge except near the vanishing values, relating the Fermi level to the sheet charge, $E_{F1} = \Delta E_{F0}(T) + an_s$. For example, for the GaAs/AlGaAs case, $a \approx 0.125 \times 10^{-16} \text{ V/m}^2$, and $\Delta E_{F0} \approx 0$ at 300 K and 0.025 meV at $T \leq 77 \text{ K}$.

In a field-effect transistor, the drain bias produces a lateral field. In long-channel devices and/or for very small drain biases one normally makes the assumption that the channel voltage, which varies along the channel between the source and the drain and finally reaches a value equal to the drain voltage, is added to the gate potential. Doing so reduces Eq. (4) to

$$n_s = \frac{\varepsilon}{q(d + \Delta d)} (V_g - V_{\text{off}} - V(x)) \quad (5)$$

where $V(x)$ is the channel potential. For small values of $V(x)$, or of the electric field in the channel, we can assume that the constant mobility regime is in effect and that

$$I_d = qn_s \mu Z \frac{dV(x)}{dx} = \mu Z \frac{\varepsilon}{(d + \Delta d)} (V_g - V_{\text{off}} - V(x)) \frac{dV(x)}{dx} \quad (6)$$

where μ is the charge mobility and z is the width of the gate. By integrating Eq. (6) from the source to drain while keeping in mind that the drain current remains constant throughout the channel, one obtains

$$I_d = \beta \left(V_g' V_{ds} - \frac{1}{2} V_{ds}^2 \right) \quad (7)$$

where $V_g' = (V_g - V_{\text{off}})$ and $\beta = \mu Z \{ \varepsilon / [(d + \Delta d)L] \}$ and where L is the intrinsic channel length or more popularly, the gate length. The current reaches saturation when the drain voltage is increased so that the field in the channel exceeds its critical value, thereby causing the velocity to saturate. In that case the drain current is expressed as

$$I_{ds} = Z \frac{\varepsilon}{(d + \Delta d)} (V_g' - V_{ds}) v_s \quad (8)$$

where V_{ds} is the saturation drain voltage, I_{ds} is the saturation current, and v_s is the saturation velocity.

The treatment above is called the *two-piece model*, meaning an abrupt transition from the constant-mobility regime to the constant velocity regime. A more accurate picture is one where this transition is smoother. In that case a phenomenological velocity field relationship can be used to more accurately describe the MODFET operation. The simplest of all these expressions is one that neglects the peak in the velocity field curve and assumes a Si-like velocity field characteristic (see Fig. 7). One such expression is

$$v = \frac{\mu F(x)}{1 + \mu F(x)/v_s} \quad (9)$$

where $F(x)$ represents the electric field in the channel that is equal to $dV(x)/dx$. We must also point out that the field is not constant throughout the channel. To calculate the drain current, one must write the drain current as

$$\begin{aligned} I_d &= v Z \frac{\varepsilon}{(d + \Delta d)} [V_g - V_{\text{off}} - V(x)] \\ &= \frac{\mu dV(x)/dx}{1 + \frac{\mu dV(x)/dx}{v_s}} \frac{\varepsilon Z}{(d + \Delta d)} [V_g - V_{\text{off}} - V(x)] \end{aligned} \quad (10)$$

where $v_s = \mu F_{cr}$, where F_{cr} is the field where the velocity assumes its saturation value. By integrating Eq. (10) from the source end of the channel to the drain end, while keeping in mind that the drain current must be constant throughout, one can obtain an expression for the drain current following the mathematical steps of Ref. 4.

Integrating Eq. (10) from the source end of the gate to the drain end of the gate while keeping in mind that the current must remain constant throughout the channel, one obtains

$$I_d = \frac{\varepsilon Z}{(d + \Delta d)} \left(V_g V_d - \frac{1}{2} V_d^2 \right) \quad (11)$$

Note that if v_s , the saturation velocity, approaches ∞ , Eq. (11) reduces to Eq. (7), which is applicable for the constant mobility case, or the long-channel case. Following the procedure of Lehocvec and Zuleeg [4], the drain saturation current I_{ds} can be found by the mutual use of Eqs. (10) and (11) and assuming velocity saturation, as

$$I_{ds} = 2(V_g - V_{\text{off}})^2 \frac{\varepsilon Z}{L(d + \Delta d)} \frac{1}{\left\{ 1 + \left[\frac{2\mu(V_g - V_{\text{off}})}{v_s L} \right]^{1/2} \right\}^2} \quad (12)$$

The transconductance is an important parameter in FETs and is defined as

$$g_m = \left. \frac{\delta I_d}{\delta V_g} \right|_{V_d = \text{constant}}$$

In the saturation regime, the transconductance is expressed as

$$\begin{aligned} g_m^{\text{sat}} &= \left. \frac{\delta I_{ds}}{\delta V_g} \right|_{V_d = \text{constant}} \\ &= \mu Z \frac{\varepsilon}{(d + \Delta d)L} (V_g - V_{\text{off}}) \left[1 + \left(\frac{V_g - V_{\text{off}}}{v_s} \right)^2 \right]^{-1/2} \end{aligned} \quad (13)$$

The maximum transconductance is obtained when the sheet charge density is fully undepleted under the gate that leads to

$$g_m^{\text{max}} = \frac{q\mu Z n_s}{L} \left[1 + \left(\frac{q\mu n_s (d + \Delta d)}{\varepsilon v_s L} \right)^2 \right]^{-1/2} \quad (14)$$

For very short gate lengths, which represent all modern MODFETs fabricated presently, Eq. (14) reduces to

$$g_m^{\text{max}} = \frac{\varepsilon v_s Z}{d + \Delta d} \quad (15)$$

The measured transconductance is actually smaller than that given in Eq. (15) in that the source resistance, which will be defined shortly, acts as a negative feedback. Through circuit considerations, the measured, extrinsic transconductance is given by

$$g_m^{\text{max}}|_{\text{ext}} = \frac{g_m^{\text{max}}}{1 + R_s g_m^{\text{max}}} \quad (16)$$

High-speed devices are commonly analyzed by two-port scattering measurements performed generally in the range of 2–26 GHz by an on-wafer microwave probe station, although 60 GHz is possible, and this figure is constantly moving upward. From the scattering measurements one can obtain an equivalent circuit for diagnosis and circuit design. From the s parameters one deduces the

y parameters from which an equivalent circuit can be generated.

The transit time under the gate of a submicrometer MODFET is on the order of a few picoseconds. If this is the case, the charging time of the input and the feedback capacitance through the input resistance R_i in the equivalent circuit is substantial. Generally two parameters, the current gain cutoff frequency and maximum oscillation frequency, are figures of merit to gauge the expected high-frequency performance of an FET.

The current gain cutoff frequency, defined as the frequency at which the current gain goes to unity, is given by (since the feedback capacitance is negligible compared to the input capacitance)

$$f_T = \frac{g_m}{2\pi C_{gs}} = \frac{v_s}{2\pi L} \quad (17)$$

As can be seen and as mentioned above, the higher the saturation velocity and the smaller the gate length, the higher the f_T .

The maximum oscillation frequency, defined as the frequency at which the power gain goes to unity, is given by [5]

$$f_{max} = \frac{f_T}{2\sqrt{r_1 + f_T \tau_3}} \quad (18)$$

where $r_1 = (R_g + R_i + R_s)G_d$ and the feedback time constant $\tau_3 = 2\pi R_g C_{dg}$.

Having derived the simple analytical expressions, it is clear that with strained layers, one can increase the band discontinuities and thus the interface sheet carrier densities [Eq. (1)]. This, in turn, leads to larger current levels [Eq. (6)], as compared to the lattice-matched cases. Coupled with large sheet carrier concentrations, higher mobilities offered by the InGaAs alloy are exploited by the strained layer concept. A larger mobility through reduced source resistance leads to a larger transconductance [Eq. (15)], which in turn leads to larger current gains [Eq. (17)] at high frequencies and larger power gains [Eq. (18)]. Better carrier confinement at the heterointerface also aids in confining the carriers and has been shown experimentally to reduce the output conductance G_d . Therefore, the r_1 term discussed above can be reduced, leading to larger f_{max} values.

To analyze the carrier confinement effect, albeit under equilibrium conditions only, Ballingall et al. [6] solved the Schrödinger's and Poisson's equations simultaneously for GaAs/AlGaAs, $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{AlGaAs}$ pseudomorphic, and lattice $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}/\text{In}_{0.52}\text{Al}_{0.48}\text{As}$ MODFETs. As expected, the results clearly show that the larger is the conduction band discontinuity on the donor barrier side as well as on the buffer side, the tighter is the electron distribution. On GaAs substrates, the strained channel MODFET fares better. The confinement gets even better in the structure on InP substrates. If the InGaAs channel on InP contained more InAs than the lattice-matched composition, the confinement as well as the sheet carrier concentration would have been better.

Power gain is also aided by the reduction of parasitic resistances and the time constant τ_3 , which to a large extent depends on the geometry of the device. We will begin our discussion of experimental results by discussing the p-channel MODFETs first, followed by n-channel MODFETs.

3. POWER MODELING

An accurate modeling of device power performance in emerging semiconductor technologies is very useful in understanding how they stack up against more established semiconductor technologies and in determining in which applications they will have the greatest impact. In high-power semiconductor devices, it is imperative that the effect of temperature on device performance be accounted for accurately because power devices typically operate at elevated temperatures.

As in small-signal modeling, the first step in power modeling is to establish the basic device geometric factors that are needed to calculate the current voltage characteristics. Once these are known, the output characteristics superimposed with the load line can be used to get an estimate of the power level that can be obtained from the device provided that it is not limited by the input drive as shown in Fig. 2. In class A operation, the maximum power that can be expected from the drain circuit of a device is given by

$$P_{max} = \frac{I_{d,son}(V_b - V_{knee})}{8} \quad (19)$$

where $I_{d,son}$ is the maximum drain current, V_b is the drain breakdown voltage, and V_{knee} is the knee voltage as shown in Fig. 2. $I_{d,son}$ is the drain current with a small positive voltage on the gate electrode. The allowable positive gate voltage (≈ 1 V) will depend on the channel doping and the workfunction of the gate metal. The positive gate voltage is limited by the onset of forward Schottky diode current. Although Eq. (19) applies specifically to pentodelike devices such as FETs, the same approach would apply

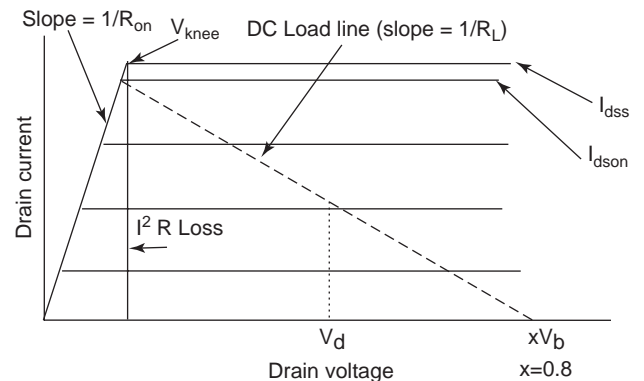

Figure 2. Output characteristics superimposed with the load line that can be used to get an estimate of the power level that can be obtained from the device provided that it is not limited by the input drive.

equally well to electronic devices with triodelike devices such static induction transistors (SITs) operated in the SIT mode, the pentodelike FET mode, or mixed mode. The DC load line shown in Fig. 2 would be used in a class A RF amplifier with the drain voltage $V_d = (V_b + V_{knee})/2$. The slope of the load line is $1/R_L$, where R_L is the value of the load resistance at the output of the FET.

To be of some value, the effect of junction temperature on the output characteristics must be taken into consideration. Temperature-dependent materials parameters, if known, can be used to calculate the output characteristics with respect to temperature. However, a more pragmatic approach, particularly when the aforementioned parameters and/or models required are not available, can be taken in which one measures the output characteristics of the device under consideration as a function of temperature. The junction temperature is critically dependent on the substrate thermal conductivity that is available for various substrates, including GaN [7]. The functional dependence of thermal conductivity on temperature is

$$\chi(T) = \chi(T_0) \left(\frac{T}{T_0} \right)^{-r} \quad (20)$$

where the coefficient r is 0.559, 0.443, 0.524, and 0.544 for Si, GaAs, SiC, and sapphire, respectively [8]. In Fig. 3, $\chi(T_0)$ has also been appropriately reduced to account for the doping of the substrate material.

4. PROCESSING

In an increasing manner, processing has become a central issue in device design and development. MODFETs represent a case of a buried-channel device and require special attention. The short gate lengths that generally accompany MODFETs necessitate unique approaches for the gate metal in an effort to keep the gate resistance from getting too large.

Figure 3. The thermal conductivity versus temperature of sapphire used for GaN devices, SiC used for some GaN devices, GaAs is used for GaAs based MODFETs, and Si for comparison.

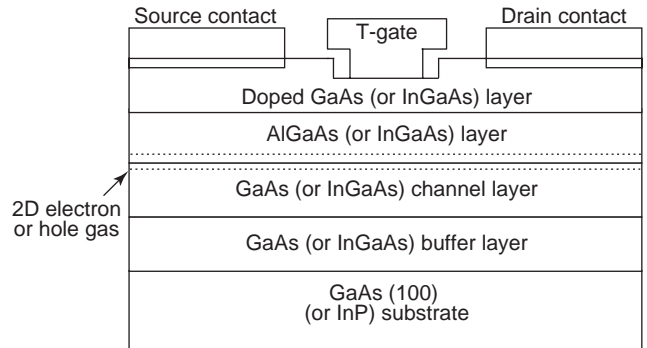

Figure 4. A cross-sectional representation of MODFET structures with the prominent “T” gate. Those within parenthesis indicate the materials used when the MODFET structure is on InP substrate. Other materials depict the case for GaAs substrates.

4.1. Gate Profile

High-performance devices require short gate lengths while keeping the gate resistance to a minimum. As shown in Fig. 4 in conjunction with a cross-sectional diagram of a MODFET structure, the T-shaped gate has proved highly beneficial because it combines low gate resistance with low gate capacitance. The upper, wide part of the T serves to reduce the gate resistance by virtue of its wide area, and the lower, narrow part of the T correspondingly reduces the gate capacitance through its narrow profile. Electron-beam (e-beam) lithography has been the favored method of fabrication, capable of submicron T-gate lengths [9]. Deep-UV lithography of submicrometer T-shaped gates has also been developed, overcoming the primary e-beam disadvantages of insufficient throughput and high cost [10]. The resist combines polymethylmethacrylate and polymethylisopropenylketone in a trilayer resist structure of PMMA/PMIPK/PMMA. Reliability studies with high-temperature accelerated failure tests have shown that the recess depth of the T-shaped gate plays a decisive role in device failure [11]. An unnecessarily deep gate recess will in time contribute to a sharp rise in the gate forward resistance due to the excess distance between the wide part of the T and its base. In order to avoid the consequent degradation of the gain and minimum noise figure, a gate recess depth less than 125 nm is sufficient. A single-etch gate recess method utilizes e-beam lithography followed by reactive-ion etching or electron cyclotron resonance plasma etching of the GaAs cap [12]. This represents an advance in simplicity over the more traditional double-gate recess process [13].

The Schottky barrier-related processes for GaN-based devices are nascent, but rapid progress is being made. Until recently it has been difficult to fabricate good quality single-crystal films on which a Schottky metal could be deposited, and properties of Schottky barrier could be studied. However, considerable progress has been made with Pt-GaN Schottky barriers [14,15] that have been successfully implemented in GaN-based MODFETs [16–21].

More recent success in growing good-quality single-crystal III–V GaN layers prompted the fundamental

electrical property studies of metal–semiconductor barriers on GaN. The formation of metal–semiconductor barriers is an essential element of a variety of semiconductor devices, particularly MODFETs. To obtain a large Schottky barrier height, metals with large work functions have been explored for rectifying metal contacts on GaN, including Au [22] and Pt [14]. Hacke et al. [22] obtained Au Schottky barriers on unintentionally doped n-GaN grown by hydride vapor phase epitaxy. The forward current ideality factor was $n_{\text{id1}} \sim 1.03$, and the reverse bias leakage current was $< 10^{-10}$ A at a reverse bias of -10 V. While the current–voltage measurement indicated the barrier height to be 0.844 eV, the capacitance measurements led to a value of 0.94 eV. However, the reported barrier height for Au/n-GaN ranges from 0.80 to 1.1 eV in various works. One possible cause is different surface treatment. Maffeis et al. [23] investigated the influence of premetallization surface preparation on the structural, chemical, and electrical of Au/n-GaN (i.e., Au/n-doped GaN) interfaces. The Schottky barrier with very low ideality factor (1.10) and high barriers (1.25 eV) was fabricated with ultra-high-vacuum (UHV) annealing at 600°C for 10 min [23].

Suzue et al. [14] have studied the Pt Schottky barriers on unintentionally doped N-GaN. Dependence of both current–voltage and capacitance–voltage characteristics on temperature was studied in the range from -195 to 42°C in an effort to gain insight about the current conduction mechanism. The excess current observed for small gate biases pointed to parasitic processes besides the thermionic emission over the Schottky barrier. This excess current is traditionally attributed to defects (generation recombination centers) and surface leakage current. The ensuing current is called the *Shockley–Read–Hall* (SRH) recombination current resulting from the midgap states. Preliminary investigations indicate that this excess current can be modeled very well with SRH current. Further experiments must be conducted to unravel the exact nature of the underlying processes involved. If one neglects this excess current, a barrier height of about 0.8 eV is deduced as opposed to about 1 eV deduced from the C/V (capacitance–voltage) measurements. Because of the excess current affecting the slope of the I/V (current–voltage) curve, the C/V measurement in this particular case is a closer representation of the metal barrier height. An examination of the C/V plots, however, indicated that under reverse bias condition, the capacitance depended insignificantly on the density of traps. The curves corresponding to all temperatures were largely linear, which yielded barrier heights ranging between 0.95 and 1.05 eV. Reduced capacitance with decreasing temperature is consistent with relatively deep donors. Binari et al. [24] studied titanium Schottky barriers on unintentionally doped n-GaN. The Schottky barrier heights estimated from the current–voltage and capacitance measurements were 0.58 and 0.59 eV, respectively. The ideality factor n_{id1} was about 1.28, and the diode series resistance $R_s = 100 \Omega$.

The ternary $\text{Al}_x\text{Ga}_{1-x}\text{N}$ is an essential component of nitride-based $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ heterostructure MODFET devices. In fact, the Schottky barriers are deposited on $\text{Al}_x\text{Ga}_{1-x}\text{N}$, which makes it imperative to investigate

metal $\text{Al}_x\text{Ga}_{1-x}\text{N}$, which so far have been lagging behind those on GaN in part because of the lack of good-quality layers. Khan et al. [25] reported the fabrication of Cr/Au Schottky barrier on N-doped AlGaIn. Moreover, Khan et al. [26] studied the Schottky barrier characteristics of the $\text{AuAl}_x\text{Ga}_{1-x}\text{N}$ system. A typical current–voltage characteristics of $\text{Al}_{0.14}\text{Ga}_{0.86}\text{N}$ Schottky diode had an ideality factor of 1.56 under reverse bias, and a threshold voltage of about 0.9 V at 0.1 A. The reverse bias leakage current was recorded to be marginally low (10^{-10} A) for a reverse bias of -10 V. Employing the current–voltage method, the barrier height and the electron affinity were determined to be 0.94 and 4.16 eV, respectively. From the C^{-2}/V plot the same barrier height and the electron affinity were deduced to be 1.3 ± 0.05 and 3.8 eV, respectively.

The measurement of barrier height to p-GaN is very difficult because of the lack of high-quality p-type epilayer and low resistance ohmic contact. The high I/V ideality factor prevents obtaining reliable barrier height from the I/V curves. In addition, these barriers obtained from I/V measurements are usually inconsistent with the ones from C/V measurements. Hartlieb et al. [27] fabricated a Pd/P-doped GaN Schottky barrier on chemical vapor cleaned p-type GaN surface. The final barrier height was 1.3 ± 0.1 eV. The difference between the predicted value (0.9 eV) and observed one arises from the interface dipole term, which is a result of the complicated interaction between extrinsic and intrinsic surface states as well as the contribution from metal-induced gap states. The work of Cao et al. [28] revealed that the removal of interfacial oxides causes the reductions in barrier height. It may partly explain considerable amount of scatter for contact properties reported in the literature.

In short, current conduction mechanism in metal–semiconductor structures is strongly affected by surface and bulk states. Deviations from an ideal ideality factor, such as the case here, are indicative of such states. The situation gets more complicated with AlGaIn and worsens as the AlN mole fraction is increased. Likewise, capacitance–voltage measurements also are affected by states that are charged, whether interface state or bulk state charge. As is the case in many facets of research and development, insights into the metal–nitride contacts will be gain in an evolutionary manner hinging on the developments in nitride layers.

4.2. Ohmic Contacts

Ohmic contact formation to the source and drain of a MODFET is complex because of the need for the ohmic contact to somehow penetrate the high-bandgap barrier layer. In case the contact metal does not penetrate through the barrier, ohmic conduction is realized by tunneling of electrons through the remaining AlGaAs barrier, models for which have been developed [29]. On the other hand, a contact with too large a lateral penetration causes short-circuiting to the gate. Several requirements should be fulfilled by a “good” ohmic contact. These requirements should include not only the short ohmic contact length mentioned above but also robust thermal stability and, of course, low contact resistance. A clear understanding and

control of the alloying reactions that occur at the metal–semiconductor interface and the effect of the wide-bandgap semiconductor on contact penetration are essential elements for optimizing the device and the ohmic contact process. Achieving all of these properties is not trivial. Also, different MODFET structures (e.g., AlGaAs/GaAs, AlGaAs/InGaAs, AlInAs/InGaAs) may interact distinctly with the metallization. Consequently, investigators have been forced to adjust their metallurgical mixes for ohmic contacts.

Alloyed ohmic contacts are the traditional ohmic contacts used for a MODFET's source and drain, and certainly are the MODFET ohmic contacts with the longest history of research behind them. Although AuGe/Ni/Au metallization has enjoyed favor as the typical ohmic contact on GaAs-type MODFETs, other similar metallizations under investigation, which address problems evident with AuGe/Ni/Au, may supplant it.

Nonalloyed ohmic contacts to the source and drain of the MODFET promise to become the ohmic contacts of choice for high-density integration. A short ohmic length with low parasitic source series resistance is a great advantage of nonalloyed ohmic contacts in high-density VLSI. Further, nonalloyed ohmic contacts suffer marginally from the orientation dependence of the specific contact resistance. The difference between the (011) and (00 $\bar{1}$) directions is very small, with insignificant variation. In contrast, alloyed ohmic contacts demonstrate a rather large difference in the specific contact resistance between the (011) and (00 $\bar{1}$) directions, as evidenced by electron microscope observations of the formation of the alloying region and the alloyed grain fluctuations in size [30,31]. The nonalloyed ohmic contact has been proscribed from actual use in a MODFET structure because of the necessarily high doping concentrations. Electron concentrations in the range of 10^{19} cm^{-3} are needed to enable electron tunneling (or, sufficient lowering of the Schottky barrier at the metal–semiconductor interface) with the result that the resistance offered by the heterojunction appears larger. The addition of a capping contact layer, typically a thin, heavily doped n-type InAs or InGaAs layer, is a common solution to enable nonalloyed ohmic contacts. This cap layer approach does have the drawback of requiring its removal for the subsequent gate metallization. A heavily Sn-doped GaAs contact layer has also been used, obviating the need for additional growth [32].

4.2.1. Contacts to III–V Nitrides Notably GaN. Ohmic contacts constitute a major obstacle in large bandgap semiconductors and thus to successful realization of GaN MODFETs. Early results for GaN indicate that ohmic contacts can be formed to both n- and p-type material. The contact resistances to n-type GaN using Al and Au metallizations [33] were in the range of 10^{-4} and $10^{-3}\ \Omega\cdot\text{cm}^2$. The current–voltage measurement revealed that while the as-deposited Al contacts were ohmic, the as-deposited Au contacts were rectifying, which became ohmic after annealing at 575°C. Using Ti/Au [34] and TiAl [35], specific contact resistivities of 7.8×10^{-5} and $8\times 10^{-6}\ \Omega\cdot\text{cm}^2$ were obtained, respectively. Nakamura et al. [36,37] used Au (and later Au/Ni) and Ti/Al as p- and

n-type contacts, respectively, in their LED (light-emitting diode) structures. Although no contact resistances were reported, an operating voltage of 4 V at 20 mA forward bias in a p-n junction device clearly demonstrates that reasonable contact resistances were obtained. Carrying the TiAl contact work one step further, Wu et al. [38] confirmed that, except at very high annealing temperatures, the ohmic contact suggested by Lin et al. [35] functions very effectively. At very high temperatures, Al of the metal contact melts and tends to ball up, resulting in rough surfaces and increased ohmic contact resistances as pointed out already by Lin et al. [35]. In an attempt to circumvent this difficulty, Wu et al. [38] designed a separate layer metallization method where a realignment and deposition of a second thin Ti layer, and a 2000-Å Au overlayer was carried out. Specific contact resistivities were in the range of $3.0\text{--}5.5\times 10^{-6}\ \Omega\cdot\text{cm}^2$ depending on the doping concentration in the semiconductor.

In an attempt to obtain an improved ohmic contact, Fan et al. [39] have designed a multilayer ohmic contact method. Utilizing a composite metal layer of Ti/Al/Ni/Au (150 Å/2200 Å/400 Å/500 Å), very low contact resistivities were obtained. Specifically, for n-GaN with doping levels between 2 and $4\times 10^{17}\text{ cm}^{-3}$, specific contact resistivities in the range of $\rho_s=1.19\times 10^{-7}\ \Omega\cdot\text{cm}^2$ and $8.9\times 10^{-8}\ \Omega\cdot\text{cm}^2$, respectively, were obtained. Calculation of the contact resistivity was based on the assumption that the semiconductor sheet resistance underneath the contacts remains unchanged, which is not true for nonalloyed contacts. As for the current conduction mechanism in these ohmic contacts, the large metal–semiconductor barriers diminish the possibility of thermionic emission-governed ohmic contacts to GaN. The alternative mechanism is naturally some form of tunneling that may take place if GaN is so heavily doped to cause a very thin depletion region. Tunneling is possible if, as a result of annealing, for example, at 900°C for 30 s, Al and Ti along with Ni undergo substantial interaction with each other and GaN. A cursory look would imply that Ti receives N from GaN, forming a metallic layer, while the lack of N on GaN provides the desired benefit of increased electron concentration through N vacancy formation. Al acts to passivate the surface and also possibly react with Ti forming TiAl. For details, the reader is referred to Ref. 7.

In contrast to n-GaN, stable ohmic contacts with low resistivity to p-GaN are much more difficult to achieve because of large workfunction of p-GaN, residual hydrogen passivation effect, and relatively low hole concentration. Ni-, Au-, Pd-, and Pt-based metal schemes with high workfunctions ($>5.0\text{ eV}$) have been widely investigated and currently relatively low resistivity in the order of 10^{-4} to $10^{-6}\ \Omega\cdot\text{cm}^2$ can be realized. Improved Ni/Au ohmic contacts to moderately doped p-GaN ($N_A=10^{17\sim 18}\text{ cm}^{-3}$) have been demonstrated by annealing in O_2/N_2 and resistivity as low as $4.0\times 10^{-6}\ \Omega\cdot\text{cm}^2$ was achieved [40–42].

5. CHANNEL DESIGN

Low-field mobilities in heterostructures rise and parasitic resistances decrease with decreasing temperature.

However, the conventional AlGaAs/GaAs MODFET exhibits the well-known collapse of the I/V characteristics and a strong threshold voltage shift [43]. The low-temperature behavior of the device is affected also by the altered behavior of the n-AlGaAs layer. As long as the Al mole fraction and the doping level are low, the activation energy of the donors is shallow. However, as the Al content exceeds 25% and the doping level exceeds $5 \times 10^{17} \text{ cm}^{-3}$, both of which are necessary for obtaining higher 2DEG and a better electron confinement in the channel, a large number of donors become deep, resulting in a freezeout of carriers, I/V collapse, and persistent photoconductivity at low temperatures. Replacing the doped n-AlGaAs layer with an n-GaAs/AlAs superlattice reduces these low-temperature effects [44]. Another novel improvement of the MODFET involves striping of the active channel. A striped-channel MODFET (SC-MODFET) is essentially the same as the conventional MODFET except that the source-to-drain region is divided into a number of narrow conducting channels referred to as wires. Thus an active AlGaAs/InGaAs layer grown on a GaAs substrate exhibits well-defined square well properties, providing good confinement of the 2DEG even at low sheet carrier density. In SC-MODFETs the 2DEG can be controlled in both vertical and lateral directions by the Schottky gate and the enhancement in transconductance is consistent with gate capacitance [45].

6. MODFET PERFORMANCE

To reiterate MODFET's performance is due to the conduction channel, which eliminates impurity scattering and unique capacitance voltage relationship. The PMODFET alleviates the DX center problem while using an InGaAs channel with superior transport properties over GaAs [46]. There is also the lattice-matched and pseudomorphic MODFETs based on InP substrates utilizing higher-mole-fraction InGaAs.

In the conventional III-V semiconductors, three types of MODFETs have been explored: those with GaAs channels on GaAs substrates, $\text{In}_x\text{Ga}_{1-x}\text{As}$ channels on GaAs substrates, and the high-InAs-mole-fraction InGaAs channels on InP substrates. The exploration has allowed the goals set for, for example, the W band (about 5 dB for gain and 4 dB for noise figures) to be well exceeded. With 0.15- μm gate devices [47], a 12.6-dB gain and minimum noise figure of 1.4 dB have been obtained at around 95 GHz. The associated gain at the bias point producing this extremely low noise figure is 6.6 dB. This value is remarkable and indicates the suitability of the InGaAs/InAlAs MODFET structure for operation near 100 GHz and beyond. Peng et al. [48] showed that the increase in the InAs mole fraction leads to an improvement in high-frequency performance. The results indicate that, as the InAs mole fraction is increased, for example, from zero to 65%, the current gain cutoff frequency increases by a factor of >2 , from about 110 to 260 GHz [49–58]. The current gain cutoff frequency corresponding to unity current gain, is an important parameter in logic gates. The maximum oscillation frequency (f_{max}), for which the maximum available gain of the

Figure 5. Minimum noise figure of pseudomorphic AlGaAs/InGaAs and InAlAs/InGaAs MODFETs with 0.15 μm for GaAs-based and 0.15, 0.1 μm for InP-based, gate lengths. (Courtesy of P. M. Smith, Lockheed Martin).

device goes to unity, is also an important factor for determining the electrical and microwave performance. This figure also shows that an increase in the InAs mole fraction leads f_{max} values, for example, for GaAs channel device to increase by about 30%, to about 350 GHz. With 53% mole fraction and a 0.15- μm gate length, it increases to a remarkable 405 GHz. The minimum noise levels from MODFETs based on GaAs and InP obtained at Lockheed Martin are shown in Fig. 5 through the courtesy of Dr. P. M. Smith.

Devices based on InP hold the highest f_t and f_{max} [59]. The promise held by PMODFETs was demonstrated with the development of 0.25- μm gate length [60]. The results obtained since show that f_t increases by a factor of >2 , from about 110 to 260 GHz, as the InAs mole fraction is increased from zero to 65% [61–64]. With the pseudomorphic approach, the f_{max} for a GaAs channel device is increased by $\sim 30\%$ to ~ 350 GHz [65]. With 53% mole fraction a remarkable 405 GHz was obtained with 0.15- μm gate devices [66]. Performance above 100 GHz has been measured by Tan et al. [67]. Using a 0.1- μm gate-length pseudomorphic $\text{In}_{0.52}\text{Al}_{0.48}\text{As}/\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{InP}$ structure, a noise figure of 1.3 dB and an associated gain of 8.2 dB at 95 GHz have been obtained. At 141.5 GHz, a D-band frequency, the device exhibited a gain of 7.3 dB.

The current gain cutoff frequency along with the maximum oscillation frequency f_{max} , the maximum transconductance g_{max} , and the maximum channel current I_{max} for some representative MODFETs are listed in Table 1.

6.1. Low-Noise Amplifiers

Low-noise amplifiers (LNAs) are required in a number of millimeter-wave and microwave applications, including radar, satellite communications, seekers, and minitions. LNAs are key components in the receiving portion of these systems. Recent advances in low-noise MODFET technology have significantly improved their performance, particularly for those at W-band frequency. Coplanar waveguides (CPWs) and conductor-backed coplanar waveguides (CBCPWs) are important alternatives to microstrip transmission lines for MMICs. These millimeter-wave monolithic CPW and CBCPW LNAs have been developed in a variety of forms, including a two-stage single-ended Q-band LNA, a 5–100-GHz distributed amplifier, a

^a L = channel length.

with these MODFETs, however, suffer from performance degradation. The latter stems from degradation of the performance of the conventional MODFETs with uniformly doped n-AlGaAs layer and channel length lower than $0.25 \mu\text{m}$ due to short-channel effects. To circumvent the degradation resulting from short-channel effects, the aspect ratio L/t , where L is the gate length and t is the thickness of the electron supply layer, is usually increased. This is achieved by lowering t , because a thin electron supply layer confines the 2DEG very effectively at the interface. InGaP-based MODFETs are particularly useful in this respect. The Schottky barrier height for this system is low and the charged DX centers practically absent. All these allow the thickness of the n-InGaP layer to be substantially reduced. Good carrier confinement thus achieved in the pseudomorphic quantum-well channel contributes to reducing short-channel effects. Because of this, InGaP/InGaAs/GaAs MODFETs may be improved alternatives to conventional AlGaAs/GaAs MODFETs. InP-based InAlAs/InGaAs/InP MODFETs may satisfy the same purpose. Recently, these MODFETs have demonstrated the lowest noise figures among all three-terminal solid-state devices. The lowest noise figures F_{\min} from various GaAs- and InP-based MODFETs [91–100] are depicted in Table 2. From this figure it may be noted that InP-based T-gate technology with noise figures below 1.0 dB has been realized.

6.2. Power Amplifiers

Power applications present another useful area in which the benefits of MODFETs can be exploited. A tabulation of power performance of some representative MODFETs,

metal semiconductor field effect transistors (MESFETs), and HBTs (heterojunction bipolar transistors) are shown in Table 3. From this table it may be noted that MODFETs demonstrate power performance better than that of MESFETs or HBTs.

High-power amplifications are necessary for achieving maximum reliability, minimum size and weight, high volume, low cost, and high performance of phased array systems such as radar, satellite communications transmitters, electronic warfare, seekers, and smart munitions. An efficient MODFET power amplifier should be not only cost-effective, but also yield superior power-added efficiencies (PAEs) and gain for phased-array systems applications. Chen et al. [121] developed 4-chip PMODFET K-band power modules that deliver 3.2W with a power added efficiency (PAE) of 35% at 3 dB compression, 10 dB saturated gain at 20 GHz, a 1-dB bandwidth of 1.7 GHz, and power density of 500 mW/mm. Such high-power modules are specially suited for spacecraft onboard applications. A $0.15\text{-}\mu\text{m}$ double-heterostructure InGaAs/AlGaAs/GaAs PMODFET has displayed a maximum transconductance over 500 mS/mm, a maximum current density over 600 mA/mm, a cutoff frequency of 90 GHz, and a maximum

Table 3. Comparison of Power Performance of GaAs-based MODFETs, MESFETs, and HBTs

Device	Power (W)	Gain (dB)	PAE (%)	Frequency (GHz)	Ref.
HBT	0.5	11	60	10	119
MESFET	8.0	9	40	10	119
PMODFET	10	13.5	63	2.45	120

oscillation frequency of 200 GHz [122]. This particular MODFET has been utilized in a V-band monolithic power amplifier with an output power of 313 mW (0.39 W/mm) with 8.95 dB power gain and 19.9% PAE at 59.5 GHz [123].

There is no doubt that AlGaAs/InGaAs/GaAs PMODFETs have demonstrated great potential as the microwave and millimeter-wave device for high-gain low-noise applications. However, there is still room for improvement. To further optimize the transmitter modules, the output power should be increased, which necessitates improvement of the power performance of PMODFETs. To this end, both the current drivability and the breakdown voltage must be increased. The breakdown voltage can be increased without deteriorating high-speed performance if the double-recess approach is employed [124] or if high-bandgap AlGaAs layers with lower mobility are used; perhaps a combination of both approaches may be viable. Alternatively, a highly p-doped, very thin surface layer in combination with GaInP as the wide-bandgap material can be used. Such a modification of device structure can lead to a distinct advantage over more typical AlGaAs/InGaAs PMODFETs [125]. Remarkably, a device with 1.8 μm gate length designed in this experiment shows a breakdown voltage of 4 V or higher, with all other parameters almost unchanged.

The main weakness of the InGaAs-based MODFETs is the impact ionization in the channel by hot electrons injected from the gate and that the weak Schottky barrier height on InAlAs allows large reverse-bias gate leakage current to flow, reducing the gate–diode breakdown. This prevents the $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ -channel MODFETs from demonstrating high power performance. In order to address this issue, various modifications to both the gate and channel regions have been investigated. These modifications include variations in the gate contact layers, variations in the channel material, and variations in the doping strategy of the 2DEG. Three different approaches are undertaken to improve the gate barrier and the gate–drain breakdown voltage: (1) incorporation of a junction to modulate the 2DEG, (2) incorporation of an AlInP Schottky barrier, and (3) increasing of barrier height by increasing the Al mole fraction in the AlInAs Schottky barrier layer. In order to realize the junction-modulated MODFETs, a heavily doped p-type AlInAs layer is incorporated on top of the conventional MODFET structures. This results in high turnon voltage, low leakage current, and high reverse breakdown voltage. The increase in the barrier height by increasing the Al mole fraction of the AlGaAs, for example, from 48 to 70%, and a proper tailoring of the dopant concentration lead also to an increase in the turnon voltage from 0.5 to about 1.0 V.

The concept of regrown contacts [126] to a 2DEG has been tested in an InAlAs–InGaAs–InP MODFET [127]. It was noted that the improvement in barrier height that results from incorporating a junction between a surface p⁺ layer and the 2DEG leads to increase in the two-terminal gate–drain and the three-terminal OFF-state breakdown voltages. Further, the formation of a stable nonalloyed contact to the 2DEG by using selection regrowth of the source and the drain regions causes a reduction in the drain fields. Interestingly, all these improvements are achieved without sacrificing the full-

channel current and transconductance. The replacement of the InGaAs channel by the InP channel also provides a significantly large microwave power of 30 GHz or so, and a three-terminal ON-state breakdown voltage of 10 V. However, the same replacement accompanies deterioration in carrier mobility in the channel [128]. The formation of a composite bilayer channel, for which both doped and undoped InP along with a thin GaInAs layer are utilized, brings about improved microwave power up to about 60 GHz. One notable advantage of a composite channel over a conventional channel is that it enjoys the effect of high electron mobility of InGaAs and of high breakdown field and velocity of InP [129]. The effect of In mole fraction alternation of the InGaAs channel material on the electrical performance of the MODFETs has been carefully explored. This investigation points to the expected reduction in the electron effective mass in the channel as the In mole fraction is increased to about 60% or more. Thus the gain at submillimeter frequencies is increased [130]. The power performance and related properties of some representative MODFETs are presented in Table 4.

The expected frequency band of operation of low-noise GaAs and InP-based MODFET technologies is approaching 100 GHz. The lower-frequency end, particularly that of wireless communication arena, is challenged by MOSFET and SiGe technologies. While the digital telephone operation band is currently slated to be near 2 GHz, with the almost certain video transmission over the wireless systems in the future, this frequency is expected to be pushed upward. Burgeoning personal communication system (PCS) technology provides excellent opportunities for the devices discussed here.

Expected frequency bands of operation of low-noise GaAs and InP-based MODFET technologies are shown in Fig. 6 for 0.25, 0.15, and 0.1 μm gate lengths. In a more applications-specific format, Fig. 7 shows the possible applications of MODFET along with competing technologies, MESFET and HBT. As Fig. 7 indicates, the bulk of the applications can be satisfied by the GaAs-based pseudomorphic MODFETs (PMODFETs), particularly so for power applications. For any device to be considered for any application at all, the longevity requirements must be met. Results of accelerated lifetime investigations are shown in Figs. 8 and 9 for low-noise and power amplifiers. Clearly, even the InP devices, while not as good as those on GaAs substrates in terms of longevity, exhibit reasonable operating lifetimes.

The lower-frequency end, particularly that of the wireless communication arena, is challenged by MOSFET and SiGe technologies. Recently burgeoning PCS technology has provided excellent opportunities for electronic devices and in particular for the devices discussed here. While the digital telephone operation band is currently slated to be near 2 GHz, with the almost certain video transmission over the wireless systems in the future, this frequency is certain to be pushed upward. At present, digital telephone components for which compound semiconductors are being considered are power amplifiers (PAs), drivers, low-noise amplifiers (LNAs), mixers, and switches as shown in Fig. 10, which shows the RF section of such a telephone. Conflicting pressures are in effect in that on one hand in-

tegration is emphasized to simplify system assembly and reduce cost and on the other hand, more integration imposes application-specific designs and manufacture. Suppliers at the moments lean in the direction of less integration for wider range of applications for each part.

Cost considerations and manufacturing simplicity have favored the use of MESFETs especially for compound semiconductors for wireless operation. However with ever-increasing demands on performance and PAE to extend the battery operation coupled with advances in

research, epitaxial technology with respect to production issues is paving the way for MODFETs. Companies such as Hewlett-Packard already produce large quantities of low-noise amplifiers and mixers on the same chip.

7. AlGaIn/GaN MODFETs

Semiconductor GaN-based field-effect transistors (FETs) are projected to be highly useful for amplification and switching in high-power and/or high-temperature environments. This optimism is justifiably fueled by the calculated large electron velocity and the robustness of the material. Other pertinent parameters include, but are not limited to, large thermal conductivity of GaN, type I

Figure 9. Accelerated lifetime tests for power GaAs-based PMODFETs. Activation energies of 2.1 and 1.7 eV are apparent for DC and RF biases, respectively. (Courtesy of P. M. Smith of Lockheed Martin).

heterojunctions, and large band discontinuities with resultant large interface carrier concentrations and large breakdown voltage, although this requires high-quality films [173,174]. Consequently, there has been a flurry of activity in GaN-based MODFETs [175–181]. The results are extraordinarily encouraging, and needless to say, research activity is on a rapid rise. These devices are receiving increased attention as the crystal growth techniques and processing methods advance to the point where the performance predicted by the material characteristics are beginning to be approached. The large conduction band offset between AlGaIn/GaN [182,183] possibly in conjunction with the strain-induced piezoelectric effect as alluded to in the literature [184–186] has enabled the realization of large measured carrier concentrations.

Electronic properties of modulation-doped structures based on the III-Nitride semiconductor system have been theoretically treated by Stengel et al. [187]. The structure considered for this particular study was a wurtzitic $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ -layered normal MODFET structure. For source and drain contacts, a scheme where the metal contact is deposited on $\text{Al}_x\text{Ga}_{1-x}\text{N}$ was considered with the well-justified assumption that contact metal penetrates down to the GaN layer, which hosts the two-dimensional electron gas. Because of conduction band discontinuity, the electrons diffusing from the larger-bandgap AlGaIn into the smaller-bandgap GaN form a triangular quantum well in the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ interface.

7.1. Band Diagram for AlGaIn/GaN MODFETs

For illustrative purposes, the energy band diagram for a normally on (N-ON) MODFET, ignoring polarization effects as calculated by Stengel et al. [187] are shown in Fig. 11 for AlN mole fraction, $x = 0.25$, donor concentration in AlGaIn, $N_d = 10^{19} \text{ cm}^{-3}$, and the undoped layer thickness (spacer layer) in AlGaIn, $W_{sp} = 20 \text{ \AA}$. Also shown is the electron gas concentration at the heterointerface. For the calculations for N-ON MODFET, a gate bias of $V_g = 0.04 \text{ V}$, and doped AlGaIn layer thickness of $d = 200 \text{ \AA}$ were used. The two-dimensional electron gas (2DEG) does not extend to the AlGaIn region because of a high $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ conduction band discontinuity (more than 500 meV as compared to 142 meV for $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ at $x = 0.3$). Because of this, and the fact that the amplitude of electron wavefunctions extending to the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ is very low, a thinner spacer would be needed to achieve the optimal mobility in the 2DEG as a result of lower alloy scattering [188]. In spite of this, the effect of Coulombic scattering could presumably be opposite, especially because of the lower dielectric constant of GaN and AlGaIn, which leads to a higher scattering potential. Very precise calculations or experiments would be needed to resolve this matter. For the MODFET of Fig. 11, the quasi Fermi level in GaN is far above the lowest energy level, and the peak concentration of electron in the 2DEG is 10^{19} cm^{-3} . Also, some of the donor atoms (for z between -100 and -50 \AA) are now neutralized, and some electrons start to appear in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ region. For these reasons, a further rise in gate bias causes an increase not only in the donor neutralization but also in the electron concentration in

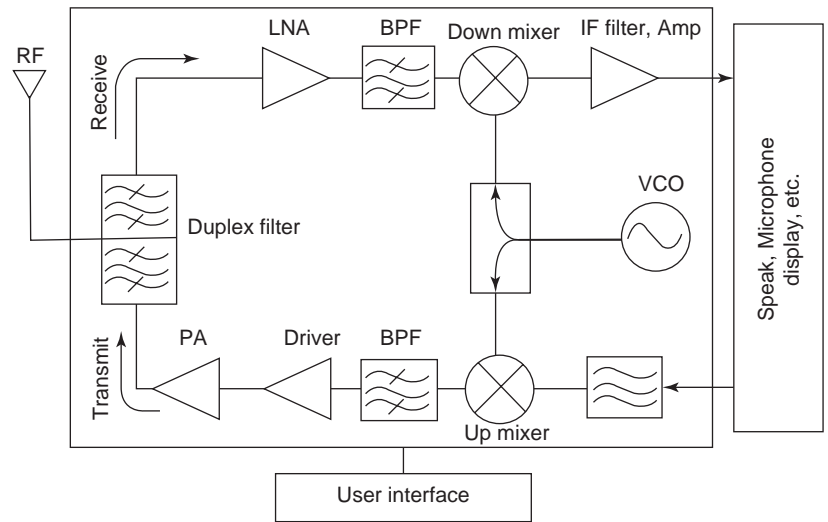

Figure 10. Mobile telephone cellphone RF section with areas of opportunity for compound semiconductor devices shown in bold lines. (After M. Golio of Motorola [234].)

$\text{Al}_x\text{Ga}_{1-x}\text{N}$. However, the 2DEG concentration remains unaltered.

Calculations employing typical parameters [7] for GaN and AlGaN indicate that the peak value of 2DEG concentration for $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ MODFETs is around $2\text{--}5 \times 10^{12} \text{ cm}^{-2}$. However, much larger values of n_{2D} have been measured, which is most likely due to ionization and redistribution of shallow charges caused by the piezoelectric effect. Figure 12 shows n_{2D}/V_g plots for various spacer thicknesses. As long as the unintentional doping level in the spacer layer is low, the effects of varying the AlN mole fraction x and W_{sp} on n_{2D} are essentially equivalent, because at the end of the spacer layer the value of $E_c - E_F$ is very close to $E_c(\text{interface}) - W_{sp}(dE_c/dz)(\text{interface})$. Experimental data describing the effect of the spacer-layer thickness on electron mobility in the 2DEG are needed in order to evaluate optimized values for this spacer layer.

Figure 11. Band diagram for a normally-on MODFET. The origin of energy for these band diagrams is the Fermi level. The left side of $z = 0$ line corresponds to the AlGaN region and the right side, to the GaN. The donor level in AlGaN is represented by E_d ; the quantum energy levels in GaN are represented by E_0 and E_1 . The term E_c represents the conduction band edge in AlGaN and GaN layers.

One may, however, predict that these values for the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ system would be smaller than those for the $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ system, because the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ system provides a deeper confinement, and the wavefunction of the 2DEG over a shorter range in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ is nonzero.

Stengel et al. [187] calculated the variation of transconductance with gate bias for various channel lengths as shown in Fig. 13. When the channel length was decreased from 1 to $0.2 \mu\text{m}$, the peak transconductance increased from 420 to above 900 mS/mm. These very large values of transconductances are made possible when the values of both V_g and V_d were chosen to be small to avert the velocity saturation of the carriers. This was indeed very encouraging considering the fact that, for all practical purposes, MODFETs with reduced channel length are very desirable, and have lower leakage current at the operating point. Notably, the peak transconductance of these MODFETs is obtained for lower gate biases.

Figure 12. Plots of the 2DEG concentration as a function of the gate-source bias V_g for various values of the spacer layer thickness in $\text{Al}_x\text{Ga}_{1-x}\text{N}$.

Figure 13. Variation of the transconductance g_m of MODFETs as a function of the gate-source bias V_g at the optimal value of the drain-source bias V_d (optimum value of V_d is defined to be the value at which transconductance peak reaches its maximum value) for each plot, for various values of the channel length L and values of 1 and $0.2\ \mu\text{m}$. The parameters used for the 2DEG are $d = 130\ \text{\AA}$, $N_d = 10^{19}\ \text{cm}^{-3}$, $W_{sp} = 20\ \text{\AA}$, $x = 0.25$, and $E_d = 45\ \text{meV}$.

The drain current can also be obtained from the model of Stengel et al. [187] as shown in Fig. 14. For a relatively relaxed geometry device, $L = 2\ \mu\text{m}$. The pinchoff depends on the relative values of the gate-source and the drain-source voltages. While the gate-source voltage tends to keep channel electrons stuck to the $\text{Al}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ surface, the drain-source voltage tends to drag them away to the drain. This competition between the gate-source and the drain-source voltages becomes increasingly imbalanced as the difference between them increases. Consequently, the length of the pinchoff region and hence the leakage become larger when the drain-source voltage becomes much larger than the gate-source voltage. This

Figure 14. Calculated drain-source current I_d for AlGaIn/GaN MODFETs under various gate-source bias conditions (0, 1, 2, and 3 V).

causes a slight decrease in drain saturation current with increasing drain-source voltage V_d .

7.2. Performance of GaN MODFETs

As stated earlier, modulation-doped field-effect transistors utilize a two-dimensional carrier gas confined at an interface between two layers with an interfacial energy barrier such as $\text{AlGaAs}/\text{GaAs}$ and $\text{AlGaAs}/\text{InGaAs}$. A GaN MODFET taking advantage of the background donors in the AlGaN layer, which is not a controllable, to say the least, was reported. Congruent with the early stages of development and defect-laden nature of the early GaN and AlGaN layers, the MODFETs exhibited a low-resistance state and a high-resistance state both before and after application of a high drain voltage (20 V). As in the case of $\text{GaAs}/\text{AlGaAs}$ MODFETs, hot-electron trapping in the larger bandgap material at the drain side of the gate is primarily responsible for the current collapse. The negative electron charge accumulated as a result of this trapping causes a significant depletion of the channel layer, more probably a pinchoff, leading to a drastic reduction of channel conductance and decrease of the drain current. This continues to be effective until the drain-source bias is substantially increased, leading to a space charge injection and giving rise to an increased drain-source current.

7.2.1. Single Heterostructures. The DC drain characteristics of MODFETs with a gate length of $2\ \mu\text{m}$, gate width of $40\ \mu\text{m}$, and drain-source separation of $4\ \mu\text{m}$ are presented in Fig. 15. The maximum drain-source current I_{ds} corresponding to a drain-source voltage $V_{ds} = 3\ \text{V}$ and strong forward gate bias ($\sim 3\ \text{V}$) is about $500\ \text{mA}/\text{mm}$. The linear characteristics of the I/V curves demonstrate that the source and drain contacts of the MODFETs are highly ohmic. Good ohmic characteristics of the source and drain contacts probably led the present MODFETs to exhibit a substantially higher drain-source current. These MODFET with $2\text{-}\mu\text{m}$ gate lengths have room-temperature extrinsic transconductances of about $g_{em} = 185\ \text{mS}/\text{mm}$.

Figure 15. DC drain characteristics of a single-heterostructure MODFET with a gate length of $2\ \mu\text{m}$, gate width of $40\ \mu\text{m}$, and drain-source separation of $4\ \mu\text{m}$.

The peak value in the g_{em}/V_{gs} curve occurs at the gate-source voltage $V_{gs} = 1$ V and the drain-source voltage $V_{ds} = 4$ V. With increase in V_{gs} , there occurs higher accumulation of electrons in the active channel and a higher variation of I_{ds} with respect to V_{gs} at a certain value of V_{ds} . Consequently the transconductance increases with V_{gs} . However, when V_{gs} exceeds a certain limit, specifically, 4 V, the accumulation of electrons in the active channel no longer increases at the previous rate with increasing V_{gs} , and the voltage drop in the extrinsic circuit increases. As a result, the transconductance decreases with V_{gs} . The drain-source breakdown voltages are in the range of 100 V per 1- μ m spacing; the exact value depends on the layer design and quality of the layered structure.

7.2.2. Double Heterostructures. In order to increase the current capability of MODFETs, multi-2DEG structures are employed. In this case, the GaN layer is straddled by two doped AlGaIn that donate electrons to the channel, increasing the number of electrons available for current conduction. By Hall effect measurement, the mobility and sheet carrier densities in the two-dimensional electron gas (2DEG) were about 304 cm²/V-s and 3.7×10^{13} cm⁻², respectively, at room temperature. The sheet carrier concentration may have been affected by piezoelectric effect. A number of double heterochannel MODFETs (DHCMODFETs) with gate lengths of 1.5–1.75 μ m and gate width of 40 μ m have been reported.

The DC drain characteristics at room temperature of the DHCMODFET device with gate length of 1.5 μ m, gate width of 40 μ m, and drain-source separation of 3 μ m are presented here. The maximum drain-source current I_{ds} corresponding to a drain-source voltage $V_{ds} = 7$ V, $V_{gs} = 3.5$ V is about 1100 mA/mm, which is important as in high-power devices the input is momentarily forward-biased. The DHCMODFET has a room-temperature extrinsic transconductance $g_m = 270$ mS/mm. The value of the total resistance R_T extracted from the linear region of the I/V curves is 4 Ω mm. Near pinchoff, the drain breakdown voltage is about 80 V, indicating excellent power potential of the device. These measurements were made in a nitrogen-pressurized container to avoid possible oxidation of the contacts and probes. The maximum drain-source current and extrinsic transconductance of the DHCMODFET are 500 mA/mm and 120 mS/mm, respectively. These devices maintain reasonable output characteristics at temperatures as high as 500°C with maximum drain current and extrinsic transconductance values of 380 mA/mm and 70 mS/mm, respectively. Cool down back to room temperature restored the characteristics, which is indicative of the robustness of this material system and metallization employed.

7.3. Interface Roughness

The mobility in AlGaIn/GaN structures ranges from about 500 to over 2000 cm²/V-s, which is higher than that obtainable in bulk GaN, but may still be lower than that eventually expected. The charge state of defects in GaN and AlGaIn near the interface and geometric effects such as interface roughness may not be negligible. The AFM

Figure 16. Schematic diagram showing three-dimensional surface and the reduction in electric field and velocity of the carriers in the channel.

(atomic force microscope) measurements indicate the presence of a 3D roughness on the surface of these samples. This roughness, combined with polarization effects, is likely to also have a strong effect on the mobility because it reduces the effective electric field on the electrons and the effective speed of electrons across the channel. As may be noted from Fig. 16, albeit somewhat exaggerated for the purpose of making the point, the effective field on the electrons in the channel is $E_{ch} \cos(\theta)$, and the effective velocity $V_{QW} \cos(\theta)$. The extent of the mobility reduction due to this effect may be calculated by taking an average over the surface, which would be difficult to perform analytically. However, for a qualitative understanding of this, we may consider the mean values of the measured roughness, which would yield $\theta = 60^\circ$ and the effective value of the mobility μ 0.25 times the original value, which may be considered to be a significant reduction in the mobility.

The value of the total resistance, $R_t = R_s + R_{ch} + R_d$, where R_s is the source area resistance, R_{ch} is the channel area resistance, and R_d is the drain area resistance, is extracted from the linear region of the I/V curves after accounting for the leakage from the gate. Using these values, we may calculate the intrinsic transconductance as a function of temperature. Assuming a long-channel operation, it would allow us to extract the μn_s product of the mobility μ and the sheet carrier concentration n_s from the intrinsic transconductance values. The same product μn_s may be extracted also from the values for R_T by assuming that the drain and source resistances are negligible. The analysis shows that the ohmic contacts do not really play a significant role in decreasing the transconductance at all temperatures. Therefore, the increase in these resistances should be due mostly to a decrease in the mobility-sheet carrier density product. Probably as a result of higher ionization of dopant atoms in n-AlGaIn, the 2DEG concentration increases slowly with increasing temperature. Thus, the observed decrease in transconductance and increase in the channel resistance is actually due to the decrease in the low field mobility and the saturation velocity. The mobility degradation caused by 3D surface roughness is not expected to have temperature dependence. Therefore, the decrease in transconductance by an increase in temperature may be an intrinsic

mechanism, most likely by polar optical phonon scattering, which is very effective at high temperatures.

7.4. RF Results

MODFETs have progressed to a point where microwave measurements have been performed on a variety of devices with gate length as wide as 2 μm and as narrow as about 0.2 μm. A typical MODFET structure with 2-μm gate lengths have been tested at small-signal *S*-parameter measurements were performed at bias conditions used for the power measurements, namely, 15 V, -2.5 V, and 20 mA for the drain voltage, gate voltage, and drain current, respectively. Short circuited current gain, maximum available power gain, and the unilateral gain calculated from the small-signal *S* parameters are shown in Fig. 17. Short-circuited current gain, maximum available gain, and unilateral gain as a function of frequency under bias conditions of $V_{ds} = 15$ V and $V_{gs} = -2.5$ V are presented. The I_{ds} at this bias was approximately 20 mA, which corresponds to 260 mA/mm. The unity current gain cutoff frequency (f_t) and maximum frequency of oscillation were 6 and 11 GHz, respectively, at both 15 and 30 V bias. Values in excess of 50 and 100 GHz have been reported for short-channel devices, respectively, at about 0.2 μm. The CW microwave power measurement results are presented in Fig. 18. The measurements were taken at 4 GHz with the input power swept from 5 to 18 dBm in 14 steps. The input and output matches, which were used during the power sweep, were determined by iterating between source and load pulls. The output match was selected to optimize the output power, and the input match was selected to maximize the delivered power. The devices were biased to $V_{ds} = 15$ V and $V_{gs} = -2.5$ V. The I_{ds} at this bias was approximately 20 mA, which corresponds to 260 mA/mm. From the figure, we see that the devices exhibited 6 dB gain for various input levels. The maximum output power was 20.6 dBm, and the peak PAE was 17.5%. This corresponds

Figure 17. Short-circuited current gain, maximum available gain, and unilateral gain as a function of frequency under bias conditions of $V_{ds} = 15$ V and $V_{gs} = -2.5$ V. The I_{ds} at this bias was approximately 20 mA, which corresponds to 260 mA/mm.

Figure 18. CW output power, power gain, and power-added efficiency versus input power level.

to a normalized output power density of 1.5 W/mm. Improved devices with shorter gate lengths have demonstrated normalized power levels of about 2.56 W/mm at X band, extrapolated from small-gate-width devices that sidesteps the thermal limitations imposed by sapphire substrates [179].

Inclusion of thermal limitations leads to the results shown in Fig. 19 for devices that compete in the high-power-device arena [8]. Since new device developments do in general compete with existing and alternative technologies, a brief account of competing technologies for the power arena will be given below. The Si MESFET analytical curve, modeled for its simplicity, is slightly above the SiC analytical curve and indicates a maximum power density of 0.35 W/mm at $V_{ds} = 7$ V, which is slightly lower than 0.39 W/mm. Since Si RF MESFETs are unavailable, commercial Si RF MOSFET results have been used for comparison instead. At low voltages the Si MOSFET data

Figure 19. Simulated and experimental RF power density data for Si, GaAs, SiC, and GaN FET's. (After C. Weitzel et al. [8].)

parallel the analytical curve, suggesting the validity of the functional dependence of power density on drain voltage. Also shown are two higher power density data points at 0.4 W/mm, with $V_{ds} = 28$ V and 0.87 W/mm, with $V_{ds} = 48$ V. These higher power densities were obtained with specially designed RF power MOSFETs that incorporate lightly doped drains and field plates that significantly increase the breakdown voltage. The GaAs analytical curve shows the highest power density of all the devices at the lowest voltages primarily because of the higher electron mobility of GaAs. However, the low breakdown field limits the GaAs MESFETs drain voltage to about 8 V and power density to 0.63 W/mm, including thermal effects. Typical commercially available GaAs MESFET power densities are below 1 W/mm. However, high-performance GaAs FETs with more complex device cross sections have achieved power densities as high as 1.4 W/mm at 18 V. The SiC MESFET has a calculated maximum power density at 100 V both with and without factoring in thermal effects of 7.96 and 9.7 W/mm, respectively. The highest demonstrated continuous-wave power density 3.3 W/mm ($V_{ds} = 50$ V) for a SiC MESFET [189] is also shown for comparison. Additional SiC data again illustrate the functional dependence of power density on drain voltage. The GaN analytical results are highly dependent on the thermal conductivity of the substrate. With a sapphire substrate, the device is severely thermally limited to 2.24 W/mm at 30 V with a resulting channel temperature of $>400^\circ\text{C}$. The GaN results of analytical models are highly dependent on the thermal conductivity of the substrate. With a sapphire substrate, the device is severely thermally limited to 2.24 W/mm at 30 V with a resulting channel temperature of $>400^\circ\text{C}$. However, with a SiC substrate, the analysis predicts that a GaN MODFET could achieve 15.5 W/mm at 100 V while keeping the channel temperature at about 300°C [8].

GaN MODFET devices on conducting 6H-SiC substrates exhibited output characteristics that lacked the negative resistance (i.e., they exhibited good heatsinking). There have subsequently been a few reports of MODFET power devices on high-resistivity SiC [190–192] and p-type SiC [193] substrates with phenomenal improvement in power-handling capability notwithstanding the rapid progress on sapphire substrates. On sapphire, recent 0.7- μm -gate-length $\text{Al}_{0.5}\text{Ga}_{0.5}\text{N}/\text{GaN}$ MODFETs exhibited a current density of 1 A/mm, three-terminal breakdown voltages up to 200 V, and CW power densities of 2.84 and 2.57 W/mm at 8 and 10 GHz, respectively, representing a marked performance improvement for GaN-based FETs. Outstanding power levels are increasingly being achieved with near-0.5- μm or smaller gate lengths. To follow the evolution of the developments, a few examples are cited here. With 0.7- μm -gate-length devices on SiC substrates, where the gate–source spacing and gate–drain spacing were 0.5 and 0.8 μm , respectively, a total output power of 2.3 W in a device with a 1.28-mm gate periphery has been obtained [191]. The power gain at the 2.3-W output power point was 3.6 dB with a power-added efficiency (PAE) of 13.3% for a drain bias of 33 V. The current and power gain cutoff frequencies were 15 and 42 GHz, respectively. The contact resistance, although not the best, was between 2.6

and $3.5 \Omega \cdot \text{mm}$. The maximum normalized transconductance was 270 mS/mm, and the drain current was 293 mA/mm. Steady improvement in power performance has led to results at HRL laboratories with recordbreaking performance [194]. Typical DC characteristics include 600 mA/mm current performance and >60 V drain breakdown voltage. The current gain cutoff and maximum power gain cutoff frequencies measured were about 48 and 100 GHz, respectively, for -5.5 and 12.5 V gate and drain bias voltages, respectively. A minimum noise figure of 0.85 dB at 10 GHz with an associated gain of 11 dB is simply remarkable. Also, 6.3 W of CW output power was obtained at 10 GHz from a 1-mm-wide transistor device. More importantly, the power density remained nearly constant as the device size was scaled upward from a 0.1 mm width, where the device exhibits 6.5 W/mm, to 1.0 mm. These record-setting transistors were epitaxially grown AlGaIn/GaN heterostructures on seminsulating SiC (silicon carbide) substrates by MBE. HRL laboratories have expanded their work to amplifiers with several cells and showed very good power scalability up to 2 mm of total gate periphery [194]. Using 250-nm-gate devices, a CW output power of 22.9 W with an associated power-added efficiency of 37% was measured for an amplifier at 9 GHz with four 1-mm-gate periphery devices. Furthermore, the same authors [194] also showed a CW power density of 4 W/mm at 20 GHz, which is the state-of-the-art figure for any three-terminal solid state device at this frequency.

7.5. Anomalies in GaN/AlGaIn MODFETs

Field-effect transistors, in general, and modulation-doped field-effect transistors, in particular, exhibit anomalies in their output I/V characteristics. Among the causes of these anomalies are channel carriers being trapped in the wide-bandgap material and bulk, meaning the buffer layers. In addition surface states, if present and not passivated, could act to reduce the sheet conducting charge, particularly between the gate and the drain regions of the FETs [195]. Some AlGaAs/GaAs MODFETs, which are predecessors of the current AlGaIn/GaN MODFET, exhibit behavior similar to what was then termed “current collapse” [196]. This behavior was attributed to carrier injection from the channel to the AlGaAs at reasonably high fields where they are trapped at low temperatures. With below-the-gap light excitation, increasing temperature, and exchange of the source and drain terminals, the effect could be eliminated. The GaAs buffer layer for the AlGaAs/GaAs-based device is of high quality, so its trapping effect was not dominant. The surface states in the AlGaAs/GaAs device were not deemed to have a profound effect on the current voltage characteristics. However, it is always a prudent approach to passivate the surface states, as was done in the AlGaAs/GaAs device, as they greatly affect device operation with time. In the AlGaAs/GaAs variety, the trapping effect in the AlGaAs barrier was attributed to DX levels, which are caused by lattice-distorting defects, which causes massive change in the bandgap of the semiconductor at the local level, and their behavior could be described by a lattice coordination diagram. Since this effect reduced with lowering the AlAs mole fraction,

AlGaAs/InGaAs pseudomorphic modulation-doped FETs were developed [197], which are the dominant compound semiconductor FETs in industry at the moment, to mitigate the effect of DX centers.

In the AlGaN/GaN system, the surface states and/or defects play a much more important role due to polarization fields as the layers are on polar surfaces. Anomalous characteristics, such as the so-called current collapse, kinks in the I/V characteristics, and long-term instability, have haunted the device from the time of its early development. Preliminary investigations of these phenomena were undertaken some years earlier [198]. Now that these devices are strong contenders in the marketplace for systems applications, these phenomena are getting a good deal of attention. One of the anomalous behaviors is the drain current lag, which prevents attainment of RF power congruent with the DC output characteristics of the device. For a maximum drain voltage of 50 V (drain bias of 25 V) and maximum drain current of 1 A, one should normally get 6.25 and 12.5 W in class A and class B operations, respectively, assuming an ideal case with zero saturation voltage, and no thermal limitation. However, the observed values in the laboratory are, in general, substantially smaller. This is due to current lag which is basically a failure on the part of drain current to keep up with the gate bias voltage in response to a high-frequency large-signal gate modulation [199], attributed to surface states.

The drain current lag is schematically shown in Fig. 20, where the load line and quiescent operating conditions for class A operation are shown. Also shown are the extremes of DC current as governed by the load line. Current lag is meant to indicate that the RF current (shaded) fails to follow the gate bias and thus the drain current at high frequencies is lower than that measured under DC conditions. The RF current can be determined by the use of the so-called load-pull tuning. It can also be measured under active loading conditions with the use of a high-speed sampling scope for measuring the output RF voltage, in response to an RF input drive, wherein the voltage measured can be converted to current, knowing the load value.

Figure 20. Schematic representation of RF current lag superimposed on top of DC drain I/V characteristics with a load line.

Traps are usually attributed to the current collapse. The loss of channel carriers as a result of being trapped at defects produces a large transverse electric field, which leads to the current collapse. The assumption is supported by the fact that light incident on the collapsed device photoionizes the trapped carriers and causes a restoration of the drain current [200,201]. The sudden removal of the current reduction at large V_{ds} (> 25 V) observed by Dietrich et al. [202] can also be explained by the field-enhanced carrier emission from traps.

The current lag can be measured as a function of frequency in the RF regime with an appropriate load line. Since the drain current does not follow the input stimulus due to surface traps, the term “lag” has been coined to describe the phenomenon. The surface must be appropriately passivated to avoid this degradation. The effective methods so far have been the use of low-temperature AlN [203] or Si_3N_4 [204] postgrowth and fabrication passivation layers. Better pinchoff characteristics, lower gate leakage current, reduction of current collapse, and increase of output power have been observed with surface passivation using Si_3N_4 [205–208]. However, whether surface state contributes significantly to current collapse remains unclear. If passivation alone is sufficient to eliminate the current lag, the issue of lattice distortion becomes an interesting one in that it raises the question as to whether the surface states are involved and if so, whether passivation layers also alter the strain picture.

7.6. Low- and High-Frequency Noise Performance

The low-frequency and high-frequency noise characteristics of GaN MODFETs are very important for the microwave applications of these devices. Investigation of the origin of noise is also important for understanding the physical processes taking place in the device. Although GaN MODFETs with excellent microwave performance have been fabricated for high-power and high-temperature applications, there is still little investigation on the noise properties.

7.6.1. Low-Frequency Noise. Low-frequency noise can be upconverted to high frequencies, limiting the performance of these transistors even in the microwave range. Low-noise electronics for communications necessitates some level of knowledge with respect to the origin of the processes responsible for low-frequency noise in GaN MODFETs. The low-frequency noise of GaN MODFETs usually exhibits flicker characteristics in the form of $1/f^\gamma$ dependence, where γ is close to 1. The dimensionless Hooge parameter α is commonly used, as shown as $\alpha = (S_I/I^2)f^\gamma N$, where f is frequency, N is the number of carriers, and S_I/I^2 is the relative spectral density of noise.

The first reported Hooge parameter (α) for the GaN MODFET has an approximate value of 10^{-2} [209]. Since then, transistors with low values of $\alpha \approx 10^{-4} \sim 10^{-5}$ have been reported [210–212], where the α parameter is comparable to that for commercial GaAs FET. It was observed that the noise level in GaN MODFETs is dependent on the structural perfection or the imperfection in the case may be. The noise level for MODFETs grown on sapphire sub-

Table 5. High-Frequency Noise Characterization of GaN MODFETs

Gate Length (μm)	Drain Bias (V)	Gate Bias (V)	f (GHz)	F_{\min} (dB)	Associated Gain (dB)	Ref.
0.15	6	≈ -3	10	0.60	13.5	218
0.25	10	-4	5/10	0.77/1.06	14/12	219
2	10	-1.5	2	0.58	14.13	220
0.12	10	-4.8	8	0.53	12.1	221

strates is one order of magnitude larger than those on SiC substrates [213,214]. In addition, Romyantsev et al. [214] observed that the noise spectrum for some samples on sapphire has a plateau at low frequencies, which is a characteristic feature of the generation–recombination (GR) noise. Only at very low noise levels (Hooge parameter on the order of 10^{-4}) does the contribution of generation–recombination noise become significant. It was found that GR noise for devices grown on sapphire has an activation energy $\Delta E \approx 0.42$ eV [214]. On the contrary, the temperature sensitivity for the noise level of devices grown on SiC is very weak, which is essential for high-temperature applications. Balandin et al. [215] reported $\Delta E \sim 0.85$ eV for transistors grown on sapphire and $\Delta E \sim 0.20$ – 0.36 eV for those grown on SiC. The trap densities for undoped and doped devices are $1.1 \times 10^{16} \text{ cm}^{-3}$ and $7.1 \times 10^{17} \text{ cm}^{-3}$, respectively [216]. Romyantsev et al. [217] reported a large activation energy $\Delta E \sim 0.8$ – 1.0 eV for GaN MODFET and MOS-MODFET (MODFET with SiO_2 whose role is prematurely likened to the gate dielectric in Si MOSFETs) grown on insulating 4H-SiC. The analysis indicates that the traps responsible for the observed GR noise could originate in the AlGaIn barrier layer, which has an estimated trap density of about $5 \times 10^{16} \text{ cm}^{-3}$.

7.6.2. High-Frequency Noise. Preliminary investigations of high-frequency noise performance have shown that GaN MODFETs have respectable microwave noise properties that are nearly comparable to those of AlGaAs/GaAs MODFETs. Table 5 displays studies of the microwave noise performance for GaN MODFETs. These encouraging results serve to motivate further investigation.

Lu et al. [222] also studied the effect of surface passivation on high-frequency GaN MODFET with $0.25 \mu\text{m}$ gate length. Although the gate leakage current was smaller after passivation, the noise measurements after passivation showed that the devices exhibited about 0.2–0.25 dB increase in F_{\min} . This was due mainly to the 1–1.5-dB decrease of associated power gain attributed to the increased C_{gs} and C_{gd} . It was concluded that the effect on microwave noise performance is a combination of effects of lower gate leakage current and higher surface dielectric constant.

7.7. Piezoelectric Effect

The III–V nitride semiconductors possess highly pronounced piezoelectric and spontaneous polarization properties. As such, any strain present in these crystals causes a distortion in atomic orbitals that leads to large polarization effects and must be taken into consideration, particularly in dealing with strained heterostructures. The

piezoelectric effect has become the focus of attention, with many claims including achievement of MODFET channels with no intentional doping anywhere in the entire heterostructure. It should be made clear that the resultant polarization field causes redistribution of the free and weakly bound charge, which could be mistakenly interpreted as bonus carriers [7]. The treatment must also include the charge redistribution in the presence of metal semiconductor contacts such as gate Schottky barriers and ohmic contacts. In positive strain (tensile strain), the direction of the polarization is from the anion, *B*-face, to the cation, *A*-face, sites. As can be easily imagined, if the growing nitride surface contains both polarities, the direction of the polarization vector would follow suit and would point either upward or downward depending on the spot. If the strain is tensile, then the polarization vector would be from the surface toward the substrate.

8. $\text{Si}_{1-x}\text{Ge}_x$ MODFET STRUCTURES

The advent of high-quality SiGe layers on Si substrates has paved the way for the exploration and exploitation of heterostructure devices in a Si environment. Tensile-strained Si films on strain-relieved SiGe buffer layers enable the formation of electron quantum wells, which exhibit enhanced electron mobilities. Compressively strained SiGe, or even pure Ge layers, can be used to create two-dimensional hole channels [223]. Silicon–germanium MODFETs have a significant high-frequency potential. Maximum oscillation frequencies of more than 100 GHz have been obtained. Capitalizing on the favorable band discontinuities outlined by Abstreiter et al. [224] Ismail et al. [225] reported encouraging values of electron mobility in a modulation-doped strained $\text{Si}_{0.7}\text{Ge}_{0.3}$ channel surrounded by $\text{Si}_{0.86}\text{Ge}_{0.14}$ donor layers. The cross-sectional view of this particular structure embedded into an FET structure is shown in Fig. 21. The electron mobilities measured were 1800, 9000, and 19,000 $\text{cm}^2/\text{V}\cdot\text{s}$ at room temperature, 77, and 1.4 K, respectively. The corresponding sheet electron densities are 1.2×10^{12} , 8.3×10^{11} , and $7.5 \times 10^{11} \text{ cm}^{-2}$, respectively. The layers were grown using UHV/CVD that offered a very low background impurity concentration in the intrinsic layers. As will be briefly mentioned below, the layered structures of this kind have been exploited for high transconductance modulation-doped FETs. Mii et al. [226] used a SiGe layer graded from 0% to 30% followed by a $\text{Si}_{0.7}\text{Ge}_{0.3}$ buffer layer, both of which were relaxed. A strained Si channel was grown on the $\text{Si}_{0.7}\text{Ge}_{0.3}$ buffer and capped with a doped $\text{Si}_{0.7}\text{Ge}_{0.3}$ layer. A maximum Hall mobility at 4 K of 125,000 $\text{cm}^2/\text{V}\cdot\text{s}$ has been obtained. The sheet electron

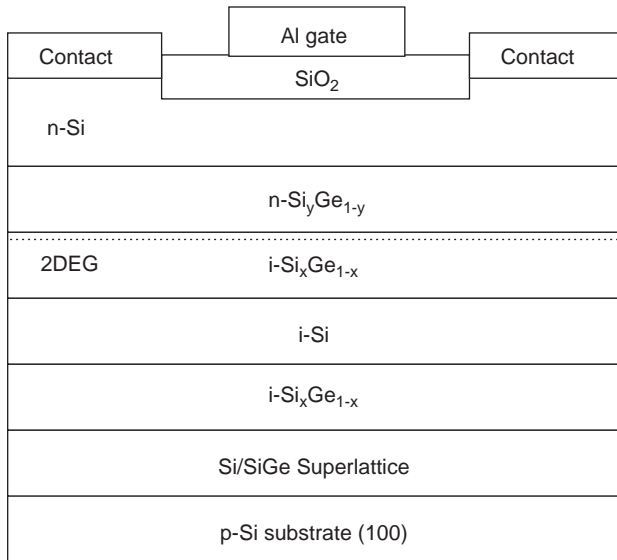

Figure 21. Schematic cross-sectional diagram of a strained layer SiGe/Si structure in conjunction with a MODFET device.

concentrations the heterostructure can sustain were 1.2×10^{12} at 300 K to 7.8×10^{11} at 77 K and below. Informal results indicate that mobilities close to $300,000 \text{ cm}^2/\text{V}\cdot\text{s}$ can be obtained, which compares with about $30,000 \text{ cm}^2/\text{V}\cdot\text{s}$ attainable in a Si/SiO₂ system. MODFETs with current gain cutoff and maximum oscillation frequency of about 32 and 40 GHz, respectively, have been reported in 0.5- μm -gate-length devices [227]. Aniel et al. [228] fabricated 100-nm T-gate strained Si/Si_{0.6}Ge_{0.4} n-MODFETs with new record performance, which has a cutoff frequency of 74 GHz at room temperature and maximum oscillation frequency of 107 GHz at room temperature. They also show a low noise figure NF_{min} of 0.4 dB and noise resistance of 52Ω at 2.5 GHz and room temperature. High quality Si/Si_{1-x}Ge_x/Si p-type modulation-doped double heterostructures with $x = 0.12$ and 0.15 have been grown using UHV/CVD by Wang et al. [229]. In this heterostructure, hole mobilities as high as $3700 \text{ cm}^2/\text{V}\cdot\text{s}$ at 14 K have been obtained with $x = 0.12$ and a Si spacer of 60 \AA for a sheet carrier concentration of $\sim 8 \times 10^{11} \text{ cm}^{-2}$. The values of hole mobility are roughly an order of magnitude higher than the highest values reported in p-type Si inversion layers and are most probably limited by remote ionized impurity scattering from the heavily doped Si layer, and/or the interfacial quality at the Si/SiGe heterointerface. Murakami et al. [230] utilized MBE grown a modulation-doped heterostructure where the strain at the heterointerface (p-Si_{0.5}Ge_{0.5}/Ge layers) is controlled by the Si composition ($1-x$) of the Si_{1-x}Ge_x buffer layer. When the Si composition is 25%, a hole mobility of $9000 \text{ cm}^2/\text{V}\cdot\text{s}$ at LN₂ temperature was achieved. Arafa et al. [231] have reported p-channel Si/SiGe MODFETs with extrinsic transconductances of 150 and 250 mS/mm for 1- and 0.25- μm -gate devices, respectively. As the gate length was reduced from 1 to 0.25 μm , the current gain cutoff frequency increased from 5 to 40 GHz. Preliminary devices with 0.1 μm gate lengths appear to show current gain cutoff frequencies of about 70 GHz. A cutoff frequency of 45 GHz, a maximum oscillation frequency of 81 GHz,

and an extrinsic transconductance of 142 mS/mm have been achieved on p-type SiGe MODFET with a 0.1 μm gate length. The minimum noise figure is 1.29 dB, while the associated power gain is 12.8 at 2 GHz [232]. The reader is referred to a review by König [233] for developments in both n-channel and p-channel SiGe-based FET technology. The more recent emphasis of SiGe technology is on bipolar and bipolarMOS (BiCMOS) technology, in which the Si bipolar devices and SiGe HBTs can be integrated for critical high-speed analog or digital functions.

9. CONCLUSIONS

In less than two decades (at the time of writing), the MODFET technology has evolved dramatically, from an interesting research innovation to an extremely formidable and yet practical device with numerous application areas, including wireless, low power communications, direct satellite broadcasting systems, millimeter-wave systems, and digital electronic systems. As is evident from the tables and figures presented in the body of the text, the MODFET has progressed to the point where the performance barriers thought to be insurmountable by three-terminal devices not long ago have been overcome with amazing dispatch. Although the GaAs channel MODFETs were formed the genesis of this unique device, the pseudomorphic MODFET with InGaAs channels has become the device of choice. Strained channel MODFETs with 80% InAs in their channel layers have shown current gain cutoff frequencies above 300 GHz. Again, strained channel MODFETs with 60% InAs in their channels exhibited measured power gain at 140 GHz. The data clearly indicate that the pseudomorphic MODFET has demonstrated increasingly enhanced electronic properties without compromising the breakdown voltage afforded by GaAs. Strained channel InGaAs MODFETs on GaAs substrates currently hold the power record. In concert with the gain and power performance, strained layer MODFETs on GaAs have shown a noise performance of 1.4 dB in the 90 GHz range. Despite the enhanced hole mobilities measured in compressively strained InGaAs, the p-channel MODFETs do not appear to have gained remarkably better performance. The bulklike properties away from the zone center and band mixing, which is very likely at high electric fields, are thought to be responsible for such a lack of enhanced performance.

Because of their large bandgaps, large high field electron velocity, large breakdown fields, large thermal conductivity, and robustness, wide-bandgap nitride semiconductors have gained considerable attention. The ensuing materials developments paved the way to AlGaIn/GaN MODFETs with superior power performance. CW power levels of about 6 W have been achieved at 10 GHz in devices with 1 mm gate periphery that are comparable to power densities extrapolated from smaller devices. When four of these devices were power combined in a single-stage amplifier, a CW output power of 22.9 W with a power-added efficiency of 37% was demonstrated at 9 GHz. On the noise figure front, a minimum noise figure of 0.85 dB with an associated gain of 11 dB at 10 GHz was obtained. A

discussion of the current collapse and the current lag occurring in GaN-based MODFETs has been presented. In closing, GaN-based MODFETs have made great strides and are continuing to do so despite the less than ideal materials properties. Anomalies in the current voltage characteristics at low and high frequencies observed in these devices are attributed to traps in the structure, surface states, and slow trapping processes associated with the field-induced lateral extension of the strain near the gate. It may be only a matter of time for inclusion of these devices in systems.

Relatively recent introduction of SiGe alloys propelled the Si technology into the realm of the heterojunction world. The new Si/SiGe system has provided a laboratory in which to study quantum phenomena and has led to an exploration into commercially important devices such as MODFETs. SiGe channel MODFETs with 0.2- μm gate lengths challenge the 100-GHz cutoff frequency benchmark. The f_{max} of n-type MODFETs peaked at 183 GHz in late 2001. Moreover, the MODFET phenomenon has expanded to include the emerging wide-bandgap GaN/AlGaIn semiconductor system, which already is beginning to demonstrate high-frequency (current and power gain cutoff frequencies of about 50 and 100 GHz, respectively) and high-power operation.

Acknowledgments

The research into MODFETs conducted by the author spanning nearly over two decades have been funded by the Air Force Office of Scientific Research (AFOSR) under the direction of Dr. G. L. Witt. The author's research in GaN MODFETs has been funded by AFOSR and the office of Naval Research (ONR) under the directions of Dr. G. L. Witt and Mr. M. Yoder, Dr. C. E. C. Wood, respectively. The author would like to thank his students and colleagues for collaboration, in particular Dr. T. J. Drummond. Finally, the grants from AFOSR (Dr. Todd Steiner), NSF (Drs. L. Hess and U. Varshni), and ONR (Dr. C. E. C. Wood, Mr. M. Yoder, and Dr. Y. S. Park), are acknowledged.

MONOLITHIC ANTENNAS

ANDERS RYDBERG
ERIK Öjefors
Uppsala University
Uppsala, Sweden

1. BACKGROUND AND APPLICATIONS

The use of high-microwave and millimeter-wave frequencies has to this date been restricted to professional applications, such as long-distance radiolinks and radar, due to the high cost of equipment and requirements for individual licenses for use of frequencies. The license-free 24-GHz, 60-GHz, and 77/79-GHz bands could, however, host mass-market consumer applications such as automobile anticollision radars, wireless LAN, and sensor devices, provided compact low-cost transceivers are made available. In conventional microwave technology for active antennas the RF frontend and the antenna are built on separate substrates, due to the size of the antenna structure. However, at millimeter-wave frequencies the small size of the antenna allows for monolithic integration between the antenna and the active chip. Such a close integration will eliminate the parasitics of interconnections in the package and promote the design of low cost wideband telecommunication and radar sensors.

It is not possible to obtain the high antenna gain required by long-range radars or radiolinks with an on-chip antenna of acceptable size. Thus, the on-chip antennas are suitable in short-range communication and sensor devices, where a low antenna gain is feasible due to the omnidirectional pattern usually required for such applications. By integrating the MMIC with the antenna in low-antenna-gain applications, advantages such as simplified packaging and considerable reduction of the space required by the radio frontend can also be achieved. One of the first trials in this respect was proposed in 1984 by Jain and R. Bansal in which a millimeter-wave (MMW) GaAs dipole antennas whose radiation characteristics could be controlled during fabrication and/or operation was to be integrated monolithically together with active devices [1]. In 1993 Robertson described a technique for employing radiating elements of a patch antenna on the backface of monolithic circuits [2], facilitating the integration between the active device and the antenna [3]. A small short-circuited H-shaped GaAs monolithic microwave integrated circuits (MMICs) patch antenna was presented by Singh et al. [4]. A new application of monolithic antennas was reported by the SiMICS Research Group, at the University of Florida, where a wireless interconnect system was proposed for clock distribution using on-chip antennas [5]. A V-band GaAs HEMT uniplanar monolithic integrated antenna and receiver frontend were presented by Chen et al. [6].

More recent advances in the realization of RF circuits using mature silicon technologies (RF CMOS and Si/SiGe HBT technologies) have led to a quantum leap in the complexity of monolithically integrated microwave circuits, even for frequencies of operation beyond 24 GHz.

MONOLITHIC ANTENNAS

ANDERS RYDBERG
ERIK Öjefors
Uppsala University
Uppsala, Sweden

1. BACKGROUND AND APPLICATIONS

The use of high-microwave and millimeter-wave frequencies has to this date been restricted to professional applications, such as long-distance radiolinks and radar, due to the high cost of equipment and requirements for individual licenses for use of frequencies. The license-free 24-GHz, 60-GHz, and 77/79-GHz bands could, however, host mass-market consumer applications such as automobile anticollision radars, wireless LAN, and sensor devices, provided compact low-cost transceivers are made available. In conventional microwave technology for active antennas the RF frontend and the antenna are built on separate substrates, due to the size of the antenna structure. However, at millimeter-wave frequencies the small size of the antenna allows for monolithic integration between the antenna and the active chip. Such a close integration will eliminate the parasitics of interconnections in the package and promote the design of low cost wideband telecommunication and radar sensors.

It is not possible to obtain the high antenna gain required by long-range radars or radiolinks with an on-chip antenna of acceptable size. Thus, the on-chip antennas are suitable in short-range communication and sensor devices, where a low antenna gain is feasible due to the omnidirectional pattern usually required for such applications. By integrating the MMIC with the antenna in low-antenna-gain applications, advantages such as simplified packaging and considerable reduction of the space required by the radio frontend can also be achieved. One of the first trials in this respect was proposed in 1984 by Jain and R. Bansal in which a millimeter-wave (MMW) GaAs dipole antennas whose radiation characteristics could be controlled during fabrication and/or operation was to be integrated monolithically together with active devices [1]. In 1993 Robertson described a technique for employing radiating elements of a patch antenna on the backface of monolithic circuits [2], facilitating the integration between the active device and the antenna [3]. A small short-circuited H-shaped GaAs monolithic microwave integrated circuits (MMICs) patch antenna was presented by Singh et al. [4]. A new application of monolithic antennas was reported by the SiMICS Research Group, at the University of Florida, where a wireless interconnect system was proposed for clock distribution using on-chip antennas [5]. A V-band GaAs HEMT uniplanar monolithic integrated antenna and receiver frontend were presented by Chen et al. [6].

More recent advances in the realization of RF circuits using mature silicon technologies (RF CMOS and Si/SiGe HBT technologies) have lead to a quantum leap in the complexity of monolithically integrated microwave circuits, even for frequencies of operation beyond 24 GHz.

The increase in complexity from a few to tens of active devices in typical III–V-based MMICs relatively recently to the hundreds of active devices possible in Si-based MMICs will enable the integration of advanced signal conditioning structures (phase and amplitude modulation) in a very compact fashion and close to the antenna. This also facilitates the interface with digital signal processing through on-chip interface circuitry. Si/SiGe BiCMOS technologies may enable the fully monolithic integration of digital signal processing and RF functions on a single chip. The discussion on monolithic antennas will thus be mostly devoted to silicon-based antennas, due to the strong progress in this area and the cost effective solutions compared to III–V technology.

2. PERFORMANCE ISSUES OF INTEGRATED ANTENNAS

One key requirement of the on-chip antennas is small size, due to the high cost of wafer space. For a typical square-shaped semiconductor die containing RF front-end circuitry, an area of $<10\text{ mm}^2$ ($3.3 \times 3.3\text{ mm}$) is usually desired. At 24 GHz, with a free-space wavelength of 12.5 mm, the die sidelength of such a chip would correspond to a quarter-wavelength.

The antenna gain for antennas is always lower than the directivity, due to conductor and substrate losses. The losses are characterized by the antenna efficiency and is defined as

$$\eta = \frac{P_{\text{rad}}}{P_{\text{in}}} \quad (1)$$

where P_{rad} is the radiated power P_{in} is the power at the antenna input terminals. Because of the fundamental limitations in antenna directivity mandated by the small size of integrated antennas, the efficiency is the most important figure of merit for such antennas. Thus, an important objective of the research on monolithic antennas is to maximize the radiation efficiency of small antennas by using micromachining methods compatible with the active circuits integrated on commercial, low-resistivity silicon substrates.

3. FABRICATION TECHNOLOGY

One objective in deriving the process technology for fabrication of monolithically integrated antennas is that the process should be compatible to a commercial foundry process. Although antennas have been integrated directly in MMIC processes, using the available metal layers, better performance and larger freedom in design of the antenna can be obtained by the use of micromachining postprocessing methods. The methods used to improve the efficiency are surface micromachining, application of the low-loss spinon polymer benzocyclobutene (BCB), and bulk micromachining. In the bulk micromachining BCB-coated silicon substrate is etched from the backside to release the BCB and form a membrane. This etching can be performed by either wet or dry etching methods.

3.1. Surface Micromachining

3.1.1. Processing of BCB Thick Dielectric. The substrate losses in low resistivity silicon wafers used for transmission lines and antennas can be reduced if a thick layer of a low-loss dielectric is deposited on the top of the wafer, before the transmission lines are metallized. A suitable dielectric is benzocyclobutane (BCB), which is a polymer with a dielectric constant $\epsilon_r = 2.65$ and low losses ($\tan \delta = 0.0005$) manufactured by Dow Chemicals. The BCB can be applied to the top of the wafer as a conventional photoresist, and thicknesses of 20–30 μm can be obtained if the polymer is applied in several subsequent spinon process steps. Photosensitive BCB is also available, allowing patterning of the polymer layer. The BCB is cured in a furnace at 250°C, and the top metallization is finally evaporated, electroplated, and patterned on top of the dielectric.

3.1.2. Silicon Bulk Micromachining. The term *bulk micromachining* refers to processes where parts of the bulk of the semiconductor substrate are selectively removed by etching processes. Two major techniques are used for bulk micromachining of silicon substrates: wet chemical etching [7] and dry etching [8].

In chemical wet etching the surface of the silicon wafer is masked by a durable mask, such as silicon nitride, with openings where a liquid is allowed to etch the substrate. Wet etching of silicon substrates can either be isotropic, where the etching progresses with the same rate in all directions, or anisotropic where the etch rate in certain directions is restricted by the (111) crystal planes in silicon. The anisotropic etch leaves slanted walls of etched cavities if a silicon wafer with the standard crystal orientation (100) is used. Anisotropic etching of silicon is a standard silicon micromachining process.

Dry etching is performed in an evacuated chamber where a plasma is generated and used to etch the silicon substrate. The wafer is masked by photoresist and patterned with photolithographic techniques to enable selective etching. In the commonly used deep-reactive-ion etching (DRIE) process by Bosch [8], the wafer is exposed to an alternating sequence of an etchant and a passivant. By the alternation between etching and passivation of the substrate the sidewalls of the etched holes are protected, thereby enabling high-aspect-ratio structures to be manufactured. Good control over the etching process and selectivity against the mask is also obtained.

3.2. Membrane Technology

Thin membranes of high-quality dielectric materials offer a way of integrating high-quality transmission-line structures and antennas [9] on silicon substrates. By suspending the conductors on membranes in air, an effective dielectric constant of close to one can be achieved. Low losses are also obtained since the silicon substrate is removed in the vicinity of the transmission lines or antenna conductors. A low-temperature membrane process, compatible with preprocessed semiconductor wafers, is obtained by combining the spinon BCB dielectric process with bulk micromachining. The BCB membrane is

Figure 1. Integrated slot loop antenna.

released by backside etching of the wafer, using wet etching methods such as KOH or DRIE.

4. ANTENNAS

The antennas that will be described here are suitable for monolithic integration with active devices. Such antennas include the slot- and wire-loop antennas, the meandered dipole, and the patch antenna. The antennas discussed here have been implemented on surface and bulk micromachined low-resistivity silicon substrates.

4.1. Slot-Loop Antennas

The slot antenna consists of an aperture in a ground plane, where an electric field is excited across the slot. Using Booker's relation [10], the straight slot antenna can be considered to be the complementary antenna to the wire dipole and many of its properties, such as input impedance, can be directly calculated from the wire antenna equivalents.

By using micromachined membrane technology, high-performance slot antenna arrays have been built on silicon substrates [11]. The size needed for such antenna arrays, fully implemented on membranes, is, however, too large for monolithic integration on preprocessed SiGe wafers.

Because of their geometric properties, slot-loop antennas are particularly interesting for compact integration on chip (see Fig. 1) Slot-loop antennas integrated with active devices have been demonstrated in hybrid technology [12] and using high-resistivity silicon and bulk micromachining [13]. In order to minimize chip size, it is of interest to keep the antenna ground-plane dimensions as small as

possible without compromising the antenna performance. The influence of the dielectric substrate on the guided-slot wavelength is characterized using the effective dielectric constant ϵ_{eff} , as the relation between the free-space wavelength and the guided wavelength. The circumference of the slot-loop antenna is governed by the resonance condition of a total slot length of one guided wavelength [14] at the frequency of operation since the antenna is operated at the second resonance.

The slot-loop antenna is normally fed across one of the voltage maximums as illustrated with the CPW feed in Fig. 1. For a square slot loop on an infinite ground plane in free space, an input impedance of 250Ω can be calculated for an antenna in free space, using the Booker relation and published results for wire-loop antennas. Introduction of a dielectric substrate in the antenna will alter the input impedance at resonance as well as change the effective dielectric constant of the slotline and will include also conductive losses in the substrate.

4.1.1. Surface-Micromachined Slot-Loop Antenna. Using surface micromachining technology the characteristics of the slot-loop antennas can be improved. A surface-micromachined 24-GHz slot-loop antenna for integration with SiGe circuits on low-resistivity silicon wafer has been designed using a BCB process [14]. A square slot loop (see Fig. 1) was designed to maximize the area utilization given a specific loop length. A relatively narrow slot width $s_a = 20 \mu\text{m}$ was selected to maintain a slot mode despite the presence of a conductive silicon substrate. The antenna slot dimensions $L_s = W_s = 2000 \mu\text{m}$, equal to a total loop length of $1.14\lambda_g$, were chosen after HFSS (high-frequency structure simulator) simulation of the antenna, including the finite ground plane with the size $G_a = G_b = 3 \text{ mm}$. The antenna was realized on a $11\text{--}15\text{-}\Omega \cdot \text{cm}$ silicon wafer to simulate the substrate properties of preprocessed SiGe wafers. In the used surface micromachining method, a layer of BCB dielectric is spun on top of the silicon wafer, and shallow trenches are optionally formed in the silicon by frontside etching. The trenches are subsequently filled by the BCB dielectric layer, which extends the height over the silicon substrate by $10\text{--}20 \mu\text{m}$. The purpose of the spin-on BCB dielectric and the forming of the shallow trenches is to reduce the effective dielectric constant of the slotline and minimize substrate losses. A schematic sketch of the stacked layers together with an SEM view are shown in Fig. 2.

In Fig. 3 the return loss for antennas with identical metallizations with 10- and $20\text{-}\mu\text{m}$ -thick BCB layers are shown, as well as results for antennas with shallow trenches. The use of a thick BCB dielectric and the

Figure 2. Surface micromachined slot-loop antenna on BCB layer and SEM view of the same.

Figure 3. Return loss for surface-micromachined antennas with different BCB dielectric thickness and optional shallow trench. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

presence of micromachined shallow trenches reduces the effective dielectric constant and thus increases the frequency of resonance from 21 GHz for a thick 10- μm -thick BCB layer to 24 GHz for a 20- μm one.

The measured and simulated *E*- and *H*-plane radiation patterns for the slot-loop antenna are plotted in Fig. 4. Because of the low directivity of these small antennas, the coplanar wafer probe as well as the metallic wafer probe holder cause multiple reflections and shadowing problems that turn up as ripples in the measured patterns. The nulls in the radiation pattern are obtained in the plane of the antenna as predicted by theory.

4.2. Wire-Loop Antennas

The full-wavelength loop antenna can be considered as an alternative for an on-chip antenna (see Fig. 5). To enable compact integration of circuits on the same substrate as the antenna, the full membrane used in earlier approaches can be replaced by localized BCB membranes, here called “trenches”, under the wire loop as shown in Fig. 5. The loop dimensions are $W_L = L_L = 3000 \mu\text{m}$, with a loop wire width of $120 \mu\text{m}$ and a trench width of $W_{tr} = 360 \mu\text{m}$. The trenches are centred around the loop metallization. Two bridges of width $W_{br} = 200 \mu\text{m}$ are kept to maintain mechanical stability of the substrate. The bridges are placed at the current maxima of the loop to minimize capacitive coupling to the substrate in the vicinity of the voltage maxima. The radiation pattern is bidirectional as in the case of the slot-loop antenna, with a backlobe of a size comparable to that of the frontlobe. A property of the loop antenna is its inherently balanced feed, which makes the antenna suitable for integration with differential circuit topologies without the use of on-chip baluns. For integration on chip, the square loop antenna is of special interest since it can be placed around the edge of a chip with active components. The presence of active circuit ground planes in the center of the antenna will, however, reduce the radiation resistance and should therefore be considered in the antenna design. At the commonly used second resonance the input impedance of a thin-wire

square loop is $80 - j100$, thus requiring a total circumference of 1.15λ , for a resistive input impedance. The loop antenna can be modeled as a dual-resonance circuit where the series resonant circuit represents the useful second resonance. The measured input impedance of 70Ω is lower than the theoretical free-space value, indicated by the simulated values for the free-space case as shown in Fig. 6, due to the presence of the low-resistivity silicon substrate in the vicinity of the radiating loop. The wire-loop antenna has a radiation pattern similar to that of the half-wave dipole, but with a compressed *H*-plane pattern. The theoretical directivity [15] of the wire-loop antenna is 3.3 dBi. In an experimental setup a gain of 1.9 dBi has been obtained for the implemented antenna at 24 GHz. An annular loop antenna has been demonstrated on micromachined silicon substrate, using a BCB membrane to suspend the loop antenna in air [16].

4.3. Dipole Antennas

The dipole has been considered as a candidate for on-chip integration. On-chip dipole antennas for clock distribution have been demonstrated at 15 GHz on CMOS substrates [5] and on high-resistivity silicon substrates [17]. A 10-GHz dipole antenna has been integrated with a VCO (voltage-controlled oscillator) in a commercial BiCMOS process [18]. The balanced feed of the dipole is an advantage for integration with differential circuits. However, its length of a half-wavelength typically makes the dipole too large for integration on chip for applications in the 10–30 GHz frequency range. To reduce the size of a half-wave dipole antenna, the radiator can be meandered [19]. Meandering of an antenna with a certain wire length largely maintains its resonant frequency but reduces the radiation resistance. Since the loss resistance in the antenna remains relatively constant, the total efficiency of the antenna decreases. A meandered dipole, implemented on a BCB membrane to reduce substrate losses, is shown in Fig. 7. The length of the dipole L_{dip} is $3000 \mu\text{m}$ with a width W_{dip} of the meandered section of $500 \mu\text{m}$. The dipole was implemented on a BCB membrane with size $W_{tr} = 760 \mu\text{m}$,

Figure 4. *E*- and *H*-plane measured and simulated radiation pattern, where -9° – 90° corresponds to topside of antenna. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$L_{tr} = 3300 \mu\text{m}$. An additional antenna with a larger membrane, where the spacing between the silicon and the meandered line was increased from 125 to $425 \mu\text{m}$, was also designed. The theoretical directivity of a reduced-size

Figure 5. Wire-loop antenna with trenches etched in silicon wafer.

Figure 6. Wire-loop antenna with trenches, measured (solid line) and simulated (dashed line, silicon substrate effects not included); impedance 20–30 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

half-wave dipole in free space is bounded by the value 1.8 dBi for an infinitely short dipole and 2.1 dBi for a full-size half-wave dipole. The measured return loss is shown in Fig. 8, together with an IE3D [20] simulation considering the silicon substrate and a Momentum [21] simulation without the silicon substrate present. The measured impedance for the two different dipoles is plotted in Fig. 9 together with Momentum simulation results for an antenna without the silicon substrate present. The radiation resistance R_{rad} is reduced from the standard dipole value of 77Ω to 20Ω because of the meandering of the line. The meandered dipole can be accurately modeled for circuit codesign purposes by a standard series-resonant circuit with series resistances representing radiation and loss resistance. It should be noted that integrated antennas are not always required to have a 50Ω input impedance since the antenna and the active circuits can be codesigned. The radiation pattern for the *E* and *H* planes are shown in Fig. 10, where angles of 0 – 180° correspond to the topside of the wafer. The antenna beam pattern exhibits typical dipole characteristics with *E*-plane nulls at 0° and 180° and maxima in the broadside directions. The antenna gain was measured at

Figure 7. Meander dipole layout.

Figure 8. Measured and simulated (2D MoM; effects of silicon substrate not included) meander dipole antenna return loss.

24.14 GHz and found to be -1 dBi in a $50\text{-}\Omega$ system, which is in good agreement with the simulated gain of -0.2 dBi.

4.4. Patch Antennas

Patch antennas have been a common choice for integrated antennas in hybrid designs, due to their low profile and high gain. The normal patch antenna type consists of a wide metal patch on top of a grounded dielectric substrate.

By exciting a TM_{010} mode between the patch and the ground plane, radiating fringing fields will occur at two of the edges. A patch antenna manufactured on silicon will exhibit small bandwidth and poor performance due to the high dielectric constant of the substrate. Conductive losses in the silicon will lead to poor efficiency, thus requiring the use of high resistivity silicon, which is generally not compatible with standard SiGe bipolar and CMOS processes. A solution to these problems is offered by micromachining methods. The lossy silicon can be removed by backside etching of the substrate, thereby creating a cavity under the patch or by depositing a low-permittivity, low-loss dielectric such as BCB to the top of the wafer and realizing the patch on top of this layer.

Two micromachined patch antennas will be described, one 60-GHz aperture-fed patch antenna on a bulk micromachined high resistivity silicon substrate, suitable for a stacked wafer integration with an active transceiver module, and a differentially fed patch antenna developed on a thick BCB layer designed for wafer level integration with a 24-GHz differential SiGe oscillator [22,23].

4.4.1. Bulk Micromachined 60-GHz Patch Antenna. To increase the efficiency and bandwidth of such an antenna, part of the substrate beneath the patch could be removed using bulk micromachining techniques, thus reducing the effective dielectric constant of the substrate [22] (see Fig. 11). A well-known problem in the design of wideband patch antennas is that the requirements on the substrate are vastly different for the radiating patch element and the feedline (typically microstrip). By using aperture coupling between the patch and the feedline, a high-permittivity substrate could be chosen for the microstrip feed, while a substrate with a lower dielectric constant could be selected for the patch antenna element. Another advantage of aperture coupling over other feed types is that the feed network is shielded from the radiating side of the

Figure 9. Measured and simulated (no silicon present) meander dipole antenna input impedance (20–30 GHz). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 10. E-plane (a) and H-plane (b) radiation patterns.

elements by the ground plane. By combining silicon micromachining techniques and aperture feed, a highly efficient patch antenna can be made by stacking two silicon substrates on each other. A thick wafer is selected for the upper wafer to obtain good radiation characteristics where a cavity is opened underneath the patch. A thinner wafer is selected for the transmission lines, thus reducing the risk for substrate modes.

The effective dielectric constant of the mixed air–silicon patch substrate can be calculated using a quasistatic capacitor model presented by Papapolymerou et al. [24]. An

Figure 11. Micromachined silicon patch antenna.

Figure 12. Side view of the micromachined patch antenna.

equivalent-circuit model of the rectangular aperture-coupled patch antenna based on transmission-line analysis has been presented by Himdi et al. [25]. By using an H slot instead of a rectangular one, the coupling can be improved, and the length of the slot can be well below the resonant region of the slot. An accurate transmission-line-based model for a H-slot feed-micromachined patch antennas was derived by Kurup et al. [26].

The antenna structure is shown in Figs. 12 and 13. A square patch was selected to allow for dual-polarization use (with a suitable feed network). A 50- μm -thick silicon membrane was selected as a compromise between surface-mode rejection and ease of manufacturing. The dielectric constant of 1.24 was calculated for a 254- μm -thick silicon substrate (H_{ant}) with a 200 μm deep cavity (H_{cav}). A patch antenna size of $W=L=1500 \mu\text{m}$ was determined for a 60 GHz resonance frequency. By selecting a $W_{\text{cav}}=L_{\text{cav}}=3 \text{ mm}$ large cavity underneath the patch element, most of the fringing fields were accommodated within the cavity, thus preventing excitation of surface waves. The microstrip line is aperture-coupled to the patch with an H-shaped slot with the dimensions $L_{\text{slot}}=1100 \mu\text{m}$, $L_{\text{H}}=600 \mu\text{m}$, and $W_{\text{slot}}=110 \mu\text{m}$. A $L_{\text{stub}}=0.45\text{-mm}$ -long quarter-wave stub is used to give the microstrip line a short-circuit termination after the slot. For measuring the antenna beam pattern a GaAs flip-chip diode was

Figure 13. Top view of the micromachined patch antennas.

Figure 14. Antenna return loss.

connected to the end of the microstrip feedline in order to detect the received signal at the antenna terminals.

The patch antenna was manufactured on high-resistivity, double-polished, (100) silicon wafers. The wafer carrying the transmission lines and the slot was thinned from 254 to 100 μm (H_{feed}). The patch antenna elements were manufactured on a polished 254- μm -thick wafer.

The return-loss measured in this setup is shown in Fig. 14. From the measurements it can be seen that the antenna resonates at 62 GHz. The -10 dB bandwidth of the antenna is 6 GHz. No measurements of the radiation efficiency have been performed, but HFSS [21] simulations indicate 77% efficiency.

Figure 16. Differentially fed patch antenna on BCB layer.

The radiation pattern measurements for the vertical E plane and horizontal H plane are shown in Fig. 15 along with a HFSS simulation of the radiation pattern. A 50° half-power beamwidth obtained in the E plane. In the H plane the half-power beamwidth was measured to only 45° . A standing-wave minimum between the reference (measurement) antenna and the patch accounts for a drop in the received power at an 25° angle from the normal of the antenna pattern.

4.4.2. A Differentially Driven 24-GHz Patch Antenna. A differentially driven patch has been demonstrated [23] using a BCB thick layer dielectric on metallized silicon as the patch substrate (see Fig. 16). The antenna is 3848 μm (L_p) long and 1928 μm (W_p) wide, where the length determines the tuning frequency and the width, the impedance of the patch. Because of its size, this antenna is suited primarily for wafer-level integration with active devices at 24 GHz.

The antenna was manufactured by metallizing a ground plane on the silicon wafer and applying a 30- μm -thick BCB layer to act as a dielectric. Because of processing

Figure 15. Antenna E - and H -plane radiation patterns.

Figure 17. Crosstalk simulation setup.

constraints, it is difficult to obtain thicker layers of BCB, which imposes a limit on the obtainable bandwidth of the antenna. The patch metallization was added as the last step in the processing.

The patch antenna is differentially fed by a balanced transmission line positioned perpendicular to a normal microstrip feed. The short circuit of the balanced feedline presented by the patch induces currents parallel to the normal radiating mode of the antenna and thus couples to the patch mode. By adjusting the separation of the feed-point, the antenna impedance can be adjusted to a suitable value for the integrated active devices. The balanced feed offers compatibility with differential circuits and obviates the need for a connection from the active devices to the patch ground plane.

MoM simulations of the antenna yielded a directivity of 6.8 dBi and 0 dBi in gain when metallic and dielectric losses were included in the simulation, corresponding to an antenna efficiency of 20%. A 200 MHz bandwidth centered at 23.4 GHz was predicted by the simulations.

The measured antenna gain has not been reported, but an antenna integrated with a monolithic oscillator [23] yielded 5 dB less radiated power than the predicted value give the known oscillator output and antenna directivity, thus indicating reasonably good agreement with the simulated gain and efficiency. The main reason for the low efficiency of the antenna is the high Q value of the antenna caused by the limited obtainable thickness of the BCB dielectric used as the patch substrate.

Figure 18. Parallel-plate-mode excitation.

Figure 19. H -field configuration with finite antenna groundplane

5. CROSSTALK

If antennas are to be successfully integrated on the same chip as the active devices, the crosstalk between distributed and lumped elements in the active circuit and the on-chip antenna must be minimized. High levels of crosstalk can cause phase noise in on-chip oscillators and instabilities in receiver and transmitter chains as well as self mixing and DC offsets in zero-IF architectures.

Crosstalk between the circuits and the antenna in an integrated 24-GHz surface micromachined slot-loop antenna has been studied [27] for typical on-chip interconnects by electromagnetic simulations. Three cases were considered: no special crosstalk reduction scheme, truncation of antenna groundplanes, and short circuiting of the antenna ground plane to the circuit ground. The silicon substrates were assumed to have a low resistivity p^+ doping in the vicinity of the active devices, a feature common in commercial SiGe processes. A 200- μm -long microstrip testline, typical for an on-chip interconnect, was used as a testline and was placed parallel to the slots at different distances from the current and voltages maxima in the ring slot (see Fig. 17).

In the first case a parallel-plate mode was excited between the antenna ground planes and the conductive silicon substrate as shown in Fig. 18. This results in strong coupling; however, the coupling is relatively independent of the distance between the testline and the slotline that resulted.

Figure 20. Simulated crosstalk at different distances from voltage maxima.

In the second case the antenna part of the antenna ground plane was removed over the area with the test interconnect line as shown in Fig. 19. By removing part of the ground plane, the performance of the slot antenna is compromised but the parallel-plate mode is prevented. However, as can be seen in Figs. 20 and 21, strong coupling is obtained when the test line is positioned close to the antenna slot, although the crosstalk decreases rapidly with increasing distance. The coupling was particularly strong close to the current maximums in the slot loop indicating primarily magnetic coupling as illustrated the H -field lines in Fig. 19.

The final case involved short-circuiting the parallel-plate mode by connecting the truncated ground plane with the conductive silicon substrate using via holes through the BCB dielectric. This grounding scheme eliminates the

Figure 21. Simulated crosstalk at different distances from current maxima.

both parallel-plate modes and magnetic coupling, yielding low crosstalk, as can be seen in Figs. 20 and 21.

Acknowledgment

We would like to thank Dr. Katia Grenier, Mr. Fouad Bouchriha, and Prof. Robert Plana at CNRS/LAAS, Toulouse, France for the work on micromachined structures. We would also like to thank Dr. Jeurgem Berntgen and Dr. Winfried Rabe at Atmel Germany GmbH, Heilbronn, Germany for information on SiGe HBT processing. MONOLITHIC MICROWAVE INTEGRATED CIRCUITS (MMICs)

INDER J. BAHL
M/A-COM, Inc.
Roanoke, Virginia

Since the late 1980s, microwave technology has gone through a significant evolution to meet the necessary requirements for lower-cost solutions, circuit miniaturization, higher levels of integration, improved reliability, lower power consumption, low-voltage operation, and

high-volume applications. Component size and weight are prime factors in the design of electronic systems for satellite communications, phased-array radar (PAR), electronic warfare, and other airborne applications, whereas high volume and low cost drive the PAR and consumer electronics market. Monolithic microwave integrated circuits (MMICs) are the key to meeting these requirements. MMICs will play a significant role in consumer electronics dealing with information transfer, communications, automotive, and entertainment and successful deployment of the PAR systems for both commercial and military applications.

The first MMIC results for transmit/receive (T/R) modules using low-frequency silicon technology were reported in 1964. The results were not promising because the low resistivity of the silicon substrate produced insufficient isolation between the individual devices in the monolithic circuit. In 1976, the first monolithic X-band amplifier, based on the GaAs metal semiconductor field-effect transistor (MESFET), was developed. By 1980, many MMIC results using MESFETs for various circuits had been reported. Since that time, tremendous progress has been made in both MMIC developments and system applications. The outstanding progress in MMIC technology is attributed to the following:

1. Rapid development of GaAs material technology, including semiinsulating wafers, epitaxial growth, and ion implantation.
2. Advanced photo- or electron-beam (e-beam) lithography technology developed for Si ICs and directly applicable to GaAs ICs.
3. Excellent microwave properties of semiinsulating GaAs substrates, which permit easy isolation of devices for high-level integration [high dielectric constant ($\epsilon_r = 12.9$) and low loss ($\tan \delta = 0.0005$)].
4. The development of low-noise MESFETs and power MESFETs operating at up to 60 GHz have provided MMIC designers with versatile active circuit components.
5. Virtually any microwave solid-state circuit. They were realized using combinations of MESFETs, dual-gate MESFETs, Schottky barrier diodes, and switching MESFETs, each of which can be fabricated simultaneously using the same or similar process. HEMT MMICs provide enhanced performance in terms of noise figure, bandwidth, and frequency range. Using HEMT monolithic technology the frequency range was extended to 180 GHz.
6. High-electron-mobility transistors (HEMTs) and heterojunction bipolar transistors (HBTs), which are, in addition to MESFETs, the other most common active devices used in MMICs.
7. The development of good models for characterizing active devices and passive components.
8. The availability of commercial CAD tools for accurate simulation and optimization of microwave circuits.
9. The availability of on-wafer high-frequency test probes that permit both low-cost MMIC screening

and the collection of a large amount of statistically significant data without the cost and variability of packaging.

10. Government funding for technology development and maturation.
11. Expanding military and commercial applications.

The MESFET, commonly referred to simply as FET, is the most mature active device and is widely used in production applications. In addition to FETs, HEMT- and HBT-based MMICs are being produced in large volumes for military and commercial applications. With MMIC technology, a typical microwave subsystem can be produced on a single chip for less than \$100, while simpler single-function chips cost less than \$10. Some very simple MMIC chips are now produced in plastic packages for less than \$1.

Whereas most MMICs currently in production operate in the 0.5–30 GHz microwave range, applications covering the millimeter-wave (mmW) spectrum from 30 to 300 GHz are increasing. Monolithic technology is particularly suited for millimeter-wave applications through the elimination of the parasitic effects of bond wires that connect discrete components in conventional hybrid microwave integrated circuits (HMICs). In MMIC-based mmW subsystems, the cost can be lowered by a factor of 10 or more as compared to hybrid solutions.

Advantages of MMICs include low cost, small size, light weight, circuit design flexibility, broadband performance, elimination of circuit tweaking, high-volume manufacturing capability, package simplification, improved reproducibility, radiation hardness, improved reliability, and multifunction performance on a single chip. Indeed, the concept of implementing a subsystem on a chip became a reality through monolithic microwave technology.

IEEE Microwave and Millimeter-Wave Monolithic Circuits Symposium Digest, published from 1982 to 1996; *IEEE RFIC Symposium Digest*, published since 1997; and *IEEE GaAs IC Symposium Digest*, published since 1980 include comprehensive information on the design, fabrication, and performance of monolithic microwave and millimeter-wave integrated circuits as well as their applications. Several other books listed [1–19] deal with this subject either partially or exclusively.

1. MMIC FABRICATION

In fabricating MMICs, all active and passive circuit elements and interconnections are formed together on the surface of a semiinsulating substrate (usually gallium arsenide). Typically MMICs use microstrip and metal-insulator-metal (MIM) capacitors for the matching networks, whereas at low microwave frequencies, lumped inductors and MIM capacitors are commonly used. Via holes, metal-filled holes from the bottom of the substrate (ground plane) to the top surface of MMICs, provide low-loss and low-inductance ground connections. Figure 1 shows a three-dimensional view of an MMIC.

There are many ways to fabricate MMICs. MMICs using MESFET and HEMT are most commonly fabricated by

Figure 1. An MMIC three-dimensional view showing MESFET, inductor, capacitor, resistor, air bridge, via hole, and a microstrip section.

a recessed-gate process, but the self-aligned gate (SAG) process is gaining popularity because it permits the efficient fabrication of devices optimized for different functions (e.g., microwave small signal, microwave power, and digital) on the same wafer at the same time. The self-aligned gate process has demonstrated superior performance uniformity in a manufacturing environment. Figure 2 shows a SAG MESFET cross section along with salient features.

In order to give the reader an understanding of the relative complexity of GaAs MMIC manufacturing, a process flowchart for the SAG process is given in Fig. 3. The process for recessed-gate MMICs has many similarities. The process includes the fabrication of active devices, resistors, capacitors, inductors, distributed matching networks, airbridges, and via holes for ground connections through the substrate. Basic process steps are similar for any MMIC technology.

It should be noted that GaAs MMIC processing is less complex than silicon processing for devices operating at the low end of the microwave spectrum. Because silicon has inherently lower frequency capability and poorer isolation properties for integration purposes, more exotic processing is required to compete in the frequency region of overlap with GaAs applicability (1–2 GHz). For example, a silicon bipolar complementary metal oxide semiconductor (BiCMOS) process for such IC applications may require 2–3 times as many mask layers, adding significantly to the cost.

1.1. Active Layers

The MMIC process starts with the formation of an active layer on or into semiinsulating GaAs substrate. There are basically two methods of forming an n-type active layer: ion implantation and epitaxy. In the ion implantation technique, the dopant Si ions bombard the GaAs substrate in an area specified by a photolithographic photoresist pattern or mask. A suitable combination of energy and dose is used for the particular FET characteristics desired. During ion implantation, the crystal lattice of GaAs is damaged, and the implanted atoms come to rest at random locations with the material. A high-temperature

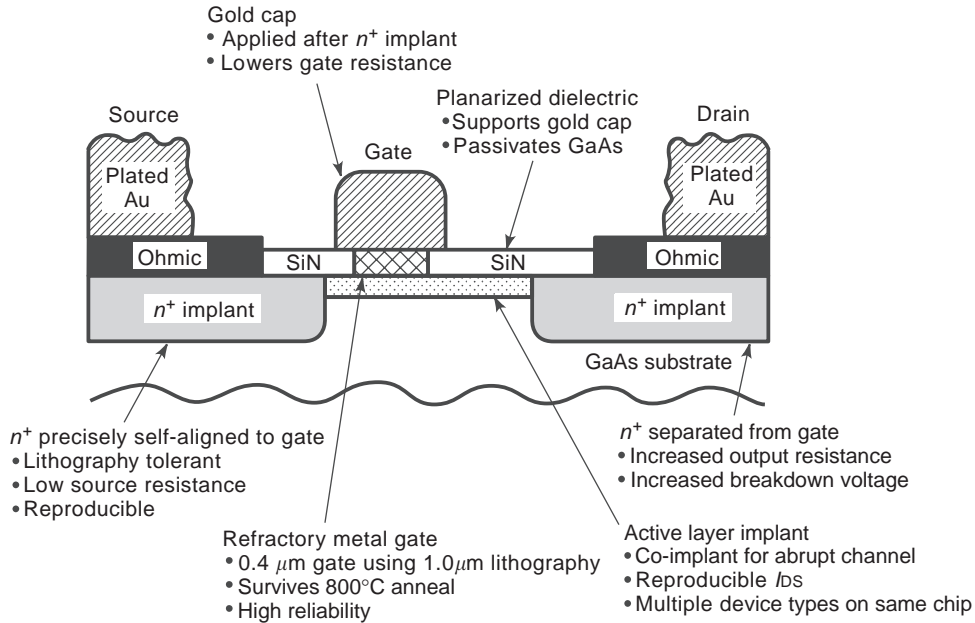

Figure 2. SAG FET cross section showing features to improve manufacturability.

($850\text{--}900^\circ\text{C}$) annealing step is performed to heal the lattice damage and allow the implanted atoms to move onto lattice sites. With this technique, different active-device types (with different active-layer properties) can be readily fabricated on the same wafer through respective selective implants defined by photoresist masks. This technique is well suited to high-volume production since the methods and equipment are nearly identical to those used in the silicon industry.

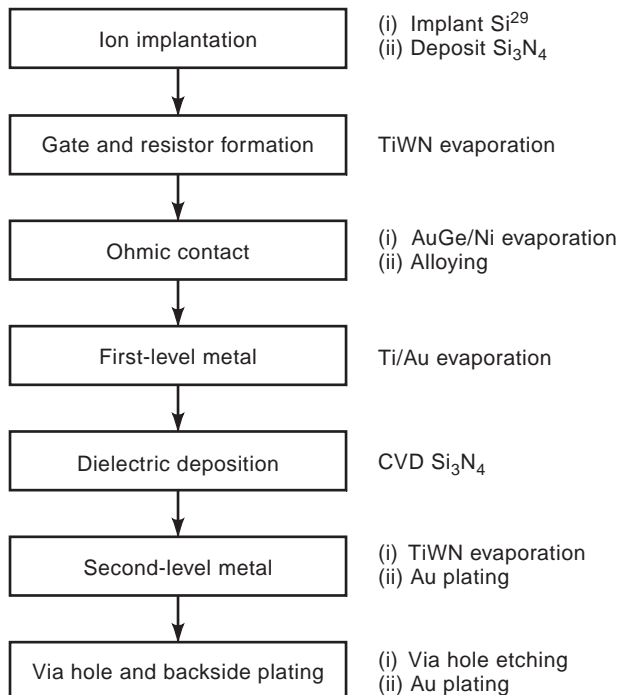

Figure 3. MMIC process flowchart for self-aligned gate process.

As discussed earlier, epitaxial devices are sometimes required for particular high-performance applications. In the epitaxial technique, additional GaAs (or other III-V compound) material layers are grown on the surface of the GaAs substrate in a manner that preserves the crystal structure. There are four basic types of epitaxy that have been used for GaAs: liquid-phase epitaxy (LPE), vapor-phase epitaxy (VPE), molecular-beam epitaxy (MBE), and metallorganic chemical vapor deposition (MOCVD). LPE is the oldest technique used to grow epitaxial layers on GaAs crystals, but it is not suitable for MMIC fabrication because of inherent surface roughness. VPE is typically used for GaAs power FETs. MBE is the most recent and powerful technique. Its advantage is that it can produce almost any epitaxial layer (III-V compound) composition, layer thickness, and doping with the highest possible accuracy and uniformity across a wafer. MOCVD has similar flexibility with the added advantage of being better suited to low-cost manufacturing; however, the material's electrical quality is not yet as good as that for MBE. The specified active areas are isolated either by mesa etching or by bombarding with ions, which increase resistivity by creating damage to the crystal lattice. A disadvantage of these techniques, relative to ion implantation, is that different device types generally require different epitaxial layers requiring not only multiple expensive growth runs but also relatively costly processing to isolate the different device types.

1.2. Schottky or Gate Formation

The quality and placement of the gate metal is critical to FET performance in both low-noise and power FETs. The choice of the gate metal is generally based on good adhesion to GaAs, electrical conductivity, and thermal stability. Recessed gate FETs utilize evaporated materials such as

TiPdAu or TiPtAu. SAG FETs [15] use a TiWN material, which forms a thermally stable, refractory Schottky gate in order to withstand the high-temperature annealing step, which is performed after the gate is in place. It is deposited by reactive sputtering.

Gate formation can be accomplished using optical lithography techniques for critical dimensions down to about 0.5 μm . Below 0.5 μm , the direct-write electron-beam lithography (EBL) method is often used. Although quite expensive because of the high cost of the equipment and relatively slow throughput, EBL provides a high degree of precision, making dimensions as small as 0.1 μm practical. The SAG technique uses lower-cost 1.0- μm optical lithography, along with a plasma underetch, to achieve 0.4 μm or smaller gate dimensions. Gate metalization is also used for thin-film resistors. Typical resistance values are about 10 Ω/square .

1.3. Ohmic Contact

Device ohmic contacts are made next. The purpose of an ohmic contact on a semiconductor material is to provide a good contact between the interconnect metal and the active channel at the semiconductor surface. The most common approach in industry to fabricate ohmic contacts on GaAs is by alloying gold and germanium (88% Au and 12% Ge by weight, with a melting point of 360°C). A thin layer of AuGe alloy, followed by a thin layer of Ni, is deposited by evaporation. The total layer thickness is about 2000 Å. The ohmic contact pads are defined by a photoresist mask and chemical liftoff of metal on the photoresist regions. The step is followed by alloying at 400°C in a hydrogen ambient.

1.4. First-Level Metal

Next a thick ($\sim 0.5\text{-}\mu\text{m}$) Ti/Au metal is overlaid on the gate by evaporation and liftoff. The metal reduces the gate resistance and also serves as a first-level metalization for MMIC fabrication (e.g., as a capacitor bottom plate or the interconnect metal under air bridges or crossovers).

1.5. Dielectric Deposition

Dielectric films are used in GaAs MMICs for passivation of active areas of FETs, diodes, and resistors; for MIM capacitors; and for crossover isolation. Silicon nitride (Si_3N_4) is commonly used as dielectric material, which is easily deposited either by plasma-assisted chemical vapor deposition or sputtering. The thickness of the dielectric film determines the capacitance per unit area of the MIM capacitor. The thickness is usually between 1000 and 3000 Å, and is optimized to have minimum pinholes, high breakdown voltage, and maximum possible capacitance. The capacitance value ranges from 240 to 1200 pF/ mm^2 with breakdown voltages from 16 V to greater than 60 V. Typical values for capacitance and breakdown voltage are 300 pF/ mm^2 and 60 V, respectively.

1.6. Second-Level Metal

Interconnection of components, airbridges, and the top plate of MIM capacitors is formed with the second-level

layer TiWN/Au metal system. In order to achieve low-resistance connections, gold plating (4.5 μm thick) is added to provide maximum current capability of about 10 mA/ μm of linewidth and a sheet resistance of less than 10 m Ω/square . Typical linewidths for microstrip line interconnects vary from 10 μm to 200 μm .

1.7. Backside Processing

Backside processing consisting of thinning by grinding or lapping, via-hole source ground contact finalization, and plating, is an important and cost-sensitive part of processing. In a production environment, a significant investment has been made in the wafer by the time the frontside processing is completed and the backside processing started. Also, several of the backside operations critically affect the circuit function and the yield as a whole. Typical functional yield for frontside processed MMICs is 90–95%, whereas for frontside- and backside-processed MMICs, yield numbers are 80–85%. After the frontside process, the wafer is thinned by a lapping technique from 600 μm to the required thickness, typically 100–125 μm for small-signal MMICs and 50–75 μm for power MMICs (to maximize heat dissipation). MMIC wafers may also be thinned down to 50–75 μm for frequencies greater than 50 GHz to minimize ground return parasitics. High-performance MMICs require low-inductance ground connections to the FET source and good thermal dissipation paths from the FET to its ground. In via-hole technology, holes are etched through GaAs substrate under each FET source connection as well as under other pads where ground connections are needed. Then the backside and the via-hole sidewalls are metallized. This provides a good connection from the frontside devices and components to the backside ground plane. This also eliminates the need for separate wire bonds to ground for each FET and other RF ground connections. The first check for a good circuit is automatic on-wafer testing with microwave probes. After identifying RF good ICs, the wafer is diced into chips.

2. MMIC SUBSTRATES

Any assessment of MMIC technology options available to the microwave designer will generally be in terms of chip size, weight, reliability, reproducibility, cost, maximum frequency of operation, and availability of a wide range of active devices for design flexibility. Various substrate materials used for MMICs are bulk silicon, silicon carbide, GaAs, InP, and GaN. Their electrical and physical properties are compared in Table 1. The semiinsulating property of the base material is crucial to providing higher device isolation and lower dielectric loss for MMICs. For example, even though bipolar silicon devices are capable of operating up to about 10 GHz, the relatively low resistivity of bulk silicon precludes monolithic integration for frequencies above the S band (2–4 GHz).

The GaAs FET as a single discrete transistor has been widely used in hybrid amplifiers (combining low noise, broadband, medium power, high power, high efficiency), mixers, multipliers, switching circuits, and gain control circuits. This wide use of GaAs FETs can be attributed to

Table 1. Comparison of Monolithic Integrated Circuit Substrates^a

Property	Silicon	SiC	GaAs	InP	GaN
Semiinsulating	No	Yes	Yes	Yes	Yes
Resistivity (Ωcm)	$10^3\text{--}10^5$	$>10^{10}$	$10^7\text{--}10^9$	$\sim 10^7$	$>10^{10}$
Dielectric constant	11.7	9.7	12.9	14	8.9

their high frequency of operation and versatility. All these benefits are automatically realized in MMICs as well. GaAs semiinsulating substrates provide isolation up to about 100 GHz. This, combined with much higher electron mobility (5–6 times that of silicon), enables GaAs MMICs to be produced for operation at up to 60 GHz. Additionally, MMICs at 94 GHz have been demonstrated using highly specialized HEMT devices epitaxially grown on semiinsulating GaAs. Hence, GaAs has been the technology of choice for most MMIC applications.

InP has been used for millimeter-wave monolithic integrated circuits using HEMTs, but very little work has been done on InP MMICs using MESFETs. The low Schottky barrier height of metals on n-type InP is a chronic impediment to the development of an InP MESFET technology of performance equivalent to that of GaAs. Pseudomorphic HEMTs fabricated on InP substrate exhibit much higher performance in terms of gain, noise figure, and power than does a GaAs-based HEMT of similar geometry. In this case, the InP substrate supports higher two-dimensional electron gas densities, resulting in high current and transconductance values. The high values of transconductance in InP HEMTs is responsible for ultralow noise figure, high gain, and high frequency of operation.

Except Si, all other substrate materials shown in Table 1 are called *compound semiconductors*. Silicon dominates the marketplace. GaAs is a distant second, with less mature technologies such as InP, SiC, and GaN only now emerging. For high-power and high-temperature applications, wide-bandgap materials with relatively high thermal conductivity, such as SiC and GaN, play a significant role. More recent advancements in the epitaxial techniques have made it possible to develop good active devices on these substrates, which is a prime requirement for any semiconductor material to be used as a substrate for MMICs.

3. TRANSMISSION LINES

The microstrip line and coplanar waveguide (CPW) are the two most commonly used transmission media in MMICs. The microstrip is more popular because of its quasi-TEM nature and excellent layout flexibility. Cross-

sectional views of these lines with physical parameters are shown in Fig. 4. Sections of microstrip lines and coplanar waveguides constitute the basic passive component building blocks of monolithic microwave integrated circuits. When the size of the microstrip section is reduced to dimensions much smaller than the wavelength, the section can be used as a lumped element. Examples of lumped microstrip elements are spiral inductors, thin-film resistors, and interdigital capacitors. Microstrip sections in lumped and distributed forms are commonly used in passive and active monolithic microwave integrated circuits.

Important parameters for designing these transmission lines are the characteristic impedance Z_0 , effective dielectric constant ϵ_{re} , attenuation constant α , discontinuity reactances, frequency dispersion, surface-wave excitation, and radiation. Several methods used to determine these parameters are summarized in Ref. 20. Basic properties such as Z_0 , ϵ_{re} , α , and maximum frequency of operation are briefly described here.

3.1. Microstrip

The microstrip propagation properties are controlled by conductor width W and substrate height h for a given dielectric constant value ($\epsilon_r = 12.9$ for GaAs). Figure 5 shows

Figure 4. Transmission lines for MMICs: (a) microstrip; (b) coplanar waveguide.

Figure 5. GaAs microstrip parameters: (a) characteristic impedance and effective dielectric constant; (b) attenuation constant measured as 1, 10, 20, and 30 GHz; substrate thickness of GaAs: 100 μm.

the variations of Z_0 , ϵ_{re} , and α . As an example, for a 50-Ω line on a GaAs substrate, the value of W/h is about 0.7.

The characteristic impedance value decreases when the strip width-to-height ratio W/h of the line increased. Wavelength in microstrip λ is related to ϵ_{re} by

$$\lambda = \frac{\lambda_0}{\sqrt{\epsilon_{re}}} \quad (1)$$

where λ_0 is the free-space wavelength.

The maximum frequency of operation of a microstrip transmission line is limited as a result of several factors including excitation of spurious modes, higher losses, pronounced discontinuity effects, low Q caused by radiation

from discontinuities, effect of dispersion on pulse distortion, tight fabrication tolerances, handling fragility, and, of course, technological processes. The frequency at which significant coupling occurs between the dominant quasi-TEM mode and the lowest-order surface-wave spurious mode is given by [20]

$$f_T = \frac{150}{\pi h} \sqrt{\frac{2}{\epsilon_r - 1}} \tan^{-1} \epsilon_r \quad (2)$$

where f_T is in gigahertz and h is in millimeters. Thus the maximum thickness of the GaAs substrate for microstrip circuits designed at 100 GHz is less than 0.3 mm.

The excitation of higher-order modes in a microstrip can be avoided by operating it below the cutoff frequency of the first higher-order mode, which is given approximately by [20]

$$f_c = \frac{300}{\sqrt{\epsilon_r}(2W + 0.8h)} \quad (3)$$

where f_c is in gigahertz and W and h are in millimeters. This limitation is applicable mostly for low-impedance lines that have wide microstrip conductors.

3.2. CPW

CPW properties are controlled by the center conductor width W and the spacing between the strip and the ground-plane conductor denoted by s in Fig. 4b. In a CPW, the substrate thickness generally used is large so that if the substrate has a conductor backing to improve the mechanical strength, it does not affect the electrical characteristics of the CPW. Figure 6 shows the variation of Z_0 , ϵ_{re} , and α as functions of the conductor width:gap separation ratio.

In addition to dielectric and ohmic losses, coupling of power to surface waves and radiation from unwanted (parasitic) modes contribute to the total loss of the coplanar lines. The parasitic mode in a coplanar waveguide is the odd mode with antiphase voltages in the two slots. This mode can be excited at discontinuities, and radiation may occur. Radiation from this mode can be minimized by maintaining symmetry of the circuits and thus avoiding its excitation or by using airbridges at regular intervals to short-circuit it out. In a conductor-backed coplanar waveguide, the parallel-plate waveguide modes are other parasitic modes. Surface waves or the substrate modes are the TM and TE modes supported by the substrate. Excitation of these modes can be avoided if a thin substrate is used such that the cutoff frequency of the surface modes is pushed above the operating frequency. This is achieved if the substrate thickness h is chosen such that

$$h \leq \frac{0.12\lambda_0}{\sqrt{\epsilon_r}} \quad (4)$$

where λ_0 and ϵ_r are respectively the free-space wavelength and dielectric constant of the substrate.

(a)

(b)

Figure 6. GaAs coplanar waveguide parameters: (a) characteristic impedance and effective dielectric constant; (b) attenuation constant.

CPW MMICs, compared with microstrip-based MMICs, can have lower loss at millimeter-wave frequencies by properly designing matching networks, require no via-hole technology for RF ground connections, and are more suitable for flip-chip mounting.

4. MMIC ACTIVE DEVICES

Since the first reported GaAs MMIC, the MESFET and the Schottky diode have been the workhorses for analog

integrated circuits (ICs). MESFET technology commonly uses $0.25\text{--}1.0\ \mu\text{m}$ gate lengths for microwave applications. MESFET low-noise and power MMICs demonstrate excellent performance at microwave frequencies. At the lower end of the microwave spectrum for new emerging wireless applications, GaAs FETs are more suitable, compared with bipolar transistors, because of their high-gain, low-noise figure and high power with good efficiency, excellent switching characteristics, and low-battery voltage (3–6 V) operation. However, increasing emphasis is being placed on new devices for better-performance and

higher-frequency operation. HEMT and HBT devices offer potential advantages in microwave and millimeter-wave IC applications, arising from the use of heterojunctions to improve charge transport properties (as in HEMTs) or p-n junction injection characteristics (as in HBTs). HEMTs appear to have a niche in ultra-low-noise and high-frequency (mmW) applications. The MMICs produced using novel structures such as pseudomorphic, lattice-matched HEMTs, also known as PHEMTs, have significantly improved the noise performance and high-frequency (up to 180 GHz) operation. PHEMTs that use multiple epitaxial III-V compound layers have shown excellent millimeter-

wave power performance from Ku through W bands. AlGaIn/GaN HEMT devices have demonstrated power densities greater than 5 times higher than that of conventional GaAs-based transistors [21,22]. HBTs are vertically oriented heterostructure devices and are gaining popularity as power devices. GaAs HBTs are extensively used as power devices for high-volume wireless applications because of their high gain, good efficiency, and single power supply low-voltage operation. They also offer better linearity and lower phase noise than do FETs and HEMTs. A cross-sectional view of the three basic device types (MESFET, HEMT, and HBT) is shown in Fig. 7. In a PHEMT

Figure 7. Schematic cross section of (a) MESFET, (b) HEMT, and (c) HBT.

structure there is another InGaAs active layer between the AlGaAs spacer and GaAs buffer that provides better carrier concentration in the channel than does a conventional HEMT structure.

MESFETs, HEMTs, and HBTs have been used to develop state-of-the-art circuit functions. GaAs-based MESFET, HEMT, and HBT devices are quite mature and versatile. These devices can be used for low-noise, switching, mixing, and power amplification depending on application requirements. For power circuits, where one needs much higher current, either a large number of cells are employed or larger gate periphery devices are used. Nearly all microwave circuit functions have now been realized as MMICs. Many of these functions have been demonstrated over the entire 1–100 GHz frequency range. Furthermore, many of these functions have been combined on a single chip to form portions of a microwave system. Examples of such single- and multifunction ICs are described in Section 9.

The upper frequency limit of MMICs is generally dictated by the active devices used. The performance of microwave transistors in MMIC technologies is improving every year. The performance of these devices (FETs, HEMTs, and HBTs) depends on the substrate material, process type, and channel physical dimensions. A commonly used figure of merit for devices is known as the *maximum frequency of oscillation* and denoted by f_{\max} . Generally, for amplifiers the maximum frequency of operation is about half of f_{\max} . For FETs on a GaAs substrate, a simplified expression for f_{\max} is given by [23]

$$f_{\max} = 38.05L^{-0.953} \quad (5)$$

where L is the gate length in micrometers. Thus, for FETs having gate length of 0.25 μm , the f_{\max} value is about 140 GHz. As reported in the literature, the f_{\max} values for a 0.1- μm -gate-length PHEMT on an InP substrate is about 600 GHz, and for a 1- μm emitter HBT it is about 170 GHz. A three-stage amplifier fabricated using a 0.1- μm PHEMT on an InP substrate has exhibited about 12 dB gain at 153–155 GHz [24].

5. COMPONENTS AND CIRCUITS

Monolithic microwave integrated circuits consist of passive components and active devices fabricated simultaneously on a semiinsulating substrate. Passive components can be divided into lumped and distributed categories, where “lumped” refers to components that are small with respect to the operating wavelength and “distributed” describes elements with sizes being comparable to the wavelength. Generally, monolithic design requires both lumped and distributed elements depending on its size, frequency of operation, types of circuit function, and cost. Examples of lumped elements [19,25], as shown in Fig. 8, are spiral inductors, thin-film resistors, interdigital capacitors, MIM capacitors, via holes, and airbridges. Distributed elements are commonly realized using sections of a microstrip transmission line or a coplanar waveguide. Lumped elements such as spiral inductors are usable in the microwave

frequency range where the size and bandwidth are critical parameters. Distributed elements are preferred in applications where lower loss and higher power-handling capability are important. However, thin-film resistors, capacitors, airbridges, and via holes are used in almost all microwave and millimeter-wave monolithic integrated circuits. The lumped elements have a lower Q than do the distributed elements, but they have the advantage of smaller size, ability of large impedance transformations, and wideband characteristics compared with distributed elements.

MMIC passive components include filters, impedance transformers, hybrids, couplers, power dividers/combiners, delay lines, and baluns. The design of such components has been thoroughly discussed in Refs. 8, 9, and 26–30. In order to predict the performance of microstrip passive components, the effect of junction and layout discontinuities and interaction effects between circuit elements caused by close proximity is usually included in the circuit analysis, with the help of electromagnetic (EM) field simulators. Figure 9 shows commonly used MMIC passive components.

In active MMIC components and subsystems, all interconnections are made along with active/passive devices on the semiinsulating semiconductor substrate, thereby eliminating discrete components and wire bond interconnects. MMIC active components use two types of devices: two-terminal devices referred to as *diodes*, such as Schottky and pin, and three-terminal devices, such as MESFET, HEMT, and HBT. Microwave circuits that use these devices include amplifiers, oscillators, multipliers, mixers, switches, phase shifters, attenuators, modulators, limiters, and many others used for receiver or transmitter applications covering microwave and millimeter-wave frequency bands. The theory and performance of most of these circuits have been well documented [1–18,31–34]. Figure 10 shows a physical layout of a broadband driver amplifier using FETs, microstrip lines, inductors, resistors, capacitors, via holes, and airbridges. Table 2 summarizes some of the key milestones in MMIC development [35]. This list is by no means exhaustive. Several examples of active circuits using various MMIC technologies are described in Section 9.

6. MMIC DESIGN

The design of MMICs requires state-of-the-art computer-aided design (CAD) tools. The need for increased design sophistication arises from the fact that the postfabrication tuning flexibility available in conventional hybrid microwave circuits is no longer present in the monolithically fabricated circuits. Consequently, a new design methodology is required. This includes development of accurately characterized standard library cells as well as subcircuits, accurate models for linear and nonlinear active devices, accurate passive component models, use of circuit topology and circuit elements that are more tolerant to process variations, tolerance centering of designs, proximity effect models, comprehensive simulation of complete circuits, and automatic RF testing of ICs on wafer. The latter is

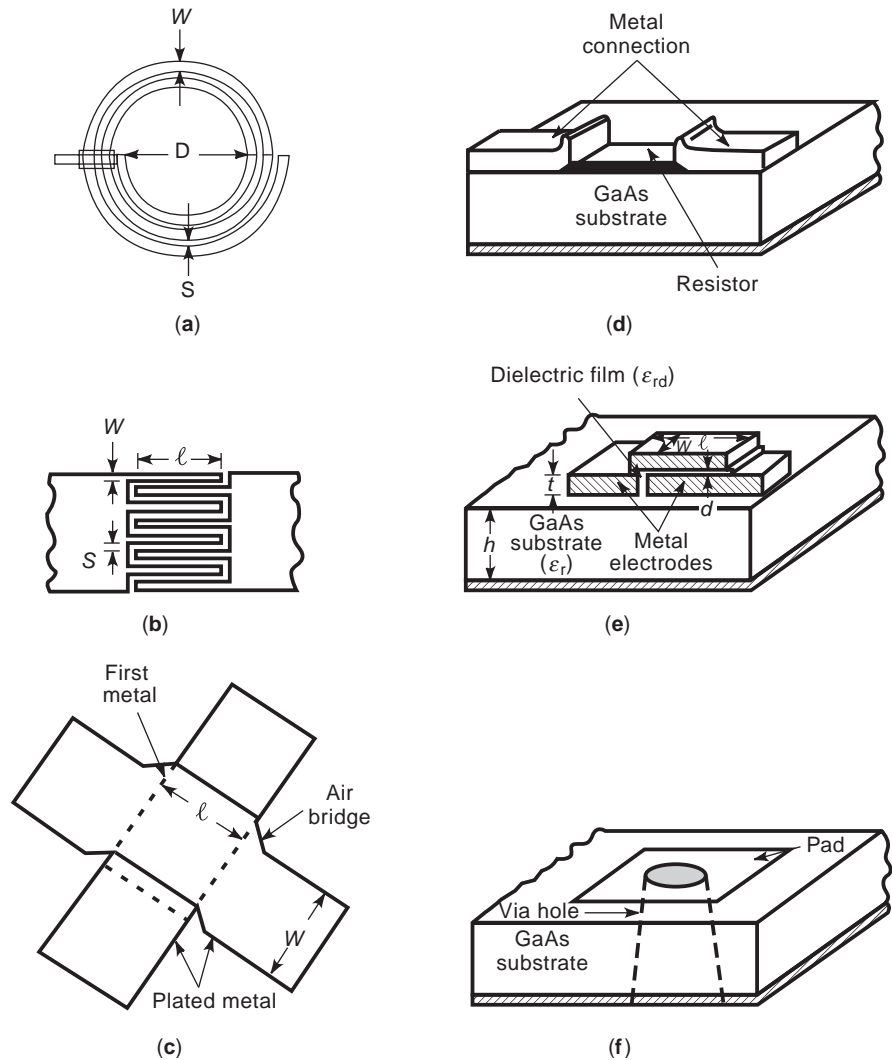

Figure 8. MMIC circuits use passive lumped elements: (a) spiral inductor; (b) interdigital capacitor; (c) airbridge crossover; (d) thin-film resistor; (e) MIM capacitor; (f) via hole.

needed in order to obtain sufficient statistical characterization data without having to do expensive mounting or packaging.

Figure 11 shows [36] a comprehensive CAD tool consisting of device, circuit, system simulators, and their accurate models (including physics-based and electromagnetic), and statistical design feature. Several microwave CAD tools are available to designers, including Agilent's ADS, Ansoft's Ansoft Designer, and Applied Wave Research's Microwave Office. A workstation-based MMIC CAD tool [37] is conceptually shown in Fig. 12. This interactive system will provide efficient coupling between the circuit simulation, the schematic captive/text editor, and the layout generator, greatly improving overall accuracy and reducing design cycle time. With such a system, first-pass design success for simple microwave functions should be achievable.

The evolution of a typical small-signal MMIC design generally follows the flow diagram depicted in Fig. 13. The design starts with the circuit specifications, which derive from the system requirements. System requirements also dictate the circuit topology along with the types of passive elements and active devices to be used (e.g., distributed or

lumped passive elements, single- or dual-gate FETs, and low-noise or power FETs). Comprehensive passive-element and active-device models developed by foundry or by users are used to simulate circuit functions. The final design is completed by taking into account layout discontinuities, interaction between the components, stability analysis in case of amplifiers, and circuit yield analysis by considering process variations. In the case of nonlinear circuit design, (e.g., power amplifier, oscillator, or mixer) an accurate nonlinear model for each device used is essential in order to design the circuit accurately.

7. EM SIMULATORS

The main contribution of electromagnetic (EM) simulators to MMIC CAD tools has been in the area of accurate modeling of passive circuit elements and components. These simulators are commonly used to model circuit elements such as microstrip and coplanar waveguide structures, discontinuities, and coupling between transmission-line sections and discontinuities, structures using multilayer dielectric and plating, inductors, capacitors, via holes, and

Figure 9. Typical MMIC passive components: (a) Lange coupler; (b) Wilkinson divider; (c) spiral Marchand balun.

crossovers. Passive components, such as filters, couplers, resonators, power dividers/combiners, baluns, matching impedance transformers, and several types of interconnects and packages, are accurately simulated using EM simulators. Accurate characterization of active-device parasitics also requires EM simulation. Another key and important role of EM simulators in successful MMIC design is the capability of incorporation of parasitic coupling effects among various parts of the circuit layout. Accurate evaluation of radiation and surface waves can be performed using simulators only. These effects become increasingly important as MMIC designs become more compact and are not easily incorporated using conventional

network-theory-based CAD tools. However, due to very large computation time, only a small portion of a circuit is analyzed using EM simulators, and the numerical results are combined with conventional CAD tools to obtain the response of the complete circuit. Most EM simulators work in the integrated simulation environment (i.e., they can be interfaced with microwave computer-aided design and engineering tools). Since the early 1990s, outstanding progress made on personal computers and workstations lead to commercial EM simulators.

7.1. Electromagnetic Simulation Methods

Several different field simulation methods have been used and described in the literature [38,39]. The most commonly used technique for planar structures is the method of moments (MoM), and for three-dimensional structures, the finite-element method (FEM) is usually used. Both these techniques perform EM analysis in the frequency domain. FEM, as compared to MoM, can analyze more complex structures but requires much more memory and longer computation time. There are several time-domain analysis techniques; among them, the transmission-line matrix (TLM) method and finite-difference time-domain (FDTD) method are commonly used. Fast Fourier transformation is used to convert time-domain data into frequency-domain results. An overview of commercially available EM simulators is given in Table 3. Here “planar” structure refers to 2D or 2.5D and “arbitrary” structure refers to full 3D configurations. More comprehensive information on these tools can be found in mid-late 1990s publications [40–42].

In EM simulators, Maxwell’s equations are solved in terms of electric and magnetic fields or current densities, which are in the form of integral-differential equations, by applying boundary conditions. When the structure is analyzed and laid out, the input ports are excited by known sources (fields or currents), and the EM simulator solves numerically the integral-differential equations to determine unknown fields or induced current densities. The numerical method involves discretizing (meshing) the space for evaluation of unknown fields or currents. Using FEMs, six field components (three electric and three magnetic) in an enclosed 3D space are determined, while MoMs results in current distribution on the surface of metallic structures.

7.2. Application to MMIC Design

All EM simulators are designed to solve arbitrarily shaped strip conductor structures and provide simulated data in single- or multiport S parameters, which can be read in a circuit simulator. To perform an EM simulation, the structure to be simulated is defined in terms of dielectric and metal layers, and their thicknesses and material properties. After creating the complete circuit/structure, the ports are defined, and the layout file is saved as an input file for EM simulations. Then an EM simulation engine is used to perform electromagnetic analysis. After the simulation is complete, the field or current information is converted into S parameters and saved for use with other CAD tools.

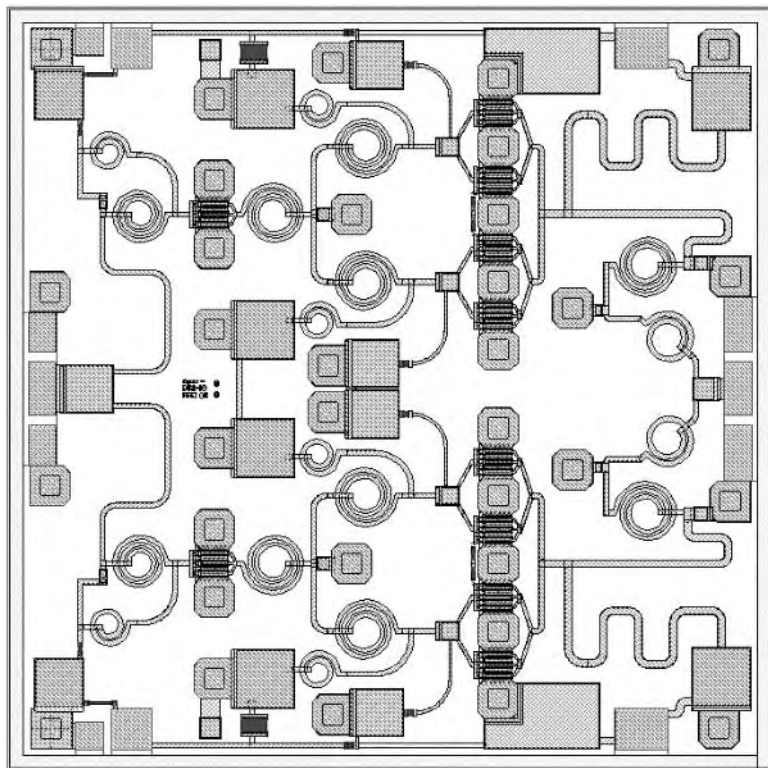

Figure 10. Physical layout of an MMIC amplifier using ten FETs, capacitors, resistors, inductors, microstrip as matching elements, and several vias.

EM simulators, although widely used, still cannot handle complex designs. There is considerable emphasis on achieving first-pass success of single- and multifunction MMICs in order to keep the MMIC development cycle time and cost low. Thus, microwave circuits should not only perform as individual components but also work as designed in the subsystem environment (e.g., T/R chip). This mandates comprehensive simulation of the complete chain including parasitic coupling effects between the closely spaced matching networks belonging to different microwave circuits. Although the advent of EM simulators has enhanced the accuracy of individual circuit functions, they are seldom used to perform comprehensive simulation of the complex MMIC chips such as T/R chips because of their large circuit size and very large CPU time. Thus, next-generation EM simulators are required to characterize compact and multilayer MMICs, highly integrated MMICs, multichip assemblies (MCAs), and for greater use of parallel computation and better integration with the circuit simulator so that they can become part of optimization. Advances in the numerical methods, computation speed, multiprocessor computations, and optimization techniques will set the course for EM simulators to become the microwave CAD tools of choice.

8. MODELING

The development of integrated CAD tools and accurate and comprehensive models for passive circuit elements and active devices was major activity during the 1980s and 1990s. Both play a key role in the successful development of MMICs. Passive circuit elements that have linear

models (independent of bias conditions and input power) include resistors, inductors, capacitors, via holes, airbridges/crossovers, transmission lines, discontinuities, and interaction effects. Active devices consist of diodes, and transistors (single- and dual-gate FETs and HEMTs, and HBTs). Transistors are of low noise, switching, and power types. Active devices use both linear and nonlinear (bias and input power-dependant) models. Figure 14 illustrates an attempt to summarize the current models for active devices and passive circuit elements. More comprehensive information on modeling can be found in several books [11,19,23,43] and other publications [44–47].

Basically there are three types of models:

1. Physics/EM-theory-based models
2. Analytical or hybrid models
3. Measurement-based models

These models are briefly described next.

8.1. Physics/Electromagnetic-Theory-Based Models

Development of accurate physics-based models for active devices that are derived in terms of doping profile and physical geometry are essential for establishing the link between the process and RF performance and for designing MMICs. These models consist of two parts: intrinsic and extrinsic. The intrinsic part deals with the active channel of the device, whereas the extrinsic part represents device pad/electrode parasitics, which are expressed in resistances, inductances, and capacitances. The intrinsic part of the model, the heart of the device, is obtained by

^aSiC substrate.

solving device equations using appropriate boundary and bias conditions in the device channel (e.g., under the gate between the gate, source and drain electrodes). The semiconductor device equations are derived from the Boltzmann transport equation coupled to the solution of the Poisson equation. These equations, which are of partial-differential type and describe carrier transport properties

of the device, are solved numerically by using such techniques as finite differences or finite elements. The physical models also include device interface phenomena, quantum effects, effects of temperature and heterostructures, low-noise and high-field phenomena, electromagnetic interaction effects between electrodes, and many other effects. These models are of general nature but quite complex.

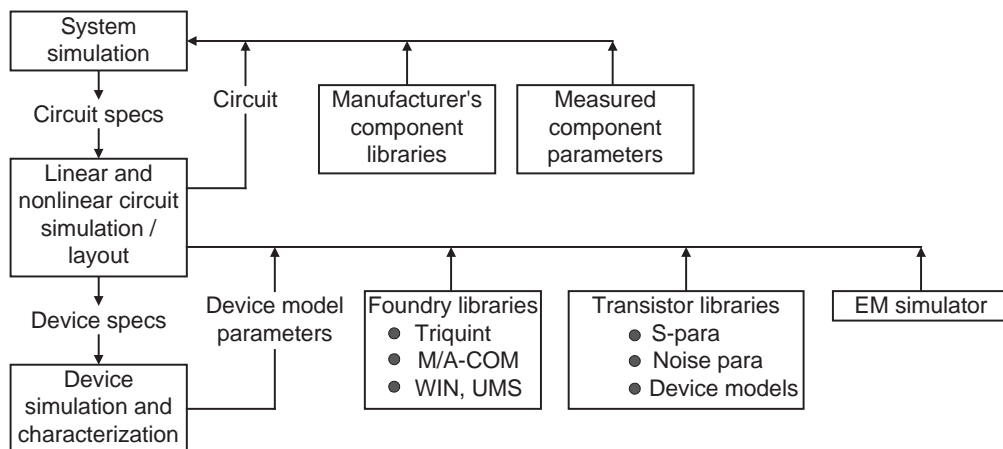

Figure 11. MMIC design system.

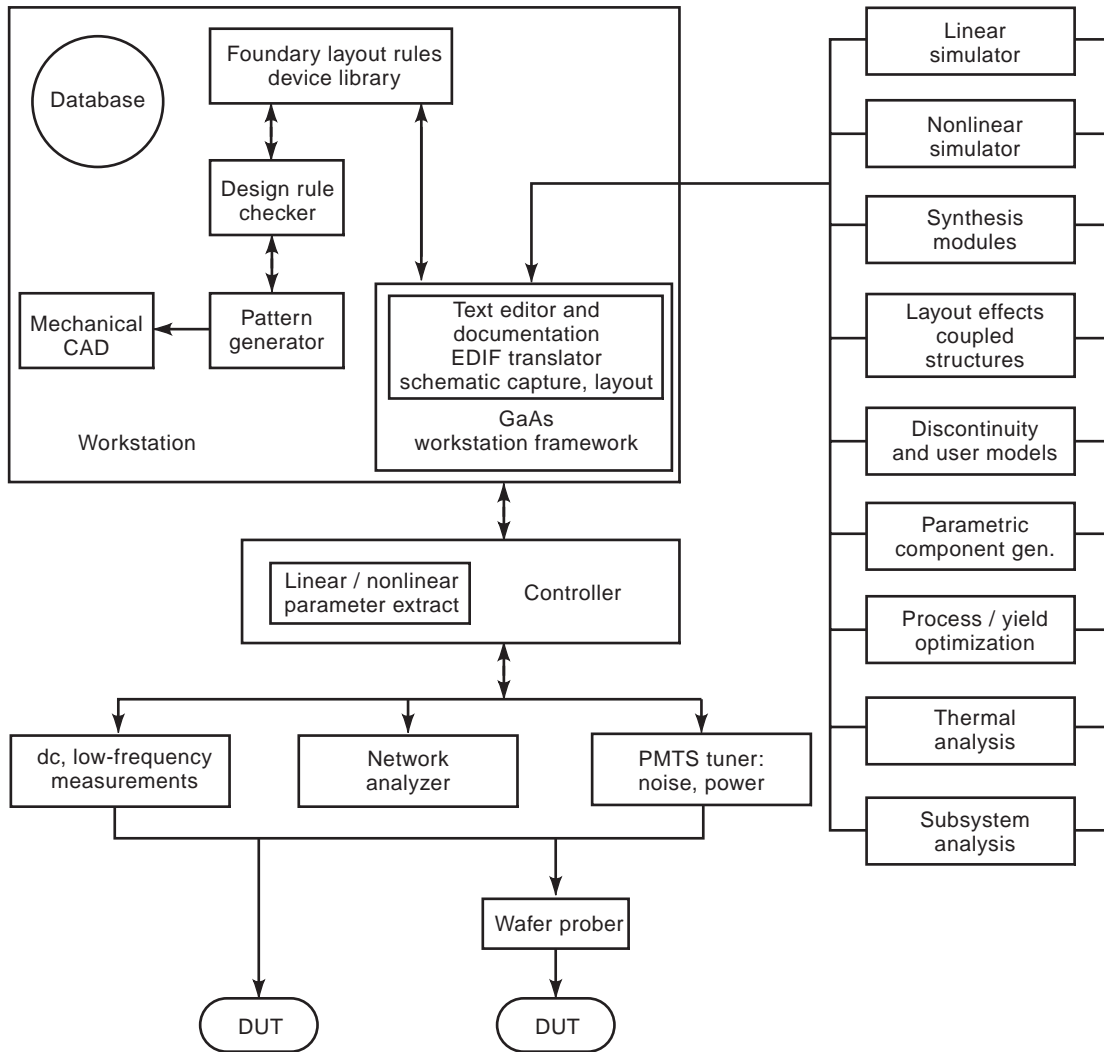

Figure 12. Next-generation MMIC workstation concept.

They include accurate parasitics and bias temperature and frequency dependence and can be used in time and frequency domains. The physical models are very useful for investigating the physical operation of active devices, predicting device performance as a function of process, material, and geometry. Thus, the device model helps in device studies, process control, and circuit yield and optimization. Any adjustment in the device can be achieved using the physics band model without costly fabrication experiments.

Because of lengthy execution times (physics-based analysis time increases rapidly with model complexity), the application of physical models is usually limited to device studies. Models are available for FETs, HEMTs and HBTs. Given sufficient computer resources, these models can become an integral part of microwave CAD tools.

8.2. Analytical or Hybrid Models

Analytical or hybrid models for passive-circuit elements and active devices are based on simple equivalent-circuit (EC) representation. Formulation of the model parameters

is based on simple equations whose values are obtained from the physics of the component, or DC or RF or both measurements. The analytical models fall between physics- and measurement-based techniques. Transmission lines and their discontinuities and nonlinear devices are generally represented by analytical models.

8.3. Measurement-Based Models

The most commonly used method of developing models for passive lumped elements and active devices is measurement of their DC characteristics and S parameters. This modeling approach gives quick and accurate results, although they are generally limited to just the devices measured. The component is represented by an equivalent-circuit model whose parameter values are extracted by computer correlation to the measured DC and S -parameter data.

The accuracy of the measurement-based models depends on the accuracy of the measurement systems, the calibration techniques, and the calibration standards. On-wafer measurements using high-frequency probes provide

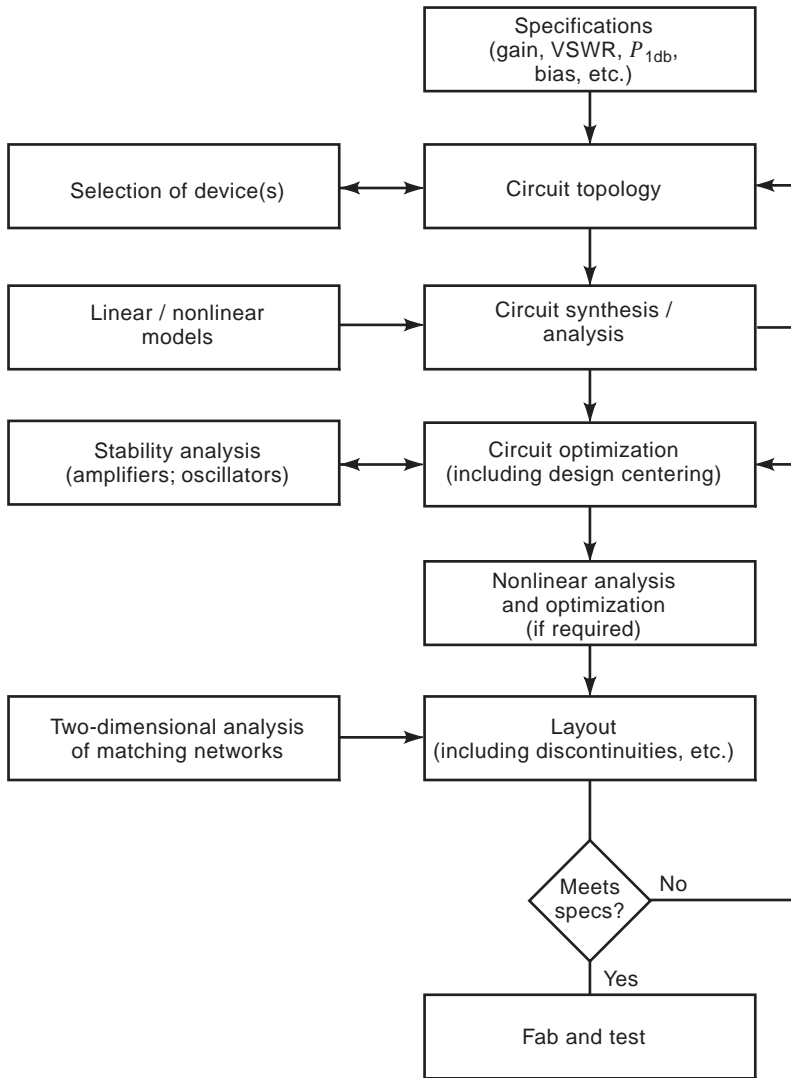

Figure 13. Typical flowchart for a MMIC design.

accurate, quick nondestructive, and repeatable results up to millimeter-wave frequencies. Various vector network analyzer calibration techniques are being used to determine a two-port error model that deembeds the device *S* parameters. The conventional short (circuit), open (circuit), load, and through (also termed *thru*) (SOLT)

calibration technique has proved unsatisfactory because the open and short reference planes cannot be precisely defined. The reference plane uncertainties for perfect short limit the accuracy of this technique. The line reflect match (LRM) calibration technique requires a perfect match on each port. The thru reflect line (TRL) calibration method is

based on the transmission-line calibration standards, which include non-zero-length thru and a reflect (open or short circuit) and delay-line standards (one or more dictated by the frequency range over which the calibration is performed). The advantage of TRL calibration lies in simple standards that can be placed on the same substrate as the components, ensuring a common transmission medium. This calibration technique accurately locates the reference planes and minimizes radiative crosstalk effects between the two probes because they are sufficiently far apart during the calibration procedure.

Measurement-based models fall into two groups: linear (passive-circuit elements and active devices for linear operation) and nonlinear (active devices for nonlinear operation such as mixing, power amplification, multiplication, and oscillation). In current measurement-based linear modeling, the components are electrically characterized

by measuring DC and RF parameters. A lumped-element equivalent-circuit model for each component that describes its frequency-dependent electrical characteristics is chosen. The lumped-element model parameter values are extracted by computer optimization to replicate the measured S parameters. Noise characterization of active devices is obtained by measuring on-wafer S parameters and noise parameters. The switching devices are modeled by two lumped-element equivalent-circuit models: one for when the device is in ON state (low-impedance state) and the second one for when the device is in OFF state (high-impedance state). The model parameter extraction is generally based on statistical data with average and standard deviation values that will help in centering designs for high yield.

As an example, an equivalent-circuit (EC) model for an inductor along with its physical layout is shown in Fig. 15.

Parameters	Units	1-511	2-511	3-511

Figure 15. Physical layout and the equivalent-circuit model of spiral inductors (1.5, 2.5, and 3.5 turns).

This figure also includes model parameter values for three different inductors. An EC model for a MESFET is shown in Fig. 16a, and its parameter values are shown in Fig. 16b. This model describes basic linear operation of an FET, and the model reproduces the small-signal RF terminal characteristics of the device with good accuracy. The model is widely used to extrapolate *S* parameters to frequencies for which experimental data are not available and can be scaled to different sizes of the same device. The main disadvantages of the equivalent-circuit model are difficulty in scaling to different physical structures, limitation to single-bias condition, frequency independence of circuit elements, no time dependence feature, and the inherent limitation to linear circuits.

Many nonlinear equivalent-circuit models have been reported in the literature. All these models have the same basic configuration as shown in Fig. 16a and generate similar common-source DC or pulsed *I-V* curves that are in qualitative agreement with experimental data. Significant differences occur, however, in the quantitative behavior of the models, in comparison to both each other and experimental data. The differences in the various models are the expressions used to characterize the drain current generator and gate-source and the gate-drain

capacitances. Some of the most commonly mentioned models are Curtice, Curtice-Ettenberg, Stratz, Materka, and TOM [48-50].

The measurement-based models need to include terminal voltage-dependent equivalent-circuit elements such as I_{ds} (g_m, R_{ds}), C_{gs} , and C_{gd} as shown in Fig. 16 to accurately predict the nonlinear behavior of the active device.

Commonly used representation of the nonlinear MESFET model is given by

$$I_{ds} = (A_0 + A_1 V_1 + A_2 V_1^2 + A_3 V_1^3) \tanh(\alpha V_{ds}) \quad (6)$$

where

$$V_1 = V_{gs}[1 + \beta(V_{ds0} - V_{ds})] \quad (7a)$$

and

$$C_{gs} = C_{gs0} \cdot f(V_{gs}, V_{gd}) \quad (7b)$$

$$C_{gd} = C_{gd0} \cdot g(V_{gs}, V_{gd}) \quad (7c)$$

Here V_{gs} , V_{gd} , and V_{ds} are the terminal voltages between gate-source, gate-drain, and drain-source of the device,

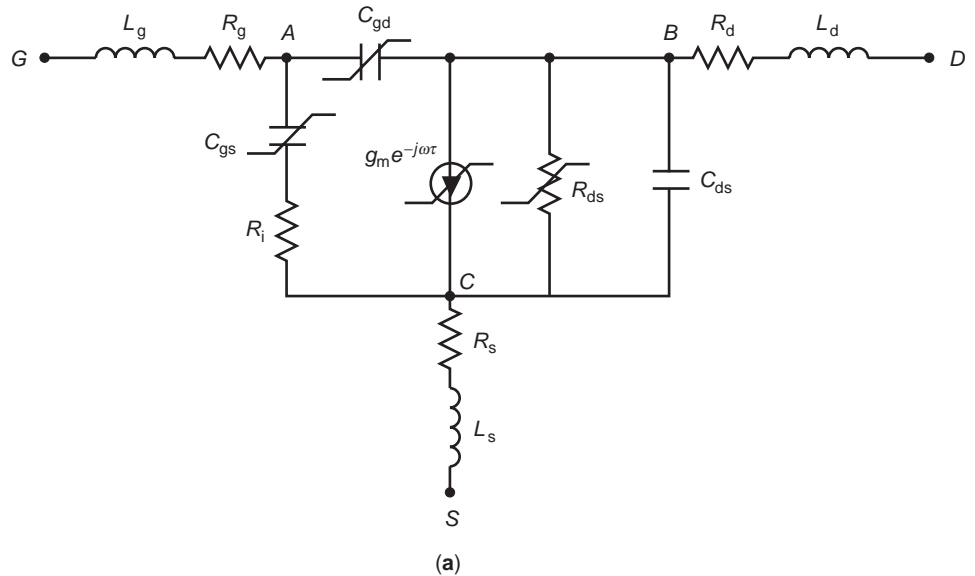

Figure 16. FET's small-signal equivalent-circuit model and typical model values for a 300- μm power FET biased at $V_{ds} = 2.5\text{ V}$, $I_{ds} = 50\% I_{ds0}$. Variable elements: C_{gs} , C_{gd} , g_m , and R_{ds} are strong functions of bias conditions.

(b)

respectively. The source of the FET is normally grounded. The A_i coefficients and constants α , β , and V_{ds0} are evaluated using measured DC or pulsed I - V data. The quantities C_{gs0} and C_{gd0} are extracted from the measured S parameter at the operating DC bias conditions, whereas f and g , which are functions of both V_{gs} and V_{gd} , are determined from measured S parameters over a large range of DC bias conditions to cover the full range of device operation.

Basically there are three steps in the development of nonlinear equivalent circuit models.

1. Extract coefficients for I_{ds} to match with measured I - V data. Important data are near the knee of the curves and break down near pinchoff.
2. Measure S parameters, extract small-signal model values, and derive coefficients for gate-source and gate-drain capacitances to describe its dependence on gate and drain voltages.
3. Validate model by comparing measured and simulated data with 50 input and output for P_{1dB} compression point and power levels for other harmonics. Simulations are generally carried out using harmonic balance analysis.

The main advantage of the equivalent-circuit models is the ease with which they can be integrated into radiofrequency (RF) circuit simulators. For linear operation (i.e., small-signal) the interface is direct because the entire device and circuit model are simulated in the frequency domain. For nonlinear applications, the device models are formulated in the time domain and are interfaced with the frequency-domain linear circuit simulators by means of the harmonic balance method (HBM). The RF performance obtained from these simulators can be satisfactory to good for a well-defined circuit, especially for mildly nonlinear applications such as a class A power amplifier not operating in hard saturation. The large-signal equivalent-circuit models generally do not scale well with varying operational conditions such as frequency or bias. As the circuit becomes increasingly nonlinear, simulator performance degrades.

The main disadvantage of the equivalent-circuit models is inherent inaccuracy resulting from simplifications in the model formulation, such as neglect of domain capacitance and the interdependencies of the nonlinear elements. In an actual device, all nonlinear elements are interdependent. For example, in a MESFET, it is not possible to change the device transconductance without also changing elements such as the gate-source capacitance. Perhaps the most significant limitation of the equivalent-circuit models, however, is the need to experimentally characterize the devices that are to be used. The devices must be designed, fabricated, and characterized before the CAD models can be defined. A change in any design parameter (such as gate width or channel impurity concentration) requires an almost complete recharacterization because scaling techniques are difficult to apply. This limits the designer's flexibility in obtaining optimum-performance integrated circuits where tailoring the device design for special applications would be desirable.

9. TYPICAL CIRCUITS AND PERFORMANCE

Since the early 1980s, tremendous progress has been made in amplifiers, including low noise, power, transimpedance, logarithmic, and limiting and variable gain. In addition to these amplifiers, control circuits, mixers, oscillators, and multifunction integrated circuits (MFICs) also have advanced the state of the art in microwave technology. Because this technology is growing rapidly, new examples of its application are constantly appearing. No attempt to include an exhaustive sampling is made; instead, a selection of circuits that have been developed for various applications will be described so that the diversity of the MMIC technology may be illustrated. Circuits chosen for exposition include low-noise amplifiers (LNAs), limiter/LNAs, power amplifiers, oscillators, mixers, phase shifters, and integrated multifunction circuits.

9.1. Low-Noise Amplifiers

A low-noise amplifier at a receiver front end sets the system noise figure. Narrowband and broadband LNAs are required depending on the system application. Table 4

Table 4. Best Reported InP HEMT MMIC LNA Results

Frequency (GHz)	Number of Stages	Minimum NF (dB)	Gain (dB)	NF over Band (dB)	Year Reported
2.3–2.5	3	0.4	35	0.5 maximum	1993
7–11	2	1.0	21	1.2 maximum	1993
19–22	3	1.1	38	1.2 maximum	1995

92–96	3	3.3	20	4.4 maximum	1995
120–124	2	–	11	–	1994
142	2	–	9	–	1995

Figure 17. A three-stage 75–110-GHz PHEMT MMIC low-noise amplifier. Chip size is 5 mm^2 . (Reprinted with permission from P. M. Smith and IEEE © 1996.)

compares the state of the art in narrowband MMIC multistage LNAs developed using PHEMTs [51]. Noise figures of about 1 and 3.3 dB have been achieved at 10 and 94 GHz, respectively. A three-stage 75–110-GHz MMIC amplifier is shown in Fig. 17. For this chip, the best noise figure measured was 3.3 dB at the W band.

9.2. Limiter/LNA

Due to fine geometry used in MMIC transistors, these circuits are susceptible to damage from high-power spurious EM radiation. To protect the front-end receiver and maintain low noise figure, a high-power and low-loss limiter in front of an LNA is required. A novel high-power limiter/LNA that can handle greater than 10 W CW power at X band was developed [52] (see Fig. 18). The limiter/LNA design is a balanced configuration using Lange couplers with a Schottky diode limiter circuit followed by a two-stage LNA. High power termination resistor is also included on the chip. Typical measured performance shows gain greater than 14 dB, $\text{NF} < 2.7 \text{ dB}$, return loss better

than 20 dB, and output third-order intercept greater than 28 dBm over the 8.3–12 GHz frequency range.

9.3. Power Amplifiers

In comparison with power tubes, microwave power solid-state amplifiers are compact in size, lightweight, low-cost, more reproducible, and more efficient and reliable, and they operate at lower supply voltages. These amplifiers are used in transmitters and require much shorter warm-up time. Furthermore, no adjustment in the bias is required over long periods of operation. The performance of MESFET, PHEMT, and HBT amplifiers is constantly improving in terms of output power, power-added efficiency, linearity, and frequency. Microwave power amplifiers using monolithic technology look attractive for realizing tens of watts of power; these chips can be combined further using standard hybrid MIC techniques to obtain much higher power levels. High-efficiency operation of these circuits is becoming one of the most important factors for enhancing battery operating life in commercial communication applications and for reducing prime power and cooling requirements for advanced microwave and millimeter-wave systems. These characteristics are particularly useful for space and military applications where weight, size, and power-added efficiency requirements can impose severe limitations on the choice of components and systems. Figure 19 depicts [53] power performance for single-chip MMIC amplifiers at microwave and millimeter-wave frequencies, and a photograph of a 15 W amplifier chip using MESFET technology is shown in Fig. 20. This C-band amplifier achieved over 60% power-added efficiency [54].

9.4. Voltage-Controlled Oscillators and Mixers

Voltage-controlled oscillators (VCOs) and mixers are integral parts of receivers. Figure 21 shows a 28-GHz VCO developed using HBT technology [55]. Output power up to -5 dBm and tuning range up to 20% were achieved for this chip. Figure 22 shows a VCO mixer, which works as

Figure 18. X-band 10-W limiter/LNA; chip size is 14 mm^2 . (Photograph courtesy of M/A-COM.)

Figure 19. Performance status of single-chip power MMIC amplifiers using MESFET, HFET, HEMT, and HBT technologies. HFET: heterojunction FET.

an upconverter developed using GaAs HEMT-HBT IC technology [56]. The compact MMIC area is only 1 mm^2 . The VCO used HBT and provided 0 dBm output power over 28.5–29.3 GHz, whereas the active mixer used HEMT and achieved 6–9 dB conversion loss over a 31–39 GHz output frequency range.

9.5. Phase Shifter

One of the important elements in the TR module is the programmable multibit phase shifter. The scanning of the beam in phased-array radars is achieved by changing

Figure 20. A C-band MESFET 15 W power MMIC amplifier. Chip size is 24 mm^2 . (Photograph courtesy of ITT Industries.)

Figure 21. A 28-GHz HBT MMIC voltage-controlled oscillator. Chip size is 1 mm^2 . (Reprinted with permission from H. Blanck and IEEE © 1994.)

the phase of the RF signal fed to or received from each radiating element. For beamsteering, programmable bidirectional phase shifters are required to adaptively adjust transceiver phase in both the transmit and the receive modes. Figure 23 shows an X-band 6-bit digital phase shifter consisting of switching FETs and lowpass and highpass lumped-element networks. The phase shifter comprises 5.6° , 11.25° , 22.5° , 45° , 90° , and 180° bits cascaded in a linear arrangement. Typical measured insertion loss is 10 dB, VSWR is better than 2:1, RMS phase error is better than 6° , peak-to-peak gain variation is 3 dB, and input $P_{1\text{dB}}$ is 23 dBm, over the 8–12 GHz frequency range.

9.6. Multifunctional MMICs

Up until now, we have described single-function monolithic circuits. The next four examples represent highly integrated MMICs. A high level of integration at the MMIC chip level reduces the number of chips and results in low test and assembly costs, which in turn reduces the subsystem cost. The downside of high integration is higher nonrecurring engineering costs, and greater difficulty in optimizing each subcircuit's performance.

In active phased-array antennas, each antenna element consisting of a transmitter, a receiver, a radiator, and control circuitry is called a *transmit/receive module*. Thus, reducing the cost of GaAs IC-based transmit/receive modules is essential to the deployment of low-cost active phased-array radars. A complete C-band multifunction monolithic transceiver, containing 16 microwave circuits, has been developed [57] on a GaAs substrate measuring $10.8 \times 15.7 \text{ mm}^2$ (170 mm^2). The chip includes a class B 4-W power amplifier with 40% power-added efficiency, a high-power T/R switch, several SPDT switches, buffer amplifiers, a 6-bit programmable phase shifter, digital and analog attenuators, and an LNA with noise figure of

Figure 22. The HEMT-HBT VCO mixer. The compact MMIC is only 1.1 mm² in size. (Reprinted with permission from K. W. Kobayashi and IEEE © 1997.)

4.5 dB. Figure 24 is a photograph of the chip. The IC used 58 separate FETs, 87 via holes, 83 MIM capacitors, 153 resistors, 6 spiral inductors and 65 airbridges. A single 2–20-GHz T/R chip on GaAs has also been developed [58]. A photograph of the chip is shown in Fig. 25. The chip, which measures 17.6 mm², consists of T/R switches, driver amplifier, power amplifier, and LNA. A basic traveling-wave design approach was used for the amplifiers. The measured performance includes a maximum noise figure of 10 dB with associated gain of 18 dB and minimum power output of 200 mW with associated gain of 12 dB. This chip used 44 FETs, 60 via holes, 44 MIM capacitors, 69 resistors, and 60 spiral inductors. Typical yield for a circuit of this complexity exceeded 50%. A highly integrated

multifunction macro synthesizer chip has also been reported by Mondal et al. [59]. It has more than 30 RF building blocks, and some individual blocks operate through 40 GHz. This MMIC represents the highest level of integration on a single GaAs chip.

Microwave and millimeter-wave components, subsystems, and systems have been experiencing ever-increasing pressure to reduce costs to support the emergence of wireless and mobile communications applications and widespread use of phased-array radars. There is a need for new technologies to meet the challenge in size, performance, and cost requirements. GaAs monolithic 3D technology has made tremendous progress in achieving both performance and cost requirement goals. 3D technologies

Figure 23. X-band 6-bit phase shifter; chip size is 4.5 mm².

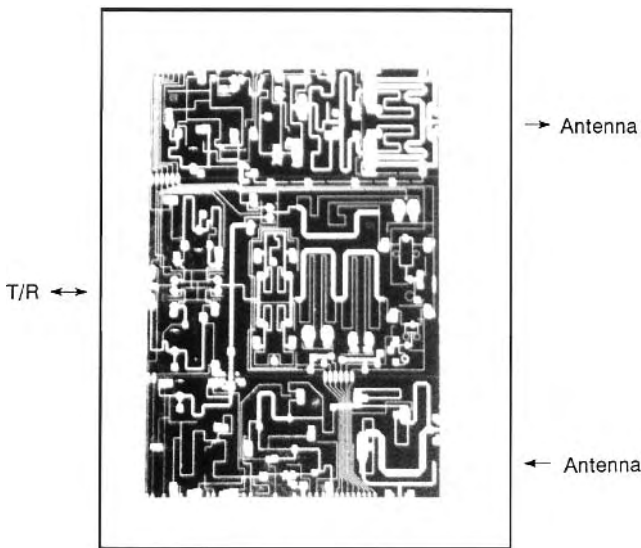

Figure 24. The 16-microwave function C-band TR chip. Chip size = 170 mm^2 . (Photograph courtesy of ITT Industries.)

provide another dimension in the integration and compaction of MMICs, where the matching networks, interconnects, and passive circuits are realized in a multilayer 3D volume. As an example, Fig. 26 shows a complete receiver [60], using low-noise amplifier, local oscillator amplifier, couplers, and voltage gain amplifier, and occupies only a 4 mm^2 chip area on GaAs when fabricated using 3D MMIC technology.

More recent advances in low-cost RF CMOS and SiGe HBT Si-based technologies offer great potential for very high-volume wireless applications. High RF performance of CMOS and HBT devices with large-scale integration capabilities make these technologies very attractive for low-cost solutions.

10. MMIC PACKAGING

Microwave packages and assembly techniques play a very important role in the performance, cost, and reliability of

Figure 25. The broadband (2–20-GHz) TR chip (Reprinted with permission from M. J. Schindler and IEEE © 1990.)

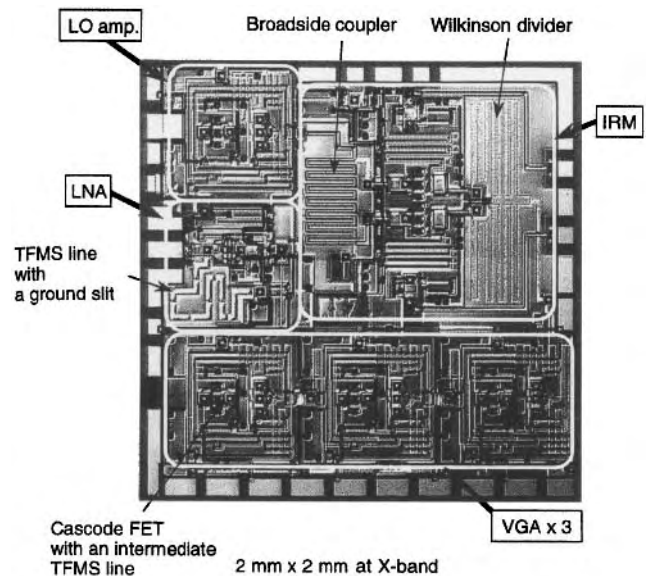

Figure 26. The 3D MMIC single-chip receiver. Chip size is 4 mm^2 (Reprinted with permission from I. Toyoda and IEEE © 1996.)

MMICs. Because MMICs represent state-of-the-art technology in terms of size, weight, performance, reliability, and cost, MMIC performance must not be compromised by packaging. The affordability requirement on packages mandates that their complexity be minimized. Minimizing both the number of dielectric layers and the overall size, dramatically improves electrical performance, production yields, and lower costs. However, a tradeoff exists between simplicity and the number of functional features in terms of costs. Some high-volume applications demand package costs as low as \$0.05 or \$0.10, whereas high-performance, low-volume applications can tolerate package costs (in the \$5 to \$25 range).

Many of the packaging considerations for MMICs are similar to those for hybrid MICs. Most ceramic/metal packages should meet the environmental requirements of MIL-S-19500 and test requirements of MIL-STD-750/883. The package must pass rigorous tests of hermetic properties, thermal and mechanical shock, moisture resistance, resistance to salt atmosphere, vibration and acceleration, and solderability. In order to minimize the effect of the package on MMIC performance, electrical, mechanical, and thermal modeling of packages must be performed.

The most important electrical characteristics of microwave packages are low insertion loss, high return loss and isolation, and no cavity or feedthrough resonance over the operating frequency range. When a chip or chip set is placed in the cavity of a microwave package, there should be minimum degradation in the chip's performance. Generally this cannot be accomplished without accurate electrical and electromagnetic modeling of the critical package elements. Microwave design must be applied to three parts of the package: RF feedthrough, cavity and DC bias lines. Of the three, the design of the RF feedthrough is the most critical in determining the performance of packaged MMIC chips.

Figure 27. Three packaging-level details: (a) MMIC in package; (b) MMIC with support circuitry; (c) MMICs with hybrid and support circuitry.

MMIC packaging can be performed at three levels as shown [15] in Fig. 27. ICs can be mounted in individual packages; ICs can be packaged with support circuitry in a housing; or the ICs can be packaged at the subsystem level. The packaging requirements depend on the application at hand. For example, in wireless communications applications below 6 GHz, GaAs MMICs are being mounted into plastic packages in order to achieve low-cost goals. Because of relatively low power operation, thermally they are acceptable. For high-frequency, high-performance, and high-power applications, we require metal base ceramic packages, which have low thermal resistance, good hermetic properties, high power capability, and good reliability characteristics.

10.1. Ceramic Packages

The selection of the substrate material and thickness for ceramic packages depends on the electrical performance requirements, cost, and frequency range of interest. The substrate thickness is selected to match its height with MMIC thickness; otherwise, a pedestal for mounting MMIC chips is required because MMIC chips are about 4 mils thick. Microwave packages generally use 10–20-mil-thick alumina substrate, whereas millimeter-wave packages use 4–5-mil-thick quartz. A low-dielectric constant is generally preferred because it makes the package interconnects electrically insensitive and tolerant to microstrip dimensions and broadband frequency ranges and results

in a high yield. The microstrip width and thickness determine the characteristic impedance and the DC resistance, whereas the spacing between the two conductors on the same plane controls the crosstalk because of coupling. Generally, sufficient space between the MMIC, the package walls, and the lid is provided in order to prevent any interactions. The effect of the package lid on the MMIC characteristics is kept to a minimum by keeping the lid above the MMIC surface about 5 times the package substrate thickness. In very high-gain applications lids with absorbing materials are also used.

Several ceramic (alumina, Al_2O_3), beryllium oxide (BeO), and aluminum nitride (AlN) packages with metal base (Kovar, copper, copper-tungsten, or copper molybdenum) are now available. Their cost depends on package size, frequency of operation, and volume. Some of these packages can be used up to 40 GHz, and others can be obtained for less than \$3 in large volume. In small quantities, they cost between \$20 and \$50. Typically, the measured dissipative loss per RF feed is less than 0.5 dB at 20 GHz. These packages provide much higher frequency of operation, low leadframe inductance, very low ground connection inductance, and much lower thermal resistance than do the plastic packages. Ceramic-type packages are well suited for high-frequency small-signal, and high-power MMICs, whereas the plastic packages are commonly used for low-cost solutions at the lower end of the microwave frequency band.

10.2. Plastic Packages

Small-outline transistor (SOT) and small-outline integrated circuit (SOIC) plastic packages are commonly used. These packages are shown in Fig. 28. SOIC packages have 8–16 pins, and they work reasonably well up to 2 GHz. The measured dissipative loss in a SOIC 8-lead package is on the order of 0.2 dB at 2 GHz. In order to improve the RF performance and power dissipation for power ICs, customer-fused lead frames with low-signal lead parasitics, and reduced-ground bond inductance are being used in custom plastic packages. Plastic packages such as FQFP-16 can be used up to 18 GHz. Plastic-molded IC packages are described in two packaging handbooks [61,62]. The dielectric

Figure 28. Plastic packages for RF and microwave applications.

constant and loss tangent values of the organic molding compound are about 3.7 and 0.01, respectively. The leadframe, which is the central support structure for ICs, is the backbone of a molded plastic package. Several different types of leadframe materials such as nickel-iron and copper-based alloys are being used. Their selection for a particular application depends on factors such as cost, performance, and ease of fabrication. The ICs are packaged using surface mounting techniques. SOIC packages are manufactured in quantities of over 10 billion per year, the material and packaging labor cost together are less than \$0.25 per package.

MONOPOLE ANTENNAS*

O. P. GANDHI
 G. LAZZI
 C. M. FURSE
 University of Utah
 Salt Lake City, Utah

This article describes the concepts underlying monopole antennas and their many applications, such as for broadcasting, car radios, and more recently for cellular

*See also section on Dipole Antennas

telephones. In its simplest form, the monopole antenna above an infinite ground plane shown in Fig. 1a can be considered as one-half of a corresponding double-length center-fed linear dipole shown for comparison in Fig. 1b. The current distribution for a vertical monopole antenna of height h is assumed to be a standing wave of the following form, in terms of the feedpoint current $I(0)$:

$$I(z') = \frac{I(0)}{\sin(kh)} \sin k(h - z') \tag{1}$$

for $0 \leq z' \leq h$. This occurs because the perfect ground plane creates an image of the monopole with a current distribution identical to that for the lower arm of the dipole. Together with this image, the monopole antenna appears to be a center-fed dipole for the upper half-space. There is negligible penetration of fields into a high conductivity ground for a monopole antenna, and all that

Figure 1. A vertical monopole antenna above ground (a) and the corresponding center-fed dipole (b). Shown also are the current variations $I(z')$ over the lengths of both the monopole and the corresponding dipole.

Table 1. Relationships between Monopole and Dipole Antennas

	Monopole Aboveground Length = h	Corresponding Dipole of Twice Length $L = 2h$
Radiation pattern	Same as that for the dipole but only for angle $0 \leq \theta \leq 90^\circ$	
Feedpoint reactance R_a	$R_a _{\text{monopole}} = \frac{1}{2}R_{a,d}(2h)$	$R_{a,d}$: function of length $L = 2h$ (see Fig. 2)
Feedpoint reactance X_a	$X_a _{\text{monopole}} = \frac{1}{2}X_{a,d}(2h)$	$X_{a,d}$: function of length $L = 2h$ (see Fig. 2)
Directivity D_a	$D_a _{\text{monopole}} = 2D_{a,d}(2h)$	$D_{a,d}$: function of length $L = 2h$

radiation is directed into the upper half-space, creating a power density for any angle θ (see Fig. 1) that is twice as high as that for a dipole radiating the same amount of power. This gives a directivity or gain of the monopole antenna that is twice that for the double-length dipole. Many of the other properties of a monopole antenna above ground are also related to those for the corresponding double-length dipole in a fairly simple manner.

In Table 1 we summarize the relationships between a monopole antenna of length h above ground and the corresponding dipole antenna of length $L = 2h$. A graph of the variation of the feedpoint resistance and reactance of the monopole antenna above ground is given in Fig. 2 as a function of length h/λ , where λ is the free-space wavelength at the radiation frequency [1]. Note that the reactance X_a depends on the conductor radius a , whereas the feedpoint resistance R_a is relatively independent of conductor radius a for thin antennas ($a/\lambda \ll 1$). The radiation patterns of a few typical monopole antennas are given in

Figure 2. Variation of feedpoint R_a and reactance X_a for an end-fed monopole above ground as a function of height h/λ . (Source: E. C. Jordan and K. G. Balmain [1].)

Fig. 3. Because a monopole antenna is symmetric with respect to angle ϕ in the azimuthal plane (xy plane), these patterns are independent of angle ϕ and depend only on angle θ (see Fig. 1). The following relationship is given for

Figure 3. Radiation patterns for some typical end-fed vertical monopoles above infinite ground: (a) $h/\lambda = 0.05$ (short monopole); (b) $h/\lambda = 0.25$ (quarter-wave monopole); (c) $h/\lambda = 0.5$ (half-wave monopole); (d) $h/\lambda = 0.75$ ($3/4\lambda$ monopole). (Adapted from E. C. Jordan and K. G. Balmain [1].)

power density $S(\theta)$

$$S(\theta) = \frac{30 W}{\pi r^2 R_a} \frac{P^2(\theta)}{\sin^2(kh)} \quad (2)$$

where W is the radiated power, r is the distance to the field point, $k = 2\pi/\lambda$ is the propagation constant, and $P^2(\theta)$ is the pattern factor given by

$$P^2(\theta) = \left[\frac{\cos(kh \cos \theta) - \cos(kh)}{\sin \theta} \right]^2 \quad (3)$$

Because monopole antennas help reduce the length of the necessary dipole by a factor of 2 and result in directivities that are twice as large, vertical monopole antennas above ground are extensively used for amplitude-modulated (AM) broadcasting in the frequency range 535–1605 kHz. For this application, the wavelengths are long, on the order of 200–600 m, and the monopole antennas are immensely helpful in reducing the required height. It is necessary, of course, to create a good conductivity ground, which for dry or rocky soil conditions is often obtained by burying a conducting screen made of radially spread metal wires with angular separations of 2–3° that extend to a radius at least equal to the height of the antenna, but preferably 20–50% larger than this minimal requirement. This screen, called a *counterpoise*, is often buried a few inches below the surface of the natural ground but may also be left slightly above ground for rocky or otherwise difficult terrain.

1. EFFECT OF FINITE CONDUCTIVITY GROUND AND CURVATURE OF EARTH

Equation (2) gives the power density radiated from a monopole antenna for a ground of infinite conductivity and for flat earth. For finite conductivity ground, the power density at the earth surface diminishes more rapidly than the square of the distance r from the antenna given by Eq. 2. Furthermore, the rate at which the power density at the surface of the ground diminishes with distance is steeper at higher frequencies. The rate of reduction of the radiated power density as compared to Eq. (2) is also higher for lower-conductivity soil such as sandy or rocky lands and cities, rather than propagation over, for instance, seawater or marshy or pastoral lands. For distances in excess of about 1000 mi, there is a precipitous drop in the surface power density at all frequencies due to the increased effect of Earth's curvature [2].

Monopole antennas are also the antennas of choice for very low-frequency (VLF) (3–30 kHz) and low-frequency (LF) (30–300 kHz) communication systems. For these applications, the height h of the antenna is generally a small fraction of the wavelength. From Fig. 2, for small values of h/λ , the feedpoint resistance R_a is very small, on the order of a few ohms, and the ohmic losses resulting from the surface resistance of the antenna can be significant by comparison. This results in reduced antenna radiation

Figure 4. A top-loaded short-monopole antenna typical of VLF/LF communication systems.

efficiency η_a , given by the following equation:

$$\eta_a = \frac{R_a}{R_a + R_o} \quad (4)$$

where R_o is the effective ohmic resistance of the antenna.

Top loading of the monopole antenna illustrated in Fig. 4 is often used to improve the feedpoint or antenna-equivalent resistance R_a . Because the top set of wires acts as a capacitance to ground rather than the open end of the antenna, the current at the top of the antenna ($z' = h$) no longer needs to go to zero as it does for an open-ended monopole [from Eq. (1), $I = 0$ at $z' = h$]. The upper region of the antenna can, therefore, support a substantial radio frequency (RF) current, resulting in improved radiation efficiency. The antenna-equivalent resistance $R_a = 395 h^2/\lambda^2$ for open-ended short monopoles may be improved by a factor of 2–3 by use of top loading, resulting in higher radiation efficiency.

It should be mentioned that the various concepts discussed here are also usable at higher frequencies. Open-ended monopole antennas are, in fact, used up to ultra-high frequency (UHF) and microwave frequencies, where metallic conducting sheets, either solid or in the form of a screen, may be used in lieu of the ground to create the image antenna. A variety of top-loading “hats” illustrated in Fig. 5 may also be used at these higher frequencies.

Because a monopole antenna above ground or similar reflector acts as a dipole antenna, several of the concepts that are useful for dipole antennas are also used for the monopole antenna. Some of these concepts that are often used in practice are discussed next.

1.1. Folded Monopoles

A folded monopole antenna is illustrated in Fig. 6a, where the feedpoint is connected to arm 1, and arm 2 is grounded at the bottom end. For dipoles, this provides a method of increasing the feedpoint impedance given in the following relationship [3]

$$Z_i = (1 + c)^2 (R_a + jX_a) \quad (5)$$

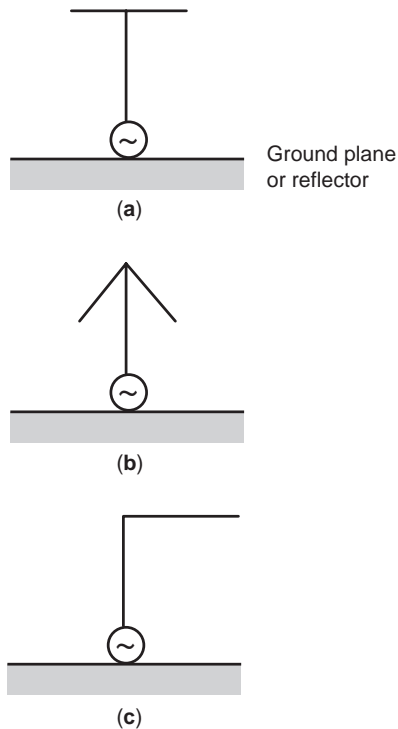

Figure 5. Some typical geometries used for top-loaded monopole antennas: (a) plate; (b) umbrella of wires; (c) inverted-L monopole.

where R_a and X_a plotted in Fig. 2 are the resistance and reactance of the single-arm (not-folded) monopole antenna, and the factor c is given approximately by

$$c \approx \frac{\ln(d/a_1)}{\ln(d/a_2)} \quad (6)$$

In Eq. (6), a_1 and a_2 are radii of wires or rods used for arms 1 and 2, respectively, and d is the center-to-center spacing between the two arms of the antenna, generally much smaller than the height of each of the arms. For a folded monopole antenna where equal radii arms are used, the feedpoint impedance is, therefore, 4 times higher than that for a monopole antenna that is not folded. This can be truly advantageous, because the feedpoint resistance may now be comparable to the characteristic impedance Z_0 of the transmission or feeder line, and the reactance of the antenna may easily be compensated by using a lumped element with a reactance that is negative of the reactance $(1+c)^2 X_a$ at the terminals of the folded monopole antenna.

1.2. Shunt-Fed Monopoles

A typical arrangement of a shunt-fed grounded monopole is shown in Fig. 6b. This corresponds to one-half of a delta match that is often used for dipoles. Because the base of the monopole is grounded for this arrangement, the antenna is fed typically 15–20% farther up on the antenna; the exact location is determined by matching the feeder line of characteristic impedance Z_0 , which is typically 200–600 Ω . Shunt-fed monopole antennas were often used in the early days of AM broadcasting when high-

Figure 6. Some special adaptations of monopole antennas: (a) folded monopole antenna; (b) shunt-fed grounded monopole; (c) four-element Yagi–Uda array of monopoles.

quality insulators were not generally available and it was convenient to ground the tall steel/aluminum masts being used for monopole antennas. With the advent of high-compression-strength insulators, the masts are now more typically mounted on these insulators, and the monopole towers are fed at the base of these antennas.

1.3. Parasitic Monopoles

Much like the Yagi–Uda arrays of dipoles [3], parasitic monopoles of grounded elements are used to help direct the beams away from the reflector monopoles in the direction of director monopoles. An illustration of a four-element Yagi–Uda array of monopoles is shown as Fig. 6c. Forward gains on the order of 10–12 dB with front-to-back ratios of 5–8 dB may be obtained using such arrangements. One or more of the parasitic monopoles have also been occasionally used for beamshaping by AM broadcast stations. Two-element antenna arrays consisting of a parasitic reflector monopole and a driven monopole antenna have also been proposed for use in handheld wireless telephones (see, e.g., Ref. 4). If they are carefully designed, such antennas may allow electromagnetic fields to be partially directed away from the human head.

1.4. Arrays of Monopole Antennas

Like arrays of dipole elements, monopole arrays of equal or arbitrarily spaced and phased elements may be used for

Figure 7. A conical monopole.

directing principal lobe(s) of radiation in desired directions. Arrays of monopole antennas are used for VLF/LF communications, for AM broadcasting, and, in general, for all frequencies up to microwave frequencies. AM broadcasters for non-clear-channel stations have, for example, used this technique to alter the diurnal and nocturnal radiation patterns by varying the phases and the magnitudes of excitations in the various elements.

1.5. Conical Monopole

A conical monopole, realized as a cone above a perfect ground plane, is commonly used because of its broadband properties. The cone may be either solid or built from a series of wires above a ground plane. Similar to conventional monopoles, the ground may also be built from a series of radial wires as shown in Fig. 7.

The analysis of this antenna may be done using either rigorous analytical solutions [5,6] or an approximate method [6]. The rigorous approach is based on a series expansion of transverse magnetic (TM) modes and is computationally complex. Numerical methods, based on the assumption that the antenna is built from a series of wires, have been commonly used for specific monopole arrangements.

An example of a conical monopole constructed of 60 evenly spaced wires above a ground plane is an antenna that has been in use by the U.S. Navy [7]. For use in the HF band 2–14 MHz, the dimensions of the monopole are $\ell = 30.6$ m, $a = 0.001$ m, and $\theta_0 = 45^\circ$ (see Fig. 7). The radius of the ground is approximately 37.5 m, constructed of 120 radial wires over average soil ($\epsilon_r = 15$ and $\sigma = 0.012$ S/m), and the radius of the screen wire is 0.002 m. This antenna performs over a 7:1 frequency band (2–14 MHz) with an input resistance varying from 44 to 64 Ω [6]. Because of the fairly narrow range of variation of input resistance, matching of this antenna to a 50- Ω line is possible over at least a 7–1 frequency range.

1.6. Monopole Antennas for Car Radio and Mobile Communications

Monopole antennas used for car radio and mobile communications commonly rely on the body of the vehicle to

provide the ground plane. Variations in the shape of the vehicle and placement of the antenna affect the radiation pattern and performance of these antennas [8]. For an antenna mounted on the automobile, it would no longer radiate isotropically in the horizontal plane but may radiate with a slightly higher gain in directions where the automobile body extends farther, thus simulating a wider ground plane in such directions.

For communication antennas in general, it is often desirable to have the shortest possible antenna. Although a quarter-wave monopole is easier to match, a shorter antenna has an associated capacitive reactance. This can, however, be canceled out by adding a loading coil (inductance) to the base of the antenna.

Another arrangement often used is to place an inductive coil at the center of the antenna [9]. Because of the altered current distribution along the length of the antenna (similar to a top-loaded monopole), this increases the feedpoint impedance of the end-fed antenna to roughly twice the value, making it easier to match to such an antenna. The value of the inductance needed at the center is approximately double that would be needed at the ends. This consequently increases the coil resistance.

In order to reduce the inductance of the loading coil required to match the antenna at either the center or top, a capacitive load (a small metal ball) may be added to the tip of the antenna.

In all this discussion of monopoles, we have assumed that the wave propagation from the antenna is over a perfectly conducting or infinite conductivity ground plane. This is hardly ever the case. For ground-wave propagation ($\theta = 90^\circ$) over a finite conductivity ground plane, the fields drop off more rapidly than $1/r^2$ given by Eq. (2). This effect is more pronounced for higher frequencies and is generally small only at very low frequencies less than a few tens of kilohertz. Also, as expected, the departure from the idealized Eq. (2) is more pronounced the lower the conductivity of the soil. Rocky and jagged hilly ground, for example, would result in a more rapid dropoff of the power density S along the ground plane than would propagation over seawater.

Yet another factor that has an impact on surface-wave propagation is the curvature of Earth. For distances larger than about 100 mi (62 km), the power density at the ground level diminishes very rapidly particularly for frequencies in excess of about 1 MHz.

2. EFFECT OF FINITE-SIZE GROUND PLANE ON IMPEDANCE AND RADIATION PATTERN

Whereas a ground plane of diameter 10 wavelengths or larger has a fairly small effect on the feedpoint impedance of a monopole antenna as compared to the values given in Fig. 2, a finite-size ground plane has a fairly significant effect on both the feedpoint impedance and radiation pattern [10].

An example of the effect on the radiation pattern is illustrated in Fig. 8a for the radiation pattern of a monopole antenna of a cellular telephone in free space. Since this monopole antenna is mounted on a plastic-covered

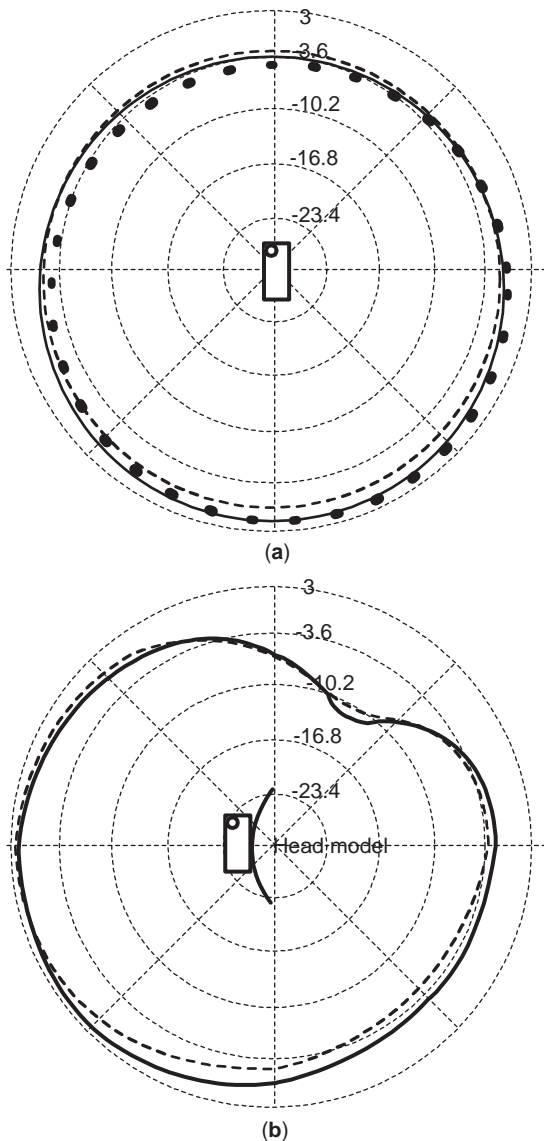

Figure 8. The computed and measured radiation patterns (in dBi) in the azimuthal plane for a commercial cellular telephone at 835 MHz (a) in free space and (b) held against the human head. (From Ref. 14.)

metal box of finite dimensions, only a finite-size ground plane of box shape is used for this radiator. One effect is to alter the radiation pattern (see Fig. 8a) from a perfect circle in the azimuthal plane to one that is crooked with a lower gain in the sector where the extent of the ground plane is minimal, specifically, on the side where the antenna shown by a circle in the inset of Fig. 8a is mounted. Also, the gain for this quarter-wave monopole antenna of about 1 dBi is considerably lower than 5.16 dBi (a factor of 3.28) for the same antenna mounted on a flat, infinite ground plane. The actual reason for this considerably reduced gain is that part of the energy is also radiated in the lower half-space for this vertical monopole antenna above the box while none would be radiated for this antenna mounted above an infinite ground plane.

3. MONOPOLE ANTENNAS FOR PERSONAL WIRELESS DEVICES

A monopole antenna with or without a helix has commonly been used for personal wireless devices, including cellular telephones [11]. Antennas of different lengths, typically from a quarter-wavelength to a half-wavelength at the irradiation frequency, have been used for handheld devices that operate at 800–900 MHz for cellular telephones and 1800–1900 MHz for PCS (personal communication system) devices. Often, these monopole antennas are in the form of a whip antenna that can be pulled out to its full length during a telephone conversation. At times, a short helical antenna is permanently mounted on the top of the handset through which the monopole antenna can be retracted and to which this monopole connects when it is completely pulled out, giving a monopole loaded with a helix at the bottom as the radiating antenna during telephone usage. Of necessity, these antennas use a finite-size reflecting plane, which is generally the metallic shielding box used either for the top RF section, or at times for the entire handset. Several authors have calculated and/or measured the radiation patterns of such monopole antennas mounted on a handset held in air or against the human head [12–14].

Figures 8a and 8b give the computed and measured radiation patterns in the azimuthal plane for a typical commercial telephone at the center-band frequency of 835 MHz in free space and in the presence of the human head, respectively [14]. This telephone uses a short helical antenna of diameter 4.2 mm, pitch 1.4 mm, and total length 16 mm. Dimensions of the handset are similar to those for many telephones and are approximately $2.4 \times 5.2 \times 14.7$ cm along the three axes, respectively. Fairly similar radiation patterns are also obtained for antennas using either monopoles or monopole–helix combinations. In the presence of the human head, gains on the order of 1.0–3.0 dBi are obtained away from the human head, with gains in directions through the head that are substantially lower due to absorption in the tissues of the head. Radiation efficiencies for monopole antennas used for personal wireless devices are typically on the order of 30–50%, with 30–50% of the power absorbed in the head and another 5–15% of the power absorbed in the hand [13,15].

4. MEDICAL APPLICATIONS

End-fed monopole antennas excited by a coaxial line have been used for a number of medical applications such as hyperthermia for cancer therapy [16] and cardiac ablation catheterization [17]. For these applications, both straight-wire and small-diameter helix monopoles have been used.

MONOPULSE TRACKING SYSTEMS

MANUEL SIERRA PEREZ
 JAVIER GISMERO MENOYO
 MANUEL SIERRA CASTAÑER
 ALBERTO ASENSIO LOPEZ
 Universidad Politecnica de
 Madrid
 Madrid, Spain

1. TRACKING SYSTEMS

The *tracking function* of a target in a radar system is found in two different types of systems:

1. Radar tracking while scanning
2. Tracking Radar

In type 1, surveillance radar equipped with a *data processor* having the necessary algorithms is used to forecast and filter the target positions encountered within its surveillance coverage. The system has an antenna with mechanical rotation that provides a directional radiation pattern that concentrates most of the radiated power into a narrow beam in azimuth (fan beam). The actual positions (range and azimuth) of targets obtained by the *detector* are the inputs to the radar data processor. The target data obtained during each antenna rotation period (scan) are first associated (if possible) with the active *tracks* in the processor (a *track* is a sequence of data belonging to the same target), through temporal and spatial correlation criteria. Once this association has been performed, the data are passed to the tracking filters [1,2] in order to perform the data filtering (accuracy improvement) and to forecast the future target position in the subsequent scan. The most common used tracking filters are the $\alpha\beta\gamma$ filter and the Kalman filter [1,2]. *Track-while-scanning* systems may use a double-radiation pattern so that the target azimuth is obtained through the output voltage of a monopulse processor that compares the pair of signals received through this pattern as described below.

The antenna subsystem in a tracking radar provides a directional radiation pattern that concentrates most of the radiated power into a narrow beam in both azimuth and elevation (pencil beam) to spatially isolate a single target and perform its tracking in range, azimuth, elevation, and/or Doppler parameters. The resolution cell size is inversely proportional to the transmitted bandwidth and the antenna physical dimension and is, in general, smaller than that in a surveillance radar. These systems normally have surveillance modes with sectorial and helicoidal scans used in the phase of target acquisition; however, usually there is another system that provides the coordinates of the target to track. Once the target has been acquired, the tracking radar provides the target coordinates at a much higher rate than does a surveillance radar. The system is equipped with range, elevation, and azimuth tracking loops for this purpose.

Range tracking is performed through the split-gate technique, which integrates the detected video signal in two contiguous windows (early–late). The signal needed by the loop filter is the difference between the outputs of the integrators. The system aims to keep the target between the two time windows, and hence if it works correctly, the target echo will be located in that position.

The angular tracking loops in both, elevation and azimuth can be used to obtain the antenna pointing error signal through three different techniques:

- Sequential lobing
- Conical scan
- Monopulse

The *sequential lobing* technique is based on switching the input to the receiver between the pair of signals obtained through a pair of pencil beams that, instead of pointing directly at the target, point slightly to one or the other side of the target in the desired angular coordinate. The

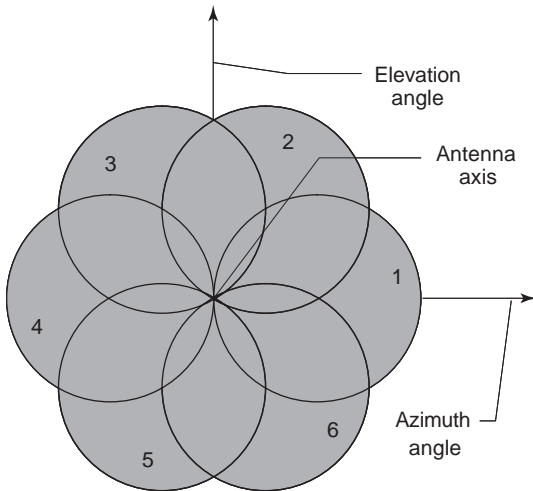

Figure 1. Conical scan in tracking antenna systems. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

difference in the amplitude of the received signals is proportional to the pointing error.

In a *conical scan* system, there is only a pencil beam rotating continuously in a circular path centered on the crossover axis at Ω rad/s. In this way the echoes produced by a target outside the pointing direction are amplitude-modulated by a sinusoid of angular frequency Ω rad/s as the amplitude of this modulation proportional to the error pointing of the system. Figure 1 shows the six beam prints in the angular coordinate plane around the boresight direction. All of these methods of measuring the target angle lose accuracy when some degree of pulse amplitude modulation exists, due to target or wave propagation pulse-to-pulse changes.

To avoid these and other problems, several simultaneous antenna patterns are used and two or more signal receivers are working at a time. This kind of system is called *simultaneous lobing* or the *monopulse system* [3,4].

2. MONOPULSE PRINCIPLE

The word *monopulse* was introduced to the radar terminology by H. T. Budenbom in 1946 to enhance the property of simultaneous lobe comparison to find the direction of a target with only one pulse, in contrast to other systems such as the switching lobe or the conical scan tracking systems, which require measurement of amplitude modulation through several pulses. Not only do radar systems use the monopulse principle to measure the direction of arrival (DoA) of a radio emission and not only can pulsed emissions be detected with this kind of receiver, but actually, most modern radar systems use this principle to accurately measure the target azimuth and elevation or to track its movement. One of the most important applications is the monopulse tracking radars, where the feedback of this information to the radar antenna servos allows one to follow the target position in both angular dimensions: elevation and azimuth.

In monopulse systems, the angle of arrival is measured by comparing the received signal through two antenna

Figure 2. Sum and difference patterns with amplitude comparison. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

patterns: the so called “sum pattern or Σ pattern,” a directive pattern with a mainlobe pointing at the boresight direction, and the “difference or Δ pattern” a pattern with a deep null in the foresight direction and two mainbeams with phase opposition between them. These two beams, with radiation patterns $F(\theta - \theta_1)$ and $F(\theta + \theta_1)$, can be obtained by adding or subtracting two antenna patterns pointing in two directions at both sides of the main direction, as shown in Fig. 2. As the system uses relative amplitude and phase measurement, the value obtained is independent of the amplitude and phase of the incoming signal. On the other hand, if only one pulse is used to measure the arriving angle, errors due to rapid change of target position or pulse to pulse amplitude modulation are avoided in monopulse systems.

The method of measuring the angular distance to boresight is through the normalized difference function obtained as a ratio of the difference to the sum function (Δ/Σ). Figure 2 shows the normalized function in these patterns.

When two angular dimensions are controlled, the antenna must create a sum pattern and two difference patterns, one in each plane. To obtain these patterns, a four-lobe antenna pointing in four directions around the boresight can be used. Then the sum-and-difference patterns are obtained by combination of these mainlobes. Usually the combination of these lobes is obtained through RF circuits such as 180° hybrid circuits.

Another way to obtain a sum-and-difference pattern is combining the patterns of two equal antennas some distance apart to form an interferometer. Then, the phase difference between the two antenna received signals depends on the direction of arrival and hence, an OBA measurement system can be mounted. Usually sum and difference patterns can be obtained by adding or subtracting the two patterns, to obtain a sine or cosine array factor, as shown in Fig. 3.

To obtain a two-dimensional monopulse system, four antennas are combined. One sum pattern and two

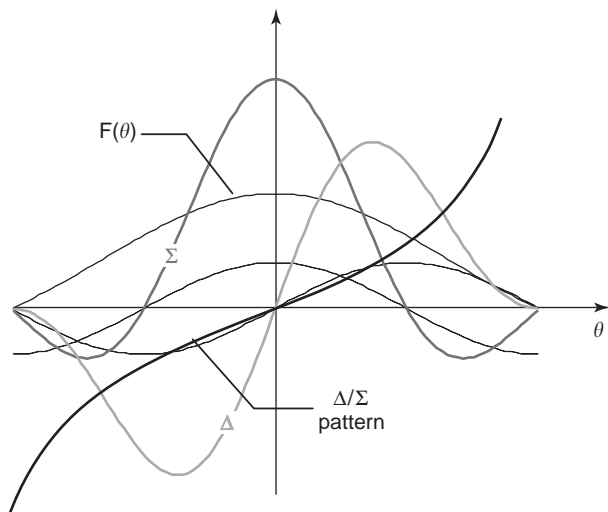

Figure 3. Sum and difference patterns obtained by phase comparison. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

difference patterns can be obtained as in the amplitude combination. Here the distance between antennas defines the angular beamwidth and the accuracy of the angle measurement. In general, as larger is the distance between antennas, the narrower is the beam and higher is the accuracy of the angle measurement.

In modern array antennas the sum and difference patterns can be designed specifically to obtain a highly linear normalized function combined with high directivity sum pattern, low lobe conditions, or a wide detection angle. All these characteristics can be controlled through the design of linear or plane arrays.

3. ANTENNAS IN MONOPULSE TRACKING SYSTEMS

Antenna design is a very important part in the design of successful monopulse tracking radar. The antenna must be capable of working in the specified bandwidth, with the desired polarization characteristics and generating the required radiation patterns. In fact, almost every kind of antenna (reflectors, arrays, horns, etc.) can be designed to

work for monopulse tracking systems. In this section, we will describe the main characteristics of antennas for monopulse systems. We will show some antenna designs and will finish with some general requirements for the antenna designer.

3.1. Antennas for Phase Comparison Monopulse Systems

One of the earliest and simplest monopulse systems was the phase comparison system. Transmitting and receiving antennas are usually different to avoid the use of duplexers. The transmitting antenna could be a parabolic reflector, while the receiving radiating system was typically composed of two parabolic reflectors for one angular direction monopulse performance. The monopulse system must have two antennas whose phase centers are displaced a required distance d . If the two antennas are equal, the amplitude patterns are identical, but the phase patterns differ by

$$\delta = \frac{2\pi}{\lambda} d \sin \theta \tag{1}$$

where d is the separation between both antennas, λ the wavelength, and θ the angle of arrival relative to broadside direction, as shown in Fig. 4.

If phases are considered with respect to the center of the antenna structure, the radiation patterns for both antennas can be expressed as the antenna pattern $P(\theta)$ multiplied by a phase factor as follows:

$$F_1(\theta) = P(\theta) \cdot \exp\left\{j\left[\frac{2\pi}{\lambda} \frac{d}{2} \sin \theta\right]\right\} \tag{2}$$

$$F_2(\theta) = P(\theta) \cdot \exp\left\{-j\left[\frac{2\pi}{\lambda} \frac{d}{2} \sin \theta\right]\right\}$$

Thus the angle of arrival is included in the difference in phase between both antenna patterns. Instead of processing the phase of both radiation patterns, it uses the more easily processed amplitude of the sum and difference

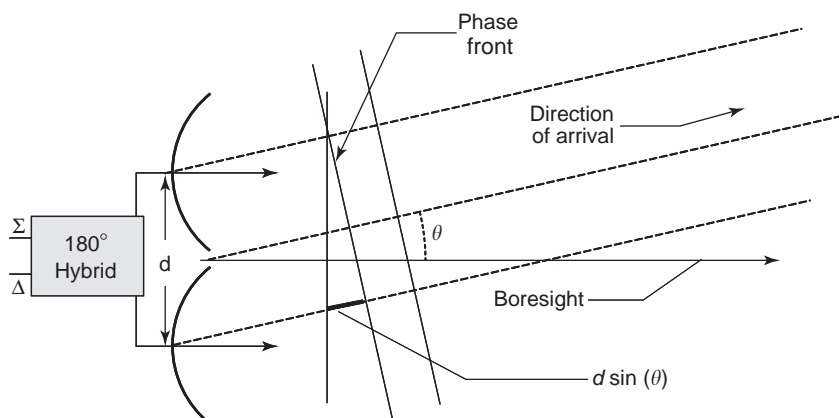

Figure 4. Interferometer array of two antennas. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

patterns:

$$\Sigma = 2P(\theta) \cos\left(\frac{2\pi d}{\lambda} \sin \theta\right)$$

$$\Delta = j2P(\theta) \sin\left(\frac{2\pi d}{\lambda} \sin \theta\right)$$
(3)

These sum and difference patterns can be obtained with a 180° or a 90° hybrid circuit as shown in the schematic in Fig. 4.

The usual antennas for this systems are parabolic reflectors because it is easy to obtain directive antenna patterns, low losses, and high bandwidths. If lower gains are required (<20 dBi), lens or horns can be used for phase comparison monopulse antennas.

Figure 5 shows a typical reflector antenna arrangement for a two-dimensional monopulse system. Here, the combination of the four antennas gives the main Σ pattern and differential combination of each two antennas allows formation of the two Δ patterns in both principal planes.

3.2. Antennas for Amplitude Comparison Monopulse Systems

The simplest monopulse system is amplitude comparison. Transmitting and receiving antennas can be one parabolic reflector: with one feed for transmitting channel and several for receiving channels, in order to avoid duplexing problems. The feeders can be horns, dipoles, or any other feeding antenna. The transmitting feed is in the focus, while the receiving antenna feeders have a lateral displacement from the reflector focus, so that both main-beams squint off in the broadside direction. The angle of arrival can be extracted from the relative amplitude from both feeders; for the broadside direction they are exactly

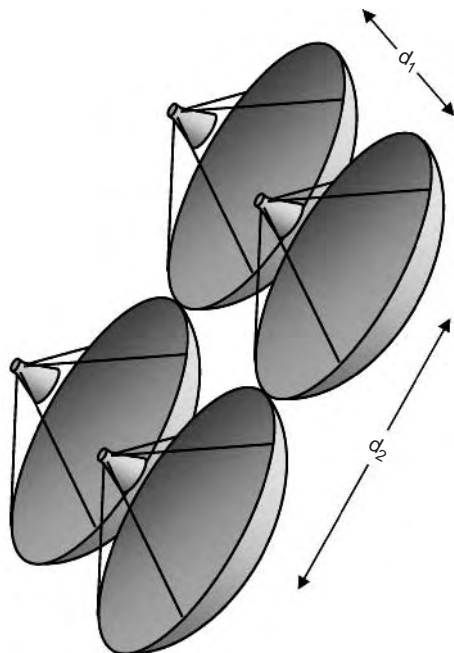

Figure 5. Four receiving parabolic reflectors for two-dimensional monopulse performance. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 6. Reflector antenna with five horns used as transmitting and receiving terminals. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the same, and the angle of arrival depends directly on the difference between both amplitude radiation patterns. The sum and difference patterns are obtained as follows:

$$\Sigma(\theta) = F(\theta - \theta_1) + F(\theta + \theta_1)$$

$$\Delta(\theta) = F(\theta - \theta_1) - F(\theta + \theta_1)$$
(4)

Physically the sum and difference patterns can be obtained through a 180° hybrid circuit such as the waveguide magic T or printed ring hybrid.

If monopulse performance in all directions is required, this can be obtained with five horns, with one transmitting feed placed in the focus of the reflector and four to form the reception systems with lateral displacements from the focus. Figure 6 is a drawing of this antenna system, while Fig. 7 represents the three-dimensional patterns of the four receivers.

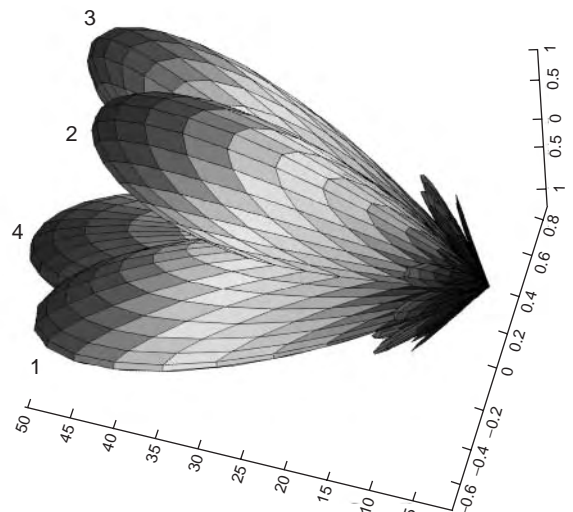

Figure 7. Schematic drawing of the four two-dimensional lobes around the antenna boresight. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 8. Feeding structure for monopulse array with independent Σ and Δ power distribution. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

feeders or a more complex cluster to improve some characteristics of the radiation pattern.

3.3. Array of Antennas as a Monopulse Antenna System

Arrays of antennas can be used exactly in the same way as reflector antennas if we consider that an array behaves as an aperture antenna to form a main pencil beam. In this sense a monopulse system can be arranged by a set of four panel arrays to form an interferometer monopulse antenna.

Because of the ability of array antennas to sweep the mainbeam in several directions of the space, a multibeam antenna array can also be built to perform similarly to the amplitude combination monopulse antenna.

Array antennas can obtain sum and difference radiation patterns directly, without processing the signals from two antenna panels or from two separated patterns pointing in two offset angles from boresight. In this antenna design, same radiating elements are used for sum and difference patterns, and two independent feeding structures are designed to obtain both patterns. The main advantage of this structure is the possibility of independent control of sum and difference patterns with the feeding networks.

In general, the array amplitude and phase distribution that produce high gain and low sidelobes for the sum pattern is different from the distribution needed for the difference pattern. Several designs have been studied to get a good monopulse function together with low sidelobes, such as those studied by Bayliss [5]. Once the designs of the sum and difference patterns are completed, the construction of feeding structures to obtain those array excitations

is another important problem. The solution of this problem depends greatly on the particular design, and one solution for linear arrays was reported by Kinsey [6], using a ladder structure of lines and hybrid couplers, like the scheme shown in Fig. 8 [7]. In this figure a printed patch antenna array is fed by two series feeding structure that use directional couplers to control the amplitude of each element. The phase is controlled by the length of the lines. The two lateral subarrays are fed by Wilkinson power dividers.

The elements of the array can be horns, dipoles, lens, slots, patch antenna, or any antenna that usually forms arrays. Of course, with a linear array only one plane monopulse performance is obtained. If both angular ranges are required, a planar one must be implemented.

Some kind of antennas and feeding structures behave as monopulse antennas with very simple physical arrangement. For instance, the antennas shown in Fig. 9 directly form sum and difference radiation patterns [8]. Figure 10 shows the measured radiation pattern in both amplitude and phase. This structure allows us to obtain both elevation and azimuth angles of arrival, with only two receiving signals. The antenna is based on a radial line with an array of slots placed on the radiating side. The antenna is 120mm in diameter and works in the 13.4–14 GHz band with left-hand circular polarization. The microstrip feeding structure on the backside is designed to excite the radial waveguide with two modes: one rotating mode to give the sum pattern and one coaxial mode to give the difference pattern, which behave as follows:

$$f_1(\theta, \phi) = \Sigma(\theta), \quad f_2(\theta, \phi) = \Delta(\theta)e^{j\phi} \tag{5}$$

Figure 9. Radial slotline array as monopulse antenna: (a) radiating face; (b) feeding structure.

Figure 10. Sum Σ and difference Δ patterns: (a) amplitude for $\phi = 90^\circ$ at 13.7 GHz; (b) phase for $\theta = 9.4^\circ$ at 13.7 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The elevation angle is obtained by comparing the amplitude of both radiation patterns and the azimuth angle, by comparing the phase for both radiation patterns, because the phase for the sum beam is uniform while the phase for the difference pattern is linear with azimuth angle of arrival.

3.4. Monopulse Antenna Parameters

To specify a monopulse antenna we have to determine two properties: the monopulse function, defined as the ratio between sum and difference patterns, and the conventional antenna parameters.

The first thing to take into account is the radiation pattern for both sum and difference patterns, defined as the spatial distribution of a quantity that characterizes the electromagnetic field generated or the signal received by an antenna. The most important parameters of the radiation pattern for monopulse performance are

- Angular range for monopulse performance, given by the angular distance between both maximum values of the monopulse function.
- Slope of the monopulse function. Usually the higher the slope, the lower the system error.
- Sidelobe levels outside the monopulse angular range. Outside the monopulse working range, it is important to have low sidelobe levels to avoid interference with or from other systems.
- Phase center. For amplitude monopulse systems, all the antennas must have the same phase center. For phase comparison monopulse systems, the angle of arrival is related to the position of the phase center of the antennas. In array systems, each element will have its own phase center.

Regarding other antenna parameters not specifically related to the monopulse application, we can mention the following:

- Frequency bandwidth. This is the frequency range within which the antenna has some specified behavior.
- Polarization. This is closely related to the radiation elements in array antennas and to feeders in reflector antennas. A cross-polar radiation pattern is the

spatial distribution of a quantity that characterizes the electromagnetic field generated by an antenna, in the polarization orthogonal to the desired one. This pattern can give a strong perturbation in the monopulse function and must be as low as possible.

- Gain. The gain was previously an important factor for the sum pattern. The gain is the difference (in dBi) between directivity (dBi) and antenna losses (dB). Directivity is closely related to the beamwidth of the radiation pattern; thus a compromise is required between monopulse angular range and sum pattern gain. The value of the gain for the difference pattern is much lower, and usually define the minimum signal we must receive for some specific error (sensitivity).
- Antenna matching to receiver. Antenna matching was previously measured in terms of reflection coefficient or standing-wave ratio. A good matching to receiver (typically 50 Ω) is required.

4. MONOPULSE PROCESSORS

The monopulse technique, also known as *simultaneous lobe comparison*, is used to measure the direction of arrival of active and passive electromagnetic radiation sources.

The monopulse processor is the subsystem that uses as input signals those received through the different antenna patterns and delivers an output signal containing information related to the target angular deviation with respect to the antenna axis [off-boresight angle (OBA)]. Although the processor could in principle deliver a signal error working directly with the antenna RF signals, the usual implementation starts with a special combination of these signals (through directional couplers, hybrids, and other specific radiofrequency elements) to form their linear combination, which we have called signals Σ and Δ (sum and difference signals). These new signals are applied to a pair of identical receivers and at the output of these receivers (at IF) is where the monopulse processor is usually found. The processor can share some hardware with the receiver, and part of the processing can be performed digitally together with other radar functions in the signal processing stages. Therefore it is correct to regard the monopulse processor more as a radar function than as an independent hardware unit. For the development of the

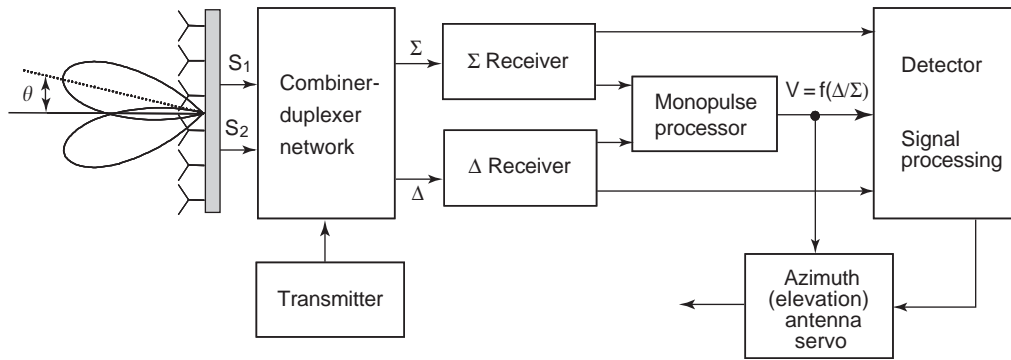

Figure 11. Monopulse location in a radar system.

monopulse function in one angular coordinate, two receivers are normally required as shown in Fig. 11.

In the design of a monopulse processor that functions with the Σ and Δ signals, it is not important whether they have been obtained by amplitude or phase comparison (except for the 90° phasing network that may be required) or the type of antenna used.

Often the Σ and Δ patterns are designed so that the Δ/Σ ratio will be an odd and nearly lineal function of the OBA in such a way that, for identical angular separations on both sides of the boresight, equal-magnitude outputs with opposite signs are produced. The linear property is specially sought for small OBAs since it simplifies the closed-loop functionality of the tracking system. Processor output must then depend on the complex ratio Δ/Σ (amplitude ratio, phase difference, or both) of the signals extracted from the antenna and not on their absolute amplitude or phase. This normalization will allow the output to depend only on the target OBA and not on the target range or radar cross section. However, this quotient represents a nonlinear operation, and the performance of any monopulse processor will depend on its correct implementation. In any case, in order to account for the nonideal behavior of the radiation patterns and the processor itself, its output signal (a voltage or digital word) must be calibrated for the specific radiation patterns of the antenna used. This calibration function or *monopulse function* $V_M = F(\Delta/\Sigma)$ allows the subsequent OBA estimation. In actual monopulse systems working with angular deviations of up to half the mainlobe width, a nonideal monopulse function is unavoidable.

4.1. Classification and Properties

Any subsystem able to deliver an output that depends on the ratio Δ/Σ can be considered as a monopulse processor. In tracking radars the outputs of the processor control the servos, allowing modification of both elevation and azimuth of the angular antenna position or pointing direction in order to situate the target in the axis of the system. In surveillance radars, the same output is used to complement the information relative to the axis of the antenna and improve the accuracy in angular estimation.

Although a large number of techniques are used to obtain a monopulse function as well as monopulse processor

implementations, all of which can be included in a first approach in one of two main classes:

1. Noncoherent processors, also known as *amplitude processors*. In these systems the amplitude of Δ and Σ signals is used to obtain the monopulse function.
2. Coherent processors, also known as *phase processors*. The information contained in the amplitude of Δ and Σ signals is transferred in some way to the phase of a new signal or signals on which it is easier to perform the processing.

In the following paragraphs some implementations of processors belonging to these categories are discussed. Obviously the number of possible variations is very large, but the ones described here are sufficiently representative to allow the reader to understand the underlying mechanisms used to obtain a valid monopulse function.

In order to compare the functionality and performances of the different processors, a pair of Δ and Σ signals is needed, as an ideal radiation pattern, applying them to the inputs of the processors. Here, Δ and Σ signals corresponding to the Jacovitti model [9] will be used, although other valid models could also be used [10]. In the Jacovitti model the amplitudes of Δ and Σ signals as a function of OBA are given by

$$G_\Sigma(\theta) = \frac{\sin\left(\frac{3\pi\theta}{2\theta_B}\right)}{\frac{3\pi\theta}{2\theta_B}} \left(1 - \left(\frac{3\theta}{2\theta_B}\right)^2\right)^{-1} \quad (6)$$

$$G_\Delta(\theta) = \frac{2\eta}{\pi} \sin\left(\frac{3\pi\theta}{2\theta_B}\right) \left(1 - \left(\frac{3\theta}{2\theta_B}\right)^2\right)^{-1} \quad (7)$$

where θ is the OBA, θ_B is the mainlobe width (defined at -3 dB below maximum), and η is the gain factor of the antenna.

Some properties of these functions are

1. Δ and Σ patterns intersect in angle $\theta = \theta_B/3\eta$.
2. The first null of the pattern is in $\theta = 1.5\theta_B$.
3. The Σ (sum) pattern is an even function of the OBA with respect to the origin and the Δ (difference)

Figure 12. Sum, difference, and monopulse patterns for Jacovitti model. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

pattern is an odd function of the OBA. Therefore the sign of the Δ pattern gives the necessary information about the target position with respect to the boresight.

- The ratio of Δ and Σ patterns is a linear function of OBA:

$$\frac{G_{\Delta}(\theta)}{G_{\Sigma}(\theta)} = 3\eta \frac{\theta}{\theta_B} \quad (8)$$

Property 4 makes this a very convenient model for comparing processors since the monopulse function is the ideal one: a straight line. Figure 12 shows the sum and difference patterns (normalized with respect to the maximum amplitude of the Σ pattern) and its ratio or monopulse function (normalized with respect to 3η) as a function of a normalized OBA (θ/θ_B) for an antenna with $\theta_B = 2.4^\circ$ and $\eta = 0.74$.

4.2. Noncoherent Monopulse Processors

4.2.1. Noncoherent Processor Type 1. This processor is represented in Fig. 13.

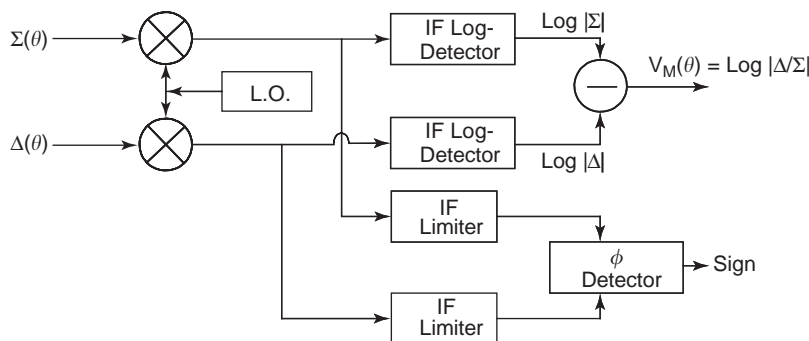

Figure 13. Noncoherent processor type 1.

Figure 14. Monopulse function for noncoherent processor type 1.

The radiofrequency Σ and Δ signals are downconverted to IF and applied to a pair of logarithmic detectors. Their video outputs are subtracted to obtain the monopulse function $V_M(\theta) = \log(|\Delta|/|\Sigma|)$. This function, obviously, has no sign information since it is lost in the detectors, so an additional measurement is necessary from the phase difference of limited input signals in a conventional phase detector; if the phase detector output is positive, the target is at the right of boresight. Although the amplitude information of $|\Sigma|$ and $|\Delta|$ signals could be obtained through conventional video detectors (AM detectors), their limited dynamic range would be insufficient in most applications. Use of AGC (automatic gain control) circuits is not always possible as they are slow-acting and cause errors for off-axis targets whose echoes fluctuate in amplitude from pulse to pulse. In phase detection the limiters also allow the inputs to the phase detector to be of constant amplitude. Modern logarithmic detectors (some of them include the limiting function) have a dynamic margin in excess of 100 dB.

Figure 14 shows the monopulse function. The main disadvantage of this processor is a direct consequence of the null amplitude of the Δ signal in the boresight; the amplifier processing this signal tends to saturation. Furthermore the monopulse function is strongly nonlinear, so calibration will be a critical factor. On the other hand, this function is nonambiguous for any OBA.

Figure 15. Noncoherent processor type 2.

4.2.2. Noncoherent Processor Type 2. In this processor Δ and Σ signals are combined before the logarithmic detection in order to obtain an odd function of OBA and to avoid the phase detection necessary otherwise. In a combining network the new signals $\Sigma + \Delta$ and $\Sigma - \Delta$ are formed and, as above, are applied to logarithmic detectors as shown in Fig. 15.

The resulting monopulse function $V_M(\theta) = \log(\text{abs}(\Sigma + \Delta)/\text{abs}(\Sigma - \Delta))$ is shown in Fig. 16, where this function's odd characteristic with respect to the OBA may be seen.

Figure 16 also shows the ideal monopulse function for comparison purposes. It must be mentioned that it is not important whether both functions are not equal, which simply implies a different (and more nonlinear) calibration function. The monopulse function obtained with this processor is nearly linear in the boresight vicinities, although is clearly nonlinear in the proximities of $\Sigma = \Delta$, showing, as before, saturation problems at this point. For $|\Sigma| < |\Delta|$ angles ($|\theta/\theta_B| > 0.42$ for the Jacovitti model used) the function is also ambiguous, so it is futile to calculate

Figure 16. Monopulse function for noncoherent processor type 2. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 17. Coherent processor type 1.

the target OBA. From the tracking viewpoint, although ambiguous, the output polarity is the correct one, so the servos will guide the antenna in the right direction (in a nonlinear fashion).

4.3. Coherent Monopulse Processors

Coherent monopulse processors convert the amplitude information of Δ and Σ signals in phase information of a new set of signals for its subsequent easier processing.

4.3.1. Coherent Processor Type 1. Figure 17 shows a block diagram of this type of processor. A combining network forms the complex signals $\Sigma + j\Delta$ and $\Sigma - j\Delta$ that are applied to a pair of limiters prior to their phase detection to obtain the monopulse output voltage.

Effectively, as shown in the phasorial diagram in Fig. 18, the ratio between the amplitudes of Σ and Δ signals (the magnitude we are interested in measuring) is contained in the arctangent of the angle formed by the new signals. Supposing a sinusoidal characteristic for the phase detector, the output voltage (monopulse function) is given by

$$\begin{aligned}
 V_M(\theta) &= K \sin(\phi) = K \sin(\phi_1 + \phi_2) \\
 &= K \sin\left(\arctan\left(\frac{\Delta}{\Sigma}\right) + \arctan\left(\frac{\Delta}{\Sigma}\right)\right) \quad (9) \\
 &= K \sin\left(2 \arctan\left(\frac{\Delta}{\Sigma}\right)\right)
 \end{aligned}$$

Figure 19 shows the monopulse function obtained. In the vicinities of the boresight the function is linear and nonambiguous, but above angles for which $|\Sigma| < |\Delta|$, the ambiguity problem is also present, although the saturation problem is corrected.

4.3.2. Coherent Processor Type 2. In this processor the signals over which a phase detection is performed are Σ and $\Sigma + j\Delta$. A block diagram and monopulse function are shown in Figs. 20 and 21.

Figure 18. Relationship between angle and amplitude of signals.

Figure 19. Monopulse function for coherent processor type 1.

This processor does not have the monopulse function ambiguity and/or saturation problems found in the other processor types. Furthermore, the linearity is maintained over a wider OBA range. These characteristics would seem to make it preferable to the others.

4.4. Nonideal Behavior

Any of the processors presented above could be used as a monopulse processor with a previous calibration of the output function. The monopulse functions shown have been obtained with supposed ideal components; however, in practice, there are a number of effects that should be analyzed since they are present to some extent in every real processor. Most representative of these effects are the thermal noise [characterized by the S/N ratio (SNR) of

Figure 21. Monopulse function for coherent processor type 2.

Figure 22. Error in angle estimation due to thermal noise.

processed signals] and amplitude imbalance and phase imbalance between Σ and Δ signals.

Deviations produced in the ideal monopulse function (that obtained supposing ideal components) due to these effects should be minimized. Processor choice is very important, as will be shown below.

4.4.1. Thermal Noise. If Σ and Δ are noisy signals (characterizing the noise as a Gaussian process with zero mean and standard deviation $\sigma_N = \sqrt{P_N}$, where P_N

Figure 20. Coherent processor type 1.

Figure 23. Normalized error versus OBA for noncoherent processor type 2 (dotted lines) and coherent processors types 1 and 2 (circles and dashed lines, respectively), for phases $\phi = 2.5^\circ, 4.5^\circ,$ and 8.5° . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Table 1. Processor Performance Comparison

Processor Type:	Noncoherent		Coherent	
	1	2	1	2
Nonambiguous range	Total	$\Delta/\Sigma \leq 1$	$\Delta/\Sigma \leq 1$	Total
Linearity	1	3	2	4
Thermal noise	2	2	2	1
Phase imbalance	4	3	4	2

is the noise power), the angle estimation error is also a zero-mean Gaussian process with standard deviation given by (for the Jacovitti model)

$$\sigma_\varepsilon = \frac{\theta_B}{3\eta G_\Sigma(\theta/\theta_B)} (1 + 9\eta^2(\theta/\theta_B)^2)^{1/2} \left(\frac{1}{\sqrt{2\text{SNR}}} \right) \quad (10)$$

for noncoherent processors types 1 and 2 and coherent processor type 1. For coherent processor type 2, the standard error deviation is given by

$$\sigma_\varepsilon = \frac{\theta_B}{3\eta G_\Sigma(\theta/\theta_B)} (1 + 9\eta^2(\theta/\theta_B)^2) \left(\frac{1}{\sqrt{2\text{SNR}}} \right) \quad (11)$$

Figure 22 shows these errors normalized with respect to the noise power and θ_B ($\sigma_\varepsilon/(\theta_B\sigma_N) = \sigma_\varepsilon\sqrt{2\text{SNR}}/\theta_B$) as a function of normalized OBA (θ/θ_B).

For SNR = 20 dB and a radiation pattern with $\theta_B = 6^\circ$, the estimation error for an arrival angle of 2.4° (normalized OBA = 0.4) is about 0.4° for coherent processor type 2.

4.4.2. Precombinational Amplitude Imbalance. If the gains of Σ and Δ receivers are not identical prior to the combination of signals, an error will be induced in the angle estimation when denormalizing the monopulse function obtained since this function is processing an erroneous value for the Δ/Σ ratio.

Let us suppose that, in the diagram corresponding to noncoherent processor type 1, the Δ signal at the input is of the form $K\Delta$, where $K = 10^{(d/20)}$ is the amplitude imbalance between Σ and Δ receivers (d is the imbalance expressed in decibels). The output of the monopulse processor would be given by

$$V'_M = \log \left| \frac{K\Delta}{\Sigma} \right| \quad (12)$$

and, taking into account the relationship between Σ and Δ in the Jacovitti model

$$\frac{\Delta}{\Sigma} = 3\eta \frac{\theta}{\theta_B} \quad (13)$$

it is found that

$$V'_M = \log \left| \frac{K3\eta}{\theta_B} \theta \right| \quad (14)$$

This value includes the error due to the amplitude imbalance. The estimated angle through the calibrated monopulse function will be the θ' which delivers the same monopulse output through the ideal function

$$V'_M = \log \left| \frac{3\eta}{\theta_B} \theta' \right| \quad (15)$$

so the error in the angle estimation is $\varepsilon(\theta) = \theta' - \theta$. It is straightforward to represent this error in the form $\varepsilon(\theta) = (K - 1)\theta$. The same error is found in any of the processors presented, since, if ratio Δ/Σ is modified because of

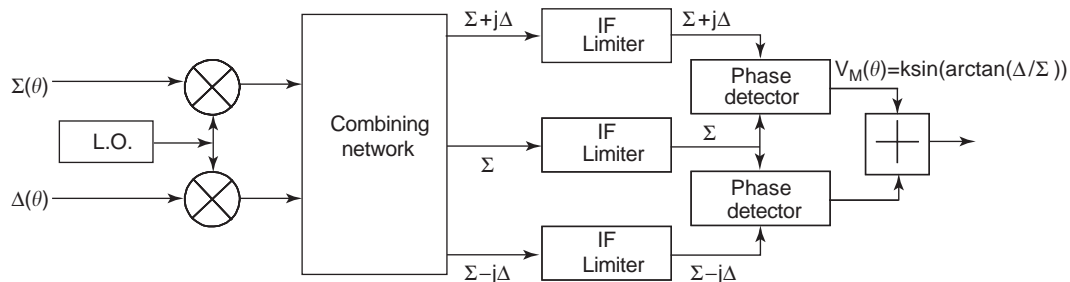

Figure 24. Coherent three-channel monopulse processor.

a gain imbalance, the underlying mechanism for measuring the angle is being modified. If there are no more error sources, any processor will give the same angle estimation (and thus the same error). For an imbalance of 1 dB and an OBA of 2.4° the error in the estimation is about 0.3° .

4.4.3. Precombinational Phase Unbalance. If the Δ signal suffers a phase deviation from the nominal, $\Delta' = \Delta e^{j\phi}$ (produced by different electrical lengths in Δ and Σ paths or different insertion phases of some component), the resultant monopulse function will be modified and, when denormalizing with respect the ideal one, an error in the angle estimation will be produced. In this case the error depends on the processor type. In noncoherent processor type 1 the resultant monopulse function is identical to the ideal since the amplitude of the phased signal is the same as that of the original one; thus the estimation error is null.

Figure 23 shows the normalized error ($\Delta\theta/\theta_B$) for the other three processors. Coherent processor type 1 is nearly immune to this source of error. Coherent type 2 suffers the maximum errors for angles near the boresight, although for all the processors the error is null in the boresight direction.

For the previous example (normalized OBA = 0.4, $\theta_B = 6$), Fig. 23 yields an error estimation of 0.17° for coherent processor type 2 if phase unbalance is only 4.5° .

Table 1 resumes different processors performances (where 1 denotes the worst and 4 denotes the best performance).

A coherent implementation known as a *coherent three-channel monopulse processor* combines the best properties of the processors listed in Table 1 at a cost of increased complexity, as may be seen in Fig. 24 [11].

The correct choice of processor for a given system will thus come from a tradeoff between performance and electronic complexity. Besides the traditional processors discussed here, there are a relatively large number of possible different structures. Among these, the I&Q processors (those based on in-phase–quadrature detection of sigma and delta signals) are probably the most attractive because of the versatility that they offer in subsequent digital processing, especially if pulse compression or spread-spectrum techniques are used [12].

MONTE CARLO ANALYSIS

PAOLO LUGLI
University of Rome

As the name suggests, the Monte Carlo (MC) method is based on the selection of random numbers [1–4]. In its present form, the method is attributed to Fermi, Von Neumann, and Ulam, who developed it for the solution of problems related to neutron transport. In principle, the MC method can be considered as a very general mathematical tool for the solution of a great variety of problems.

Among the various applications of the method, the following are probably the most important:

- Integrodifferential equations
- Matrix inversion
- Transport of nuclear particles
- Transport in semiconductors
- Modeling in semiconductor devices
- Process simulation

An important feature of the MC technique is that more precise results can be obtained by generating larger numbers of points. More generally, being based on random numbers, the results obtained with an MC procedure are never exact, but are rigorous in a statistical sense: The exact result lies in given intervals with given probabilities. The uncertainty of the results is strictly related to the variance of the possible outcomes, and it is smaller if the size of the sample (i.e., the amount of computations devoted to the solution of the problem) is larger. One basic element of the numerical procedure is the possibility to generate random numbers with given distributions starting from pseudorandom numbers uniformly distributed between 0 and 1. Modern computers provide sequences of numbers obtained with precise mathematical algorithms, starting from a given element (seed). For each seed, the sequence is perfectly predictable. However, it satisfies a large number of statistical test of randomness. Those pseudorandom numbers offer two great advantages: They

can be generated in a very fast way, and they are reproducible (which is essential, for example, in debugging a code).

The applications of MC methods can be divided into two major groups. One consists of the direct reproduction on a computer of the microscopic dynamics of the physical process in a system that is already statistical in nature. We use in this case the term "MC simulation." The second group consists of MC methods devised for the solution of well-defined mathematical equations or problems. In such cases, the methods provide a way of sampling a given statistical distribution. The majority of real cases are a mixture of the two extreme limits indicated above. The application to the study of semiconductor devices and processes is a good example. In fact, transport processes are statistical in nature, but are also accurately described by well-defined equations that may or may not correspond to the direct simulation of the physical system under examination. For instance, the MC solution of the Boltzmann transport equation (BTE) not only gives the distribution function that verifies the equation but also yields information that is lost in the BTE itself. On the other hand, the direct simulation is at times very inefficient, as, for example, in the analysis of situations that are rare in the actual physical system. In such cases it is necessary to distort the simulation by applying some more sophisticated MC techniques that reduce the variance of the quantity of interest, giving up partially the advantages offered by the direct simulation.

The applications of the MC methods that we will focus on are particularly important in light of the growth in the field of microelectronics achieved in recent years. Semiconductor devices are nowadays built with their active dimensions well below 1 μm . Metal oxide semiconductor field-effect transistor (MOSFET) technology has moved already into the 0.25 μm size, while high-electron-mobility transistors (HEMTs) are commercially available with 0.15 μm gate length. The reduction in size leads to a higher integration level as more devices can be put into a single chip. Such a push toward smaller and more powerful devices (which immediately translate into higher levels of integration and enhanced performance of the single devices as well as of the overall circuit) has been sustained by enormous advances in the area of fabrication and processing. A very precise control is nowadays possible on the device geometry and doping profile through techniques such as ion implantation, reactive-ion etching, and electron and X-ray lithography. Furthermore, new possibilities for novel devices are offered by the capability to grow nanometer layered structures with extremely high quality by molecular-beam epitaxy (MBE) and metal organic chemical vapor phase epitaxy (MOCVD). As we will see, MC approaches can be of great help in understanding and overcoming the limits of several technological or in attempting to improve the yield of integrated circuits. Moving into the submicron scale, many new physical phenomena become important that require a sophisticated theoretical treatment. There exists, therefore, a new challenge toward the understanding of the principles of operation of those novel devices. The MC method offers great advantages also in this direction.

Computer programs are extremely important for technology development. Computer-aided design (CAD) has become one of the keystones in microelectronics. The importance of such a field can be greatly appreciated focusing on the steps required for the fabrication of integrated circuits (ICs). The development of new technologies is traditionally driven by an experimental approach. A useful alternative is offered by software tools, which can lead to a speed up of the development cycle and a reduction of the development costs. In fact, those calculations can be considered as simulated experiments, which can be much faster and less expensive than real experiments. Furthermore, computer experiments allow a deep physical interpretation of the final results that leads to a better understanding of the problem at hand. This is particularly true for the MC simulations. The characteristic links between the different aspects of CAD can be summarized as follows [5]. The output of the process simulation is fed directly into a device simulation program, which determines the electrical characteristics and the performance of the device. At this stage, the interplay between process and device simulation can suggest improvements on the processing steps deduced from the simulated device performance. The output of the device simulator is then compacted in order to be inserted in a circuit simulation program, which determines the characteristics of the overall circuit. As this article will show, MC approaches are finding more widespread use as CAD tools, both at the level of device and at the level of process simulation.

Although it will not be possible to exhaust the complexity of the MC methods in such a short review, the present contribution is intended to give a critical overview of the MC algorithms used for device and process modeling and for circuit yield analysis. A more thorough investigation can be found in the references. For the MC simulation of semiconductor devices, a complete review can be found in Ref. 6.

1. MONTE CARLO DEVICE SIMULATION

The Monte Carlo technique is a fairly new tool in the area of device modeling, traditionally dominated by simulators based on drift-diffusion models or on balance-equation models (for an overview of the subject, see Refs. 7 and 8). The first MC application to the study of electronic transport in semiconductors is due to Kurosawa in 1966 [9]. Shortly afterward the Malvern group, in UK (Boardman, Fawcett, Hilsun, Swain, among others), provided the first wide application of the method to device simulation, focusing mainly on GaAs devices [10]. Applications to Si and Ge boomed in the 1970s, thanks to work performed at the University of Modena, Italy, and at IBM Yorktown, USA. The reviews in Refs. 4 and 11 provide a deeper historical and technical perspective. The great attention reserved in recent years to the MC analysis of devices is strictly connected to the availability of powerful and relatively inexpensive computers and workstations, which guarantee the necessary numerical resources for the computationally quite heavy simulations. Furthermore, with the recent advances in material growth, contact

deposition, and impurity control, devices have become more transparent from a physical point of view. Incidentally, this has provided physical systems of extreme interest. At the same time, MC algorithms have gained in sophistication and are now able to handle phenomena and systems of great complexity. These are two fundamental steps since the necessary input for an MC simulation of semiconductor materials and devices is an accurate microscopic description of the physical system under investigation. Many semiconductor devices can be nowadays simulated with the MC method, which is becoming more and more a very useful modeling tool.

The most common (and also the most interesting) simulation of a semiconductor device is performed for many particles in parallel [Ensemble Monte Carlo (EMC), procedure] and coupled to Poisson's equation in order to obtain the self-consistent potential related to the charge distribution given directly by the MC procedure. For systems of great complexity, a one-particle Monte Carlo (OPMC) simulation can be performed on a given fixed potential previously determined.

Since no a priori assumptions are needed on the form of the real- and k -space carrier distributions, an MC simulator is the only reliable tool for the investigation of those physical phenomena that critically depend on the shape of the distribution or on the details of its tail (such as electron injection over potential barriers). Furthermore, the MC technique allows us to focus on particular physical mechanisms that might be of importance with regard to the device performance (e.g., intercarrier scattering, impact ionization, generation-recombination, etc.). The price one has to pay are a very time-consuming algorithm and the requirement of a complete knowledge of the physical system under investigation. Often many assumptions have to be made in order to reduce the complexity of the model describing a given device.

1.1. The Monte Carlo Algorithm

In recent years, EMC simulations have been widely used to study the properties of semiconductor devices. Particular emphasis has been lately attributed to submicron structures, because of their performances in switching and high frequency operations [12]. Once the basic physics involved in the transport of such devices is known, EMC simulation provides a formidable tool to determine their limits and characteristics and can be very helpful in modeling. Together with the determination of the macroscopic properties of a device, EMC also gives a microscopic description of the local electric field, charge density, velocity distribution, and so on.

The basic steps of a standard EMC self-consistent device simulation are (see Fig. 1) as follows:

1. *Set up Geometry and Discretization Scheme.* Two parameters that play an important role in the choice of the time step and the grid size are the plasma frequency and the Debye length. For simple device geometry a one-dimensional description can be sufficient. Normally, MC simulations are performed using a two-dimensional grid (that is, assuming

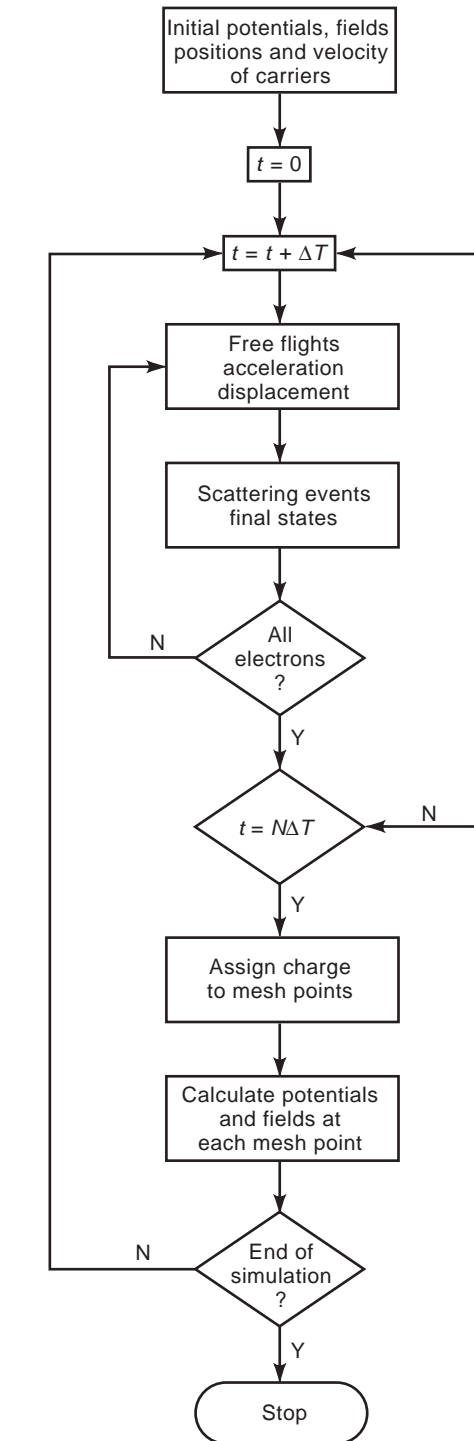

Figure 1. Flowchart of typical self-consistent MC device simulation.

homogeneity along the third direction). Since the simulation is inherently three-dimensional, there are no principal reasons that prevent a fully three-dimensional analysis.

2. *Charge Assignment.* The charge of each particle is assigned to a particular mesh point. Since it is not possible to simulate all the electrons present in a

real device, each simulated particle (also referred to as “superparticle”) represents a cloud of electrons for the purpose of estimating currents, charge, and field distributions. For all other purposes, each individual particle carries its elementary charge e . The doping charge is also added to the mesh according to its distribution. A sufficiently large number of simulated particles is needed to guarantee the statistical validity of the results and to reduce the level of numerical noise. Such a number depends on the dimensionality of the spatial grid, ranging typically from thousands of particles for one-dimensional descriptions, up to several tens of thousand particles for two- or three-dimensional systems.

3. *Potential Solution.* Poisson’s equation is solved to determine the electrostatic potential at the mesh points. In connection to EMC simulations, a finite-difference scheme is generally used, although some attempts to use a finite-element approach have been presented [13]. The solution can be obtained in several ways, among which we can list the Fourier analysis cyclic reduction, the conjugate gradient, the multigrid, and the direct matrix inversion methods. The first three methods provide effective algorithms that allow the inclusion of special boundaries. The latter requires a matrix inversion at the beginning of the simulation. The new potential is calculated with a simple matrix multiplication at fixed times during the simulation. The electrostatic field is then obtained from the potential with a finite-difference algorithm.
4. *Flights.* Each particle, now treated as an individual electron, undergoes the standard MC sequence of scattering and free flights, subject to the local field previously determined from the solution of the Poisson equation. The MC sequence is stopped at fixed times, at which the field is adjusted following the steps described above. The carrier dynamics is computed by solving Newton’s equations of motion in the crystal, described by its band structure. The length of a free flight is generated randomly according to the total scattering rate (i.e., the number of collisions per unit time). At the end of each flight, carriers scatter (with impurities, lattice vibrations, other carriers, etc.), with the probability of each event being weighted by its scattering rate (relative to the total one). Finally, a new state (i.e., the new energy, wavevector, occupied band) following the collision is determined according to the differential cross section of the process that has terminated the free flight. The scattering probability and the probability distribution of the final states are computed using quantum mechanics (starting from the so-called Fermi Golden Rule). A particular event (collision or no collision, which type of collision, which final state) is selected randomly, by comparing the probability of occurrence of that event to a random number.

The description of the problem is completed by setting initial and boundary conditions. The initial conditions are

not so important, since only the self-consistent steady-state result is usually retained. Boundary conditions are instead crucial, in particular in submicrometer devices, where contact properties drastically influence the behavior of the whole device.

The steady-state current is given directly by the net number of particles crossing one contact per unit time. More effectively, an extension of Ramo’s theorem to two-dimensional situations allows the calculation of the current in three terminal devices simply by summing the velocities of all particles found inside given portions of the device [14]. By performing several computer runs, it is possible to construct the I – V characteristics of the device. Important device parameters can also be extracted from the simulation. For example, the output resistance $R_{\text{out}} = \Delta V_{\text{ds}} / \Delta I_{\text{ds}}$ for constant gate bias V_{gs} and the transconductance $g_{\text{m}} = \Delta I_{\text{ds}} / \Delta V_{\text{gs}}$ for constant drain bias V_{ds} can be obtained from a series of runs, starting from normal operating conditions and varying the drain-to-source and gate-to-source biases, respectively. Parasitic elements can also be calculated, referring to an equivalent circuit description of the device. For example, the source-to-gate C_{sg} and source-to-drain C_{gd} capacitances are obtained by applying a step change respectively to the gate (ΔV_{gs}) and drain voltage (ΔV_{gd}) and $C_{\text{gs}} = \Delta Q_{\text{gs}} / \Delta V_{\text{gs}}$ and $C_{\text{gd}} = \Delta Q_{\text{gd}} / \Delta V_{\text{gd}}$, where ΔQ is the total equivalent charge flowing from the gate in response to the step potential. From the time dependence of the charge flow, it is also possible to estimate the parasitic source and drain resistance.

In an MC simulation, ohmic contacts are usually treated as ideal contacts, by maintaining a neutrality condition near the metal boundary. Due to such an assumption, the simulation results are those of an ideal intrinsic device. The comparison of the simulated characteristics with the one measured on real devices requires the consideration of a finite resistance for each ohmic contact. This can be done quite simply by scaling the simulated I – V characteristics using independently determined values of the contact resistances [15].

Traditionally, device simulators have been based on drift diffusion (DD) or hydrodynamical (HD) models. The basis of the two methods (as also the MC) is the Boltzmann transport equation. By taking the first three moments of BTE, three coupled equations are obtained which describe the spatial and temporal evolution of the average carrier concentration, velocity, and energy. Within the HD approach, the three equations are solved numerically, with some simplifying assumptions (such as the introduction of momentum and energy relaxation times for the equations of first and second moments). The DD approach assumes that carriers are always in equilibrium with the lattice temperature. Thus the energy equation drops out, and only the continuity equation is left, provided that the current density is expressed in a phenomenological way in terms of the carrier mobility and diffusivity. Clearly, the HD scheme is far superior to the DD one, since it can account (when all terms are considered) for carrier heating and nonhomogeneous distributions of the carrier temperature. The MC procedure stands on an even higher level, since it provides (also in nonhomogeneous, nonstationary

conditions) an exact solution of the Boltzmann equation. It correctly describes nonlocal effects (in space \mathbf{r} or time t) typical of situations where the field inside the device varies appreciably over lengths comparable with the electron mean free path, and the electrons at a given position carry information about the field value at another position. Unfortunately, the complexity and cost of each approach is inversely proportional to the refinement of the physical model it is based on. Therefore, the use of one approach or another depends on the specific device under investigation. The MC is the best technique to study situations where nonstationary effects are important (as, e.g., in submicrometer devices). It is safe to anticipate that as the tendency toward the miniaturization of devices will continue in the future, MC simulators will progressively extend their applicability. The success of MC in device modeling will ultimately depend on the compromise between two tendencies, one to use very sophisticated physical models (which lead to very costly but extremely accurate simulations), the other to rely on simplified models, sacrificing a bit of accuracy for a reduced complexity and cost of the algorithms. Along this line, it will be extremely useful to be able to combine different methods in order to fully exploit the potential of each approach. Examples of MC simulators present in the literature can be found in Refs. 16–42.

1.2. Special Features

In the following section, we focus on special aspects of the MC simulation that are not generally considered because of their difficulty, although they can be of great importance in the device performance.

1.2.1. Full Band Simulation. A physical description of the semiconductor band structure is needed as input to the MC simulation. Traditionally, bands have been described via nonparabolic dispersion relations, because this allows the analytical calculation of the differential and total scattering rates for a variety of scattering mechanisms. Furthermore, the calculation of the field-induced acceleration during a free flight is trivial. A typical example is the model used for GaAs [43], which includes a three-valley description of the conduction band (T, L, and X valley) and a description of the three valence bands (heavy, light, and split off holes). The nonparabolic dispersions are introduced with nonparabolicity factors treated as fitting parameters and adjusted as to reproduce a variety of experimental results, including those provided by time-resolved spectroscopy [6]. The carrier interaction with polar optical, acoustic, equivalent and nonequivalent intervalley, intraband and interband phonons, and ionized impurities can be easily considered. Unfortunately, nonparabolic dispersions provide an adequate band description only up to energies not too far from band edge (typically 1 eV or less). Thus, higher band states need to be described more accurately any time high-energy effects are important in a device (as, for instance, in the case of carrier injection above energy barriers, or when impact ionization occurs). The most popular approach is that based on a full band description, achieved via pseudopo-

tential methods [44]. The full $\varepsilon(\mathbf{k})$ dispersion is calculated numerically, either on the entire Brillouin zone or only on the irreducible wedge. The scattering rates are then calculated using directly the electronic states coming out of the numerical routine. The improvement in the band description level is paid in terms of computational time and memory required with respect to simpler band models.

1.2.2. Pauli Exclusion Principle. Electrons obey the Fermi–Dirac statistics and must satisfy the Pauli exclusion principle (PEP). This means that not all the states are available because only two electrons of opposite spin can reside in each state. This aspect is not very important in the nondegenerate case, and electrons are distributed in a large interval of states; in the degenerate case the problem becomes more conspicuous. For instance, GaAs electrons are degenerate at room temperature at densities around 10^{19} cm^{-3} . This is the case for many devices of interest. Degeneracy is equivalent to a many-body interaction which reduces the phase space available for the electron final state in an induced transition. If $p(\mathbf{k})$ and $p(\mathbf{k}')$ are the probabilities that the initial and final state are, respectively, occupied, the total rate of transition $P(\mathbf{k}, \mathbf{k}')$ between two different states is given by $P(\mathbf{k}, \mathbf{k}') = p(\mathbf{k})S(\mathbf{k}, \mathbf{k}')[1 - p(\mathbf{k}')]$. Normally a semiclassical MC procedure works with the approximation $p(\mathbf{k}') = 0$ because all the states are considered available as final states. The inclusion of the PEP is then essentially the inclusion of this term in the total scattering rate. In the EMC procedure, this is obtained very easily because the particle distribution is known step by step. The algorithm generating the distribution function is set up by multiplying the scattering probability by the correction factor $1 - p(\mathbf{k}')$; $p(\mathbf{k}')$ is determined self-consistently, and a rejection technique is used after selecting the final state without the correcting Pauli factor [45].

1.2.3. Contact Simulation. The simulation of contacts is one of the most serious problems in MC device simulations, due in part to the limited knowledge of the physics of contacts. On the other hand, contacts are of great importance in a number of semiconductor devices, whose applications range from high-speed logic to microwaves. As the dimensions of these devices reach the submicron limit, contacts become the limiting factor for the performance in the ballistic or quasiballistic mode of operation. In general, semiconductor devices do not operate under charge neutrality conditions. The net charge inside the device is directly related through Gauss' law to the flux of the electric field on the boundaries, and consequently to the potential inside the device. Therefore, charge neutrality (that is, conservation of the number of particles) cannot be enforced in the simulation. Rather, an appropriate handling of the boundaries is required to simulate a number of electrons that vary in time self-consistently with the potential distribution. Taking a field-effect transistor as an example, the most significant boundaries are at the source, drain, and gate electrodes. Source and drain contacts are usually treated as ideal ohmic contact by absorbing all the electrons that hit the electrodes and by injecting a number of electrons which maintain a neutral

region in the adjacency of the electrodes. The Schottky barrier at the gate is treated as a perfectly absorbing electrode with a potential equal to the applied potential minus the barrier height. Although commonly assumed, the above conditions have never really been tested. One attempt to deal with the problem of contacts in a simulation of a one-dimensional metal–n–n⁺ structure has been presented in Ref. 46.

1.2.4. Carrier–Carrier Scattering. Many devices are characterized by very high electron concentrations. In such a situation, one might have to worry about the possible influence of the interaction among the conducting electrons. A good example is provided by the heterojunction bipolar transistor (HBT), which will be examined later. In a standard device, such as a metal semiconductor field-effect transistor (MESFET) or HEMT, electrons are injected into the channel with a thermal energy distribution and a small initial velocity. In an HBT, electrons are injected from the emitter into the base, which they cross before being swept away from the high field at the base–collector junction. Due to the high doping (p-type) in the base region, electrons can be scattered by the collective excitations of the hole gas, as well as through normal binary collisions with the other electrons. Two main contributions to the carrier–carrier scattering can be identified:

- The individual carrier–carrier interaction via a screened Coulomb potential which accounts for two-body short-range interaction
- The electron–plasmon interaction, which accounts for the collective long-range behavior of the electron gas

In semiconductors, the plasmon energy at a reasonable electron density can be of the same order of magnitude as the characteristic phonon energies. In a device simulation, the scattering rates for electron–electron and electron–plasmon processes can be tabulated at the beginning of the simulation. Carrier–carrier scatterings are then treated as any other mechanisms in the MC algorithm, using appropriate rejection algorithms to account for the current carrier distribution function [47,48].

1.2.5. Optimization Procedures. An original, efficient algorithm has been implemented to calculate the appropriate duration of the free flights (depending on the actual carrier status). The method, which is based on a space-dependent definition of the scattering rate [49], leads to a drastic reduction in the number of self-scatterings, thus allowing a large savings in computation time (more than one order of magnitude compared with the conventional approaches). In areas where the electron population is very small, it is possible to extend a technique originally proposed by Phillips and Price [49], which allows one to obtain good statistics in rarely visited energy regions. Two situations are of particular interest. If a device presents regions with a high doping density N^+ connected to regions with low densities N^- , the carrier concentration will reflect (except at the interface between the different regions) the doping distribution. Therefore, most of the simulated carriers (roughly in the ratio N^+/N^-) will populate

the highly doped, low-field regions, requiring an extensive amount of computation for the simulation of a quasithermal distribution. This is the case, for example, of the MOSFET or a MESFET with ion implanted source and drain contacts. A similar case is found in k space, when we are interested in the population of high-energy states, which are rarely touched by the carriers but might cause very important physical phenomena (a typical example is the carrier injection into SiO₂ for the channel of a MOSFET). The latter situation is the one examined by Phillips and Price. The population of the high-energy states can be enhanced by generating a fixed number N of carrier histories every time one of the simulated particles enters the rarely populated region. Each one of the N generated particles will have the same initial condition (equal to the state of the “parent” particle at the moment of the multiplication) and a weight $1/N$ for the calculation of the average quantities. The multiplication algorithm can be repeated several times at higher energies, originating an “avalanche” of carriers that fill up the tail of the distribution function at higher and higher energies [35]. A similar multiplication technique has been also used in real space in Ref. 39. A peculiar situation is found when impact ionization phenomena are important. The knowledge of the high-energy tail of the carrier distribution function is then required. Furthermore, in the presence of carrier multiplication, the number of simulated particles would grow above the initially set value, diverging as breakdown is approached. A special multiplication technique for both energy and real space has been implemented [50], which is an extension of the approaches described above. Each particle is assigned a statistical weight that varies with its position in the device and its energy. With such approach, it is possible to account for regions with very different doping levels (as in bipolar transistors) and to obtain a reliable statistics of rare processes, keeping at the same time a constant number of particles.

1.3. Simulation Results

We show some results obtained by MC simulation of GaAs devices, leaving the interested reader to the variety of applications listed as references at the end of this article.

1.3.1. Heterojunction Bipolar Transistors. HBTs are receiving considerable attention because of their high-speed performance and high current-handling capability. The device shown in Fig. 2 has been simulated [43] and the results have been compared with measured data. By varying the base–collector voltage (in the common-base configuration), the electric field profile changes as depicted in Fig. 3. Very high values are reached in the collector region, with the maximum occurring at the base–collector interface. Electrons, injected from the emitter, cross the base where they strongly interact with the dense hole plasma. As they enter the collector, they are ballistically accelerated by the junction field, reaching velocities as high as 6×10^7 cm/s. The spatial extent of the velocity overshoot is limited to about 100 Å, as the electrons are rapidly scattered into the satellite valleys where they move at saturated velocity. Figure 4 indeed shows that

Figure 2. Energy band diagram and cross section of the simulated HBT.

for a collector voltage of 16 V, almost all electrons in the collector populate, in equal number, the L and X valleys. There, they are strongly heated by the collector field, obtaining the high values of average energy illustrated in Fig. 5. Correspondingly, the calculated $(M - 1)$ factor, which measures the relative increase of collector current due to multiplication phenomena, is around unity at this voltage, in excellent agreement with the measured value [43]. As V_{BC} is further increased, the holes created by primary ionization processes are in turn able to ionize, marking the onset of breakdown, which is predicted around 18 V.

Figure 3. Electric field profile of the simulation HBT at various V_{BC} .

1.3.2. High Electron Mobility Transistors. HEMTs are extremely appealing for microwave low-noise applications. Their superior performance is due to the spatial separation of the electrons (confined in a small-gap channel layer, typically GaAs or InGaAs) from the donors (fixed in the large-gap region or regions surrounding the channel). In the simulated device [51] a special type of doping is considered, denoted δ -doping, where two dopant planes are located in the AlGaAs layers respectively above and below an InGaAs channel. The substrate material of the device is GaAs. Because of the different lattice constant of GaAs and InGaAs, strain is present in the channel region. This type of HEMT is referred to as “pseudomorphic HEMT.” Typical two-dimensional contour plots for a device with a gate length of 180 nm are shown in Figs. 6–9. The source-to-drain bias is 2 V. The potential distribution (Fig. 6) reveals that a high-field region exists in the channel between the end of the gate and the beginning of the cap layer (which is a doped GaAs region above the AlGaAs confining barrier, used in technology to reduce the capacitance and resistance at source–drain contact region). Entering this region, an electron becomes very hot, reaching average kinetic energies of few tenths of electronvolts, as indicated in the energy map of Fig. 7. Electron heating results in reduced confinement within the channel, since many of the electrons have sufficient energy to surmount the confining barrier. Furthermore, as a result of heating, the population of the upper L valley is very high in correspondence of the high-field region, as visible in Figs. 8 and 9 which show respectively the total and L valley electron concentrations. Because of the hot-electron-induced real-space transfer, the current flows through both the bottom AlGaAs layer (and partially

Figure 4. Electron concentration in the different valleys for $V_{BC} = 16$ V.

through the substrate) and the top AlGaAs barrier, which actually constitutes the access path to the drain cap region. The actual value of the electric field along the channel, along with the corresponding carrier drift velocity and average energy, is presented in Fig. 10. Due to the very

short gate length, the field reaches a peak value of 200 kV/cm, resulting in the strong electron heating discussed above and a remarkable velocity overshoot, which is in turn responsible for the excellent microwave performance of such devices.

Figure 5. Electron average energy in the different valleys for $V_{BC} = 16$ V.

Figure 6. Two-dimensional plot of the equipotential lines for the simulated HEMT at a drain bias of 2 V.

2. MONTE CARLO PROCESS SIMULATION

We are going to discuss MC process simulation from the point of view of integrated circuit (IC) fabrication, since this is certainly the area where simulation plays the most important role. Many different interrelated steps contribute to the realization of the final product. The main processing steps can be classified into the following three categories:

1. Thermal processing and doping (ion implantation, predeposition, annealing, oxidation, epitaxial growth)
2. Pattern definition (reactive ion etching, deposition, evaporation, sputtering)
3. Pattern transfer (optical X-ray, electron-beam lithography)

Figure 7. Two-dimensional representation of the electron average energy for the simulated HEMT at a drain bias of 2 V. The darkest region corresponds to an energy of 0.35 eV.

Figure 8. Two-dimensional representation of the total electron concentration for the simulated HEMT at a drain bias of 2 V. The darkest region corresponds to a density of $5 \times 10^{18} \text{ cm}^{-3}$.

Setting up mathematical models for each step requires the knowledge of very complex physical and chemical phenomena, such as, for instance, the redistribution of atoms or impurities into a given material, or the energy exchange between fast projectiles and the substrate they interact with. As we will see in the examples, some drastic approximations are made in order to define a tractable model.

As for the case MC device simulation, several analytical and numerical approaches exist in the literature that cover all the processing steps outlined above [5,52]. The MC technique has been very successful in some applications, especially those where the simulation can be reduced to a series of uncorrelated events describing the trajectories of projectiles against target atoms. This is the case of the examples we will discuss below—that is, ion implantation and electron beam lithography. Other

Figure 9. Two-dimensional representation of the L valley electron concentration for the simulated HEMT at a drain bias of 2 V. The darkest region corresponds to a density $5 \times 10^{18} \text{ cm}^{-3}$.

Figure 10. One-dimensional plot (along the channel direction) of the electric field (left), average velocity (center), and average energy (right) for two different drain voltages, respectively equal to 0.5 V (dashed lines) and 2 V (solid lines).

attempts have been made to use MC techniques to describe epitaxial growth [53,54].

As a general comment, we can say that once the mathematical model has been set up, the MC algorithm for process simulation presents fewer difficulties than the one for device simulation. This is because no self-consistency is required between internal potential and charge distribution and also because the transition probabilities are assumed to be constant between two successive stochastic events.

2.1. Ion Implantation

Ion implantation is one of the most important doping techniques for device fabrication, in particular for very-large-scale integration (VLSI) circuits. The successful application of this technique depends strongly on the ability to control the impurity profile for any implant condition. The three main processes involved in the penetration and slowing down of energetic ions into a material are

1. The energy loss via collisions with the target atoms. Thousands of atoms (called “recoils”) are displaced by each impinging ion. Local disorder and very high temperatures are reached in the region where the cascade occurs.
2. The thermalization of the excited zone, with possible diffusion of defects.
3. The long-range migration of defects.

Computer-aided design models for ion implantation fall into two broad categories: analytic distribution functions and MC methods. The former are computationally very inexpensive, but rely upon fits to experimental data to reproduce the observed profile of dopants ion and work well only for simple geometries in one dimension. In contrast, the MC approach attempts a first-principle calculation based on two-body scattering theory. Although computationally expensive, it can handle the most complicated structures.

An MC simulation offers the following advantages [55,56]:

- It accounts for implant profile discontinuities at the interface between different layers.
- It allows for a rigorous treatment of elastic scattering with the different types of atoms in a multiatomic target.
- It gives a full implant distribution rather than only a few of its moments.
- It can generate as-implanted profiles as a function of key parameters such as dose, energy, tilt, and rotation angles.
- It can include the recoil effect due to atoms that are knocked into deeper layers from an impinging ion.
- It allows the simulation of the defect generation due to ion implantation.

Furthermore, once a physically based model has been set up and verified, the MC method can be used to generate “experimental data” for semiempirical models that are highly computationally efficient and desirable in technology development and process optimization. Other important features of the MC simulation of ion implantation are its inherent three-dimensionality, the fact that ion backscattering is naturally accounted for, and the fact that both amorphous and crystalline targets can be considered. Those distinctive features make the MC simulation the most suitable approach to the study of ion implantation.

The MC simulation is performed by following a large number of individual ion histories; each of them is made up of collisions with target atoms, along with straight flights between them. The model relies on two main assumptions. The first is that the projectile interacts with one atom at a time, and thus multiple collisions can be neglected. Such a “binary collision” model breaks down at low energies, when deflections can occur even at greater distances from a target atom. The second approximation involves the mechanisms for energy and momentum losses. The contributions coming from electronic losses (where the incident ion is excited or ejects atomic electrons, with large energy and small momentum transfer) and from nuclear losses (originated from nearly elastic collisions with the target atoms, characterized by large exchange of momentum) are considered independent of each other. The

slowing down of the projectile results from the simple addition of the two effects. In the past, the basic theory to describe the penetration of charge particles into a solid was the one due to Lindhard, Scharff, and Schidøtt (LSS). The LSS theory has been successful in the prediction of primary ion range and damage distribution in amorphous semi-infinite substrates. Because of its assumption, it is not applicable to multilayers structures as often encountered in VLSI processing.

The simulation is made up of successive paths. After each of them, the energy of the ion is reduced by the amount of the electronic and nuclear losses, which are related to the momentum transfer to the target atom occurring during the collision. The history of each ion terminates either when its energy drops below a specified value or when the ion exits the target.

Different physical models can be used for the various phenomena involved in the energy loss process. An exhaustive review is found in [57]. A series of optimizations of MC procedures are discussed in Ref. 58. Such optimizations are crucial in order to overcome the major limitation of the MC approach—that is, the amount of computation needed to achieve an acceptable statistical accuracy.

A good example of a situation where the MC simulation works at its best is provided by channeling. If the target is crystalline in nature (and it is not damaged during the implantation process, as guaranteed by using low implant doses), then the stopping power of the medium is greatly reduced because of the large open spaces of the axial channels. The average ion penetration is then considerably increased with respect to amorphous targets. Although the number of ions that are well-channeled is considerably less than the number of the dechanneled ones, the well-channeled ions travel deep into the crystal and form a channeling tail in the resulting profile. It is the channeling tail that determines the junction depth. While the formulation of suitable transport equations for the channeling effect presents many problems, the direct MC simulation of the ion path through the target can be quite straightforward. The main obstacle is again the inadequacy of several available models for electronic stopping. Although still widely used, the LSS theory cannot properly describe channeling effects. Its shortcoming lies in the inability to account for the variation of electron densities between the atoms of the crystalline structure. In fact, an ion traveling along a crystal channel will experience less electronic stopping than another ion which more closely encounters the electron clouds of the target atoms. A proper model must therefore account for the electron distribution around each atom. For boron ions implanted in crystalline silicon, it has been shown that a combination of the two concepts of effective charge and proton stopping power lead to reasonable models. There, the solid-state Hartree–Fock theory with a muffin tin structure has been employed, with the assumption of a spherically symmetric electron distribution around the Si atoms. While such an assumption is fairly reasonable for boron, which has most of the bound electrons in *s* orbitals (i.e., with spherically symmetric distribution), it has been pointed out that a further improvement is needed for the implantation of

arsenic ions, where the electrons occupy *p* and *d* orbitals. One possibility is to calculate self-consistently the potential for the As projectile within the local density approximation, and then to determine the scattering phase shift and the scattering cross section needed in the simulation.

In the theoretical study of the implantation process, it is very important to be able to determine the cumulative damage imparted to the semiconductor crystal by the implanted ions. The MC simulation directly accounts for the effect of damage by explicitly simulating the formation of point defects, their recombination, and the effect that such defects have on each subsequently implanted ion [59,60]. The procedure is as follows. As the simulated ion travels through the crystal, target atoms that receive sufficient energy (15 eV for Si) leave their lattice site, forming a vacancy or an interstitial. The interstitials travel until they lose the energy gained from the incident ion. The location of interstitials and vacancies are recorded for each collision cascade. At the end of each of these cascades, the interstitials and vacancies within the cascade are annihilated if they are located within a specified capture radius of one another. Furthermore, the recombination with damage caused by previous cascades is taken into account via a statistical recombination algorithm. The defects that survive recombination are weighted to reflect the fraction of the overall dose that the simulated projectile represents, and then they are summed to obtain the simulated point defect distribution as a function of depth. This distribution is then used to modify the crystal structure that subsequent ions will cross by determining the rate of statistical creation of (1) interstitials at one of the eight interstitial sites in the diamond lattice unit cell and (2) vacancies on lattice sites. Such a model is inherently homogeneous, and it appropriately describes the damage caused by lighter ions, such as for instance boron, where the net formation of cumulative damage occurs by the overlap of the damage caused by individual cascades. Heavier ions, such as arsenic, can lead to local phase transitions from the crystalline to the amorphous phase. This can be simulated by considering the presence of highly localized disordered regions, which are formed whenever the relative number of displaced atoms during an ion cascade exceeds a specified value (for instance, 10% in the region under consideration).

The traditional MC approach described above is based on the calculation of a large number of independent ion trajectories, where each ion is followed from its entrance in the target material down to its stopping or exit point. Peripheral areas with low exposure (that is, with a dopant concentration that is order of magnitudes lower than the maximum values) cannot be adequately represented, because insufficient statistics is provided by the simulation. This is a typical situation where rare events can play an important role. An approach similar to the one already used in electronic transport simulation has been suggested [61]. The fundamental idea is to locally increase the number of calculated ion trajectories in areas with large statistical uncertainty. To this purpose, the simulated region is subdivided into layers, each characterized by a certain relative concentration level (with respect to the current maximum concentration achieved in the whole

region). For each simulated ions, a number of “check-points” is set up during the flight path. At a checkpoint, the local dopant concentration is calculated together with the global maximum concentration. The corresponding layer of fixed relative concentration is determined, and a “trajectory split point” is defined at the checkpoint if the ion has moved into a layer with lower relative concentration than the one touched at the previous checkpoint. The position, energy, and velocity of the ion are stored, and they are used to generate a series of virtual branches of the ion trajectory that start at this split point. In this way, a tree of virtual trajectories is formed for each regular ion, so that the peripheral areas of the dopant concentration are represented by a much higher number of ion trajectories and the statistical noise is reduced. To obtain the correct concentration, each branch is assigned a weight. The virtual trajectories are generated with the same model and parameters as the regular ones, with their initial condition (energy, velocity, and position) being determined by the regular ion characteristic at the checkpoint.

2.2. Electron-Beam Lithography

Electron-beam lithography (EBL) is the standard way of fabricating masks for optical and X-ray lithography. Furthermore, direct electron-beam writing on wafers is the only practical way to obtain ultrasmall linewidths. In EBL, finely focused beams are used to expose polymeric resist layers. The ultimate resolution obtainable is not limited by the characteristics of the incident beam but rather by the electronic scattering with the resist and the underlying substrate. Such scattering leads to the so-called proximity effect and can be subdivided into three distinct contributions, namely the forward scattering within the resist, the backscattering within the resist, and the backscattering from the substrate.

The actual process of electron scattering in solids is very complex, and simplifying models are needed to achieve quantitative results via numerical techniques. As for the case of ion implantation, the best approach is the MC simulation. In fact, the simulation is very similar to the one described before in this section. In the simplest model [62,63], electrons undergo a series of elastic scatterings with the target nuclei. They also suffer energy losses because of the inelastic scatterings with the target electrons. The elastic scattering is modeled using the screened Rutherford cross section, while in the inelastic contributions the energy is assumed to be lost continuously between two successive collisions according to Bethe’s formula. Between scattering events, the simulated electrons travel in a straight path, whose length is determined randomly according to the calculated cross sections. The sequence of free paths and scattering events is repeated until the electrons come to rest. Contrary to the ion implantation case, the quantity of interest here is the deposited energy rather than the position where the particle stops. It is, in fact, the energy passed by the incident electrons to the medium that creates the condition for the selective removal of the polymeric resist.

Several improvements have been suggested to the simple model described above. In particular, it was pointed

out [64] that the production of secondary electrons as a result of an ionization process caused by the incident beam has to be accounted for. Since the energy deposition is inversely proportional to the electron energy, the contribution of the secondary electrons (which are slower and move in a direction almost perpendicular to the incoming flux) can be significant. An hybrid model has been set up which includes a discrete energy loss mechanism corresponding to ionization, in addition to the continuous energy loss mechanism described above. A further refinement of the model has led to the use of Mott cross section for the treatment of elastic collisions [65]. Another improvement is needed in order to consider multilayered structures, as for instance those that serve as masks for X-ray lithography [66,67]. Such masks are obtained by direct writing via EBL on a thin resist, followed by pattern transfer in a thick resist multilevel structure. An example is shown in Fig. 11, where the radial profile of the energy deposited at the resist–substrate interface is plotted for three different values of the beam energy, namely, 20, 30, and 40 keV. The simulated multilayer is constituted by 10 nm of Al, 1000 nm of resist [polymethyl methacrylate (PMMA)], 20 nm of Au as base plating, 200 nm for Cr for adhesion purposes, and 2000 nm of Si substrate. The length of the free path has to be determined by taking into account the details of the electron dynamics— that is, the possibility for an electron to cross one or more layers during its path. Forward and backward contributions are shown separately in the figure, each characterized by its own range. The parameter η is the ratio between the energy deposited by backscattered versus forward scattered electrons. The MC results show that the ultimate resolution limit is set by forward scattering, which has a width of 90 nm at the interface. The backscattering contribution from the metal is important despite the reduced thickness of the layer, but can be eliminated by increasing the beam energy. The simulation results can be parameterized in order to predict the EBL resolution under various exposure conditions. This is done via the so-called proximity function, defined from a Gaussian fit to the MC data. By a numerical convolution of the proximity function with the

Figure 11. Radial distribution function of the total absorbed energy density for three different beam energies, with the relative contributions of forward scattering and backscattering.

Figure 12. Profile of absorbed energy density for a nominal pattern of 5 lines/spaces of 0.1/0.4 μm .

experimental pattern, it is possible to calculate the absorbed energy densities correspondent to the experimental situations. Figure 12 shows the absorbed energy density profile for the structure considered before and after an electron energy of 40 keV. The nominal line/space dimension is 100/400 nm. By assuming (according to the “Threshold solubility model” [68]) that the solvent develops all the PMMA irradiated above the threshold energy E_t , the developed lines would be around 150 nm. This value reproduces very well the experimental findings.

3. MC ANALYSIS OF CIRCUIT YIELD

The number of transistors on a single chip is approximately doubling every 2 years, as predicted by Moore’s law. Such progress is sustained by the continuous drive toward smaller feature sizes, larger dies, and better packing efficiency. While technology allows a general reduction of the manufacturing costs per transistor, the level of investment to continuously upgrade such technology is becoming enormous. It is then vital for any manufacturer to improve the yield of the IC production. *Yield* can be defined as the ratio of the number of designs that pass the performance specifications to the total number of designs that are produced. Since the total number of designs produced might be large or unknown, yield is usually measured over a finite number of design samples or trails in the process known as yield estimation. As the number of trials become large, the yield estimate approaches the true design yield. Parameter values that have statistical variations are referred to as yield variables.

Statistical design techniques for ICs, including yield maximization and sensitivity minimization, are becoming increasingly important in IC technology development because cost effectiveness and competitiveness demand minimal experimental passes and short development times. A valuable statistical circuit simulation methodology must inherently predict device and circuit performance reliably

and efficiently, relate their performance to fabrication process parameters and account for the fluctuations of such parameters, and account for physical correlations among device model parameters. The use of numerical process and mixed-mode device/circuit simulators provides the needed capabilities for predicting the effects of technological variations on device/circuit performance. However, such an approach cannot be generally used for yield predictions or other statistical modeling due to the waste amount of computation time required. This is very efficiently done via MC techniques.

In general, there are two basic sources of yield loss in a fabrication process: local process faults and global process faults. The latter include, for instance, mask misalignment and linewidth variations. They can cause variations in speed and power consumption, thus affecting primarily parametric yield. The former include spot defects, such as oxide pinholes, extra metal, and extra or missing material defects. They affect functional yield, because they primarily affect circuit topology and can cause the chip to completely fail functionally. Local process faults are therefore called “catastrophic” faults. The most probable origin of such faults is the presence of dust particles, or in general some contaminant, on the mask or on the wafer surface. During the photolithographic processes, these particles lead to unexposed photoresist areas, or resist pinholes, thus causing unwanted material or unwanted etching of material on a layer. Although some crossover and coupling between the two types of faults occur, and manifest themselves at a circuit level, usually they are considered as uncorrelated and they are treated separately.

3.1. Catastrophic Yield

The effect of catastrophic faults on yield can be determined via a MC simulation made up of the following steps [69,70]: (1) generation of a chip sample, according to specified layout design rules, (2) generation and placement of defects on the layout, and (3) analysis of the modified layout for circuit faults. A filtering step prevents uninteresting faults to be considered. Many chip samples are generated in a simulation. The defect diameter, type, and spatial distribution on each sample are selected randomly according to the defect statistics observed in the fabrication line. Once the defects have been placed on the layout, a series of fault analysis procedures are performed by looking at the defect neighborhood in order to determine which type of circuit fault has occurred (if any): short, open, open device, shorted device, new via, new device due to extra metal, or new device due to extra active material. Out of the resulting faults, only those affecting functional yield are kept, the others being filtered out. Some faults can also be combined together into a composite fault. Both fault analysis and filtering operation are guided by defect models, which specify which circuit faults can be caused by each defect type, which layers interact with the defect, and how layers are electrically connected together. The resulting output is a chip sample containing a list of the circuit faults that have occurred on it during the simulated fabrication. The chip sample fault lists are summarized to record the frequency of each unique fault

combination and are then passed to an application post-processor when the simulation is completed. In a typical simulation, the random number generator can be called millions of times. It is therefore essential to use fast generation algorithms.

3.2. Parametric Yield

Parametric yield analysis is the process of varying a set of parameter values, using specified probability distributions, to determine how many possible combinations result in satisfying predetermined performance specifications. The design is simulated over a given number of trials in which the yield variables have values that vary randomly about their nominal values with specified probability distribution functions. The number of passing and failing trials are recorded, and these numbers are used to compute an estimate of the yield.

Statistical design is the process of (1) accounting for the statistical variation in the parameters of a design, (2) measuring the effects of these variations, and (3) modifying the design to minimize these effects. This can be achieved by resorting to a purely numerical process and device simulators [71], to macro- (response surface polynomials) models [72], or to a seminumerical mixed-mode device/circuit simulator coupled to a parameter evaluator [73]. In all three approaches, the first step is the specification of a set of measurable process parameters, which act as input variables for the simulation.

These variables have to be measurable, and they should be linked to more fundamental process parameters so that they can be used to control a fabrication process. For bipolar technology they can, for instance, be the base sheet resistivity, the epicollector doping density, and the effective surface recombination velocity at the emitter contact. The probability distribution for the input parameters has to be determined from measurements on different wafers and lots. In the second step, device model parameters are calculated, together with their variation following a given process fluctuation. In the example cited above for bipolar technology, model parameters can be the peak base doping density, the metallurgical base width, and the epicollector width. Seminumerical approaches resorting to analytical formulation of device operation can be used, or, as an alternative, extensive process simulations coupled to physical device simulations can be performed. Clearly, the first approach is fast and inexpensive, while the second can be computationally very demanding but is free from the deficiency intrinsic to compact and simplified process and device models. The third step consists of a mixed-level device/circuit simulation that predicts the performance of a given circuit and its variation with fluctuation of process parameters.

In the MC-based yield analysis a series of trials is run in which random values are assigned to the design's statistical variable of interest, a simulation is performed, and the yield specifications are checked against the simulated measurement values. The number of passing and failing simulations is accumulated over the set trials and used to compute the yield. The method is

widely used and well-accepted as a way to estimate yield. The strength of the method is twofold—the accuracy of the MC estimates is independent of the number of statistical variables, and no simplifying assumptions are needed on the probability distribution of either component parameters values or performance responses. The weakness of the method is that a full network simulation is required for each trial and that a large number of trials is required to obtain high confidence and an accurate yield estimate.

Multiple yield analysis can be performed in order to adjust the nominal value of the yield variables to maximize the yield estimate. This process is called yield optimization or design centering.

MONTE CARLO SIMULATION IN RELIABILITY

LAWRENCE M. LEEMIS
The College of William & Mary
Williamsburg, Virginia

Simulation is a generic term used loosely in engineering, with application areas ranging from flight simulators used in cockpit design to simulated annealing used in optimization. Simulation is presented here as a mathematical and computational technique used to analyze probabilistic models. Simulation can be divided into *Monte Carlo simulation*, where *static* models are analyzed; and *discrete-event simulation*, where *dynamic* models involving the passage of time are analyzed. Since simulation is presented here in the context of reliability modeling, Monte Carlo simulation models are emphasized.

Monte Carlo simulation methods are often used when analytic methods become intractable, and they typically give a modeler added insight into the structure of a problem. As reliability and lifetime models become less mathematically tractable, Monte Carlo methods will have increasing importance. Monte Carlo simulation techniques mirror the relative frequency approach for determining probabilities. The estimate for the probability of interest converges to the true value as the number of replications increases. This article considers methods for generating random lifetimes and random processes from probabilistic models. The basic methods are inversion [inverse cdf and inverse chf (see Section 1 for acronym definitions)], linear combination methods (composition and competing risks), majorizing methods (acceptance/rejection and thinning), and special properties.

The basic methods are followed by a discussion of order statistics. The generation of order statistics is useful for estimating measures of performance associated with series, parallel, and k -out-of- n systems. The accelerated life and proportional hazards lifetime models can account for the effects of covariates on a random lifetime. Variate generation for these models is a straightforward extension of the basic methods when the covariates do not depend on time. Variate generation algorithms for Monte Carlo simulation of nonhomogeneous Poisson processes are a simple extension of the inverse-chf technique. Methods for generating failure times for a repairable system modeled by a nonhomogeneous Poisson process are also reviewed.

1. PROBABILITY MODELS FOR LIFETIMES

In reliability modeling, a continuous positive random variable typically represents the lifetime of a component or system. The generic term “item” is used in this section to apply to either a component or a system. Several functions completely specify the distribution of a random variable. Five of these functions are useful in describing variate generation algorithms: cumulative distribution function (cdf), survivor function, probability density function (pdf), hazard function, and cumulative hazard function (chf). Other functions, not used here, include the characteristic function [1], density quantile function [2], mean residual life function [3], moment-generating function [4], and total time on test transform [5].

Although Monte Carlo simulation is applied here to problems in reliability, the techniques are applicable to any problem setting concerning random variables that can assume only positive values. Thus the setting here is actually “survival analysis” and includes fields as diverse as biostatistics, actuarial science, economics, and sociology.

This section considers techniques for generating random variates for Monte Carlo simulation analysis. Two textbooks [6,7] are devoted entirely to this topic. The purpose of this section is to review algorithms capable of transforming random numbers to *random variates* possessing known probabilistic properties for use in reliability studies. With the generation of random variates as a basis, several other topics, namely, generating order statistics, generating lifetimes from models with covariates, and generating point processes, are considered.

In the interest of brevity, we assume that a source of randomness is available (i.e., a stream of independent random numbers). These random numbers are uniformly distributed between 0 and 1, and most high-level programming languages now include a random-number generator. The random numbers are denoted by U , and the random variates (lifetimes) are denoted by T . Algorithms for generating the random numbers and desirable properties associated with random-number generators (such as insensitivity to parameter values, speed, memory requirements, relationship to variance reduction techniques) are reviewed by Schmeiser [8], as well as by many of the simulation textbooks that he references. Park and Miller [9] also overview Lehmer random-number generators, and L'Ecuyer, et al. [10] survey more recent work in random-number generation.

The discussion here is limited to generating *continuous*, as opposed to discrete or mixed, distributions. Generating variates from discrete distributions is useful for evaluation of certain types of reliability analysis tools such as fault trees. For simplicity, the examples are confined to the exponential and Weibull distributions, which have been chosen because of their tractability and widespread use. Any continuous lifetime distribution with a closed-form inverse cdf could have been used. Several reliability textbooks discuss Monte Carlo techniques [11–17].

The survivor function, also known as the *reliability function* and *complementary cdf*, is defined by

$$S(t) = P[T \geq t], \quad t \geq 0$$

which is a nonincreasing function of t satisfying $S(0) = 1$ and $\lim_{t \rightarrow \infty} S(t) = 0$. The survivor function is important in the study of *systems* of components since it is the appropriate argument in the structure function to determine system reliability [18]. $S(t)$ is the fraction of the population that survives to time t , as well as the probability that a single item survives to time t . For continuous random variables, $S(t) = 1 - F(t)$, where $F(t) = P[T \leq t]$ is the cdf.

When the survivor function is differentiable, the associated pdf is

$$f(t) = -S'(t), \quad t \geq 0$$

For any interval (a, b) , where $a < b$, we obtain

$$P[a \leq T \leq b] = \int_a^b f(t) dt$$

Finite mixture models for k populations of items may be modeled using the pdf

$$f(t) = \sum_{i=1}^k p_i f_i(t), \quad t \geq 0$$

where $f_i(t)$ is the pdf for population i and p_i is the probability of selecting an item from population i , $i = 1, 2, \dots, k$. Mixture models are used in composition, a density-based variate generation technique. Also, $H(t) = -\log S(t)$.

The hazard function, also known as the *rate function*, *failure rate*, and *force of mortality*, can be defined by

$$h(t) = \frac{f(t)}{S(t)}, \quad t \geq 0$$

The hazard function is popular in reliability work because it has the intuitive interpretation as the amount of *risk* associated with an item that has survived to time t . The hazard function is a special form of the complete intensity function at time t for a point process [19]. In other words, the hazard function is mathematically equivalent to the intensity function for a nonhomogeneous Poisson process, and the failure time corresponds to the first event time in the process. Competing risks models are easily formulated in terms of $h(t)$, as shown in the next section.

The cumulative hazard function can be defined by

$$H(t) = \int_0^t h(\tau)d\tau, \quad t \geq 0$$

If T is a random lifetime with cumulative hazard function H , then $H(T)$ is an exponential random variable with a mean of one. This result is the basis for the inverse-chf technique.

2. RANDOM LIFETIME GENERATION

Techniques for generating a single, continuous lifetime from a known parametric probabilistic model can be partitioned into density-based and hazard-based algorithms. Density-based algorithms may be applied to any random variable, whereas hazard-based algorithms can only be applied to nonnegative lifetimes. In this section, both types of algorithms are assumed to generate a nonnegative lifetime T .

The three classes of techniques for generating variates reviewed below are *inversion*, *linear combination methods*, and *majorizing methods*. For each class, there is a density-based method and a hazard-based method that are similar in nature. Examples of the use of all these techniques are given in Leemis and Schmeiser [20]. More recently, Devroye [21] reviewed variate generation techniques requiring just one line of code.

2.1. Inversion

The density-based inverse cumulative distribution function technique, or *inverse-cdf* technique, is based on the probability integral transformation which states that $F(T) \sim U(0, 1)$, where F is the cdf for the random lifetime T . Thus

$$T \leftarrow F^{-1}(U)$$

generates a lifetime T , where \leftarrow denotes assignment. If the cdf has a closed-form inverse, this method typically requires one line of computer code. If the inverse is not closed-form, numerical methods must be used to invert the cdf.

Example 1. Consider a Weibull distribution with scale parameter λ and shape parameter κ . The cdf is

$$F(t) = 1 - e^{-(\lambda t)^\kappa}, \quad t \geq 0$$

which has the closed-form inverse

$$F^{-1}(u) = \frac{1}{\lambda} [-\log(1 - u)]^{1/\kappa}, \quad 0 < u < 1$$

Thus, an algorithm for generating a Weibull random variate is

$$T \leftarrow \frac{1}{\lambda} [-\log(1 - U)]^{1/\kappa}$$

where $U \sim U(0,1)$. Most random-number generators currently in use do not return exactly 0 or exactly 1. If U is

generated so that 1 is excluded, $1 - U$ can be replaced with U for increased speed without concern over taking the logarithm of 0.

The inverse-chf technique is based on $H(T)$ being exponentially distributed with a mean of one. So

$$T \leftarrow H^{-1}(-\log(1 - U))$$

generates a single random lifetime T . This algorithm is easiest to implement if H can be inverted in closed form.

Example 2. Consider an arrangement of three identical components with independent and identically distributed Weibull lifetimes with parameters λ and κ as arranged in the block diagram in Fig. 1. Find the mean time to system failure.

It is possible to use both analytic and Monte Carlo techniques to solve this problem. Let T_1, T_2 , and T_3 be the lifetimes for the three statistically identical components; let T be the system lifetime; and let $S_i(t) = e^{-(\lambda t)^\kappa}$ be the survivor function for component i for $i = 1, 2, 3$ and $t \geq 0$. The system survivor function is

$$\begin{aligned} S(t) &= S_1(t)[1 - (1 - S_2(t))(1 - S_3(t))] \\ &= e^{-(\lambda t)^\kappa} [1 - (1 - e^{-(\lambda t)^\kappa})(1 - e^{-(\lambda t)^\kappa})] \\ &= 2e^{-2(\lambda t)^\kappa} - e^{-3(\lambda t)^\kappa}, \quad t \geq 0 \end{aligned}$$

Thus, the mean time to system failure is

$$E[T] = \int_0^\infty S(\tau)d\tau = \frac{\Gamma(1 + 1/\kappa)}{\lambda} (2^{1-1/\kappa} - 3^{-1/\kappa})$$

To solve the problem exactly as stated, this analytic solution is ideal. For many applications, however, a Monte Carlo solution can provide additional insight into a problem. Furthermore, a less restricted problem (e.g., with more complicated failure distribution or dependent component failure times) might not have a mathematically tractable analytic solution. A Monte Carlo estimate for the mean time to failure requires each component lifetime to be generated, and the inverse-chf technique is used here. The cumulative hazard function for the Weibull

Figure 1. A block diagram for a three-component system.

distribution is

$$H(t) = (\lambda t)^\kappa, \quad t \geq 0$$

which has the closed-form inverse

$$H^{-1}(y) = \frac{1}{\lambda} y^{1/\kappa}, \quad y \geq 0$$

Thus an algorithm for generating a Weibull random variate is

$$T \leftarrow \frac{1}{\lambda} [-\log(1 - U)]^{1/\kappa}$$

which is identical to the inverse-cdf technique. In general, the inverse-cdf and inverse-chf techniques are interchangeable in this fashion. An algorithm to estimate the mean time to system failure using N system lifetimes is given below. Indentation is used to indicate nesting:

```

S ← 0
for i from 1 to N
    generate  $U_1, U_2, U_3 \sim U(0,1)$ 
     $T_1 \leftarrow \frac{1}{\lambda} [-\log(1 - U_1)]^{1/\kappa}$ 
     $T_2 \leftarrow \frac{1}{\lambda} [-\log(1 - U_2)]^{1/\kappa}$ 
     $T_3 \leftarrow \frac{1}{\lambda} [-\log(1 - U_3)]^{1/\kappa}$ 
     $T \leftarrow \min\{T_1, \max\{T_2, T_3\}\}$ 
     $S \leftarrow S + T$ 
A ← S/N
    
```

The variable S contains a cumulative sum of the system lifetimes, and A contains the average of the system lifetimes generated. The estimate for the average time to system failure A converges to the analytic result as the number of replications $N \rightarrow \infty$. This algorithm can be written more efficiently since the components have identical distributions. To save on the number of logarithms and exponentiations, properties such as $T_2 \geq T_3$ when $U_2 \geq U_3$ can be exploited so that only one Weibull variate needs to be generated for each system lifetime, based on the order of U_1, U_2, U_3 , as shown in the next example. The algorithm given above is inferior to the analytic method presented earlier in the example because it produces a *point estimator* A for the system reliability. It is appropriate to place a *confidence interval* around the point estimator in order to assess its accuracy [1].

A final example is given to illustrate an alternative way of generating the system lifetime of a coherent system [18] of components.

Example 3. Consider the same system as Example 2, which used three random numbers to generate a single system lifetime T . Thus the algorithm was not synchronized. A technique for achieving synchronization is illustrated in this example. The first step is to determine $\pi_i = P[T_i = T]$ for $i = 1, 2, 3$, which is the probability that component i is the component that “causes” system failure. Second, the conditional lifetime distribution of all components, given that they are the cause of failure, should be

determined, and a lifetime variate generated from the appropriate distribution. For the three-component example, we obtain

$$\pi_2 = P[T_3 < T_2 < T_1]$$

and, by symmetry

$$\pi_3 = P[T_2 < T_3 < T_1] = \pi_2$$

and

$$\pi_1 = 1 - \pi_2 - \pi_3$$

since $\pi_1 + \pi_2 + \pi_3 = 1$. The algorithm for generating a system lifetime from a single $U(0, 1)$ is given below. The U that is used in the last step of the algorithm has been rescaled so that it is conditionally $U(0, 1)$.

Setup

determine π_1, π_2, π_3
 find the conditional lifetime distributions for all components

Algorithm

```

generate  $U \sim U(0,1)$ 
if  $0 < U < \pi_1$ , then
     $J \leftarrow 1$  and  $U \leftarrow \frac{U}{\pi_1}$ 
if  $\pi_1 < U < \pi_1 + \pi_2$ , then
     $J \leftarrow 2$  and  $U \leftarrow \frac{U - \pi_1}{\pi_2}$ 
if  $\pi_1 + \pi_2 < U < 1$ , then
     $J \leftarrow 3$  and  $U \leftarrow \frac{U - \pi_1 - \pi_2}{\pi_3}$ 
generate  $T$  from conditional lifetime distribution  $J$  using  $U$ .
    
```

Inversion techniques exhibit some important properties:

- They are synchronized (i.e., one random number produces one lifetime).
- They are monotone (i.e., larger random numbers produce larger lifetimes).
- They accommodate truncated distributions.
- They can be modified to generate order statistics (useful for generating the lifetime of a k -out-of- n system, as shown in the next subsection).

2.2. Linear Combination Methods

Linear combination techniques are the density-based composition method and the hazard-based competing risks method. The composition method is viable when the pdf can be written as the convex combination of k density functions

$$f(t) = \sum_{j=1}^k p_j f_j(t), \quad t \geq 0,$$

where $\sum_{j=1}^k p_j = 1$. The algorithm is

```

choose pdf  $j$  with probability  $p_j, j = 1, 2, \dots, k$ 
generate  $T$  from pdf  $j$ 
    
```

The first step is typically executed using a discrete inversion algorithm.

The second linear combination technique is called *competing risks*, which can be applied when the hazard function can be written as the sum of hazard functions, each corresponding to a “cause” of failure

$$h(t) = \sum_{j=1}^k h_j(t), \quad t \geq 0$$

where $h_j(t)$ is the hazard function associated with cause j of failure acting in a population. The minimum of the lifetimes from each of these risks corresponds to the system lifetime. Competing risks is most commonly used to analyze series systems, but it can also be used in actuarial applications. The competing risks model is also used for modeling competing failure modes for components that have multiple failure modes. The algorithm is

```
generate  $T_j$  from  $h_j(t), j = 1, 2, \dots, k$ 
 $T \leftarrow \min\{T_1, T_2, \dots, T_k\}$ 
```

2.3. Majorizing Methods

The third class of techniques for generating random lifetimes is the majorizing techniques: the density-based acceptance/rejection and a modified version of thinning, which is hazard-based. In order to use acceptance/rejection, there must be a majorizing function $f^*(t)$ that satisfies $f^*(t) \geq f(t)$ for all $t \geq 0$. The pdf corresponding to $f^*(t)$ is

$$g(t) = f^*(t) / \int_0^\infty f^*(\tau) d\tau$$

The algorithm is

```
repeat
  generate  $T$  from  $g(t)$ 
  generate  $S \sim U(0, f^*(T))$ 
until  $S \leq f(T)$ 
```

Generating T may be done by inversion or any other method. The name *acceptance/rejection* comes from the loop condition; the random variate T is accepted for generation if $S \leq f(T)$ and rejected if $S > f(T)$.

Thinning was originally used by Lewis and Shedler [22] for generating the event times in a nonhomogeneous Poisson process. Thinning can be adapted to produce a single lifetime by ignoring all except the first event time generated. A majorizing hazard function $h^*(t)$ must be found that satisfies $h^*(t) \geq h(t)$ for all $t \geq 0$. The algorithm is

```
 $T \leftarrow 0$ 
repeat
  generate  $Y$  from  $h^*(t)$  given  $Y > T$ 
   $T \leftarrow T + Y$ 
  generate  $S \sim U(0, h^*(T))$ 
until  $S \leq h(T)$ 
```

Generating Y in the loop can be done by inversion or any other method. The term *thinning* comes from the fact that

T can make several steps, each of length Y , that are thinned out before the loop condition is satisfied.

2.4. Special Properties

The fourth class of techniques for generating random lifetimes is called *special properties*. It is neither density-nor hazard-based since it depends on relationships between random variables. Examples of special properties include generating an Erlang random variable as the sum of independent and identically distributed exponential random variables, and generating a binomial random variable as the sum of independent and identically distributed Bernoulli random variables. Examples of special properties associated with random variables are given in the encyclopedic work of Johnson et al. [23].

The four techniques described in this section are often combined in order to generate a variate from a particular distribution. Devroye [6] and Dagpunar [7] review variate generation techniques for some of the more intractable distributions (e.g., normal and gamma) that are not considered here. Most computer installations have access to subprograms capable of generating variates from a wide range of distributions.

The generation of independent univariate random variates provides the basis for Monte Carlo simulation analysis of reliability models. There are a number of directions that a section of this nature could take at this point. I have opted for surveying the following: generating order statistics, generating lifetimes for models with covariates, and generating nonhomogeneous Poisson processes. Other important topics include generating random vectors [17,24], civil engineering applications [13], mechanical engineering applications [17], fault-tree analysis [14], or discrete-event simulation [25].

3. ORDER STATISTIC GENERATION

In many reliability applications, the efficient generation of order statistics can be useful for generating a random system lifetime. Order statistics play a central role in the analysis of simple arrangements of systems consisting of n statistically identical components. Let T_1, T_2, \dots, T_n be the n independent failure times of components in a system, and let $T_{(1)}, T_{(2)}, \dots, T_{(n)}$ be the ordered failure times. If T denotes the system failure time, then $T = T_{(1)}$ for a series system, $T = T_{(n)}$ for a parallel system, and $T = T_{(n-k+1)}$ for a k -out-of- n system. The most straightforward approach to generating the system lifetime for these models is to generate the lifetimes of each component, sort the lifetimes, and then choose the appropriate order statistic. This approach is adequate when n is small and the lifetimes are simple to generate. When one or both of these conditions do not hold, the following results from the literature [26–29] can be used to generate order statistics more efficiently. The algorithms presented in this section are effective ways of decreasing the central processing unit (CPU) time to generate a system lifetime since only one inversion of F is necessary and no sorting is required.

The random variables $\min\{U_1, U_2, \dots, U_n\}$ and $1 - (1 - U)^{1/n}$ have the same distribution, where $U_i, i = 1,$

2, ..., n and U are independent random numbers. If the function $F^{-1}(u)$ can be evaluated in closed form or numerically, an algorithm to generate the system lifetime of a series system of identical components is

$$T \leftarrow F^{-1}(1 - (1 - U)^{1/n})$$

Since $\max\{U_1, U_2, \dots, U_n\}$ and $U^{1/n}$ have the same distribution, the system lifetime of a parallel system of statistically identical components can be generated by

$$T \leftarrow F^{-1}(U^{1/n})$$

Example 4. A system of n statistically identical components is arranged in parallel. If each component has an independent Weibull lifetime with scale parameter λ and shape parameter κ , devise a method to generate a system lifetime variate from a single random number U.

The inverse of the Weibull cdf is

$$F^{-1}(u) = \frac{1}{\lambda} [-\log(1 - u)]^{1/\kappa}, \quad 0 < u < 1.$$

A system lifetime T, which corresponds to the order statistic $T_{(n)}$, is generated by

$$T \leftarrow \frac{1}{\lambda} [-\log(1 - U^{1/n})]^{1/\kappa}$$

This is clearly faster than generating n Weibull variates and returning the largest generated.

The algorithm below generates order statistics efficiently for a k-out-of-n system when a beta variate generator is available.

generate $X \sim \text{beta}(n - k + 1, k)$
 $T \leftarrow F^{-1}(X)$

The variate generated corresponds to $T_{(n-k+1)}$. Efficient algorithms for generating beta variates are given by Law and Kelton [25].

4. ACCELERATED LIFE AND PROPORTIONAL HAZARDS MODELS

The effect of covariates (explanatory variables) on survival often complicates the analysis of a set of lifetime data. In a medical setting, these covariates are usually patient characteristics such as age, gender, or blood pressure. In reliability, covariates (such as the turning speed of a machine tool or the stress applied to a component) affect the lifetime of an item. Two common models to incorporate the effect of the covariates on lifetimes are the *accelerated life* and *Cox proportional hazards* models. This section describes algorithms for the generation of lifetimes that are described by one of these models.

The $q \times 1$ vector \mathbf{z} contains covariates associated with a particular item or individual. The covariates are linked to

the lifetime by the function $\psi(\mathbf{z})$, which satisfies $\psi(\mathbf{0}) = 1$ and $\psi(\mathbf{z}) \geq 0$ for all \mathbf{z} . A popular choice is $\psi(\mathbf{z}) = e^{\beta^T \mathbf{z}}$, where β is a $q \times 1$ vector of regression coefficients.

The cumulative hazard function for T in the *accelerated life* model is [19]

$$H(t) = H_0(t\psi(\mathbf{z}))$$

where H_0 is a baseline cumulative hazard function. When $\mathbf{z} = \mathbf{0}$, then $H_0 \equiv H$. In this model, the covariates accelerate [$\psi(\mathbf{z}) > 1$] or decelerate [$\psi(\mathbf{z}) < 1$] the rate at which the item moves through time. The cumulative hazard function for T in the *proportional hazards* model is

$$H(t) = \psi(\mathbf{z})H_0(t)$$

In this model, the covariates increase [$\psi(\mathbf{z}) > 1$] or decrease [$\psi(\mathbf{z}) < 1$] the failure rate of the item by the factor $\psi(\mathbf{z})$ for all values of t.

All the algorithms for variate generation for these models are based on the fact that $H(T)$ is exponentially distributed with a mean of one. Therefore, equating the cumulative hazard function to $-\log(1 - U)$ and solving for t yields the appropriate generation technique.

In the accelerated life model, since time is being expanded or contracted by a factor $\psi(\mathbf{z})$, variates are generated by

$$T \leftarrow \frac{H_0^{-1}(-\log(1 - U))}{\psi(\mathbf{z})}$$

In the proportional hazards model, equating $-\log(1 - U)$ to $H(t)$ yields the variate generation formula

$$T \leftarrow H_0^{-1}\left(\frac{-\log(1 - U)}{\psi(\mathbf{z})}\right)$$

In addition to generating individual lifetimes, these variate generation techniques can be applied to point processes. A renewal process, for example, with time between events having a cumulative hazard function $H(t)$ can be simulated by using the appropriate generation formula for the two cases shown above. These variate generation formulas must be modified, however, to generate variates from a nonhomogeneous Poisson process (NHPP).

In an NHPP, the hazard function $h(t)$ is analogous to the intensity function, which governs the rate at which events occur. To determine the appropriate method for generating variates from an NHPP, assume that the last event in a point process has occurred at time a. The cumulative hazard function for the time of the next event, conditioned on survival to time a, is

$$H_{T|T>a}(t) = H(t) - H(a), \quad t \geq a.$$

Table 1. Lifetime Generation in Regression Models

	Renewal	NHPP
Accelerated life	$T \leftarrow a + \frac{H_0^{-1}(-\log(U))}{\psi(\mathbf{z})}$	$T \leftarrow \frac{H_0^{-1}(H_0(a\psi(\mathbf{z})) - \log(U))}{\psi(\mathbf{z})}$
Proportional hazards	$T \leftarrow a + H_0^{-1}\left(\frac{-\log(U)}{\psi(\mathbf{z})}\right)$	$T \leftarrow H_0^{-1}\left(H_0(a) - \frac{\log(U)}{\psi(\mathbf{z})}\right)$

In the accelerated life model, where $H(t) = H_0(t\psi(\mathbf{z}))$, the time of the next event is generated by

$$T \leftarrow \frac{H_0^{-1}(H_0(a\psi(\mathbf{z})) - \log(1 - U))}{\psi(\mathbf{z})}$$

Equating the conditional cumulative hazard function to $-\log(1 - U)$, the time of the next event in the proportional hazards case is generated by

$$T \leftarrow H_0^{-1}\left(H_0(a) - \frac{\log(1 - U)}{\psi(\mathbf{z})}\right)$$

An example of the application of these algorithms to a particular parametric distribution is given by Leemis [30], who later extended the case where the covariates are time-dependent [31,32]. Table 1 summarizes the variate generation algorithms for the accelerated life and proportional hazards models (the last event occurred at time a). The $1 - U$ has been replaced with U in this table to save a subtraction, although the sense of the monotonicity is reversed.

The renewal and NHPP algorithms are equivalent when $a = 0$ (since a renewal process is equivalent to an NHPP restarted at zero after each event), the accelerated life and proportional hazards models are equivalent when $\psi(\mathbf{z}) = 1$, and all four cases are equivalent when $H_0(t) = \lambda t$ (the exponential case) because of its memoryless property.

5. GENERATING A NONHOMOGENEOUS POISSON PROCESS

This section describes two techniques for generating event times for NHPPs. Homogeneous Poisson processes and renewal processes are not considered since they are a straightforward generalization of the inversion algorithms. An NHPP is often suggested as an appropriate model for the failure times of repairable systems whose rate of occurrence of failures varies over time, as outlined elsewhere [4,33–35]. The repair time must be negligible in order to use an NHPP to approximate the probabilistic mechanism governing the sequence of failures. The two techniques considered here are *inversion*, which relies on a timescale transformation given by Cinlar [36], and *thinning*, developed by Lewis and Shedler [22].

An NHPP is a generalization of an ordinary homogeneous Poisson process with events occurring randomly over time at the rate of λ . Events occur over time at a rate defined by the *intensity function* $\lambda(t)$. The *cumulative*

intensity function is defined by

$$\Lambda(t) = \int_0^t \lambda(\tau) d\tau, \quad t > 0$$

and is interpreted as the mean number of events by time t .

5.1. Inversion

For cases where $\Lambda(t)$ can be inverted in closed form, or when it can be inverted numerically, Cinlar [36] showed that if E_1, E_2, \dots are the event times in a homogeneous Poisson process with rate 1 (often called a *unit* Poisson process), then $\Lambda^{-1}(E_1), \Lambda^{-1}(E_2), \dots$ are the event times for an NHPP with cumulative intensity function $\Lambda(t)$. This is a generalization of the result that formed the basis for the inverse-chf algorithm. An algorithm for generating the event times T_1, T_2, \dots , for an NHPP with cumulative intensity function $\Lambda(t)$ is

```

T0 ← 0
E0 ← 0
i ← 0
repeat
    i ← i + 1
    generate U ~ U(0,1)
    Ei ← Ei-1 - log(1 - U)
    Ti ← Λ-1(Ei)
until Ti ≥ S
    
```

The algorithm returns the event times T_1, T_2, \dots, T_{i-1} , where S is a prescribed termination time of the point process. The algorithm is valid because $-\log(1 - U)$ is the appropriate way (via inversion) of generating an exponential variate with a mean of one. As before, replacing $1 - U$ with U reduces the CPU time.

Example 5. The cumulative intensity function is given by

$$\Lambda(t) = (\lambda t)^\kappa, \quad t > 0$$

often known as the *power-law process* [34]. If $\kappa > 1$, the population of items is deteriorating; if $\kappa < 1$, the population of items is improving; and if $\kappa = 1$, the NHPP simplifies to a homogeneous Poisson process. Since the inverse cumulative intensity function is

$$\Lambda^{-1}(y) = \frac{1}{\lambda} y^{1/\kappa}, \quad y > 0$$

the last statement in the loop becomes $T_i \leftarrow (1/\lambda)E_i^{1/\kappa}$.

The techniques for estimating the cumulative intensity function for an NHPP from one or more realizations is too broad a topic to be reviewed here. Examples of parametric and nonparametric techniques for estimation and generating realizations for simulation models are given in the literature [37–39], and the paper by Leemis [39], is illustrated in the following example.

Example 6. This example considers nonparametric estimation of the cumulative intensity function of an NHPP from

one or more realizations and the associated algorithm for generating random variates. This method does not require the modeler to specify any parameters or weighting functions.

The cumulative intensity function is to be estimated from k realizations of the NHPP on $(0, S]$, where S is a known constant. Let n_i ($i = 1, 2, \dots, k$) be the number of observations in the i th realization, $n = \sum_{i=1}^k n_i$, and let $t_{(1)}, t_{(2)}, \dots, t_{(n)}$ be the order statistics of the superposition of the k realizations, $t_{(0)} = 0$ and $t_{(n+1)} = S$. Setting $\hat{\Lambda}(S) = (n/k)$ yields a process where the expected number of events by time S is the average number of events in k realizations, since $\Lambda(S)$ is the expected number of events by time S . The piecewise linear estimator of the cumulative intensity function between the time values in the superposition is

$$\hat{\Lambda}(t) = \frac{in}{(n+1)k} + \frac{n(t - t_{(i)})}{(n+1)k(t_{(i+1)} - t_{(i)})},$$

$$t_{(i)} < t \leq t_{(i+1)}; i = 0, 1, 2, \dots, n.$$

This estimator passes through the points

$$\left(t_{(i)}, \frac{in}{(n+1)k} \right),$$

for $i = 1, 2, \dots, n + 1$.

The rationale for using a linear function between the data values is that inversion can be used for generating realizations without having tied events. If the usual step function estimate of $\Lambda(t)$ is used, only the $t_{(i)}$ values could be generated.

Using inversion, the event times from a unit Poisson process, E_1, E_2, \dots , can be transformed to the event times of an NHPP via $T_i = \Lambda^{-1}(E_i)$. For the NHPP estimate considered here, the events at times T_1, T_2, \dots can be generated for Monte Carlo simulation by the algorithm below, given n, k, S and the superpositioned values:

```

i ← 1
generate  $U_i \sim U(0,1)$ 
 $E_i \leftarrow -\log(1-U_i)$ 
while  $E_i < \frac{n}{k}$  do
  begin
     $m \leftarrow \lfloor \frac{(n+1)kE_i}{n} \rfloor$ 
     $T_i \leftarrow t_{(m)} + [t_{(m+1)} - t_{(m)}] (\frac{(n+1)kE_i}{n} - m)$ 
     $i \leftarrow i + 1$ 
    generate  $U_i \sim U(0,1)$ 
     $E_i \leftarrow E_{i-1} - \log(1 - U_i)$ 
  end
end
    
```

Thus, it is a straightforward procedure to obtain a realization of $i - 1$ events on $(0, S]$ from the superpositioned process and $U(0,1)$ values U_1, U_2, \dots, U_i . Inversion has been used to generate this NHPP, so certain variance reduction techniques, such as antithetic variates or common random numbers, may be applied to the simulation output. Replacing $1 - U_i$ with U_i in generating the exponential variates will save CPU time, although the direction of the monotonicity is reversed. Tied values in the superposition do not pose any problem to this algorithm, although there may be tied values in the realization. As n increases, the amount of

memory required increases, but the amount of CPU time required to generate a realization depends only on the ratio n/k , the average number of events per realization.

If the inverse cumulative intensity function is not available, but a majorizing intensity function can be found, then thinning can be used to generate variates.

5.2. Thinning

In describing the basic techniques for variate generation, thinning was adapted to generate a single lifetime. Thinning was originally devised to generate the event times for an NHPP [22]. Assume that a majorizing intensity function $\lambda^*(t)$ exists such that $\lambda^*(t) \geq \lambda(t)$ for all $t \geq 0$. The algorithm is

```

 $T_0 \leftarrow 0$ 
 $i \leftarrow 0$ 
repeat
   $i \leftarrow i + 1$ 
   $Y \leftarrow T_{i-1}$ 
  repeat
    generate  $U_1, U_2 \sim U(0,1)$ 
     $Y \leftarrow Y - \log(1 - U_1)$ 
  until  $U_2 \leq \lambda(Y)/\lambda^*(Y)$ 
   $T_i = Y$ 
until  $T_i \geq S$ 
    
```

If the inside loop condition is not met, then this particular Y value is “thinned” out of the point process and not included as a failure time in the realization. Choosing a majorizing function that is close to the intensity function $\lambda^*(t)$ results in fewer passes through the inside loop, and hence reduces CPU time. Guo and Love [40] have adapted this algorithm for the generation of variates when covariates are included in the model.

The discussion in this article has focused primarily on variate generation for various Monte Carlo applications in reliability. The estimation of unknown parameters from data is an equally important topic that has not been considered here. Several authors [41–43] provide sections on a facet of discrete-event simulation known as ‘input modeling’, where the estimation of parameters is considered. Finally, Fishman [44] presents a comprehensive work on Monte Carlo simulation without taking the reliability modeling perspective that has been taken here.

SYMBOLS

T	a continuous nonnegative random variable
\sim	“is distributed as”
$f(t), F(t), S(t)$	the pdf, cdf, and survivor function of T
$h(t), H(t)$	the hazard function, cumulative hazard function of T
U	a random number [i.e., a $U(0,1)$ random variable]
λ	scale parameter for an exponential distribution
λ, κ	scale and shape parameters for a Weibull distribution

\log	natural logarithm
Γ	the gamma function
$T_{(i)}$	order statistic i
\mathbf{z}	a $q \times 1$ vector of covariates
β	a $q \times 1$ vector of regression coefficients
$\psi(\mathbf{z})$	link function
$\lambda(t)$	intensity function
$\Lambda(t)$	cumulative intensity function
E_1, E_2, \dots	homogeneous Poisson process event times
T_1, T_2, \dots	event times for an NHPP

1. MOSFET AND ITS SMALL-SIGNAL ANALYSIS

1.1. Introduction

In 1925 and 1926 J. E. Lilienfeld filed Canadian and U.S. patent applications entitled *Method and Apparatus for Controlling Electric Current* [1] disclosing a semiconductor device using a gate electrode. Interest in the insulated gate field-effect transistor (IGFET) was revived by the successful experiments of Attalla *et al.* [2] in 1959, in passivating silicon surfaces through the use of grown SiO₂ layers. Kahng and Attalla [3] in 1960 proposed a Si-SiO₂ structure in which a metal gate was used to induce conduction between two normally reversed biased surface diodes. This is known as the *metal oxide semiconductor field-effect transistor* (MOSFET), as shown in Fig. 1.

In VLSI circuits, the MOSFET plays an important role because of its low fabrication cost, small size, and low power consumption. The important characteristics of a MOS transistor are bilateral symmetry, unipolarity, high input impedance, voltage controllability, and self-isolation. The property of bilateral symmetry render the source and the

Figure 1. Three-dimensional view of MOSFET.

drain electrically interchangeable. Unipolarity allows conduction exclusively via one type of carriers. The input impedance is also high because of the gate oxide. There is no DC path between the gate and the other terminals. The input impedance is then extremely high and is primarily capacitive. Its DC resistance is greater than $10^{14} \Omega$, and it is a voltage-controlled device. At the beginning of the semiconductor era, manufacturers concentrated on the germanium devices, but the emphasis soon shifted to silicon, and it was on silicon substrates that the integrated circuit (IC) was developed. IC development has taken place in two main streams: bipolar and MOS technologies. At the outset, bipolar technology seemed to provide the most promising approach to fast logic arrays, but MOS technology holds the promise of higher levels of integration and the latest high-speed operation.

More recent developments in MOS technology include a large variety of new device architectures proposed to greatly improve MOS speed while retaining its high packing density. Thin-film fully depleted (FD) SOI (silicon on insulator) MOSFET is one promising option. The absence of latchup, the reduced parasitic source and drain capacitances, and the ease of forming shallow junctions are merely three obvious examples of the advantages presented by SOI technology over bulk. There are many other properties that allow SOI devices and circuits to exhibit performances superior to those of their bulk counterparts such as radiation hardness, high-temperature operation, improved transconductance, and subthreshold slope. The thin-film SOI can easily overcome many of the hurdles faced in implementation and isolation of the devices. As the scaling of the MOS transistor approaches the submicrometer regime, FD-SOI MOSFET, which shows no kink effect and has excellent short-channel effects (SCEs), seems to be a good alternative device structure [4].

According to the ITRS roadmap 2001, several new device features such as nonplanar or elevated S/D (source/drain) structures, strained heterostructures in the channel, vertical FETs, and other double-gate (DG) or a surrounding gate are viable alternatives to bulk CMOS for gate lengths down to 20 nm. However, due to complicated and innovative processing technology for DG-MOSFET, single-gate FD-SOI CMOS is a viable option.

Advances in process technology and device design has allowed Si-MOSFET to be applied successfully to RF circuits. To expedite VLSI circuit design and reduce manufacturing cost, it is important to model and predict circuit behavior in the early stages of technology development. For today's competitive analog designs, accurate DC and high-frequency (HF) AC models are needed. Modeling of parasitic elements and certain key issues such as low-frequency (LF) noise, generation-recombination (GR) noise, and noise at RF level is required to be incorporated in equivalent circuit. In this article small-signal analysis for Si-MOSFET with respect to the substrate effect is presented first. Modified expressions of power gain after incorporating the substrate effect are reported. In the next portion of the article, a drain current and capacitance model is developed after incorporating the fringing field effect. An equivalent circuit including the fringing field effect and gate inductance has a definite advantage of

physical significance to predict the admittance parameters. When the device length shortens, channel length modulation (CLM) takes place and increases the output conductance. Therefore, the CLM effect cannot be neglected. In the latter portion of the article, admittance and scattering parameters are derived after incorporating the CLM effect. Simple expressions of transconductance, scattering parameters, and power gain are presented incorporating the distributed gate inductance and the fringing field effects.

To achieve the VLSI goals of higher density and greater performance, MOSFET channel lengths continue to be reduced. However, hot-electron effects become more severe as channel length decrease. In order to reduce the hot-carrier effect, different drain engineered structures such as the lightly doped drain (LDD) and fully overlapped/lightly doped drain (FOLD) have been proposed. In FOLD structure, overlapping of the LDD region with the gate electrode is done to reduce the peak electric field; therefore this type of structure is not susceptible to spacer-enhanced degradation. The series parasitic resistance of FOLD structure is less than that of conventional LDD of equal reliability. Therefore, a two-dimensional analytical model to determine the intrinsic drain-source series resistance of FOLD MOSFET along with the I-V characteristics, drain conductance, transconductance, and cutoff frequency of the device has been discussed. In the concluding part of the article, a low-frequency (LF) noise model and generation-recombination (GR) model of FOLD MOSFET incorporating the voltage drop in the n^- region due to the parasitic resistance is studied.

1.2. RF MOSFET Modeling

The scaling of MOS devices has reduced channel length and/or width to submicrometer ranges. This reduction in device size has improved the circuit speed and increased circuit density. As these devices are scaled, various second-order effects such as fringing field effect, substrate effect, velocity saturation, and hot-carrier effect have come into existence. The enhanced performance of a device includes faster switching speed, lower power dissipation, and less circuit area. In developing a new device, modeling is very relevant when a totally new device concept is being developed or when an existing device is to be extended for a new task. The device model describes the terminal behavior of a device in terms of current-voltage, capacitance-voltage characteristics, and the carrier transport process, which takes place within the device. The models thus reflect device behavior in all regions of operations of the device [5]. Because of the 2D and 3D nature of the physical effects governing electrical behavior of a VLSI MOS transistor, it is very difficult to obtain closed-form analytical formulation, which is valid in all regions of operation. However, it is still possible to obtain closed-form analytical models, based on device physics, which are generally valid over a limited region of device operation.

Despite this limitation, such models are becoming increasingly important because of ease of computation. The models are categorized as (1) physical device models and (2) equivalent-circuit models. Physical device models can

be used to predict both terminal characteristics and transport phenomenon. The equivalent circuit models describe electrical properties of the device by connecting electrical circuit elements in such a way that the model simulates the electrical terminal behavior of the device [6]. The device model to be used in a circuit simulator should be accurate and simple so that it simulates actual transistor behavior over all regions of operation of interest.

1.3. Equivalent Circuit and Frequency Response

MOS transistors are by nature distributed elements. At present, most MOS circuits are designed as lumped-parameter systems, with the devices assumed to exhibit quasistatic behavior [7]. However, a careful look at the nonquasistatic behavior, RF operation of the MOS transistor is justifiable. The frequency response of a MOS device on the inversion region depends on the rate at which minority carriers can be supplied to, or removed from, the inversion region. In principle, at least, there appear to be a number of possible mechanisms [8–12] by which minority carriers can be supplied or removed when an AC source is applied, such as (1) generation-recombination (GR) centers within the depletion region, (2) changes in surface state occupancies, and (3) diffusion of minority carriers to and from the undepleted portions of the semiconductor. For n-type devices or p-type silicon devices in which care is taken to remove any oxide not covered by the metal gate for which the equivalent interface charge remains independent of bias, it appears that mechanism 1—generation-recombination within the depletion region—predominates. Measurements by Grove *et al.* [13] on both n- and p-type silicon devices have shown that the observed transition frequency to low-frequency type characteristics occurs at about 50 Hz for room-temperature conditions. Observations on the temperature dependence of the transition frequency indicate that the major source of generation-recombination corresponds to impurity centers having an activation energy equal to approximately half of the total bandgap. This is discussed by Sah *et al.* [14] as corresponding to the most effective energy level for GR within a space charge layer. Order-of-magnitude calculations [13–15] based on this mechanism yield a transition frequency very close to that observed. Hence it can be concluded that for this ideal form of MOS structure, mechanism 1 predominates.

For p-type silicon devices in which the oxide layer extends over an area greater than the metal gate area, the transition frequency between the two types of capacitance characteristics is often observed to be many orders greater than 100 Hz. The reason for this is that the positive oxide charge induces an inversion layer in all regions underlying the oxide, including those not covered by the metal.

The inversion layer can be considered as consisting of two parts: an intrinsic portion lying directly beneath the metal and an extrinsic portion consisting of those areas of the semiconductor covered by the oxide but not by the metal [10–12]. Usually, highly doped polysilicon is used as a material for making a gate in MOSFET, but insufficiently high doping in polysilicon gates becomes inevitable in modern CMOS process. But there is conflict in

requirements for low-energy ion implantation and various annealing conditions to achieve ultrashallow junctions. This results in a polydepletion width effect [16] in ultrathin oxide MOSFETs and as the polydepletion capacitance along with the oxide capacitance causes degradation of the inversion gate capacitance and transconductance. Further, metallic gates eliminate the polydepletion problem as well as boron penetration [17] through the gate oxide. Conventional alternative to amorphous silicon such as poly-SiGe or fine-grain columnar poly-Si seems to be a more promising option for 0.1–0.08 μm generation. Beyond these dimensions, metallic gates and high- K dielectrics seem to be mandatory as a result of gate leakage, boron penetration, polydepletion width effect, and oxide reliability [18].

1.3.1. Low-Frequency (LF) Characteristics. At low frequencies all circuit elements are lumped, since their physical dimensions are negligible compared with the wavelength of electromagnetic signals inside the components. In such a network, since Kirchhoff's voltage and current relationships are applicable, the current within any branch is the same at all points of the branch between its terminating nodes, and the voltage along any perfect conductor is constant and changes only at the components [19].

1.3.2. High-Frequency (HF) Characteristics. At higher frequencies, if the signal wavelength becomes comparable to the physical dimension of the components, then the spatial variations of voltages and currents along the wires and in the components must be considered. In such circuits, called *distributed networks*, Kirchhoff's laws are no longer valid and Maxwell's laws must be applied [20,21]. Another very important aspect of MOSFET is its RF and switching performance [22,23].

1.4. Small-Signal Analysis with Bulk Substrate Resistance Effect

Several methods of calculating the small-signal characteristics of JFET and MOSFET have been reported in the literature. These include the approximate power series [24,25] method and the exact [26–30] functional and computer method of solving the basic channel differential equations, and also the matrix method [31–35] of RC transmission-line analog solutions. Park *et al.* [36], Bagheri and Tsividis [37] and Das [38] did some work on modeling the distributed parameters along the channel length in which channel inductance was introduced. However, these models do not incorporate the distributed gate effect. In a model presented by Kim and Dutton [39] and Razavi *et al.* [40], the distributed nature of the gate region was modeled by treating the transistor as an array of smaller transistors connected together via a resistive gate.

Allam and Manku [41] presented a small-signal model for an integrated MOS transistor, which took into account the distributed nature of the gate structure. But they didn't consider the effect of gate inductance in their analysis from 0.1- to 1.0-GHz applications. The presence of a small bulk substrate resistance can cause an indirect excitation of the substrate, which can modify the overall

Figure 2. Equivalent circuit of MOSFET for small-signal analysis.

device characteristics. The equivalent circuit shown in Fig. 2 clearly indicates the influence of the substrate properties on frequency performance [42].

If an epitaxial active substrate layer is used on a very-low-resistivity bulk substrate material, the element R_{sub} can become negligible. Under these circumstances the contributions of the transfer admittance parameters Y_{13} and Y_{23} can be ignored when the source and substrate are short-circuited, but do not eliminate the physical substrate effects on admittance parameters Y_{21} and Y_{11} . The gate bulk capacitance, C_{gb} incorporated into C_{gs} for the same reason. Goswami *et al.* [42] developed a substrate-effect-dependent scattering parameter extraction of short-gate-length insulated gate field-effect transistor (IGFET) for microwave frequency applications in which the gate to drain capacitance has been considered only to evaluate admittance (Y) parameters. The expressions for Y parameters include the substrate effect on the device RF performance, and the new element added to this equivalent circuit is C_{sub} , which includes the effect of substrate.

The lossy element g_{bd} (substrate–drain conductance) has been neglected because of its reduced value in more recent technologies. The effect of channel charging resistance r_i and the gate–drain resistance r_{gd} are included in the analysis in addition to the well-known lumped elements. The drain–substrate capacitance (C_{dsub}) and source–substrate capacitance (C_{ssub}) will be in parallel when R_{sub} is taken to be negligible due to a very-low-resistivity bulk substrate material.

The variation of Y_{11} with frequency, including the substrate effect for devices with different dimensions ($L = 0.4 \mu\text{m}$ and $L = 1.6 \mu\text{m}$) is shown in Figs. 3a and 3b, respectively. For a given frequency, Y_{11} is greater when the substrate effect is taken into account. This is because with substrate effect the channel potential increases, leading to increase in the depletion layer width and thus reducing the capacitance. For a short-gate-length device, the substrate effect is more prominent because the capacitance is lower in comparison to large gate length. The value of Y_{11} is less for

Figure 3. (a) Variation of input admittance parameter with frequency [$\diamond\diamond\diamond\diamond$ —Re (Y_{11}) of Ref. 43 excluding the substrate effect; $\circ\circ\circ\circ$ —Im (Y_{11}) of Ref. 43 excluding the substrate effect]; (b) variation of input admittance parameter with frequency [$\bullet\bullet\bullet\bullet$ —Re (Y_{11}) of Ref. 43 excluding the substrate effect; $\triangle\triangle\triangle\triangle$ —Im (Y_{11}) of Ref. 43 excluding the substrate effect].

short gate length because of decrease in capacitance. The reverse transfer admittance (Y_{12}) with and without the substrate effect shows a similar variation with frequency as without considering the substrate and can be seen in

Figs. 4a and 4b, respectively. Figure 5 shows variations of the forward transfer admittance parameter (Y_{21}), which is one of the important parameters used to calculate the gain of a device with frequency for the two different devices.

Figure 4. (a) Variation of reverse transfer admittance parameter with frequency [$\diamond\diamond\diamond\diamond$ —Re (Y_{12}) of Ref. 43 excluding the substrate effect; $\circ\circ\circ\circ$ —Im (Y_{12}) of Ref. 43 excluding the substrate effect]; (b) variation of reverse transfer admittance parameter with frequency [$\bullet\bullet\bullet\bullet$ —Re (Y_{12}) of Ref. 43 excluding the substrate effect; $\triangle\triangle\triangle\triangle$ —Im (Y_{12}) of Ref. 43 excluding the substrate effect].

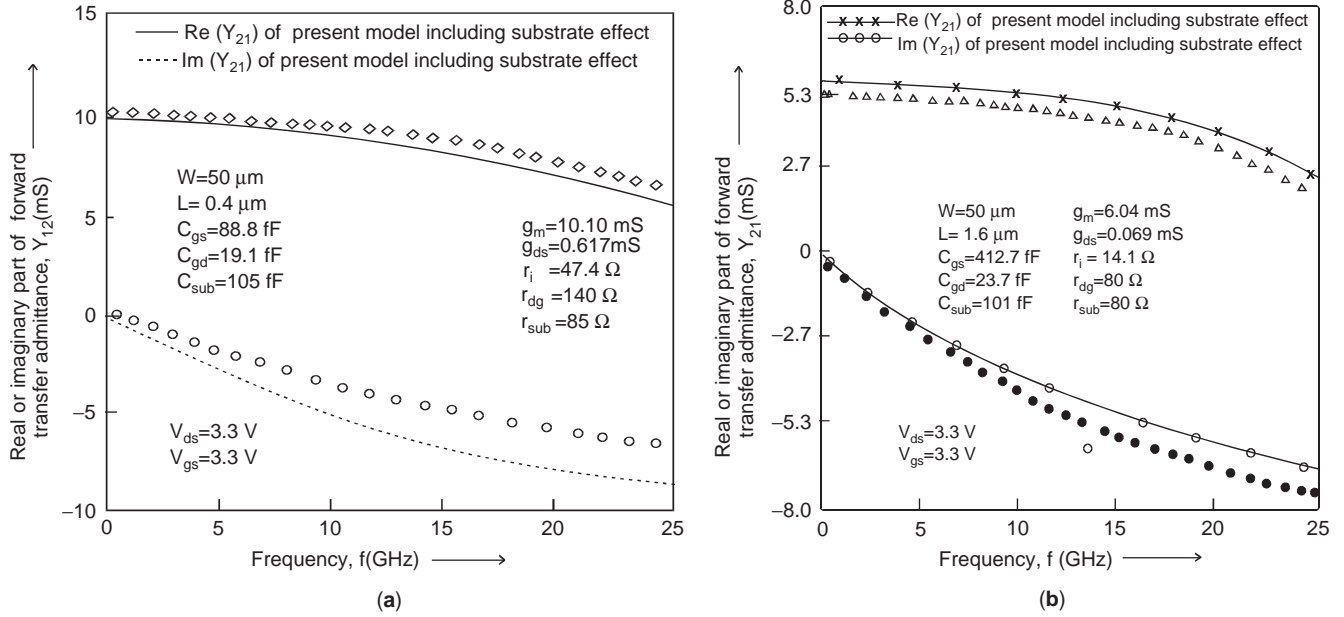

Figure 5. (a) Variation of forward transfer admittance parameter with frequency [$\diamond \diamond \diamond \diamond$ — $\text{Re}(Y_{21})$ of Ref. 43 excluding the substrate effect; $\circ \circ \circ \circ$ — $\text{Im}(Y_{21})$ of Ref. 43 excluding the substrate effect]; (b) shows variation of forward transfer admittance parameter with frequency [$\bullet \bullet \bullet \bullet$ — $\text{Im}(Y_{21})$ of Ref. 43 excluding the substrate effect; $\triangle \triangle \triangle \triangle$ — $\text{Re}(Y_{21})$ of Ref. 43 excluding the substrate effect].

Figure 5a shows that at a given frequency the value of the forward transfer admittance parameter (Y_{21}) incorporating the substrate effect is less, in comparison with excluding the substrate effect. This is because the substrate effect capacitance decreases, thereby increasing the channel charging resistance. At a given frequency it is observed that Y_{21} is less for short gate length because with decreasing gate length, gate–source capacitance decrease, thereby increasing the gate–source resistance, which in turn decreases Y_{21} . In case of Fig. 5b, the phenomenon is reverse for large gate length. At very high frequencies, Y_{21} decreases because of the decrease in time constant (resistance and capacitance).

The variations of output admittance Y_{22} with frequency is shown in Figs. 6a and 6b for different devices. It is observed that with the substrate effect one gets the lower value of Y_{22} at a given frequency because of decrease in depletion-layer capacitance as well as substrate capacitance.

1.5. Scattering Parameters

For a two-port network, the z, h parameters cannot be measured accurately at higher frequencies because the required short-and open-circuit tests are difficult to achieve over a broadband range of microwave frequencies. A set of parameters that is very useful in the microwave range is the scattering parameters (S parameters) [44,45]. The S parameter of short-gate-length IGFET for microwave frequency applications is required and as reported in Ref. 42, the equivalent-circuit model is scalable since all its elements have physical significance and new elements

added to this model are inclusive of the substrate effect, the overlap effect, the fringing field effect, and the effect of gate and drain contact pads. The final expressions of the various S parameters on the basis of Ref. 42 are discussed below. The S_{11} is given as

$$S_{11} \frac{b_1}{a_1} \Big|_{a_2=0} = \frac{\left\{ \frac{1 + s(C_{gd} + C_{gs})(r_i - 1) + sC_{gs}r_i(1 - sC_{gd})}{1 + s(C_{gd} + C_{gs})r_i + sC_{gs}r_i} \right\} A_2 + \frac{A}{B}}{\left\{ \frac{1 + s(C_{gd} + C_{gs})(r_i + 1) + sC_{gs}r_i(1 + sC_{gd})}{1 + s(C_{gd} + C_{gs})r_i + sC_{gs}r_i} \right\} A_2 - \frac{A}{B}} \quad (1a)$$

where

$$A = (1 + C_{gd}r_{gd})[-sC_{gd}g_m - s^2C_{gd}^2g_mr_{gd} + s^2C_{gd}^2 + s^3C_{gd}^2C_{gs}r_i] \quad (1b)$$

$$A_1 = \{1 - s^2C_{sub}^2r_{sub}(r_{sub} + r_0)\}(1 + sC_{gd}r_0) \quad (1c)$$

$$A_2 = \frac{F\{r_0 - (sC_{sub}r_{sub})^2r_0\} + A_1 + sC_{gd}r_0 - s^3C_{gd}^2C_{sub}^2r_{sub}^2r}{r_0F - s^2C_{sub}^2r_{sub}^2C_{gd}r_0 - s^3C_{sub}^2r_{sub}^2C_{gd}r_{dg}r_0} \quad (1d)$$

$$B = (1 + sC_{gd}r_{gd})^3(1 + sC_{gs}r_i) \quad (1e)$$

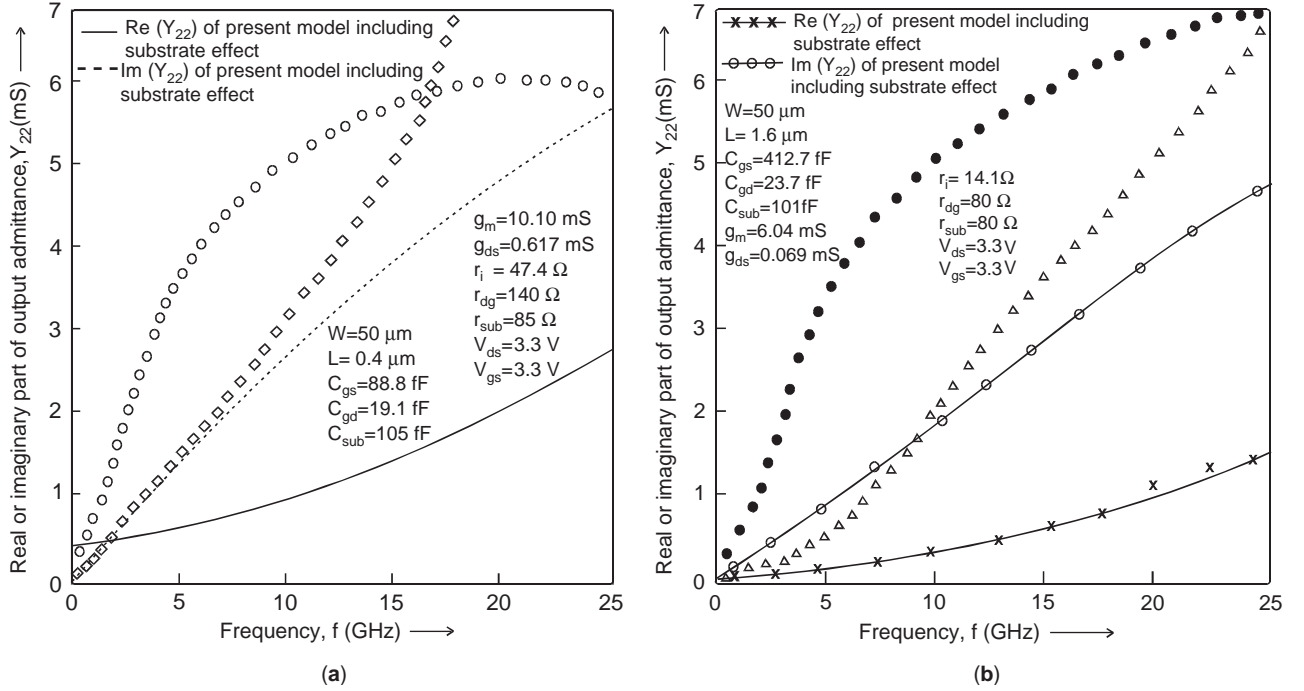

Figure 6. (a) Variation of output admittance parameter with frequency [$\diamond \diamond \diamond \diamond$ — $\text{Re}(Y_{22})$ of Ref. 43 excluding the substrate effect; $\circ \circ \circ \circ$ — $\text{Im}(Y_{22})$ of Ref. 43 excluding the substrate effect]; (b) variation of output transfer admittance parameter with frequency [$\bullet \bullet \bullet \bullet$ — $\text{Im}(Y_{22})$ of Ref. 43 excluding the substrate effect; $\triangle \triangle \triangle \triangle$ — $\text{Re}(Y_{22})$ of Ref. 43 excluding the substrate effect].

The reverse transmission scattering coefficient (S_{12}) is given as

$$S_{12} = \frac{b_1}{a_2} \Big|_{a_1=0} = \frac{\frac{2sC_{gd}}{1+sC_{gd}r_{gd}}}{\left\{ \frac{1+s(C_{gd}+C_{gs})(r_i+1)+sC_{gs}r_i(1+sC_{gd})}{1+s(C_{gd}+C_{gs})r_i+sC_{gs}r_i} \right\} (C/D) - C_1} \quad (2a)$$

$$C = (1 + C_{gd}r_{dg}) + \{1 - s^2C_{sub}^2r_{sub}(r_{sub} + r_0)\}(1 + sC_{gd}r_0) + sC_{gd}r_0 - s^3C_{gd}C_{sub}^2r_{sub}^2r \quad (2c)$$

$$D = (1 + sC_{gd}r_{dg}) - s^2C_{sub}^2r_{sub}^2C_{gd}r_0 - s^3C_{sub}^2r_{sub}^2C_{gd}r_{dg}r_0 \quad (2d)$$

The forward transmission scattering coefficient (S_{21}) is given as

$$S_{21} = \frac{b_2}{a_1} \Big|_{a_2=0} = \frac{2g_m F - sC_{gd}(1 + sC_{gs}r_0)}{\{(1 + sC_{gs})F\} \left\{ \frac{1 + s(C_{gd} + C_{gs})(r_i + 1) + sC_{gs}r_i(1 + sC_{gd})}{1 + s(C_{gd} + C_{gs})r_i + sC_{gs}r_i} \right\} E - E_1} \quad (3a)$$

where

where

$$E = \frac{(1 + sC_{gd}r_{dg}) + \{1 - s^2C_{sub}^2r_{sub}(r_{sub} + r_0)\}(1 + sC_{gd}r_0) + sC_{gd}r_0 - s^3C_{gd}C_{sub}^2r_{sub}^2r}{r_0(1 + sC_{gd}r_{dg}) - s^2C_{sub}^2r_{sub}^2C_{gd}r_0 - s^3C_{sub}^2r_{sub}^2C_{gd}r_{dg}r_0} \quad (3b)$$

$$C_1 = \frac{F \{ sC_{gd}g_m - s^2C_{gd}^2g_m r_{gd} + s^2C_{gd}^2 + s^3C_{gd}^2C_{gs}r_i \}}{F^3(1 + sC_{gs}r_i)} \quad (2b)$$

$$E_1 = \frac{FC}{F - s^2C_{sub}^2r_{sub}^2C_{gd}r_0 - s^3C_{sub}^2r_{sub}^2C_{gd}r_{dg}r_0} \quad (3c)$$

$$F = 1 + sC_{gd}r_{gd} \quad (3d)$$

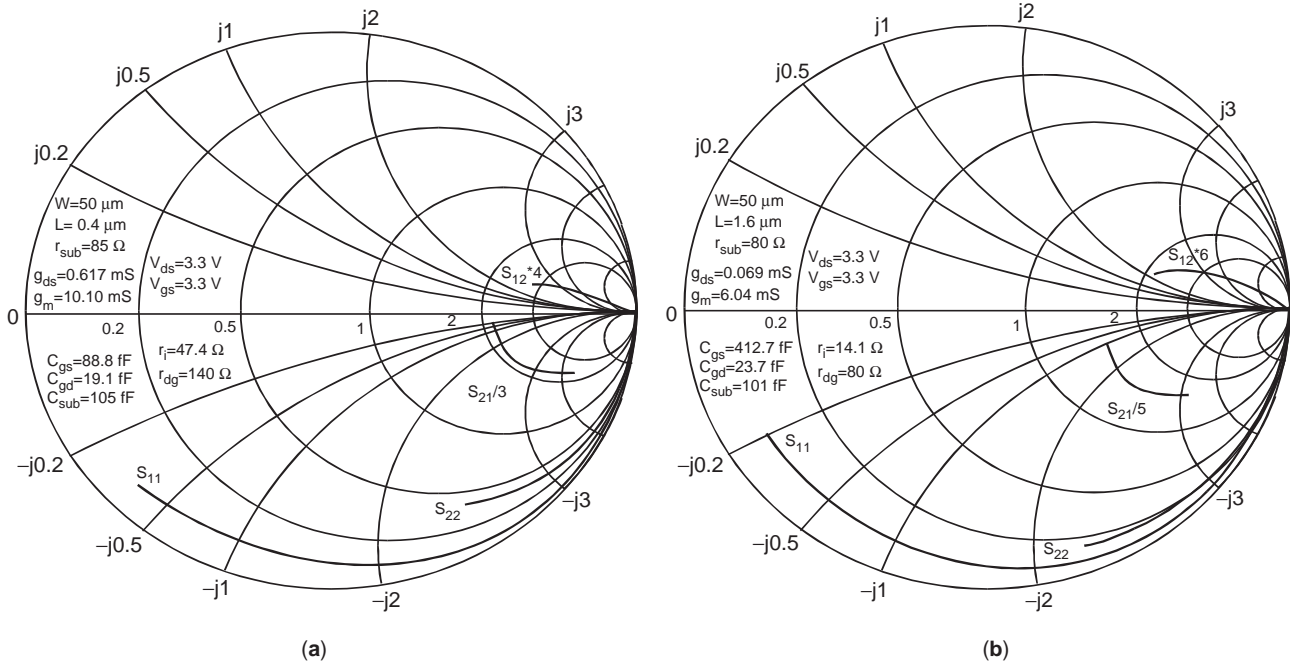

Figure 7. Variation of S parameter for (a) short-gate-length and (b) larger-gate length MOSFETs.

The output reflection scattering coefficient (S_{22}) is given as

$$S_{22} = \left. \frac{b_2}{a_2} \right|_{a_1=0}$$

$$= \frac{\left\{ \frac{1 + s(C_{gd} + C_{gs})(r_i + 1) + sC_{gs}r_i(1 + sC_{gd})}{1 + s(C_{gd} + C_{gs})r_i + sC_{gs}r_i} \right\} G_1 + A/B}{\left\{ \frac{1 + s(C_{gd} + C_{gs})(r_i - 1) + sC_{gs}r_i(1 - sC_{gd})}{1 + s(C_{gd} + C_{gs})r_i + sC_{gs}r_i} \right\} G_2 - \frac{A}{B}}$$

(4a)

where

$$G = s^2 C_{sub}^2 r_{sub}^2 C_{gd} r_0 + S^3 C_{sub}^2 r_{sub}^2 C_{gd} r_0 r_{gd} \tag{4b}$$

$$G_1 = \frac{r_0 F - G - FH + sC_{gd} \{r_0 - (sC_{sub} r_{sub})^2 r_0\}}{F \{r_0 - (sC_{sub} r_{sub})^2 r_0\}} \tag{4c}$$

$$G_2 = \frac{F \{r_0 - (sC_{sub} r_{sub})^2 r_0\} + A \times 1 + sC_{gd} r_0 - s^3 C_{gd} C_{sub}^2 r_{sub}^2 r}{r_0 F - s^2 C_{sub}^2 r_{sub}^2 C_{gd} r_0 - s^3 C_{sub}^2 r_{sub}^2 C_{gd} r_{dg} r_0} \tag{4d}$$

$$H = 1 - s^2 C_{sub}^2 r_{sub} (r_{sub} + r_0) + sC_{gd} r_0 \tag{4e}$$

For a given frequency, the imaginary part of Y_{22} for larger gate length ($L = 1.6 \mu\text{m}$) is greater than that for a shorter gate length ($L = 0.4 \mu\text{m}$) because C_{gd} and $r_0 [(g_{ds})^{-1}]$ for $L = 1.6 \mu\text{m}$ are more. But the real part of Y_{22} for $L = 0.4 \mu\text{m}$ is more than that of $L = 1.6 \mu\text{m}$ because r_{sub} is more for $L = 0.4 \mu\text{m}$. The scattering parameters are evaluated from admittance parameter, and their variations with frequency are shown in Figs. 7a and 7b for two different devices

with the substrate effect. The reflection scattering coefficient at port 1 (S_{11}) and the reflection scattering coefficient at port 2 (S_{22}) are less for short gate length ($L = 0.4 \mu\text{m}$) than for large gate length ($L = 1.6 \mu\text{m}$) because the input admittance (Y_{11}) and the reverse transfer admittance (Y_{12}) for short gate length are less than those for the large gate length.

Similarly, S_{21} and S_{12} for large gate length ($L = 1.6 \mu\text{m}$) are more than those for the short gate length ($L = 0.4 \mu\text{m}$). As the channel length decreases, the incident and reflected scattering parameters reduce but the variation in transmitted S parameters decreases.

1.6. Power Gain

Several definitions of power gain are important in the design of amplifiers. Consider the power flow from the generator to load as shown in Fig. 8, where M_1 and M_2 are lossless matching networks.

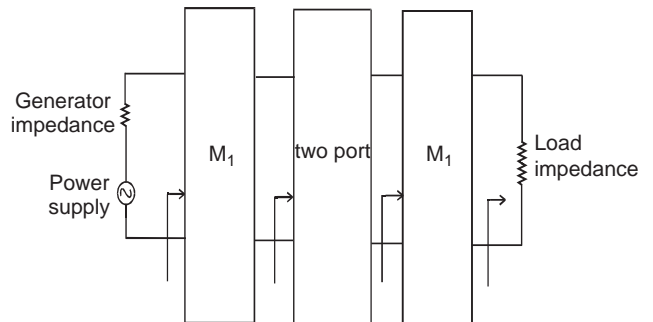

Figure 8. Available power and actual power for a two-port connected to a generator and a load.

The maximum stable power gain is given by

$$G_{ms} = \frac{|S_{21}|}{|S_{12}|} \quad (5)$$

This is the gain that can be achieved by resistively loading the two-port such that the stability factor (K) is unity and then simultaneously conjugately matching the input and output ports. For conditionally stable two-ports, the maximum stable gain is an upper limit in power gain that can be approached only as the input and output mismatch is reduced. If a simultaneous conjugate match is attempted, the two-port will oscillate if $K < 1$.

The unilateral power gain, which is the maximum available power gain when the two-ports are simultaneously conjugately matched and the two feedback parameters have been neutralized, has been developed. The conditions for unilateral gain are indicated in Fig. 9.

The unilateral power gain U_g , which is the maximum available power gain when the two ports are simultaneously conjugate-matched and the two feedback parameters have been neutralized, can be expressed in terms of S parameters [42] and is given as

$$U_g = \frac{\left[\frac{2g_m F - sC_{gd}(1 + sC_{gs}r_0)}{2sC_{gd}/(1 + sC_{gd})} - 1 \right]^2}{2K \left| \frac{2g_m F - sC_{gd}(1 + sC_{gs}r_0)}{2sC_{gd}/(1 + sC_{gd})} \right| - \operatorname{Re} \left(\frac{2g_m F - sC_{gd}(1 + sC_{gs}r_0)}{2sC_{gd}/(1 + sC_{gd})} \right)} \quad (6)$$

where K is the stability factor, given as

$$K = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |D|^2}{2|S_{12}| |S_{21}|} \quad \text{and } D = S_{11}S_{22} - S_{12}S_{21} \quad (7)$$

This gain is the highest possible gain that the active two-port could ever achieve. The frequency where the

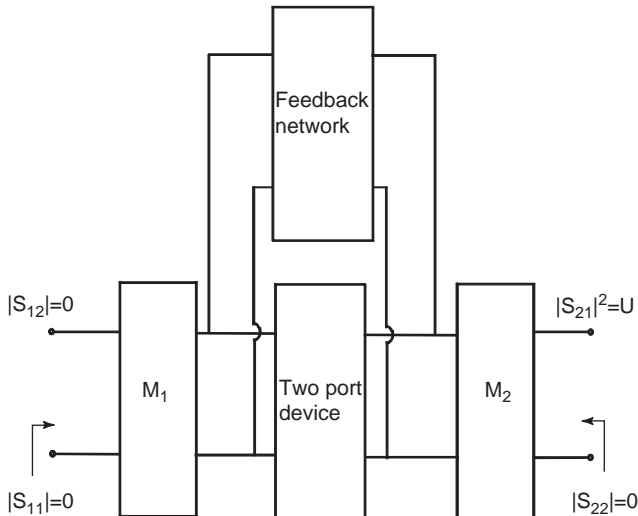

Figure 9. Condition for unilateral power gain.

unilateral gain becomes unity defines the boundary between an active and a passive network. This frequency is usually known as the *frequency of oscillation*. The maximum unilateral transducer power (G_{TUmax}), and unilateral figure of merit (U) are

$$G_{TU \max} = \frac{|S_{21}|^2}{(1 - |S_{11}|)^2(1 - |S_{22}|)^2} \quad (8a)$$

$$U = \frac{|S_{11}||S_{12}||S_{22}||S_{21}|}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (8b)$$

Figures 10a and 10b predict the variations of different gains and unilateral figure of merit with frequency. As the frequency increases, the power gain decreases for both devices. This is due to the decrease in admittance. For a given frequency the power gain for short gate length ($L = 0.4 \mu\text{m}$), as shown in Fig. 10a, is more than for large gate length ($L = 1.6 \mu\text{m}$), as shown in Fig. 10b, and is due to increase in transconductance. The power loss in the short-gate-length device is less than that in the large-gate-length device. The unilateral figure of merit is more for short-gate-length device, and the device becomes more unilateral when the gate length decreases.

Therefore, it can be concluded that as the gate length is reduced, the performance in the power gain increases. This shows that the circuits with small-gate-length devices are useful for microwave frequency applications.

2. SMALL-SIGNAL ANALYTICAL MOSFET MODEL WITH FRINGING FIELD EFFECT

2.1. Introduction

The design of analog and radiofrequency (RF) circuits in CMOS technology becomes increasingly difficult as device modeling faces new challenges in submicrometer processes and emerging circuit applications [46,47]. As the device geometry shrinks, various effects such as the reverse short-channel effect (RSCE), narrow-width effect, short-channel effect (SCE), and fringing field effect mix up with the circuit complexity and degrade the overall device performance [48,49]. The circuit designers need an accurate model in circuit simulation to describe the electrical characteristics of pocket implant process MOSFETs, incorporating RSCE, the hot-electron effect [50], the short-channel effect (SCE) [51], the narrow-width effect [52,53], and the fringing field effect [54,55]. Several methods of evaluating the small-signal characteristics have been reported [56–58]. The analytical results derived on the basis of a two-port model cannot be applied to many practical cases of high-frequency MOST structures. In MOS devices substrate doping is locally changed in the region between source and drain, and this is achieved by ion implantation. This results in variation of effective substrate doping concentration as one moves away from the channel/gate oxide interface toward bulk. Therefore, a complete drain current–voltage model [59] for small-geometry MOSFET with a nonuniformly doped (Gaussian) channel that covers the entire operating range and

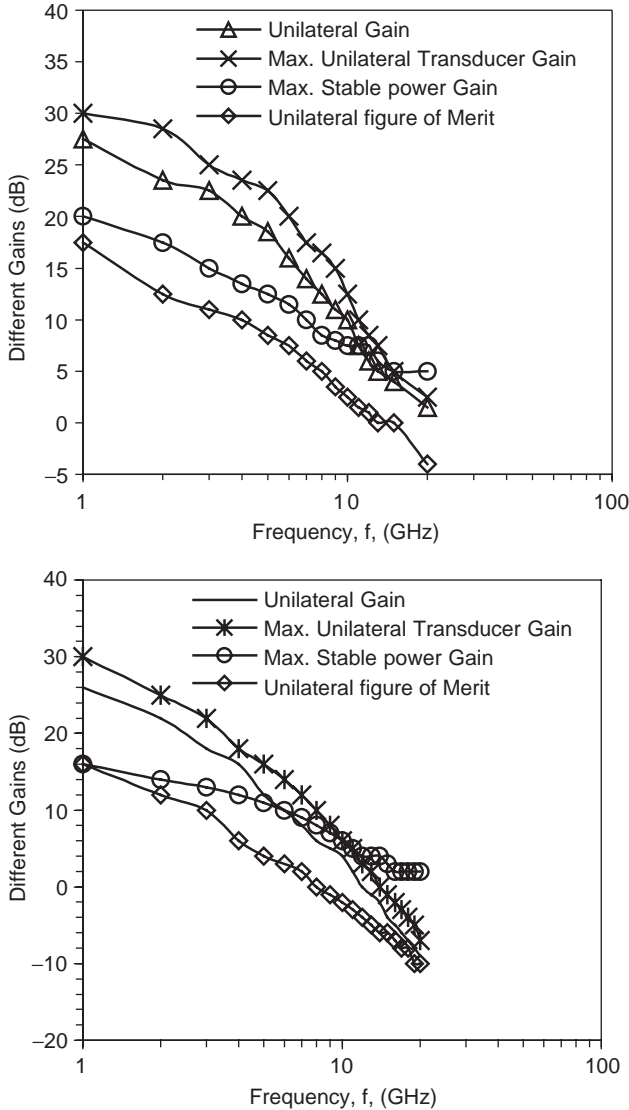

Figure 10. (a) Variation of different gains with frequency for short-gate-length MOSFET ($W = 50 \mu\text{m}$, $L = 0.4 \mu\text{m}$, $C_{gs} = 88.8 \text{ fF}$, $C_{gd} = 19.1 \text{ fF}$, $C_{sub} = 105 \text{ fF}$, $g_m = 10.10 \text{ mS}$, $g_{ds} = 0.617 \text{ mS}$, $r_i = 47.4 \Omega$, $r_{dg} = 140 \Omega$, $r_{sub} = 85 \Omega$, $V_{ds} = V_{gs} = 3.3 \text{ V}$); (b) variation of different gains with frequency for large-gate-length MOSFET ($W = 50 \mu\text{m}$, $L = 1.6 \mu\text{m}$, $C_{gs} = 412.7 \text{ fF}$, $C_{gd} = 23.7 \text{ fF}$, $C_{sub} = 101 \text{ fF}$, $g_m = 6.04 \text{ mS}$, $g_{ds} = 0.069 \text{ mS}$, $r_i = 14.1 \Omega$, $r_{dg} = 80 \Omega$, $r_{sub} = 85 \Omega$, $V_{ds} = V_{gs} = 3.3 \text{ V}$).

includes the fringing field effect is required for circuit simulation.

2.2. Drain Current Model

A MOSFET equivalent circuit used to evaluate various admittance parameters, including the fringing field effect for a RF amplifier, is shown in Fig. 11.

The drain current in MOSFET after incorporating fringing field effect [59] is

$$I_d = \frac{-\mu_{\text{eff}}W}{L} \int_{V_{ms}}^{V_{md}} Q_m dV \tag{9}$$

Figure 11. The equivalent circuit for evaluation of the admittance parameter.

where L and W are the channel length and width, respectively; μ_{eff} is the effective mobility [62]; and $V_{ms} = V_s + V_{bi}$ and $V_{md} = V_d + V_{bi}$ at the source and drain terminals, respectively. After incorporating all the charge density components, which are present in the short-geometry MOSFET, and the total charge density Q_m in the channel is now given by

$$Q_m = Q_i + Q_j + Q_s + \Delta Q_b \tag{10}$$

where Q_i is the inversion-layer charge [54], Q_j and Q_s are the p-n junction space charge density and the surface charge density, respectively, given as

$$Q_j = qNX_j = K_e \sqrt{V_m} \tag{11}$$

where the implanted layer is approximated by a rectangle of height N (doping per meter³) and width X_j (meter) further, $K_e = \sqrt{2eqN_e}$, $N_e = N_a N / (N_a + N)$, and $V_m = V + V_{bi}$. V takes the values V_s and V_d while V_m takes the values V_{ms} and V_{md} at the source and drain terminals, respectively. Then

$$\begin{aligned} Q_s &= -C_{ox}(V_{mg} - V_m) && V_{mg} > V_m && \text{(accumulation)} \\ &= qNX_s && V_T < V_{mg} < V_m && \text{(depletion)} \\ &= qNX_{sm} && V_{mg} < V_T && \text{(inversion)} \end{aligned} \tag{12}$$

where $V_{mg} = V_g - V_{fb} + V_{bi}$.

The surface space charge region thickness (X_s) is given by

$$X_s = \frac{K_n (\sqrt{V_m - V_{mg} + V_c} - \sqrt{V_c})}{qN} \tag{13}$$

Figure 12. Drain current–drain voltage characteristics at different gate voltages.

where

$$V_c = \frac{qN\epsilon_{si}}{2C_{ox}^2} \quad \text{and} \quad K_n = \sqrt{2\epsilon_{si}qN} \quad (14)$$

When the inversion occurs at the surface, the space charge region X_s attains a maximum value X_{sm} given by $X_{sm} = (K_n\sqrt{V_m})/qN$. The term ΔQ_b is the increased charge density due to narrow gate width and shift of the threshold voltage and is given as [61]

$$\Delta Q_b = C_{ox} \left[\frac{0.17}{W} 10^{-6} V_{ms} + 1.5 \exp[-(10^6 \cdot W)] \sqrt{V_s + V_{bi}} \right] \quad (15)$$

Utilizing Eq. (10) in Eq. (9), the drain current is obtained after integrating the inversion-layer charge expression from source region to drain region [59]. The variation of drain current with drain to source voltage at different gate–source voltages is shown in Fig. 12.

It is seen that at a given V_g , I_d increases with V_d with increase in carrier mobility in the channel. Also at a given V_d , I_d is increasing with V_g because of the increase in inversion-layer charge. Fig. 13 shows the variation of drain current with gate voltage at different drain voltages. The theoretical result for $V_d = 0.05 \text{ V}$ is found to be in perfect agreement with experimental data [51]. The variation of drain current with gate width for different drain voltages is shown in Fig. 14. At a given V_d , the variation of I_d with W is linear and the slope of the line increases with V_d , which results in decrease in current at a faster rate at high value of V_d . Because of lateral diffusion of the depletion layer boundary toward the field oxide region, there will be an additional bulk side charge that results in a

Figure 13. Drain current–gate voltage characteristics at different drain voltages.

decrease of channel current with the narrowing of gate width. With the increase in W , curves of a usual long-channel MOSFET are obtained. It is seen from Fig. 15, that as the channel length decreases I_d increases; this occurs because, with the shortening of channel length, the depletion region under the channel is widened. Therefore with the increase of potential at drain, the surface potential increases, which results in an increase of drain current.

Figure 14. Variation of drain current with gate width at different drain biases.

Figure 15. Variation of drain current with channel length at different gate widths.

2.3. Capacitance Model

The total charge in the gate side is obtained from the expression

$$Q_G = \frac{-\mu_{eff}W^2}{I_d} \int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m \tag{16}$$

where Q_g is the gate accumulation charge density given as $Q_g = C_{ox}(V_{mg} - V_m)$. Substituting the values of Q_m from (10) and Q_g in expression (16), we get

$$Q_G = \frac{-\mu_{eff}W^2}{I_d} \left[C_{ox}Q_i \left\{ V_{mg}(V_{md} - V_{ms}) - \frac{(V_{md})^2 - (V_{ms})^2}{2} \right\} + K_e C_{ox} \left\{ \frac{2}{3} V_{mg} \left((V_{md})^{3/2} - (V_{ms})^{3/2} \right) - \frac{2}{5} V_{mg} \left((V_{md})^{5/2} - (V_{ms})^{5/2} \right) \right\} + (-C_{ox})^2 \left\{ (V_{mg})^2 (V_{md} - V_{ms}) + \frac{(V_{md})^3 - (V_{ms})^3}{3} - V_{mg}(V_{md})^2 - (V_{ms})^2 \right\} + Q_b C_{ox} \left\{ V_{mg}(V_{md} - V_{ms}) - \frac{(V_{md})^2 - (V_{ms})^2}{2} \right\} \right] \tag{17}$$

The gate-to-source capacitance (C_{gs}) and gate-to-drain capacitance (C_{gd}) are evaluated after incorporating the

fringing field effect are obtained as [59]

$$C_{gs} = \mu_{eff}W^2 \left(\left(-I_d \right)^{-2} \int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m \right) \frac{dI_d}{dV_s} + \frac{1}{I_d} \frac{d}{dV_s} \left(\int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m \right) \tag{18}$$

$$C_{gd} = \mu_{eff}W^2 \left(\left(-I_d \right)^{-2} \int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m \right) \frac{dI_d}{dV_d} + \frac{1}{I_d} \frac{d}{dV_d} \left(\int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m \right) - \frac{(-\theta\delta + \theta_c) \int_{V_{md}}^{V_{ms}} Q_g Q_m dV_m}{I_d [1 + \theta(V_g - V_t - \delta V_d) + \theta_b V_{sb} + \theta_c V_d]} \tag{19}$$

The variation of gate–source capacitance (C_{gs}) and gate–drain capacitance (C_{gd}) with drain current for a channel-length ($L = 0.8\text{-}\mu\text{m}$) and gate-width ($W = 60\text{-}\mu\text{m}$) device is shown in Fig. 16 as a function of saturation current.

It can be seen that C_{gd} is almost constant for higher-drain currents in saturation. It is obvious from the figure that C_{gd} , including the gate–drain capacitance and overlap capacitance, has a strong dependence on V_{gs} and consequently, from gate–drain bias conditions, C_{gd} is less dependent on V_{ds} , due to the reverse p-n junction depletion at the drain end. As in the case of C_{gs} , which is associated with gate oxide, capacitance in the depletion region near the source end is determined mainly by V_{gs} and is less V_{ds} dependent on and is almost constant in the saturation region. When drain current increases with increasing V_{gs} at saturation (at a fixed V_{ds}), the pinchoff point moves toward the drain end. Hence C_{gs} will increase

Figure 16. Variation of gate–source capacitance and gate–drain capacitance with saturation drain current (xxx—experimental data) [60].

Figure 17. Variation of transconductance and drain conductance with saturation drain current (xxx—experimental data) [60].

with saturation drain current because of the increase in V_{gs} .

2.4. Transconductance and Cutoff Frequency Model

For optimization of FET in RF applications, the transconductance (g_m) plays a significant role, and is one of the most important indicators of device quality for microwave and millimeter-wave applications and in the linear region is given as [59].

$$g_m = \left. \frac{\partial I_d}{\partial V_g} \right|_{V_d = \text{constant}} \quad (20)$$

Figure 17 shows the variation of transconductance (g_m) and drain to source conductance (g_{ds}) with saturation drain current (I_{dsat}) of a device with $W/L = 60/0.8 \mu\text{m}$. The transconductance is evaluated from the first-order derivative of drain current versus gate–source bias characteristics in saturation at drain–source bias of 3 V. It can be seen that transconductance increases rapidly up to 3.0 mA and then increases slowly. The drain conductance increases gradually throughout the plot. The current gain cutoff frequency f_t is an important figure of merit for microwave semiconductor devices. It is the frequency at which the short-circuit current gain of the device falls to unity. It also indicates the ultimate speed of the device. Therefore, cutoff frequency (f_t), which is an indicator of device high-frequency performance, determines the utilizing switching speed of the device, given as [61].

$$f_t = \frac{g_m}{2\pi(C_{gs} + C_{gd})} \quad (21)$$

Although the cutoff frequency represents an important figure of merit of the device, it does not represent the lim-

Figure 18. Variation of transconductance with channel length at different drain biases.

iting frequency of operation for microwave circuitry. However, for most microwave applications there is a figure of merit called *maximum frequency of oscillations* f_{max} that is than f_t more useful because microwave designers are typically concerned with power gain into conjugately matched conditions. Therefore, the maximum frequency of oscillation is defined as the frequency at which the unilateral power gain (U) of a device goes to unity.

The variation of I_d with gate width for a given channel length shows a variation similar to that seen in Fig. 14. Figure 18 shows a variation of transconductance with channel length at different drain voltages. For a given gate width and drain voltage, the transconductance increases with decrease in channel length, which is due to the increase in drain current as shown in Fig. 15. According to Fig. 19, as the width scales down, the transconductance decreases because of the decrease in drain current with channel width, as be seen from Fig. 14.

Figure 20 shows the variation of cutoff frequency (f_t) as a function of channel length. The operating frequency is found to be inversely proportional to the channel length. As the channel length reduces, the electron takes less time to cross the channel, which in turn increases frequency. According to Fig. 21, the cutoff frequency is directly proportional to the device width and can also be explained from Fig. 19.

2.5. Admittance (Y) Parameters

The kind of circuit shown in Fig. 11 has a definite advantage of physical significance in predicting the distributed gate resistance effect accurately. It is also convenient to represent its RF behavior as well as to simulate Y-parameter performance over a wide range of frequencies. The effective channel resistance is seen by the signal flowing via C_{gs} from gate to source. It is a representation of

Figure 19. Variation of transconductance with channel width at different drain biases.

the distributed resistance of the channel and spreading bulk resistance, capacitively coupled to the channel, and is responsible for the real part of intrinsic Y_{11} . This element is important for matching in analog circuit designs.

The presence of distributed gate inductance (L_g) plays a vital role upto 1.0 GHz and cannot be ignored while using the device below 1.0 GHz. In an earlier model [41], the effect of gate inductance was neglected below 1.0 GHz. After incorporating the fringing field effect, gate resistance (R_g), and gate inductance, Goswami *et al.* [61] derived modified expressions for the input and output Y parameters, with

Figure 20. Variation of cutoff frequency with channel length at different drain biases.

Figure 21. Variation of cutoff frequency with channel width at different drain biases.

and without incorporating the effect of gate inductance, which are applicable at low as well as at high frequencies for circuit applications. Table 1 shows Y parameters with and without incorporating the gate inductance. The total capacitance C_g is equal to the sum of C_{gs} and C_{gd} . Y_{ds} is admittance between source and drain; $s (=j\omega)$ is a complex number. γ is also a complex number and is given in Ref. 41.

As shows in Fig. 22, it is seen that in the frequency range $0.01 \text{ GHz} < f < 1.0 \text{ GHz}$, the real part of $\tanh[(sC_g(R_g + sL_g))/sC_g(R_g + sL_g)]$ is more, due to the effect of gate inductance (L_g), which is due to increase in the input impedance. In the frequency range greater than 1.0 GHz the effect of gate inductance is negligible and the gate becomes resistive.

Figure 23 shows variation of the input admittance Y_{11} with frequency. The real part of Y_{11} increases when distributed gate inductance is incorporated in the analysis, which results in increase in input impedance and thus in Y_{11} . A similar explanation can be given for decrease in the imaginary part of Y_{11} , which is shown in Fig. 24. Also, Y_{11} increases with the frequencies as it is directly related to frequency. The calculated value of Y_{11} without incorporating L_g matches the simulated data [41].

Figure 25 shows variation of the real part of reverse transfer admittance parameter (Y_{12}) with frequency. The real part of Y_{12} increases and the imaginary part of Y_{12} , shown in Fig. 26, decreases with the incorporation of distributed gate inductance. An explanation similar to that for Figs. 20 and 21 can be given for such type of variation of Y_{12} when the effect of L_g is considered. Y_{12} decreases with frequency, which is obvious from the expression of Y_{12} . This parameter is very small because the transistor is biased in the saturation region where C_{gd} is very small.

Variations of the real and imaginary parts of the forward transfer admittance parameter (Y_{21}) with frequency

Table 1. Y Parameter Relative to Inclusion or Exclusion of Gate Inductance in Analysis

Without Incorporating the Effect of Gate Inductance	Incorporating the Effect of Gate Inductance
$Y_{11} = s(C_{gd} + C_{gs}) \frac{\tanh(\gamma W)}{\gamma W}$	$Y_{11} = s(C_{gd} + C_{gs}) \frac{\tanh \sqrt{sC_g(R_g + sL_g)}}{\sqrt{sC_g(R_g + sL_g)}}$
$Y_{12} = -sC_{gd} \frac{\tanh(\gamma W)}{\gamma W}$	$Y_{12} = sC_{gd} \frac{\tanh \sqrt{sC_g(R_g + sL_g)}}{\sqrt{sC_g(R_g + sL_g)}}$
$Y_{21} = (g_m - sC_{gd}) \frac{\tanh(\gamma W)}{\gamma W}$	$Y_{21} = (g_m - sC_{gd}) \frac{\tanh \sqrt{sC_g(R_g + sL_g)}}{\sqrt{sC_g(R_g + sL_g)}}$
$Y_{22} = Y_{ds} + sC_{gd} + \frac{(g_m s C_{gd}) C_{gd}}{C_{gs} + C_{gd}} \left(1 - \frac{\tanh(\gamma W)}{\gamma W}\right)$	$Y_{22} = Y_{ds} + sC_{gd} + (g_m - sC_{gd}) C_{gd} \times \left[\left(\frac{\tanh \sqrt{sC_g(R_g + sL_g)}}{\sqrt{sC_g(R_g + sL_g)}} \right)^{-1} - 1 \right] \left(\frac{\tanh \sqrt{sC_g(R_g + sL_g)}}{\sqrt{sC_g(R_g + sL_g)}} \right)$

are shown in Figs. 27 and 28, respectively, and it can be seen that from 0.01 to 1.0 GHz the real part increases with decreasing frequency while the imaginary part decreases with decreasing frequency up to 0.1 GHz and then increases with decreasing frequency. The calculated results, without considering the effect of distributed gate inductance, are in close agreement with simulated data [41]. Figure 29 shows variation of the real part of the output admittance parameter with frequency. It is found that from frequency 0.01 to 1.0 GHz the real part of the output parameter (Y_{22}) incorporating the effect of gate inductance gives a larger value than without incorporating the gate inductance effect. Therefore the amplifier used up to 1.0 GHz should incorporate gate inductance to achieve better performance. Figure 30 shows variation of the

imaginary part of the output admittance parameter (Y_{22}) of the device with frequency.

2.6. Scattering Parameter

The downscaling of MOSFETs to deep-submicrometer dimensions and the resulting high unity-gain frequency make MOSFETs increasingly attractive for applications in IC used in RF analog electronics and wireless communications [63,64]. For efficient circuit design in the microwave and millimeter-wave bands the availability of an accurate and reliable device model is a key factor. The small-signal behavior of a MOSFET at higher frequencies around a bias point is usually determined by S parameters over its operational bandwidth. The S parameters are

Figure 22. Variation of the $\tanh[(sC_g(R_g + sL_g))/sC_g(R_g + sL_g)]/sC_g(R_g + sL_g)$ with frequency.

Figure 23. Variation of real part of input admittance parameter with frequency.

Figure 24. Variation of imaginary part of input admittance parameter with frequency.

used to represent the signal power gain and mismatch losses, as they are frequency-dependent, and therefore adequate representation of circuit elements over their entire operational ranges is essential for MMIC design [65,66]. Earlier models developed include the substrate effect and the gate-drain contact pad effect [59], for prediction of microwave characteristics of MOSFET. But in those models, *S*-parameter extraction incorporating the fringing field effect and the effect of distributed gate inductance was not done. When the device geometry is done in the submicrometer range, the fringing field effect comes into play. Therefore, simple expressions for *S* parameters

Figure 26. Variation of imaginary part of reverse transfer admittance parameter with frequency.

useful for circuit analysis and optimization are required that incorporate the distributed gate inductance and the fringing field effect. An equivalent circuit of short-channel MOSFETs with fringing field lines to evaluate the *S* parameters necessary in designing a RF amplifier was shown in Fig. 11. When the MOSFET geometry is small enough, the front-gate bias generates the fringing field, which results in an even stronger inversion along the sides of the wall of the edges than in the MOS interface. Therefore, as the device size shrinks and the contact pad is also scaled down, the fringing field effect and the effect of distributed gate inductance cannot be neglected. When

Figure 25. Variation of real part of reverse transfer admittance parameter with frequency.

Figure 27. Variation of real part of forward transfer admittance parameter with frequency.

Figure 28. Variation of imaginary part of forward transfer admittance parameter with frequency.

the scattering concept is applied to lumped circuits, the S parameters [67] in terms of device parameters are given as

Figure 30. Variation of imaginary part of output admittance parameter with frequency.

where

$$S_{11} = \frac{\{\xi - s(C_{gs} + C_{gd}) \tanh \xi\} \{\xi(1 + g_{ds} + sC_{gd}) + (g_m - sC_{gd})C_{gd}(\xi - \tanh \xi)\} - sC_{gd}(g_m - sC_{gd}) \tanh^2 \xi}{(\xi + sC_g \tanh \xi)(\xi(1 + g_{ds} + sC_{gd}) + \beta) + s(C_{gs} + C_{gd})(R_g + sL_g) \tanh \xi} \quad (22)$$

$$\xi = \sqrt{sC_g(R_g + sL_g)} \quad (23)$$

$$\beta = (g_m - sC_{gd})C_{gd} \left[\left(\frac{\tanh \xi}{\xi} \right)^{-1} - 1 \right] \tanh \xi \quad (24)$$

Then S_{12} and S_{21} are given as

$$S_{12} = \frac{2sC_{gd}\xi \tanh \xi}{\{\xi + s(C_{gs} + C_{gd}) \tanh \xi\} \delta + sC_{gd}(g_m - sC_{gd}) \tanh^2 \xi} \quad (25)$$

where

$$\delta = \xi(1 + g_{ds} + sC_{gd}) + (g_m - sC_{gd})C_{gd}(\xi - \tanh \xi) \quad (26)$$

and

$$S_{21} = \frac{-2\xi(g_m - sC_{gd}) \tanh \xi}{\gamma + sC_{gd}(g_m - sC_{gd}) \tanh^2 \xi} \quad (27)$$

$$\gamma = \xi^2(1 + g_{ds} + sC_{gd}) + \xi sC_g \tanh \alpha + \xi(g_m - sC_{gd})C_{gd}(\xi - \tanh \xi) \quad (28)$$

Figure 29. Variation of real part of output admittance parameter with frequency.

The reflection scattering coefficient at port 2 (S_{22}) is given as

$$S_{22} = \frac{\{\xi + s(C_{gs} + C_{gd}) \tanh \alpha\} \{(\xi(1 - g_{ds} - sC_{gd}) + \beta)\} - sC_{gd}(g_m - sC_{gd}) \tanh^2 \xi}{\gamma + sC_{gd}g_m \tanh^2 \xi - s^2C_{gd}^2 \tanh^2 \xi} \quad (29)$$

2.7. Power Gains

The unilateral power gain is given as

$$U_g = \frac{\left[\frac{2\xi(g_m - sC_{gd}) \tanh \xi}{2sC_{gd}\xi \tanh \xi} - 1 \right]^2}{2K \left| \frac{2\xi(g_m - sC_{gd}) \tanh \xi}{2sC_{gd}\xi \tanh \xi} \right| - \text{Re} \left(\frac{2\xi(g_m - sC_{gd}) \tanh \xi}{2sC_{gd}\xi \tanh \xi} \right)} \quad (30)$$

where K is the stability factor given in terms of scattering parameters as

$$K = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |D|^2}{2|S_{12}||S_{21}|} \quad (31)$$

$$D = S_{11}S_{22} - S_{12}S_{21} \quad (32)$$

The maximum unilateral transducer power G_{TUmax} , the unilateral figure of merit U , and the maximum stable power gain G_{ms} are given as

$$G_{TUmax} = \frac{|S_{21}|^2}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (33)$$

$$U = \frac{|S_{11}||S_{12}||S_{22}||S_{21}|}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (34)$$

$$G_{ms} = \frac{|S_{21}|}{|S_{12}|} \quad (35)$$

The variation of scattering parameters with frequency for the device with channel length $L = 0.8 \mu\text{m}$ incorporating the fringing field effect and distributed gate inductance is predicted in Fig. 31 for drain current of 6.0 mA with $L_g = 850 \text{ pH}$, $L_s = 0.1 \text{ pH}$ and $L_d = 240 \text{ pH}$. As a result of the wide channel width, the series inductance is caused mainly by the gate itself instead of interconnects. Therefore it is included in the analysis. Figure 32 predicts the variations of different gains and the unilateral figure of merit with frequency. As the frequency increases, the power gain decreases and is basically due to decrease in admittance.

It can be observed that at a given frequency, unilateral transducer power gain is the largest gain and is due to the positive stability factor of the device. The maximum stable power gain shows input/output mismatch, and it is found that as the frequency is increased, the input/output

Figure 31. Variation of S parameter of MOSFET for a frequency range of 100 MHz–10 GHz (—present model; xxx—experimental data) [41].

mismatch decreases. Thus a simultaneous conjugate match has been obtained in the analysis. This shows that the circuit with a short-channel device is useful for microwave frequency applications. The unilateral figure of merit decreases with frequency but can be improved by reducing the gate length. Therefore high circuit performance can be obtained with small-gate-length devices.

Figure 32. Variation of different gain with frequency.

3. SMALL-SIGNAL AC MOSFET MODEL FOR RF APPLICATIONS

3.1. Introduction

MOSFETs have been widely used in digital VLSI circuits as well as in analog circuits. But the MOSFET device models available in the circuit simulation programs are not adequate in some applications [68–71]. During RF operation, the transit time of carriers from source to drain in the MOSFET is comparable to the rise/fall time of the signals, and during RF switching, the charge in the MOSFET is in a transient condition and quasistatic assumptions of steady-state conditions are no longer valid.

A nonquasistatic (NQS) model predicts the source, drain, gate, and substrate currents, taking into account the inertia in the charge transport of carriers from source to drain and the charge distribution transient when fast turnon and turnoff voltages are applied to the device terminals [72]. One of the NQS models proposed by Oh et al. [73] is valid in all regions of operation (weak, moderate, and strong inversion). Unfortunately, this model requires the use of time-consuming boundary-value methods and therefore cannot be used in a circuit simulator. Turchetti and Masetti [74] developed a simplified CAD oriented model for MOSFETs that is essentially a strong inversion model, and except for the short-channel charge sharing effect, no other SCEs such as velocity saturation or mobility degradation are considered. Park et al. [36,69,75] developed a computationally efficient long-channel NQS model, but, this model does not factor in the 2D effects that determine the boundary conditions at the drain end of the channel or any other small-geometry effects. Quasistatic capacitance models [76] are traditionally used for transient circuit analysis by simulators such as SPICE. These models represent the MOSFET by voltage-dependent node capacitances, where the node capacitors are assumed to charge and discharge instantaneously with the applied bias. However, it is well known that node currents cannot change instantaneously with bias, therefore requiring NQS models to simulate this condition.

It is well known that, for frequencies higher than a given device-dependent limit, the current gain of a MOS transistor decreases quickly. This phenomenon is due to the fact that the modulation of the channel charge distribution to rapidly varying external potentials can no longer be considered instantaneous. Hence, neglecting these NQS effects can result in unpredictable behavior of RF circuits [77]. Earlier models developed include the substrate effect, fringing field effect, and gate–drain contact pad effect. However, when $V_d > V_{dsat}$, the channel pinchoff point, or the velocity pinchoff point starts to move toward the source. This movement is referred to as the *channel length modulation* (CLM) [62,78]. When the device length is large, this effect can be neglected. But as the device length shortens, the CLM takes place and provides an additional AC output current, which increases the output conductance. Therefore, a new model is required through which the relations between the AC small-signal Y parameter and the structure parameters of the MOSFET can be established by incorporating the CLM effect.

3.2. AC Characteristic Analysis

When a small AC voltage (v_g) is applied to the gate electrode, along with DC voltage (V_G), an electric field (AC and DC) is developed in the channel. The drift current in the channel consists of four components. The first is due to the DC sheet charge and DC potential gradient; the second component corresponds to the DC sheet charge and the AC potential gradient, while the third is related to the AC sheet charge and DC potential gradient. The latter two are the main components of AC currents in the MOSFET. The fourth one is a second-order term formed by the AC sheet charge and AC potential gradient. An AC current density per unit length is given by

$$j(x) = -\mu_{\text{eff}} Q_{\text{DC}} \frac{d\psi_{\text{AC}}}{dx} - \mu_{\text{eff}} q_{\text{AC}} \frac{d\psi_{\text{DC}}}{dx} + D_n \frac{dq_{\text{AC}}}{dx} \quad (36)$$

where ψ_{AC} is the AC potential and ψ_{DC} is the DC potential [12] and is given by

$$\psi_{\text{AC}} = \psi_0 e^{i\omega t} \quad (37)$$

$$\begin{aligned} \psi_{\text{DC}} = & \frac{\sin\left(\frac{\pi y}{2d}\right)}{\sinh\left(\frac{\pi L}{2d}\right)} \left(\frac{4V_1}{\pi} + \frac{16Kd^2}{\pi^3} \right) \sinh\left(\frac{\pi(L-x)}{2d}\right) \\ & + \left\{ \frac{4(V_1 + V_d)}{\pi} + \frac{16Kd^2}{\pi^3} \right\} \sinh\left(\frac{\pi x}{2d}\right) \\ & + \frac{1}{2} Ky^2 - Kdy + \psi_{s0} \end{aligned} \quad (38)$$

where $V_1 = V_{\text{bi}} - 2\phi_f$, $\psi_{s0} = 2\phi_f - V_d$, and $K = (qN_a/\epsilon_{\text{si}})$, where V_{bi} is the built-in potential of drain/source–body junction, $2\phi_f$ is the potential required to invert the surface, V_d is the DC drain voltage, d is the depletion-layer depth, L is channel length, and x y denote the position of charge carriers along channel length and depth, respectively. D_n is the diffusion coefficient for electrons, and μ_{eff} is the effective mobility given by

$$\mu_{\text{eff}} = \frac{\mu_0}{1 + \theta(V_g - V_{\text{th}}) + \theta_c V_d} \quad (39)$$

where θ is the mobility degradation coefficient, $\theta_c = (LE_c)^{-1}$, and E_c is the critical field. Q_{DC} is the DC sheet charge, q_{AC} is the AC sheet charge, and the total sheet charge is $Q = Q_{\text{DC}} + q_{\text{AC}}$.

The DC sheet charge is considered to be along x [79] and is given by

$$Q_{\text{DC}} = \left[V_d - V_g + V_{\text{th}} + V_w \left(\left(1 + \frac{V_d}{2\phi_f} \right)^{1/2} - 1 \right) \right] C_{\text{ox}} \quad (40)$$

where V_g is the DC gate voltage, N_a is the acceptor density, V_{th} is the threshold voltage, given [80] as

$$V_w = \frac{1}{C_{ox}} \sqrt{4\epsilon_{si}q\phi_f N_a} \quad (41)$$

$$V_{th} = V_{th0} + K_1(\sqrt{\phi_{s0}} - V_{bseff} - \sqrt{\phi_{s0}}) - K_2 V_{bseff} + K_1 \left(\sqrt{1 + \frac{N_{LX}}{L}} - 1 \right) \sqrt{\phi_{s0}} + (K_3 + K_{3b} V_{bseff}) \times \frac{T_{ox}}{W + W_0} \phi_{s0} \quad (42)$$

where V_{th0} is the threshold voltage for a long-channel device at zero backbias, T_{ox} is the thickness of gate oxide, ϕ_{s0} is termed as $2\phi_b$ and is given by $2V_t \ln(N_{ch}/n_i)$, N_{ch} is the doping concentration in the channel, n_i is the intrinsic carrier density, and K_3 , K_{3b} , W_0 , and N_{LX} are parameters as given in Ref. 80. In (42) the second and third terms describe the vertical nonuniform doping effect, and the fourth term includes the lateral nonuniform doping effect. Now the effective V_{bs} given by

$$V_{bseff} = V_{bc} + 5[V_{bs} - V_{bc} - \delta_1 + \sqrt{(V_{bs} - V_{bc} - \delta_1)^2 - 4\delta_1 V_{bc}}] \quad (43)$$

where $\delta_1 = 0.001$ and $V_{bc} = 0.9(\phi_{s0} - [(K_1)^2/4(K_2)^2])$:

$$K_1 = \gamma_2 - 2K_2 \sqrt{\phi_{s0} - V_{bm}},$$

$$K_2 = (\gamma_1 - \gamma_2) \frac{\sqrt{\phi_{s0} - V_{bx}} - \sqrt{\phi_{s0}}}{2\sqrt{\phi_{s0}}(\sqrt{\phi_{s0} - V_{bx}} - \sqrt{\phi_{s0}}) + V_{bm}}$$

with

$$\gamma_1 = \sqrt{\frac{2q\epsilon_{si}N_{ch}}{C_{ox}}} \quad \gamma_2 = \sqrt{\frac{2q\epsilon_{si}N_{sub}}{C_{ox}}}, \quad V_{bm} = -3.0 \text{ V},$$

$$V_{bx} = \phi_{s0} - \frac{qN_{ch}(X_t)^2}{2\epsilon_{si}}$$

where v_g is the AC voltage between gate and source and the AC sheet charge is given by

$$q_{AC} = (\psi(x) - v_g)C_{ox} \quad (44)$$

The current density equation given by (35) does not include the effect of generation of carriers in the depletion region on the AC current. Additionally, the variation of depletion region width with AC voltage is small when the surface is inverted. Therefore an AC current, which is generated in the depletion region, is of second order and is neglected.

The continuity equation is given by

$$\frac{\partial q_{AC}}{\partial t} = \frac{\partial j(x)}{\partial x} \quad (45)$$

Therefore, using (35), (44), and the assumption that DC potential varies with x and the channel is fully inverted, the right side of (45) becomes

$$\frac{\partial j(x)}{\partial x} = -\mu_{eff} Q_{DC} \frac{d^2 \psi_{AC}}{dx^2} - \mu_{eff} \left[q_{AC} \frac{d^2 \psi_{DC}}{dx^2} + \frac{d\psi_{DC}}{dx} \frac{dq_{AC}}{dx} \right] + D_n \frac{d^2 q_{AC}}{dx^2} \quad (46)$$

Using $\frac{\partial q_{AC}}{\partial t} = i\omega q_{AC}$ and $(d^2 q_{AC}/dx^2) = (d^2 \psi_{AC}/dx^2)C_{ox}$ in (32), we get

$$\frac{d^2 q_{AC}}{dx^2} - \frac{\mu_{eff}}{D_1} \left\{ -AB \frac{\sin(Ay)}{\sinh(AL)} + AB_1 \cosh(AL) \right\} \frac{dq_{AC}}{dx} - \frac{1}{D_1} \{ \mu_{eff} A^2 B_1 \sinh(AL) + i\omega \} q_{AC} = 0 \quad (47)$$

where $A = (\pi/2d)$, $B = (4V_1/\pi) + (16Kd^2/\pi^3)$, $B_1 = [4(V_1 + V_d)]/\pi + 16Kd^2/\pi^3$, and $D_1 = (\mu_{eff} Q_{DC}/C_{ox}) - D_n$.

Using (47) and $Q = Q_{DC} + q_{AC}$, D_1 comes out to be

$$D_1 = \mu_{eff}(V_d - V_g + V_{th} + V_w) \left(\left(1 + \frac{V_d}{2\phi_f} \right)^{1/2} - 1 - \frac{kT}{q} \right) \quad (48)$$

Using the boundary conditions

$$x = 0, \quad q_{AC} = -C_{ox}v_g \quad (49)$$

$$x = L, \quad q_a = (v_d - v_g)C_{ox} \quad (50)$$

$$q_{AC}(x) = \left\{ \frac{(v_d - v_g)C_{ox} + C_{ox}v_g e^{\delta L}}{e^{\delta L} - e^{\alpha L}} \right\} e^{\alpha x} + \left\{ \frac{(v_d - v_g)C_{ox} + C_{ox}v_g e^{\alpha L}}{e^{\delta L} - e^{\alpha L}} \right\} e^{\delta L} \quad (51)$$

where

$$\alpha = \frac{1}{2} \left[\left\{ \frac{\mu_{eff}}{D_1} \left\{ -AB \frac{\sin(Ay)}{\sinh(AL)} + AB_1 \cosh(AL) \right\} \right\} + \sqrt{\left\{ \frac{\mu_{eff}}{D_1} \left\{ -AB \frac{\sin(Ay)}{\sinh(AL)} + AB_1 \cosh(AL) \right\} \right\}^2 + \alpha_1} \right] \quad (52)$$

with

$$\alpha_1 = 4 \frac{1}{D_1} \{ \mu_{eff} A^2 B_1 \sinh(AL) + i\omega \} \quad (53)$$

$$\delta = \frac{1}{2} \left[\left\{ \frac{\mu_{\text{eff}}}{D_1} \left\{ -AB \frac{\sin(Ay)}{\sinh(AL)} + AB_1 \cosh(AL) \right\} \right\} - \sqrt{\left\{ \frac{\mu_{\text{eff}}}{D_1} \left\{ -AB \frac{\sin(Ay)}{\sinh(AL)} + AB_1 \cosh(AL) \right\} \right\}^2 + \alpha_1} \right] \quad (54)$$

The current density in the channel is obtained as

$$j(x) = \frac{D_n}{(e^{\delta L} - e^{\alpha L})} \left[\{(v_d - v_g) + v_g e^{\alpha L}\} C_{\text{ox}} \delta e^{\delta x} - \{(v_d - v_g) + v_g e^{\delta L}\} C_{\text{ox}} \alpha e^{\alpha x} \right] \quad (55)$$

Finally, the AC source current (i_s) is given by $i_s = i_d + i_g$. The AC source current (i_s) can be obtained using $i_s = Wj(x=0)$, and the AC drain current (i_d) is obtained as $i_d = Wj(x=L)$. Therefore the drain current and gate current, excluding the parasitic elements, can be obtained as

$$i_d = \frac{WD_n C_{\text{ox}}}{e^{\delta L} - e^{\alpha L}} \left[v_d (\delta e^{\delta L} - \alpha e^{\alpha L}) + v_g \times (\delta e^{(\alpha+\delta)L} - \delta e^{\delta L} + \alpha e^{\alpha L} - \alpha e^{(\delta+\alpha)L}) \right] \quad (56)$$

$$i_g = \frac{WD_n C_{\text{ox}}}{e^{\delta L} - e^{\alpha L}} \left[v_d (\delta - \alpha) + v_g (\delta e^{\alpha L} - \alpha e^{\delta L} - \delta + \alpha) \right] \quad (57)$$

3.3. Channel Length Modulation (CLM)

According to bulk charge theory [81], the DC drain current is given as

$$I_d = \frac{WC_{\text{ox}} \mu_{\text{eff}}}{L} \left[(V_g - V_{\text{th}}) V_d - \frac{V_d^2}{2} - \frac{4}{3} V_w \phi_f \right] \times \left[\left(1 + \frac{V_d}{2\phi_f} \right)^{3/2} - \left(1 + \frac{3V_d}{4\phi_f} \right) \right] \quad (58)$$

where L is a function of voltage (V_d) beyond the pinchoff point. Thus the variation of drain current (I_d) with V_d is given by

$$\frac{dI_d}{dV_d} = \frac{\partial I_d}{\partial L} \frac{\partial L}{\partial V_d} + \frac{\partial I_d}{\partial V_d} \quad (59)$$

This can be presented as an AC variation given by

$$i_{d0} = \left(\frac{\partial I_d}{\partial L} \frac{\partial L}{\partial V_d} + \frac{\partial I_d}{\partial V_d} \right) v_d \quad (60)$$

On differentiating (58) with respect to L , we get

$$\frac{\partial I_d}{\partial L} = -\frac{I_d}{L} \quad (61)$$

Also by differentiating (58) with respect to V_d , we get

$$\frac{\partial L}{\partial V_d} = -\frac{\xi}{2(2\phi_f + V_d - \gamma)} \quad (62)$$

where

$$\xi = \sqrt{\frac{2e_{\text{si}}(2\phi_f + V_d - \gamma)}{qN_a}} \quad (63)$$

$$\gamma = V_g - V_{\text{th}}$$

$$-V_w \left[\left\{ \left(\frac{V_g - V_{\text{th}}}{2\phi_f} \right) + \left(1 + \frac{V_w}{4\phi_f} \right)^2 \right\}^{1/2} - \left(1 + \frac{V_w}{4\phi_f} \right) \right] \quad (64)$$

Substituting $\partial I_d / \partial L$, $\partial L / \partial V_d$, and $\partial I_d / \partial V_d$ in (60) yields

$$i_{d0} = \frac{I_d \xi}{2L(2\phi_f + V_d - \gamma)} v_d = y_{22}^0 v_d \quad (65)$$

The drain current including the effect of channel length modulation is given as

$$i_d = \frac{WD_n C_{\text{ox}}}{e^{\delta L} - e^{\alpha L}} \left[v_d (\delta e^{\delta L} - \alpha e^{\alpha L}) + v_g (\delta e^{(\alpha+\delta)L} - \delta e^{\delta L} + \alpha e^{\alpha L} - \alpha e^{(\delta+\alpha)L}) \right] + y_{22}^0 v_d \quad (66)$$

3.4. Admittance Model

The equivalent-circuit model shown in Fig. 33 is scalable since all its elements have physical significance. The new elements added to this model are inclusive of the effect of CLM [83] and the overlap effect. The current-voltage

Figure 33. A small-signal equivalent-circuit model for Si-MOSFET.

equations that define the Y parameters are given as

$$i_g = Y_{11}v_g + Y_{12}v_d \quad (67)$$

$$i_d = Y_{21}v_g + Y_{22}v_d \quad (68)$$

The intrinsic Y parameters for the MOSFET are given as

$$Y_{11} = \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} [\delta e^{\alpha L} - \delta + \alpha - \alpha e^{\delta L}] \quad (69)$$

$$Y_{12} = \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} (\alpha - \delta) \quad (70)$$

$$Y_{21} = \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} [(\delta - \alpha)e^{(\alpha+\delta)L} - \delta e^{\delta L} + \alpha e^{\alpha L}] \quad (71)$$

$$Y_{22} = \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} [\delta e^{\delta L} - \alpha e^{\alpha L}] + Y_{22}^0 \quad (72)$$

Equations (69)–(72) describe the frequency dependence of the Y parameters for the MOSFET excluding parasitic parameters but including the CLM effect. The intrinsic Y parameters do not by themselves represent actual effects in a MOSFET. It is found that the input and output parasitic capacitances as well as resistances have to be incorporated to obtain total input and output admittances. Figure 33 shows the equivalent circuit used to evaluate the admittance parameters. A parasitic capacitance C_1 , which includes overlap capacitance between gate and source, is thus added along with resistance R_1 in series with C_1 . These elements are in parallel with the input circuit, and the total input admittance is given by

$$Y_{11} = \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} [\delta e^{\alpha L} - \delta + \alpha - \alpha e^{\delta L}] + R_1 C_1^2 \omega^2 + i\omega C_1 \quad (73)$$

Figure 34. Variation of input admittance parameter with frequency.

Figure 35. Variation of reverse transfer admittance parameter with frequency.

After incorporating the parasitic output capacitance C_2 , which includes the drain depletion region capacitance, along with a resistance R_2 in series with C_2 , we then consider the total output admittance, is given by

$$Y_{22} = y_{22}^0 + R_2 C_2^2 \omega^2 + i\omega C_2 + \frac{WD_n C_{ox}}{e^{\delta L} - e^{\alpha L}} [\delta e^{\delta L} - \alpha e^{\alpha L}] \quad (74)$$

Equations (73) and (74) show the frequency response of the MOSFET admittance parameters incorporating the CLM and parasitic elements [84].

Variation of the input admittance parameter (Y_{11}) with frequency up to 10 GHz for a device ($W = 200 \mu\text{m}$, $L = 10 \mu\text{m}$) is shown in Fig. 34. The real part of Y_{11} is proportional to

Figure 36. Variation of forward transfer admittance parameter with frequency.

Figure 37. Variation of output admittance parameter with frequency.

the square of the frequency and the imaginary part of Y_{11} varies linearly. Figure 35 shows variation of the reverse transfer admittance parameter (Y_{12}) with frequency for $V_g = 1.18\text{ V}$ and $V_d = 1.0\text{ V}$. Excellent agreement with experimental data [82] is observed with minor deviation at high frequency due to CLM. As shown in Figure 36, at high frequencies, Y_{21} decreases with to the decrease in time constant. Figure 37 shows the variation of the output admittance (Y_{22}) with frequency for the same device. It can be seen clearly that the effect of CLM significantly contributes to the real part of Y_{22} at high frequencies.

3.5. Scattering Parameters

The input reflection scattering parameter coefficient (S_{11}) is given as [84,85]

$$S_{11} = \frac{\frac{1}{(e^{\delta L} - e^{\alpha L})^2} \{A_1 - (e^{\delta L} - e^{\alpha L})(R_1 C_1^2 \omega^2 + i\omega C_1)\} \{e^{\delta L} - e^{\alpha L}\} + WD_n C_{ox} (\delta e^{\delta L} - \alpha e^{\alpha L}) + A_2\} - A_4}{A_5 \{e^{\delta L} (1 + WD_n C_{ox} \delta) - e^{\alpha L} (1 + WD_n C_{ox} \alpha) + A_2\} + A_3 \{ \delta (e^{(\alpha + \delta)L} - e^{\delta L}) - \alpha (e^{(\alpha + \delta)L} - e^{\alpha L}) \}} \quad (75)$$

where

$$A_1 = (e^{\delta L} - e^{\alpha L}) - WD_n C_{ox} \{ \delta e^{\alpha L} - \alpha e^{\delta L} + \alpha - \delta \} \quad (76)$$

$$A_2 = (e^{\delta L} - e^{\alpha L}) (i\omega C_2 + R_2 C_2^2 \omega^2 + Y_{22}^0) \quad (77)$$

$$A_3 = \frac{W^2 D_n^2 C_{ox}^2 (\delta - \alpha)}{(e^{\delta L} - e^{\alpha L})^2} \quad (78)$$

$$A_4 = A_3 \{ (\delta - \alpha) e^{(\delta - \alpha)L} - (\delta e^{\delta L} - \alpha e^{\alpha L}) \} \quad (79)$$

$$A_5 = \frac{1}{(e^{\delta L} - e^{\alpha L})^2} \{ (e^{\delta L} - e^{\alpha L}) - WD_n C_{ox} \times \{ \delta e^{\alpha L} - \alpha e^{\delta L} + \alpha - \delta \} \} \quad (80)$$

The reverse scattering parameter (S_{12}) and the forward scattering parameter (S_{21}) are

$$S_{12} = \frac{2WD_n C_{ox} (\delta - \alpha) (e^{\delta L} - e^{\alpha L})}{\{A_1 - (e^{\delta L} - e^{\alpha L})(R_1^2 C_1^2 \omega^2 + i\omega C_1)\} B_1 - A_3 (e^{\delta L} - e^{\alpha L})^2 \{ (\delta - \alpha) e^{(\alpha + \delta)L} - (\delta e^{\delta L} - \alpha e^{\alpha L}) \}} \quad (81)$$

where

$$B_1 = A_2 + (e^{\delta L} - e^{\alpha L}) + WD_n C_{ox} (\delta e^{\delta L} - \alpha e^{\alpha L}) \quad (82)$$

and

$$S_{21} = \frac{2WD_n C_{ox} (e^{\delta L} - e^{\alpha L}) \{ (\alpha - \delta) e^{(\alpha + \delta)L} - \alpha e^{\alpha L} + \delta e^{\delta L} \}}{\{A_2 + (e^{\delta L} - e^{\alpha L}) + WD_n C_{ox} (\delta e^{\delta L} - \alpha e^{\alpha L})\} B_2 - A_3 (e^{\delta L} - e^{\alpha L})^2 \{ (\delta - \alpha) e^{(\alpha + \delta)L} - (\delta e^{\delta L} - \alpha e^{\alpha L}) \}} \quad (83)$$

where

$$B_2 = \{A_1 - (e^{\delta L} - e^{\alpha L})(R_1^2 C_1^2 \omega^2 + i\omega C_1)\} \quad (84)$$

The output scattering parameter (S_{22}) is given as

$$S_{22} = \frac{[\{ (e^{\delta L} - e^{\alpha L}) + WD_n C_{ox} (\delta e^{\delta L} - \delta + \alpha - \alpha e^{\alpha L}) + B_3 \} \{B_4 - (e^{\delta L} - e^{\alpha L})(i\omega C_2 + R_2 C_2^2 \omega^2 + Y_{22}^0)\} - B_5}{(A_1 + B_3) \{ (e^{\delta L} - e^{\alpha L}) + WD_n C_{ox} (\delta e^{\delta L} - \alpha e^{\alpha L}) \} A_2 + A_3 (e^{\delta L} - e^{\alpha L})^2 \{ (\delta - \alpha) e^{(\alpha + \delta)L} - (\delta e^{\delta L} - \alpha e^{\alpha L}) \}} \quad (85)$$

where

$$B_3 = (e^{\delta L} - e^{\alpha L}) (R_1 C_1^2 \omega^2 + iC_1 \omega) \quad (86)$$

$$B_4 = (e^{\delta L} - e^{\alpha L}) + WD_n C_{ox} (\delta e^{\delta L} - \alpha e^{\alpha L}) \quad (87)$$

$$B_5 = (e^{\delta L} - e^{\alpha L})^2 \{ (\delta - \alpha) e^{(\alpha + \delta)L} - (\delta e^{\delta L} - \alpha e^{\alpha L}) \} \quad (88)$$

Figure 38 shows the modeled S parameters of Si-MOSFET ($W = 200\ \mu\text{m}$, $L = 10\ \mu\text{m}$) at bias point of $V_g = 1.18\text{ V}$ and

Figure 38. Variation of *S* parameter of MOSFET for a frequency range of 100 MHz–10 GHz.

$V_d=1.0V$ in the frequency range of 0.1–10.0 GHz. It is clear that the reflection scattering coefficient at gate (S_{11}) and the reflection coefficient at drain (S_{22}) are more than the transmitted *S* parameters. This occurs because as the channel length decreases, the input admittance and reverse transfer admittance also decrease. It can also be seen that the reverse scattering parameter has the higher magnitude than the forward scattering parameter.

Figure 39 predicts the variation of different gains and the unilateral figure of merit with frequency. It is observed

Figure 39. Variation of different gains with frequency.

that as the frequency increases, the power gain decreases and is basically due to decrease in admittance. For a given frequency, maximum unilateral transducer power gain is the largest gain and is due to the positive stability factor of the device. The maximum stable power gain shows the input/output mismatch, and it is found that as the frequency increases, the input and output mismatch decreases. Thus a simultaneous conjugate match has been obtained in the analysis. This shows that a circuit with a short-channel device is useful for RF application.

4. PARASITIC RESISTANCE AND ELECTRICAL CHARACTERISTIC OF FOLD MOSFET

4.1. Introduction

Various modifications to the transistor drain structure have been proposed to help counter this degradation using graded drain or lightly doped drain (LDD) devices [86–89]. The LDD structure can reduce the high-field effects in scaled-down devices by introducing n^- regions between the channel and n^+ source-drain. Since part of the high electric field can be absorbed into the n^- regions, this structure helps minimize the hot-carrier effect, for example. However, the n^- regions give large parasitic resistances that cause the reduction of device transconductance and the increase of saturation voltage [90]. One of the new approaches to drain engineering is the fully overlapped lightly doped drain (FOLD) structure. The angled ion implantation method has been applied to fabricate the n^- fully overlapped structure. From the reliability viewpoint, the greatest reduction in substrate current directly leads to the most reliable n^- design for the FOLD structure. The current path modulation phenomenon due to the trapped charge at the n^- extension region dominates the hot-carrier-induced characteristics change for the conventional LDD structure with the sidewall spacer. This phenomenon is minimized in the FOLD structure, due to its higher controllability of the gate electrode than the LDD structure at the n^- extension region.

4.2. The Series Resistance of the n^- Region

The schematic diagram with an equivalent circuit of a FOLD MOSFET structure, which is a combination of two buried-channel MOSFETS in series with an enhancement mode n -type MOSFET, is shown in Fig. 40, where R_s and R_d are the parasitic resistances of source and drain sides, respectively, including n^+ diffusion, contacts, and wiring series resistances. Taking the n^- region to be a buried-channel MOSFET, the drain current is expressed as [91]

$$I_{ds} = W(\mu_b Q_b + \mu_s Q_s) \frac{dV(y)}{dy} \tag{89}$$

where W is effective channel width, $\mu_b(\mu_s)$ is effective electron mobility of the conducting charge in the bulk (surface) of the n^- region, and Q_b and Q_s are the charge densities in the bulk and the surface, respectively.

Figure 40. (a) Schematic diagram of the LDD structure; (b) schematic diagram of the FOLD structure; (c) equivalent circuit of the FOLD MOSFET; (d) schematic structure for calculating the geometrical factor and capacitance of the bulk in the n^- region.

In FOLD, it is assumed that the drain voltage is high and the depleted charges in the bulk of the n^- region are caused by the substrate and normal electric field from the gate. Therefore in the drain side, Q_b can be expressed as

$$Q_b(\text{FOLD}) = qN_d(r_n - \Delta r_n - D_n) \quad (90)$$

where r_n is the junction depth of the n^- region, Δr_n is the depletion depth of the bulk in the n^- region with respect to the substrate and is a function of potential [91], N_d is the average doping concentration in the n^- region, and D_n is the depletion depth of the n^- surface due to normal electric field. The surface charge Q_s is given as

$$Q_s = C(V_{g2} - V_{FBn} - V(y)) \quad (91)$$

$$V_{g2}(= V_g - V_d') \quad (92)$$

where V_{g2} is the voltage between gate and the intrinsic drain; V_{FBn} is flatband voltage of the n^- region, and C is the capacitance per unit area of the n^- region. Following Refs 92 and 93, the capacitance C for FOLD structure can be derived as

$$C(\text{FOLD}) = \frac{C_{of} + C_{ov} + C_{if}(\text{FOLD})}{r_n} \quad (93)$$

where

$$C_{ov} = \epsilon_{ox} \frac{(l_2 - \Delta r_n)}{\left(t_{ox} + \frac{\epsilon_{ox}}{\epsilon_{si}} D_n\right)} \quad (94)$$

$$C_{of} = \frac{2}{\pi} \epsilon_{ox} \ln \left(1 + \frac{h}{t_{ox}}\right) \quad (95)$$

$$C_{if}(\text{FOLD}) = \frac{2}{\pi} \epsilon_{ox} \ln \left(1 + \frac{(r_n - \Delta r_n - D_n)}{\left(t_{ox} + \frac{\epsilon_{ox}}{\epsilon_{si}} D_n\right)} \sin \left(\frac{2\epsilon_{ox}}{\pi\epsilon_{si}}\right)\right) \quad (96)$$

where l_2 and h denote overlap length and height of the gate electrode, respectively. For LDD with no overlap, C_{ov} is zero and $C_{if}(\text{FOLD})$ reduces to

$$C_{if}(\text{LDD}) = \frac{2}{\pi} \epsilon_{ox} \ln \left(1 + \frac{r_n}{t_{ox}} \sin \left(\frac{2\epsilon_{ox}}{\pi\epsilon_{si}}\right)\right) \quad (97)$$

Integrating Eq. (89) across the two ends of the n^- region near the drain, one gets

$$I_{ds}(l_1 + l_2) = W \left(\mu_b q N_d (r_n - \Delta r_n - D_n) V_{d2} + \mu_s C \right. \\ \left. \times \left(V_{g2} - V_{FBn} - \frac{V_{d2}}{2} \right) V_{d2} \right) \quad (98)$$

where $l_1(l_2)$ is without (with) overlapped length of the n^- region with respect to the gate

$$V_{d2}(= V_d'' - V_d') \quad (99)$$

V_{d2} is voltage drop in the n^- region near the drain side, V_d'' is n^- - n^+ junction voltage in the drain side. At large drain voltage, the depleted charges exist not only in the n^- /substrate junction but also in the n^- /channel junction. From charge-sharing scheme, the depleted charges in the bulk of the n^- region have the same amount of charge depleted in the substrate and channel regions (Fig. 40). The conducting charge density of the n^- region expressed in (90) is modified as

$$qN_d(r_n - \Delta r_n - D_n) = qN_d r_n f_b(\text{FOLD}) \quad (100)$$

where $f_b(\text{FOLD})$ is the geometric factor of the bulk in the n^- region and can be expressed as

$$f_b(\text{FOLD}) = 1 - \frac{N_a \left(W_d(l_1 + l_2) + \frac{\Delta L_d}{2}(2(W_d + r_n) - Y_d) \right)}{N_d r_n (l_1 + l_2)} \quad (101)$$

$$\Delta L_d = r_n \left(\sqrt{1 + \frac{2W_d}{r_n}} - 1 \right) \quad (102)$$

where W_d is effective depletion depth of the substrate with respect to the n^- region and Y_d is the depletion width in the channel region. On substituting

$$V_{d2} = I_{ds} R_{nd} \quad (103)$$

$$V_{gs2} - V_{FBn} - \frac{V_{d2}}{2} = V_{gs} - V_{ds} - V_{FBn} + I_{ds} \left(R_d + \frac{R_{nd}}{2} \right) \quad (104)$$

In Eq. (98) a quadratic equation for the resistance of the n^- region near the drain side (R_{nd}) is obtained and on simplifying

$$R_{nd} = \frac{l_1 + l_2}{W(\mu_b q N_d r_n f_{b0} + \mu_s C(\text{FOLD})(V_{gs} - V_{ds} - V_{FBn} + R_d I_{ds}))} \quad (105)$$

The term $R_d I_{ds}$ cannot be neglected in the high-current condition and can be approximated as

$$R_d I_{ds} = \frac{\mu_n C_{ox} W}{L} (V_{gs} - V_{t0}) R_d V_{ds} \quad (106)$$

Linearizing the geometric factor at the zero drain bias as

$$f_b = f_{b0} - S V_{ds} \quad (107)$$

where f_{b0} is the geometric factor at zero drain bias and S is the slope of the geometric factor versus drain voltage curve at zero drain bias. Putting (106) and (107) into (105), R_{nd} can be expressed as

$$R_{nd} = \frac{l_1 + l_2}{W(\mu_b q N_d r_n f_{b0} + \mu_s C(\text{FOLD})(V_{gs} - V_{FBn}) - G V_{ds})} \quad (108)$$

where

$$G = \mu_b q N_d r_n S + \mu_s C(\text{FOLD}) \left(1 - R_d \frac{\mu_n C_{ox} W}{L} (V_{gs} - V_{t0}) \right) \quad (109)$$

The resistance of the n^- region near the source side can be derived by the same method. In the general case, $V_{gs} - V_{FBn}$ is much greater than $I_{ds} R_s$. Therefore, the $I_{ds} R_s$ term can be neglected and the resistance of the n^-

region near the source side can be obtained as

$$R_{ns} = \frac{l_1 + l_2}{W(\mu_b q N_d r_n f_{b0} + \mu_s C(\text{FOLD})(V_{gs} - V_{FBn}))} \quad (110)$$

Figure 41 shows the simulated results of in-depth profiles of channel current density and schematic channel current path diagram at the drain edge for the LDD and FOLD structures. Filled circles and dashed-line arrows indicate the channel current profiles and paths with trapped electron charge above the n^- region. Open circles and solid-line arrows indicate the channel current profiles and paths without trapped charge. In case of LDD structure (Fig. 41a), the amount of channel current density at the surface is drastically decreased because of trapped electron charge at the n^- extension region. The peak channel current density at the drain edge shifts to about 10 nm depth from the surface. This result indicates that the LDD structure suffers from a peculiar degradation mode, since a charge is trapped above the n^- region. The trapped electron charge pushes the channel current path down from the surface. Consequently, the parasitic resistance at this region is modulated. Drain current is also modulated because of this effect. In the FOLD structure, in-depth profile and path of channel current density at drain edge are little affected by a trapped charge above the n^- extension region and are shown in Fig. 41b.

The decreasing ratio of the surface channel current density in the FOLD structure is smaller than that in the LDD structure. It is noted that the difference behavior of channel current density and channel current path between the LDD and FOLD structure is related to gate electrode controllability at the n^- extension region. The n^- extension region of the FOLD structure is fully controlled by the gate electrode. This leads to less channel modulation effect, caused by trapped electron charge at n^- extension region, and is also shown in Fig. 41b. The variation of parasitic resistances (R_{sd}) of FOLD and LDD structures with gate voltage at different drain voltages is plotted in Fig. 42. The results are compared with experimental data and are in excellent agreement. Because of the electrode controllability and higher n^- dose in the FOLD structure, less current flow modulation takes place. Consequently the parasitic resistance for FOLD is smaller than that for the LDD. In the present model outer and inner fringing capacitances and the depletion of the n^- surface, caused by the normal electric field from the gate have been considered. FOLD structure can achieve higher derivability than the LDD due to less parasitic resistance.

4.3. The I_d - V_d Characteristics

The drain current in the linear region can be written as

$$I_{ds} = \mu_n W Q_n \left(-\frac{dV(y)}{dy} \right) \quad (111)$$

where W is the effective channel width, μ_n is the electron mobility in the surface inversion layer along the channel direction, Q_n is the electron density per unit area along the channel direction, $V(y)$ is the potential distribution

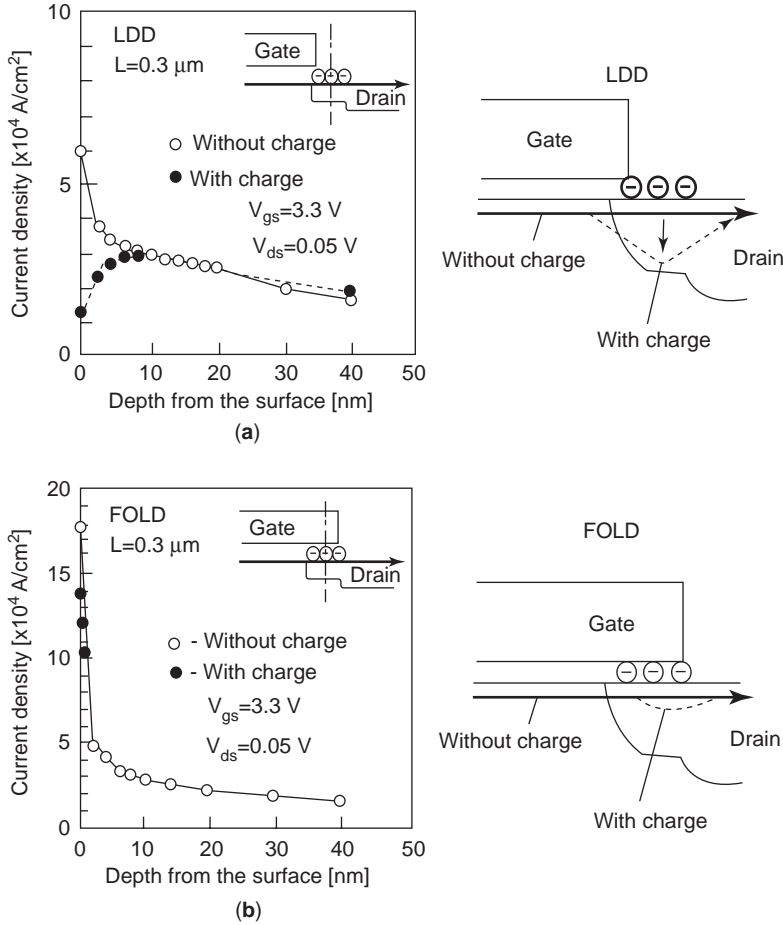

Figure 41. In-depth profiles for the channel current density at n^- region with or without fixed charge by two-dimensional device simulation: (a) LDD; (b) FOLD.

along the channel, and $E_1 = -dV(y)/dy$ is the electric field along the channel. The electron mobility μ_n in the surface inversion layer can be expressed as [94].

$$\mu_n = \frac{\mu_{n0}}{1 + \alpha|E_N| + \beta|E_L|} \quad (112)$$

where E_N is average transverse electric field across the channel, E_L is the longitudinal electric field along the inversion channel, μ_{n0} is the maximum electron mobility in the inversion layer, α is an empirical fitting parameter, $\beta = \mu_{n0}/v_{sl}$, where v_{sl} is the scattering-limited velocity. The average transverse electric field across the channel can be calculated by

$$E_N = \frac{E_1 + E_2}{2} \quad (113)$$

where E_1 is the transverse electric field at the SiO_2/Si interface and E_2 is the transverse electric field under the inversion layer. These two electric field components can be easily calculated using Gauss' law and are expressed as

$$E_1 = \frac{1}{\epsilon_{si}}(Q_B + Q_n) \quad (114)$$

$$E_2 = \frac{Q_B}{\epsilon_{si}} \quad (115)$$

where Q_B is the surface depletion charge density per unit area under the gate and ϵ_{si} is the dielectric permittivity of the bulk semiconductor. Therefore in a MOS structure

$$V_{gs} - V_{FB} - \phi_s = -\frac{Q_n + Q_B}{C_{ox}} \quad (116)$$

where V_{gs} the gate-source voltage, V_{FB} is the flatband voltage of the MOS capacitor without the surface implanted layer, ϕ_s is the surface potential along the channel with respect to the neutral substrate, and C_{ox} is the gate oxide capacitance per unit area. Substituting (113)–(116) into (112), one obtains

$$\mu_n = \frac{\mu_{n0}}{1 + \frac{\alpha C_{ox}}{2\epsilon_{si}} \left(V'_{gs} - V_{FB} - \phi_s + \frac{Q_B}{C_{ox}} \right) + \beta \left| \frac{dV(y)}{dy} \right|} \quad (117)$$

Substituting (117) into (111), and integrating along the channel, one gets

$$I_{ds} = \frac{\mu_n W C_{ox} \left(V'_{gs} - V_{th} - \frac{1}{2} V'_{ds} \right) V'_{ds}}{L \left(1 + \frac{\alpha C_{ox}}{2\epsilon_{si}} \left(V'_{gs} + V_{th} - 2(V_{FB} + 2\phi_F) - \frac{1}{2} V'_{ds} \right) + \left(\eta + \frac{\beta}{L} \right) V'_{ds} \right)} \quad (118)$$

Figure 42. Parasitic resistance dependence on gate voltage for the optimized FOLD and the LDD structures [$N_a = 3.0 \times 10^{16} \text{ cm}^{-3}$, $N_d(\text{LDD}) = 1.8 \times 10^{17} \text{ cm}^{-3}$, $N_d(\text{FOLD}) = 1.3 \times 10^{17} \text{ cm}^{-3}$, $R_s = 13 \Omega$, $R_d = 13 \Omega$, $r_n = 0.15 \mu\text{m}$, $D_n = 0.05 \mu\text{m}$, $h = 0.16 \mu\text{m}$, $l_1(\text{FOLD}) = l_2(\text{LDD}) = 0$, $l_1(\text{LDD}) = l_2(\text{FOLD}) = 0.10 \mu\text{m}$, $V_{\text{BG}} = 1 \text{ V}$, $V_{\text{Fbn}} = -0.5 \text{ V}$, $t_{\text{ox}} = 11 \text{ nm}$, $\mu_n = 570 \text{ cm}^2/\text{V} \cdot \text{s}$, $\mu_b = 542.74 \text{ cm}^2/\text{V} \cdot \text{s}$, $\mu_s(\text{LDD}) = 542 \text{ cm}^2/\text{V} \cdot \text{s}$, $\mu_s(\text{FOLD}) = 562 \text{ cm}^2/\text{V} \cdot \text{s}$].

with

$$|Q_{\text{B,eff}}(V'_{\text{ds}})| = \frac{1}{L} \int_0^L |Q_{\text{B}}| dy = \frac{1}{V'_{\text{ds}}} \int_0^{V'_{\text{ds}}} |Q_{\text{B}}| dV(y) \quad (119a)$$

$$\frac{1}{2} V'_{\text{ds}} (1 - \gamma) = \frac{1}{L} \int_0^L V(y) dy \quad (119b)$$

$$V_{\text{th}} = V_{\text{FB}} + \phi_s + \frac{|Q_{\text{B}}|}{C_{\text{ox}}} \quad (119c)$$

$$\eta = \frac{\alpha C_{\text{ox}}}{4\epsilon_{\text{si}}} \gamma \quad (119d)$$

where γ is the correction factor, which is zero if the electric field along the inversion layer is constant. The threshold voltage no longer remains independent of drain bias and varies as

$$V_{\text{th}} = V_{t0} - k V_{\text{ds}} \quad (120)$$

where V_{t0} is the threshold voltage at zero drain bias and k is the slope of threshold voltage–vs drain voltage curve at zero drain bias [94]. Substituting (120) into (118), one

obtains

$$I_{\text{ds}} = \frac{\mu_n W C_{\text{ox}} (V'_{\text{gs}} - V_{t0} - \alpha V'_{\text{ds}}) V'_{\text{ds}}}{L \left(1 + \frac{\alpha C_{\text{ox}}}{2\epsilon_{\text{si}}} (V'_{\text{gs}} + V_{t0} - 2(V_{\text{FB}} + 2\phi_{\text{F}}) - b V'_{\text{ds}}) + \left(\eta + \frac{\beta}{L} \right) V'_{\text{ds}} \right)} \quad (121)$$

where $a = \frac{1}{2} - k$, $b = \frac{1}{2} + k$ and k is the slope of the threshold voltage versus V'_{ds} curve at zero drain bias. Using the following terminal relations, the drain–source current in the device can be obtained:

$$V'_{\text{gs}} = V_{\text{gs}} - I_{\text{ds}}(R_{\text{ns}} + R_{\text{s}}) = V_{\text{gs}} - I_{\text{ds}} R_{\text{st}} \quad (122)$$

$$V'_{\text{ds}} = V_{\text{ds}} - I_{\text{ds}}(R_{\text{ns}} + R_{\text{s}} + R_{\text{nd}} + R_{\text{d}}) = V_{\text{ds}} - I_{\text{ds}} R_{\text{t}} \quad (123)$$

According to Fig. 43, the FOLD structure shows drain current better than that of LDD structure. Figure 44 shows the behavior of drain current with channel length of both FOLD and LDD structure. It is demonstrated that the scaling down the device length increases the current driving capability and the FOLD promises better current driving capability.

According to the experimental data given in Ref. 89 a peak in the performance of FOLD MOSFET occurs at $L = 0.20 \mu\text{m}$. Below this length, performance suffers because of increase in the length of FOLD finger to maintain hot-electron reliability under the given conditions. Therefore $0.20 \mu\text{m}$ is the least technologically attainable length for the FOLD structure.

This peak in performance can be shifted to $L = 0.15 \mu\text{m}$ by introducing FOLD fingers only at the drain end to form

Figure 43. The $I_{\text{d}}-V_{\text{d}}$ characteristics of FOLD and LDD MOSFETs for different gate voltages ($\mu_n = 570 \text{ cm}^2/\text{V} \cdot \text{s}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 4.90 \times 10^{-5} \text{ cm/V}$, $\eta = 2.05 \times 10^{-2} \text{ V}^{-1}$).

Figure 44. Variation of drain current with channel length ($\mu_n = 570 \text{ cm}^2/\text{V}\cdot\text{s}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 4.90 \times 10^{-5} \text{ cm/V}$, $\eta = 2.05 \times 10^{-2} \text{ V}^{-1}$, $V_{ds} = 2 \text{ V}$, $V_{gs} = 2 \text{ V}$, $r_n = 0.15 \text{ }\mu\text{m}$).

asymmetric FOLD MOSFET. Drain voltage dependence of drain current at $V_{gs} = V_{ds}$ for the FOLD and the LDD structures is shown in Fig. 45. According to Fig. 46 shows that the drain current increases gradually as the gate voltage is increased above the threshold voltage. Figure 47 shows the variation of I_d - V_d characteristics of FOLD and LDD MOSFETs with different channel lengths. It is observed that the drain current increases with decrease in channel length. This clearly demonstrates the increased current driving capability of scaled-down devices. The figure also shows that the FOLD devices have a higher value of drain current compared with LDD MOSFETs.

Figure 45. Drain voltage dependence of drain current $V_{gs} = V_{ds}$ for the FOLD and the LDD structures. (Experimental data from Ref. 95.)

Figure 46. Gate voltage dependence of drain current at different drain voltages for FOLD and the LDD structures. ($\mu_n = 570 \text{ cm}^2/\text{V}\cdot\text{s}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 4.90 \times 10^{-5} \text{ cm/V}$, $\eta = 2.05 \times 10^{-2} \text{ V}^{-1}$).

4.4. Transconductance

The transconductance (g_m) and drain conductance (g_d) of a FOLD MOSFET can be derived by from drain-source current [97]. The channel resistance is defined as

$$R_{ch} = \frac{1}{g_d} \quad (124)$$

4.5. Cutoff Frequency and Transit Time

The cutoff frequency is an important figure of merit of all microwave solid-state devices. It indicates the speed of

Figure 47. The I_d - V_d characteristics of FOLD and LDD MOSFETs for different channel lengths ($\mu_n = 570 \text{ cm}^2/\text{V}\cdot\text{s}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 4.90 \times 10^{-5} \text{ cm/V}$, $\eta = 2.05 \times 10^{-2} \text{ V}^{-1}$) (Experimental data from Ref. 96.)

operation of a device. The cutoff frequency is estimated from the relation

$$f_c = \frac{g_m}{2\pi C_g} \tag{125}$$

where C_g is the gate capacitance and is expressed as

$$C_g(\text{FOLD}) = WL(C_{ox} + 2C_{if}(\text{FOLD}) + 2C_{of}) + 2W \frac{(l_2 - \Delta r_n)}{t_{ox} + \frac{\epsilon_{ox} D_n}{\epsilon_{si}}} \epsilon_{ox} \tag{126a}$$

In the no-overlap case C_g is given as

$$C_g(\text{LDD}) = WL(C_{ox} + 2C_{if}(\text{LDD}) + 2C_{of}) \tag{126b}$$

The transit time is defined as the finite time required for the carriers to travel from source to drain. Transit time represents the finite time taken by the carrier to travel from source to drain. It should represent the minimum delay for a given gate length since it assumes that electrons are traveling at their maximum velocity through the length of the channel. Here the transit time is directly evaluated from the cutoff frequency. The transit time for a FOLD MOSFET structure can be calculated from

$$\tau = \frac{1}{2\pi f_c} \tag{127}$$

where f_c is the cutoff frequency.

Figures 48–50 depict the transconductance and drain conductance variation of both FOLD and LDD devices with drain voltage. There is increase in transconductance due to the reduction in series resistance in FOLD. The drain conductance having a finite value at higher drain

Figure 48. Variation of transconductance and drain conductance with drain voltage ($h = 0.16 \mu\text{m}$, $V_{gs} = 3\text{V}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V}\cdot\text{s}$). (Experimental data from Ref. 96.)

Figure 49. Variation of drain conductance with drain voltage ($h = 0.16 \mu\text{m}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V}\cdot\text{s}$). (Experimental data from Ref. 96.)

voltages shows that the model is valid in the saturation regime of device operation. It is also demonstrated that the drain conductance is almost equal for FOLD and LDD MOSFETs at higher drain voltages.

This shows that the effect of series resistance is more prominent in the linear region of operation where the conductance degraded. Figure 51 depicts the transconductance variation of both FOLD and LDD devices with channel length. Transconductance increases as the channel length is reduced. FOLD structure has better transconductance.

Figure 50. Variation of drain conductance with drain voltage ($h = 0.16 \mu\text{m}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V}\cdot\text{s}$) (Experimental data from Ref. 96.)

Figure 51. Variation of transconductance with channel length ($h = 0.16 \mu\text{m}$, $V_{ds} = 3 \text{V}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V} \cdot \text{s}$).

It is evident from the Fig. 52 that the drain conductance increases and channel resistance decreases with gate voltage and the FOLD device shows higher drain conductance. The difference in conductance is less for lower gate biases. It is observed from Fig. 53 that the channel resistance increases with increase in drain voltage. Cutoff frequency also increases with drain voltage and becomes constant at higher drain voltage. It is also observed that the FOLD structure shows cutoff frequency lower than that of the LDD structure because of its larger fringing capacitance.

Fig. 54 shows the variation of cutoff frequency and transit time with channel length. It is evident from the

Figure 52. Variation of drain conductance channel resistance with gate voltage ($h = 0.16 \mu\text{m}$, $V_{ds} = 0.5 \text{V}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V} \cdot \text{s}$).

Figure 53. Variation of channel resistance and cutoff frequency with drain voltage ($h = 0.16 \mu\text{m}$, $V_{gs} = 3 \text{V}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V} \cdot \text{s}$).

figure that the cutoff frequency shows a drastic increase with the channel length reduction when the channel length approaches the submicrometer region and the FOLD devices have a transit time larger than that of LDD device. Fig. 55 depicts the transit-time behavior with drain voltage. It is seen that the transit time decreases with increase in drain voltage and becomes constant at higher voltages.

Although FOLD structure has lower cutoff frequency and larger transit time, FOLD MOSFET is overall better than LDD MOSFET because

1. FOLD structure has lesser parasitic resistance than LDD.
2. This structure shows the better current driving capability due to the reduction in parasitic resistance.

Figure 54. Variation of cutoff frequency and transit time with channel length ($h = 0.16 \mu\text{m}$, $V_{gs} = 3 \text{V}$, $\alpha = 8 \times 10^{-7} \text{cm/V}$, $\beta = 4.90 \times 10^{-5} \text{cm/V}$, $\eta = 2.05 \times 10^{-2} \text{V}^{-1}$, $\mu_n = 570 \text{cm}^2/\text{V} \cdot \text{s}$).

Figure 55. Variation of transit time with drain voltage ($h = 0.16 \mu\text{m}$, $V_{gs} = 3.3 \text{ V}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 4.90 \times 10^{-5} \text{ cm/V}$, $\eta = 2.05 \times 10^{-2} \text{ V}^{-1}$, $\mu_n = 570 \text{ cm}^2/\text{V} \cdot \text{s}$).

The n^- extension region of the FOLD structure is fully controlled by the gate electrode. This leads to less channel modulation effect, caused by trapped electron charge at the n^- extension region. Therefore, the n^- extension design for reducing the substrate current is consistent with high reliability for FOLD structure in terms of reliability.

In the present analysis an analytical model for parasitic resistances (R_{sd}) has been developed for submicrometer FOLD MOSFET. The hot-carrier reliability for the optimized FOLD structure has been studied and compared with the optimized LDD structure. The parasitic resistance for FOLD structure is described considering the n^- region as a modified buried-channel MOSFET and the channel region as an intrinsic enhancement-mode n-type MOSFET. It is observed that the FOLD structure shows better results than that of the LDD structure because of reduction in series resistance.

5. LOW-FREQUENCY (LF) NOISE MODELS FOR FOLD MOSFET

5.1. Introduction

The response of a system to any force can be transient or steady-state in nature. In the absence of such a disturbance, the system exists in a state of equilibrium. However, even in this state parameters describing the system are actually fluctuating about their mean value. These fluctuations are popularly termed *noise*.

5.2. Different Types of Noise

5.2.1. Thermal Noise. This is due to the random motion of carriers in any conductor; as a consequence of this random motion, a fluctuating electromotive force (emf) $V(t)$ is developed across the terminals of the conductor. It is the dominant noise source in any device that is electrical in

nature and in thermal equilibrium with a temperature bath kept at a fixed temperature T .

5.2.2. Popcorn or “Burst” Noise. Popcorn noise, also called “burst” noise, was first discovered in semiconductor diodes and later reappeared in integrated circuits. If burst noise is amplified and fed into a loudspeaker, it sounds like corn popping, with thermal noise providing a background frying sound; thus the name “popcorn noise” [98]. The power density of popcorn noise has a $1/f^n$ characteristic, where n is typically 2.

5.2.3. Shot Noise. This noise occurs whenever a noise phenomenon can be considered as a series of independent events occurring at random. For example, in the case of emission of electrons by a thermionic cathode or by a photocathode, the emission of electrons consists of a series of independent random events; hence the emission currents show shot noise [99]. In p-n junctions and transistors the crossing of a junction by electrical carriers (electrons or holes) constitutes a series of independent random events; hence the currents in such devices show shot noise. This rule equally holds when transition occurs between two energy levels, such as in the generation and recombination of carriers in a semiconductor, or when photons are emitted by a laser. In each case one must ask what entities make up the series of independent random events that produce shot noise. The current carried by electrons emitted from a hot cathode in a vacuum diode, or by electrons that cross a potential barrier in a semiconductor are randomly generated. Random generation leads to fluctuations around the average current I :

$$S_I = 2qI \quad (128)$$

5.2.4. Generation–Recombination (GR) Noise. This noise occurs whenever free carriers are generated or recombine in a semiconductor material. The fluctuating rates of generation and recombination can be considered as a series of independent events occurring at random, and hence the process can be considered as a shot noise process [99]. As a consequence the number of carriers, and hence the resistance R , fluctuates. However, it is also useful to consider the fluctuation δn in the carrier density n as giving rise to a fluctuation δR in the resistance R of the device. This resistance fluctuation δR can be detected by passing a DC current I through the sample; the current I develops a fluctuating emf $V(t) = I\delta R(t)$ across its terminals, and this emf can be amplified and measured by standard techniques. The number of free electrons in the conduction band may fluctuate because of generation and recombination processes between the band and traps. The number fluctuations cause fluctuations in the conductance G , and, therefore, in the resistance R .

$$\frac{S_R}{R^2} = \frac{S_G}{G^2} = \frac{S_N}{N^2} = \frac{(\Delta N)^2}{N^2} \frac{4\tau}{1 + \omega^2\tau^2} \quad (129)$$

where τ is a relaxation time, characteristic of the trap, usually in the range from 10^{-6} to 10^{-3} s. If there is one

type of trap only, then the variance $(\Delta N)^2$ is given by

$$\frac{1}{(\Delta N)^2} = \frac{1}{N} + \frac{1}{X_n} + \frac{1}{X_p} \quad (130)$$

where X_n is the average number of occupied traps and X_p the average number of empty traps. The variance thus approximates the smallest of the quantities N, X_n, X_p . The complicated problem of a semiconductor with two kinds of traps, X and Y , has been solved [100–103].

5.2.5. 1/f Noise or Flicker Noise. Johnson discovered flicker noise in vacuum tubes in 1925, and this type of noise was interpreted by Schottky in 1926. Flicker noise [104] was found in a great variety of other components and devices. Because the spectrum varies as $1/f^\gamma$, with γ close to unity, one often uses the term *1/f noise* for “flicker noise”. This is a fluctuation in the conductance with a power spectral density proportional to $f^{-\gamma}$, where $\gamma = 1$ in a wide frequency range, usually measured from 1 Hz to 10 kHz. The spectral density cannot be exactly f^1 from $f = 0$ to $f = \infty$, since neither the integral of the power density nor the Fourier transform would be able to have finite values. Measurements down to 10^{-6} Hz showed that even there the spectrum still is f^1 [105].

5.3. Theory of Low-Frequency (LF) Noise

The study of LF noise in electronic devices in the past has received great attention, not only because noise limits circuit and devices performance. Two of the most frequently observed types of noise in semiconductors are (1) flicker and (2) generation–recombination (GR) noises. GR noise is due to random emission of electrons and holes from defect centers in the depletion region of the semiconductor.

For devices with high surface noise and low concentration of the Shockley–Read–Hall (SRH) centers, GR noise is usually overshadowed by the higher interfacial $1/f$ noise component. For Si MOSFETs there are three models explaining the observed $1/f$ noise: (1) fluctuation model [106,107], (2) mobility fluctuation model [108,109], and (3) combination of the number fluctuations and mobility fluctuations in an uncorrected or corrected manner [110–112]. Hung et al. [111] presented a unified flicker noise theory, which incorporates both the number fluctuation and the correlated surface mobility fluctuation mechanisms. The latter is attributed to the scattering effect of the fluctuating oxide charge. In addition, the $1/f^k$ spectrum where $0.7 < k < 1.2$ has also been found [113], and a modified McWhorter model has been presented to explain its frequency dependence.

5.4. Formulation of the Flicker Noise Model

Consider a section of the transistor channel with width W and length Δx . The coordinate system in use is defined in Fig. 56. Fluctuations in the amount of trapped oxide charge will introduce correlated fluctuations in the channel carrier number and mobility. The resulting fractional

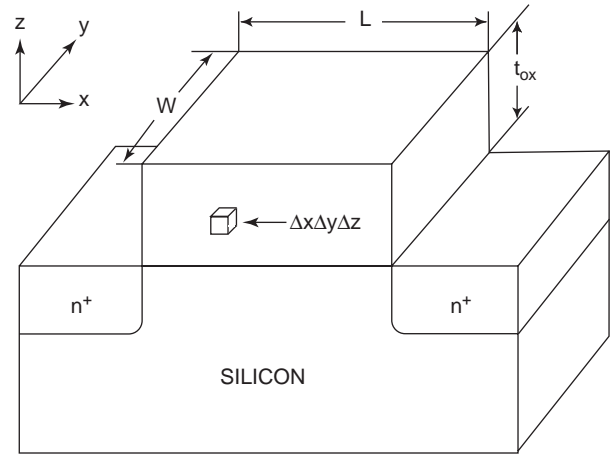

Figure 56. 1.55 MOSFET structure and coordinate system.

change in the local drain current can be expressed as

$$\frac{\delta I_{ds}}{I_{ds}} = - \left(\frac{\delta \Delta N}{\Delta N \delta \Delta N_t} + \frac{\delta \mu}{\mu \delta \Delta N_t} \right) \delta \Delta N_t \quad (131)$$

where $\Delta N = NW \Delta x$ and $\Delta N_t = N_t W \Delta x$, where N_t is the number of occupied traps per unit area. The ratio $\delta \Delta N / \delta \Delta N_t$ is the coupling coefficient of the fluctuation in channel carriers to fluctuation in occupied traps. At moderate to strong inversion, the coupling coefficient is virtually equal to unity [114]. To evaluate $\delta \mu / \delta \Delta N_t$, the relationship between the carrier mobility and the oxide charge density is needed.

A widely accepted model is the one based on the Matthiessen’s rule

$$\frac{1}{\mu} = \frac{1}{\mu_n} + \frac{1}{\mu_{ox}} = \frac{1}{\mu_n} + \alpha_1 N_t \quad (132)$$

where μ_{ox} is the mobility limited by oxide charge scattering and μ_n is the mobility limited by other scattering mechanisms [115,116]. It is expected that the scattering coefficient α_1 is a function of the local carrier density due to the screening effect as well as the distance of the trap from the interface [117]. Based on (132), it can be readily shown that

$$\frac{\delta \mu}{\delta \Delta N_t} = - \frac{\alpha_1 \mu^2}{W \Delta x} \quad (133)$$

and (131) becomes

$$\frac{\delta I_{ds}}{I_{ds}} = - \left(\frac{1}{N} + \alpha_1 \mu \right) \frac{\delta \Delta N_t}{W \Delta x} \quad (134)$$

It follows that the power spectral density of the local current fluctuations is

$$S_{M_d}(x, f) = \left(\frac{I_{ds}}{\Delta N} (1 + \alpha_1 \mu N) \right) S_{\Delta N_t}(x, f) \quad (135)$$

where $S_{\Delta N_t}(x, f)$ is the power spectral density of the mean-square fluctuation in the number of occupied traps over the area $W \Delta x$. According to the conventional number fluctuation theory [118], $S_{\Delta N_t}$ is given by

$$S_{\Delta N_t}(x, f) = \int_{E_v}^{E_c} \int_0^W \int_0^{t_{ox}} 4N_t(E, x, y, z) \Delta x f_t(1 - f_t) \times \frac{\tau(E, x, y, z)}{1 + \omega^2 \tau(E, x, y, z)^2} dx dy dz \quad (136)$$

where $N_t(E, x, y, z)$ is the distribution of the traps over the space and energy, $\tau(E, x, y, z)$ is the trapping time constant, $f_t = (1 + \exp(E - E_{fn})/kT)^{-1}$ is the trap occupancy function, E_{fn} is the quasi-Fermi level, $\omega = 2\pi f$ is the angular frequency, t_{ox} is the oxide thickness, and $(E_c - E_v)$ is the silicon energy bandgap.

To evaluate the integral in (136), two assumptions are made: (1) the oxide traps have a uniform spatial distribution near the interface, [i.e., $N_t(E, x, y, z) = N_t(E)$] and (2) the probability of an electron penetrating into the oxide decreases exponentially with the distance from the interface. As a result of the second assumption, the trapping time constant is given by

$$\tau = \tau_0(E) \exp(\gamma z) \quad (137)$$

where $\tau_0(E)$ is the time constant at the interface and γ is the attenuation coefficient of the electron wavefunction in the oxide [118]. WKB (Wentzel Kramer Brillouin) theory for carrier tunneling predicts that

$$\gamma = \frac{4\pi}{h} (2m^* \phi_B)^{1/2} \quad (138)$$

where m^* is the effective mass of the carrier in the oxide, h is Planck's constant, and ϕ_B is the tunneling barrier height faced by the carriers at the interface [118]. For the Si-SiO₂ system the value of γ is typically taken to be 10^8 cm^{-1} . Since $f_t(1 - f_t)$ in (136) behaves like a delta function around the quasi-Fermi level, the major contribution to the integral will be from those trap levels around E_{fn} . Thus $N_t(E)$ can be approximated by $N_t(E_{fn})$ and taken out from the integral. Replacing $f_t(1 - f_t)$ by $-kT df_t/dE$ and carrying out the integration yields

$$S_{\Delta N_t}(x, f) = N_t(E_{fn}) \frac{kTW\Delta x}{\gamma f} \quad (139)$$

The total drain current noise power turns out to be

$$S_{Id} = \frac{1}{L^2} \int_0^L S_{Id}(y, f) \Delta y dy \quad (140)$$

$$= \frac{kTI_{ds}^2}{W\gamma f L^2} \int_0^L N_t(E_{fn}) \left(\frac{1}{N} + \alpha_1 \mu_{n0} \right)^2 dy$$

where k is the Boltzmann constant, T is the absolute temperature, γ is the attenuation coefficient of the electron

wavefunction in the oxide, f is the frequency of the noise spectrum, α_1 is the scattering coefficient associated with the trapped charge, N_t is the trap density per unit energy, and E_{fn} is the quasi Fermi level. Using (111) and (117), Eq. (140) is modified for FOLD structure taking the series resistance into account to obtain

$$S_{Id} = \frac{kTI_{ds}}{W\gamma f L^2} \int_0^{V'_{ds}} \frac{(-\mu_{n0} W Q_n - \beta I_{ds})}{1 + \frac{\alpha C_{ox}}{2\epsilon_{si}} \left(V'_{gs} - V_{FB} - \phi_s + \frac{|Q_B|}{C_{ox}} \right)} \times N_t(E_{fn}) \frac{1}{N^2} (1 + \alpha_1 \mu_{n0} N)^2 dV(y) \quad (141)$$

where Q_n is the electron density per unit area along the channel direction given by

$$Q_n = qN = -C_{ox}(V'_{gs} - V_{th} - V(y)) \quad (142)$$

where q is the electron charge and N is the number of channel carriers per unit area. Threshold voltage no longer remains independent of drain bias and varies as

$$V_{th} = V_{t0} - KV(y) \quad (143)$$

where V_{t0} is the threshold voltage at zero drain bias, and K is the slope of threshold voltage-vs drain voltage curve at zero drain bias. Substitution of (143) in (142) gives

$$Q_n = -C_{ox}(V'_{gs} - V_{t0} - \lambda V(y)) \quad (144)$$

where $\lambda = 1 - K$ and α_1 and μ_{n0} are functions of the local carrier density, which by itself is a function of the local quasi-Fermi level. Using (142), (141) can be written as

$$S_{Id} = \frac{q^2 kTI_{ds}}{W\gamma f L^2} \int_0^{V'_{ds}} \frac{(-\mu_{n0} W Q_n - \beta I_{ds})}{1 + \frac{\alpha C_{ox}}{2\epsilon_{si}} \left(2(V'_{gs} - V_{FB} - \phi_s) + \frac{Q_n}{C_{ox}} \right)} \times \frac{N_t^*(E_{fn})}{Q_n^2} dV(y) \quad (145)$$

where

$$N_t^*(E_{fn}) = N_t(E_{fn})(1 + \alpha_1 \mu_n N)^2 \quad (146)$$

Using (144), one obtains

$$N_t^*(E_{fn}) = N_t(E_{fn}) \left(1 + \alpha_1 \mu_{n0} \frac{Q_n}{q} \right)^2 \quad (147)$$

$$\approx A_2 + B_2 Q_n + C_2 Q_n^2$$

where

$$A_2 = N_t, \quad B_2 = \frac{2\alpha_1 \mu_n N_t}{q}, \quad \text{and } C_2 \text{ is a fitting constant}$$

Also from (144) we obtain

$$dQ_n = C_{ox} \lambda dV \quad (148)$$

Therefore in the strong inversion regime, (145) can be written as

$$S_{Id} = \frac{q^2 k T I_{ds}}{W \gamma L^2} \int_{Q_{ns}}^{Q_{nd}} \frac{(-\mu_{n0} W Q_n - \beta I_{ds})}{1 + \frac{\alpha C_{ox}}{2 \epsilon_{si}} \left(2(V'_{gs} - V_{FB} - \phi_s) + \frac{Q_n}{C_{ox}} \right)} \left(\frac{1}{\lambda C_{ox}} \right) \times \left(\frac{A_2}{Q_n^2} + \frac{B_2}{Q_n} + C_2 \right) dQ_n \quad (149)$$

Therefore, S_{Id} and the drain voltage spectral density $S_{vd} = S_{Id}/g_d^2$ can be obtained from Equ. (149) and the derivation is given in Refs. 119 and 120.

The variations of S_{vd} and S_{Id} with drain voltage V_{ds} are shown in Figs. 57 and 58, respectively, with the gate voltage V_{gs} as a parameter. The oxide interface traps interact with the channel through carrier capture and generation, which causes a change in scattering rate when the trap becomes occupied. Therefore with the increase in drain voltage, the scattering phenomenon in the channel increases, thus increasing the noise.

In Fig. 59 S_{Id} increases with the gate voltage and saturates at higher gate and drain voltages. Figure 60 shows the variation of S_{vd} with gate voltage V_{gs} for LDD and FOLD devices with V_{ds} as a parameter. Since the trap concentration increases exponentially from midgap to band edges, a bias across the oxide will cause the tunneling of carriers to encounter more traps deeper into the oxide, which in turn will make the lower frequency region of the power spectrum more pronounced.

Figure 57. Variation of S_{vd} with V_{ds} ($\mu_{n0} = 604 \text{ cm}^2/\text{V} \cdot \text{s}$, $\gamma = 10^8 \text{ cm}^{-1}$, $\alpha_1 = 10^{-16} \text{ V} \cdot \text{s}$, $\eta = 5.05 \times 10^{-2} \text{ V}^{-1}$, $\alpha = 1.6 \times 10^{-7} \text{ cm V}^{-1}$, $\beta = 0.15 \times 10^{-6} \text{ cm/V}$).

Figure 58. Variation of S_{Id} with V_{ds} ($\mu_{n0} = 600 \text{ cm}^2/\text{V} \cdot \text{s}$, $\gamma = 10^8 \text{ cm}^{-1}$, $\alpha_1 = 4 \times 10^{-15} \text{ V} \cdot \text{s}$, $\eta = 4 \times 10^{-2} \text{ V}^{-1}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 3 \times 10^{-6} \text{ cm/V}$).

Therefore, as the gate bias increases, the slope of the power spectral density should increase. The comparison of the $1/f$ noise of the LDD and FOLD MOSFET is also shown in the figure. It is observed that the noise is less in FOLD MOSFET.

5.5. Formulation of the G-R noise model

It is assumed that the drain current spectral density contributed by the n^- regions is negligible compared with that produced in the intrinsic channel. Accounting for the

Figure 59. Variation of S_{Id} with V_{ds} at different V_{gs} ($\mu_{n0} = 600 \text{ cm}^2/\text{V} \cdot \text{s}$, $\gamma = 10^8 \text{ cm}^{-1}$, $\alpha_1 = 4 \times 10^{-15} \text{ V} \cdot \text{s}$, $\eta = 4 \times 10^{-2} \text{ V}^{-1}$, $\alpha = 8 \times 10^{-7} \text{ cm/V}$, $\beta = 3 \times 10^{-6} \text{ cm/V}$). (Experimental data from Ref. 122.)

Figure 60. Variation of S_{vd} with V_{gs} ($\mu_{n0}=604 \text{ cm}^2/\text{V}\cdot\text{s}$, $\gamma=10^8 \text{ cm}^{-1}$, $\alpha_1=10^{-16} \text{ V}\cdot\text{s}$, $\eta=5.05 \times 10^{-2} \text{ V}^{-1}$, $\alpha=1.6 \times 10^{-7} \text{ cm/V}$, $\beta=0.15 \times 10^{-6} \text{ cm/V}$). (Experimental data from Ref. 121.)

field-dependent mobility and bias-dependent series resistance, the theory of low-frequency GR noise derived by Yau and Sah [123] can be modified. The drain current spectral density due to the GR process in the depletion region of a FOLD MOSFET can be written as

$$S_{I_{GR}} = \frac{4q^2 I_{ds} N_t}{C_{ox}^2 L} \int_0^{V'_{ds}} \frac{\mu_n}{V''_{gs} - V(y)} dV(y) \cdot \int_0^{W_d} f_t \frac{(1-f_t)t_{GR}}{1+\omega^2 t_{GR}^2} \left(1 - \frac{x}{W_d}\right) dx \quad (150)$$

where N_t is the trap density, f_t is the fraction of occupied defect centers, and t_{GR} is the fluctuation constant given in Ref. 124. If the depletion approximation is assumed, then f_t and t_{GR} can be approximately taken as constant, and one gets

$$S_{I_{GR}} = \frac{4q^2 I_{ds} N_t f_t (1-f_t) t_{GR}}{3C_{ox}^2 L (1+\omega^2 t_{GR}^2)} \int_0^{V'_{ds}} \frac{\mu_n}{V''_{gs} - V(y)} W_d dV(y)$$

$$W_d = \sqrt{\frac{2\epsilon_{si}}{qN_a} (2\phi_F + V(y))} \quad (151)$$

Using (111), (116), and (117), one gets

$$\frac{dV(y)}{dy} = \frac{I_{ds} + \frac{\alpha C_{ox} I_{ds}}{2\epsilon_{si}} \left(V'_{gs} - V_{FB} - \phi_{ss} + \frac{|Q_B|}{C_{ox}} \right)}{\left(\mu_{n0} W C_{ox} \left(V'_{gs} - V_{FB} - \phi_{ss} - \frac{|Q_B|}{C_{ox}} \right) - \beta I_{ds} \right)} \quad (152)$$

Figure 61. Variation of (S_{vd}) due to GR noise and (S_{vd1}) due to $1/f$ noise with V_{ds} ($\mu_{n0}=597.3 \text{ cm}^2/\text{V}\cdot\text{s}$, $N_t=7.99 \times 10^{11} \text{ cm}^{-3}$, $\eta=4.459 \times 10^{-2} \text{ V}^{-1}$, $\alpha=0.72 \times 10^{-6} \text{ cm/V}$, $\beta=4.9 \times 10^{-6} \text{ cm/V}$). (Experimental data from Ref. 125.)

After some mathematical manipulation of (117), μ_n can be rewritten as

$$\mu_n = \frac{\mu_{n0} \left(V''_{gs} - V(y) - \frac{\beta I_{ds}}{\mu_{n0} W C_{ox}} \right)}{(V''_{gs} - V(y)) \left(1 + \frac{\alpha |Q_B|}{\epsilon_{si}} + \frac{\alpha C_{ox}}{2\epsilon_{si}} (V''_{gs} - V(y)) \right)} \quad (153)$$

where

$$V_{t0} = V_{FB} + 2\phi_F + \frac{|Q_B|}{C_{ox}} \quad (154a)$$

$$V''_{gs} = V_{gs} - V_{t0} - I_{ds}(R_{ns} + R_s) = V'_{gs} - V_{t0} \quad (154b)$$

Figure 62. Variation of S_{vd} due to GR noise with V_{gs} ($\mu_{n0}=597.3 \text{ cm}^2/\text{V}\cdot\text{s}$, $N_t=7.99 \times 10^{11} \text{ cm}^{-3}$, $\eta=4.459 \times 10^{-2} \text{ V}^{-1}$, $\alpha=0.72 \times 10^{-6} \text{ cm/V}$, $\beta=4.9 \times 10^{-6} \text{ cm/V}$, $V_{ds}=0.5 \text{ V}$).

Substituting (154) into (152) and integrating, one gets the GR noise as a function of device terminal voltage [120]. The drain voltage spectral density due to the $1/f$ and GR noises in the intrinsic channel can be written as

$$S_{Vd} = \frac{(S_{1/f} + S_{IGR})}{g_d^2} \quad (155)$$

where g_d is the drain conductance and $S_{1/f}$ is the $1/f$ current noise. In Fig. 61 the variation of GR noise and $1/f$ noise with drain voltage is shown. It is found that the noises increase in direct proportion to drain voltage. The variation of GR noise with gate voltage is shown in Fig. 62. It is clear from the figure that GR noise decreases with increase in gate voltage. It is also observed that noise in a FOLD structure is less than that in a LDD MOSFET.

6. SUMMARY

The MOSFET plays an important role in the design of analog circuits. In designing a RF amplifier, it is necessary to explore the circuit parameters such as admittance parameters and scattering parameters. The small-signal behavior of a device at higher frequencies around a bias point is usually determined by scattering parameters over its operational bandwidth. The scattering parameters are used to represent the signal power gain and mismatch losses, as they are frequency-dependent, and an adequate representation of circuit elements over their whole operational ranges is essential for MMIC design. Therefore, there is a need for an optimized model that can account for these process parameter variations (such as basic physical effects of geometry) in addition to SCEs encountered in submicrometer Si MOSFET. There is also a need to develop an AC model to explore RF circuit performance of a MOSFET.

In the article, a comparative study has been made to explore the circuit parameters, and the results have been verified through the characterization. As device dimensions are scaled down, the long channel device characteristics are no longer retained. In order to retain the long-channel characteristics of submicrometer devices, it is proposed to incorporate the various SCEs such as narrow channel effect, mobility degradation effect, subthreshold degradation, substrate effect, and fringing field effect.

The microwave characteristics of short-gate-length MOSFET in terms of S parameters have been reported incorporating various effects such as substrate effect, fringing field effect and the effect of gate and drain contact pads. The results so obtained show that the circuits with shorter-gate-length devices are useful in RF circuit models. Since the analysis relates the intrinsic network parameters to the basic device physical parameters, it should be possible to exploit them not only for calculation of RF circuit performance of various types of MOS transistors but also to improve the device performance through proper design and optimization of the structure itself. Later, an analytical model of MOSFET for the drain characteristics is presented to show its variation with gate-source voltage. Besides this, a small-signal analysis

is carried out incorporating the SCEs and the effect of gate distributed inductance.

A detailed study of AC analysis of MOSFET from its current equations, obtained from analyzing the current continuity equation, is presented next. The design of RF CMOS ICs requires MOS transistor models that are accurate up to and beyond the gigahertz range. Simple expressions for Y parameters and S parameters are derived from the physics of the device incorporating the CLM effect, which is generated from decreasing the channel length and provides an additional AC output current. Therefore this effect enhances the output conductance. The model gives a better insight into the device frequency behavior at HF and for a direct extraction of RF model parameters. Modified expression of scattering parameters is also presented, including the fringing field effect and the effect of distributed gate inductance. The results so obtained show that the circuits for a short-channel-length device are useful in microwave frequency applications.

In Section 5, the parasitic resistance for a FOLD structure is considered as a combination of two buried-channel MOSFETs in series with an enhancement-mode MOSFET. Further, an analytic I_d-V_d model is also developed and the impact of series resistance on drain current is studied. It is found that the FOLD MOSFET has better current drivability than does the LDD MOSFET. Transconductance, drain conductance, channel resistance, cutoff frequency, and transit time are also studied. It is observed that the FOLD structure shows results better than those for the LDD structure because of reduced series resistance. An analytical model has been presented to characterize the $1/f$ and GR noise in the FOLD MOSFETs operating in the linear region. The $1/f$ noise model is developed on the basis of oxide-trap-induced carrier number and surface mobility fluctuations. The model takes into account the longitudinal and transverse field-dependent mobility and the series resistance of the n^- region. It is observed that the noise is less in FOLD MOSFET because of the lesser voltage drop in the n^- region.

MULTIBEAM ANTENNAS

PETER BALLING
 ASC, Antenna Systems
 Consultant, ApS
 Taastrup, Denmark

A *multibeam antenna* (MBA) may be defined as an antenna with the ability to generate multiple independent beams simultaneously from a single aperture. MBAs play an increasingly important role. They add more functions to the systems that they are a part of, increase the capacity of communications systems, preserve the available frequency spectrum and other limited assets, and reduce interference.

This article is divided into three parts:

1. An introductory part (Sections 1–3) that briefly reviews MBAs for radar, satellite, and mobile base station applications and presents simple guidelines for the preliminary antenna sizing. We discuss the implementation of MBAs focusing on the beamforming techniques, giving a number of examples mainly from the satellite antenna field.
2. The central part (Section 4), which reviews the problem of forming simultaneous multiple beams from a common antenna aperture. Much of the early work considered arrays and investigated the limitations and implementation of passive MBA networks. Separate sections discuss the Stein limit of the maximum efficiency possible of an MBA and means to finding passive networks that will realize the Stein limit. The results are extended to array-fed reflector antennas considering also quasiorthogonal beams and dual- and multimode antenna systems.
3. The final part (Section 5), which considers array-fed offset reflector antenna systems, presenting simple design formulas and discussing performance limitations due to scan aberrations and polarization effects caused by the reflector offset. This part ends with a review of compensated dual-offset reflector antenna systems.

1. MULTIBEAM ANTENNA (MBA) APPLICATIONS

MBAs find use, for example, in radar and communication systems, with some typical beamshapes outlined in Fig. 1. A radar may need to illuminate a large sector in elevation with several beams of different widths, see the 1D eleva-

tion pattern cut in inset of Fig. 1a. A narrow high-gain beam is used near the horizon toward distant targets, with increasingly wider beams at higher elevation angles toward closer targets. This provides total coverage in elevation with a single antenna with a small number of beams.

Communication and broadcast satellites have beams tailored to the areas they serve on Earth. The service area is often served by several smaller beams to increase the antenna gain to meet the link budget and/or to increase the communications capacity of the satellite. Beams that are isolated spatially or by polarization can reuse the same frequency band, multiplying the communications capacity by the number of beams using the same band. Modern communication satellites in the geostationary orbit implement this *frequency reuse* by beams in two orthogonal polarizations, namely, either left-hand and right-hand circular polarization or two perpendicular linear polarizations. This technique requires a low level of cross-polarization in the service area and is termed *frequency reuse by polarization isolation*. Satellites with a large coverage reuse the frequency band by spatially separated copolarized beams. Then, the sidelobes falling in the frequency reuse areas must be low, and we talk about *frequency reuse by sidelobe isolation*. The 2D pattern contours in the inset of Fig. 1b indicate a global telecommunication coverage with two large “hemi” beams indicated by the solid line in one hand of polarization and two smaller “spot” beams indicated by the dotted line in the orthogonal hand of polarization.

Mobile communication satellites and satellites in lower Earth orbits designed to work with simpler terminal antennas on the ground use only a single polarization. These satellites often provide a large number of contiguous spot beams of simple shapes, and current mobile satellites may implement a large number of frequency reuses. The inset of Fig. 1c shows about 70 circular footprints and the total frequency bandwidth divided into seven subbands or colors indicated by numbers 1–7. Each subband may then be reused about 10 times.

Cellular mobile or wireless systems with omnidirectional antennas mimic this pattern of multiple spot beams with a base station serving each cell. Cells placed sufficiently far apart can reuse the frequency band. By shrinking the cells and deploying more base stations, the total communication capacity can in principle be increased almost indefinitely. However, this has been found to be a costly and difficult approach except in special dense areas. Therefore, advanced mobile base stations implement multiple beams either by switching between multiple fixed beams in azimuthal sectors or by using smart or adaptive antenna technology, ultimately allowing a single mobile user to be tracked by the base station. Mobile communications are complicated by the fact that the signal, particularly in urban areas, may propagate not only along the line of sight but also along multiple paths providing strong fading and other degradations, or there may be no direct signal. Multibeam base station antennas reduce multipath effects compared to omnidirectional antennas. Alternatively, smart antennas such as MIMO (multiple-input/multiple-output) systems may use the multipath interference to establish multiple independent paths between the

Figure 1. Examples of multibeam antenna applications and patterns: (a) 1D elevation pattern traces of search radar antenna; (b) 2D contours of satellite multiple contoured beam antenna; (c) 2D footprints of satellite multiple spot beam antenna; (d) 1D azimuth pattern traces of mobile base station antenna system.

base station and the mobile station. This requires more complex antenna systems also on the mobile terminal and signal processing [1,2]. MIMO systems are currently subject to intense research as a means to increase the communications capacity, but will not be dealt with in this article.

The inset of Fig. 1d illustrates the 1D pattern cuts of a base station antenna system consisting of three $\pm 60^\circ$ sector antennas with five beams each. Dotted and full lines are used as in inset (a) to distinguish adjacent beams. Some imperfections are evident:

1. The beams are not confined to the desired coverages, but extend into adjacent coverage areas via the finite-gain rolloff and sidelobes. This represents a power loss and an interference if beams reuse the same frequency band.
2. The beamshapes are not constant within their coverages, but intersect at a lower level, the *crossover level*, which often is at least 3 dB below the peak level. Thus, the quality of service will depend on the location in the coverage area even disregarding scattering and shadowing objects between the base station and the mobile terminal.

Similar imperfections due to gain rolloff, sidelobes, and other factors exist for the radar and satellite scenarios. Increasing antenna size and complexity can reduce the imperfections, but may result in unacceptable high costs and difficulties in accommodating the antenna system on the platform.

2. ANTENNA SIZING

The minimum gain that an MBA achieves over its service area depends on many factors such as the extent of the area and antenna size and complexity. Often a preliminary design must be carried out to assess the achievable performance. Some crude estimates may be obtained from tables for linear and circular aperture distributions presented in most antenna textbooks. See Milligan's book [3] for a large collection. These tables apply to antenna apertures that are large compared to the wavelength as the obliquity or Huygens' factor is neglected. Table 1 summarizes for a circular aperture of diameter D normalized with the wavelength λ the amplitude taper, the amplitude taper loss L_{ap} , the half-power beamwidth $\Delta\theta_3$, and the location θ_0 of the first null versus the level of the first sidelobe below peak level. The first line of the table applies to a

Table 1. Properties of Circular Aperture Distributions versus Sidelobe Level^a

Sidelobe (dB)	Taper (dB)	L_{ap} (dB)	$\Delta\theta_3/(\lambda/D)^\circ$	$\theta_0/(\lambda/D)^\circ$
17.6	0	0	59.0	69.9
20	4.3–4.5	0.09	61.7–61.8	75.1–86.5
25	10.7–12.4	0.50–0.60	66.3–67.3	85.2–86.5
30	14.9–19.3	0.92–1.19	69.8–72.2	94.2–97.9
35	17.8–25.8	1.23–1.75	72.3–76.8	101.9–109.5

^aLower limit is truncated Gaussian and upper limit, Hansen one-parameter distribution.

uniformly illuminated aperture, where the on-axis directivity is

$$D_0 = \left(\frac{\pi D}{\lambda}\right)^2$$

Ranges are given for the tapered illuminations. The lower limit corresponds to truncated Gaussian distributions and the upper limit, to the Hansen single-parameter distribution. These distributions are not optimum. (No null location is indicated for the Gaussian distribution with 40 dB sidelobe level where the inner sidelobes merge; the Gaussian distribution is not suitable for low sidelobe levels.) The table shows how lower sidelobes require a stronger aperture taper and result in a directivity loss and a wider beam. If the directivity and the beamwidth are to be maintained, a larger antenna is required. The difference $\theta_0 - \Delta\theta_3/2$ indicates the minimum separation between beams reusing the same frequency band. Hansen [4] and Duan and Rahmat-Samii [5] discuss more distributions also applicable to elliptical apertures. Table 2 summarizes properties of the Taylor circular n -bar distribution, which offers narrower beam and lower taper loss for the same peak sidelobe level than those presented in Table 1. It is derived from the uniform distribution by adjusting the first zeros near the main beam to provide n -bar roughly equal sidelobes at the specified level near the main beam. Farther out sidelobes decay as those of the uniform pattern. The values of n -bar in Table 2 have been chosen so that no peak occurs at the edge of the aperture. Antenna tolerance effects due to the array excitation errors, reflector surface errors, and other anomalies degrade in particular sidelobe levels. To implement a peak sidelobe level of 35 dB, it may be necessary to design for 40 dB or even lower sidelobes.

For a circular spot-beam coverage as in Fig. 1c, losses due to amplitude taper and beam crossover must be subtracted. Depending on the technology other losses due to

Table 2. Properties of Taylor Circular n -Bar Aperture Distribution versus Sidelobe Level

Sidelobe (dB)	n -Bar	Taper (dB)	L_{ap} (dB)	$\Delta\theta_3/(\lambda/D)^\circ$	$\theta_0/(\lambda/D)^\circ$
25	3	8.1	0.36	66.1	83.9
30	4	10.7	0.72	68.7	91.7
35	5	13.0	1.09	71.6	100.3
40	6		1.48	74.6	109.4

scan, spillover, tolerances, non-orthogonality of beams, mismatch, and other factors must be subtracted. Finally, Ohmic losses must be subtracted to obtain the antenna gain. For shaped-beam and contoured-beam coverages as in Figs. 1a and 1b, the relation between minimum gain and antenna size is more complex, but some simple expressions have been given by Badessi [6] and Balling [7] for contoured-beam antennas. Badessi derived an expression for the *minimum coverage area directivity*

$$\text{MCAD} = \frac{41253}{A + 67.5C/(D/\lambda)}$$

where A is the area in square degrees and C the contour length in degrees of a contoured beam. This expression neglects the effect of sidelobe isolation. DiFonzo [8] derived an expression for the reflector diameter required to achieve a sidelobe isolation of 27–30 dB between two frequency reuse areas

$$D = \frac{100\lambda}{\sigma}$$

where σ is the spacing between the two areas in degrees.

3. MBA IMPLEMENTATION

Array antennas and phased-array antennas are useful when the multiple beams cover a large angular field of view as in the case of radars, mobile base stations, and satellites in low and medium Earth orbits. Chapters in books by Mailloux [9] and Hansen [4] and Section 4 of this article treat multibeam array antennas, including the crucial problem of how to feed the array by a suitable *beamforming network* (BFN). For applications with a limited field of view as in the case of geostationary satellites, arrays are used as feeds in lens and in particular in offset-fed reflector antenna systems as discussed in book chapters by Ricardi [10] and Rusch et al. [11] and in Section 5 of this article. Satellite applications pose special problems due to the extreme environment during launch and in space and the long lifetimes and high reliability required—see the book by Kitsuregawa [12] and the book chapter by Han and Hwang [13]. Array-fed quasioptical systems provide the ultimately simple MBA when a single feed generates a beam so that no BFNs are required. In general, the feed array of a quasioptical system is smaller and has a smaller BFN than the corresponding direct radiating array.

A fundamental distinction exists between *passive antennas* with the RF amplification (transmitter or receiver) prior to the input of the BFN and *active antennas* with amplifiers at the radiating elements or distributed at various levels in the BFN. Active antennas allow higher losses and more flexibility in the beamforming and are required when the beamforming occurs at an intermediate frequency or by one of the more recently developed techniques such as optical and digital beamforming. Radar array antennas often use *transmit/receive modules* with power amplifier for transmit, low-noise amplifier (LNA) for receive, transmit/receive switch, variable attenuation,

and phase shift integrated with the radiating elements. Switching between receiving and transmit functions to use the same beamforming components for transmit and receive cannot be used in communication systems that receive and transmit continuously. Books by Kumar [14] and by Litva and Lo [15] discuss optical beamforming (OBF) and digital beamforming (DBF).

In OBF the RF signals are converted to optical signals by modulators or by direct modulation of laser diodes. The beamforming is carried out by an optical processor or a fiberoptic network that can provide the time delays required for wideband phased-array antennas. Photodetectors recover the RF signals after the beamforming. Alternatively, a coherent optical network may be used. Advantages includes small size and mass, wide bandwidth, flexible arrangement of the fibers, and low electromagnetic interference. Disadvantages are the power consumption and the significant conversion losses from RF to optical and back. OBF is expected to find use in advanced wireless communications and in radars.

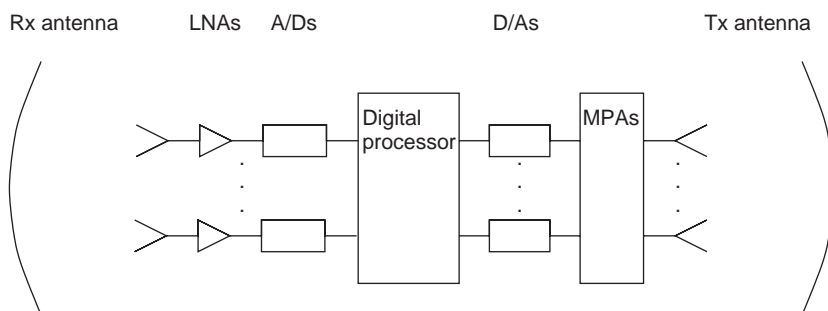

DBF is conceptually very simple and at the same time the ultimately capable approach. On receive, the RF signal is low-noise-amplified at each radiating element and converted to a digital stream by analog-to-digital (A/D) converters preserving the phase information. A digital processor applies the array antenna weights on the digital streams using either precalculated weights stored in the processor or, in smart systems, weights calculated by an adaptive algorithm to optimize some performance criterion or to track each single mobile terminal. Advantages include the very high flexibility at the level of the channels in a communication system and the ability to reset excitations to compensate, for example, for amplifier failures and component variations over temperature and age. The antenna may be upgraded by uploading new software and reconfigured by uploading new weights. Disadvantages include the high power consumption and the huge requirements to the high-speed digital processor for wideband signals. DBF's find use on board mobile commu-

nications satellites as discussed by Brain [16] and in radar antennas, and is a key technology for advanced mobile communications systems with and without MIMO [17]. Current DBF systems operate mainly at lower bands (L and S bands and below) and require lots of coaxial cable for interconnections. Some use of optical fiber links could be useful. Figure 2 illustrates the principal components of an active satellite receive/transmit DBF antenna system. The active transmit antenna part is discussed in more detail below.

Special problems relating to active antennas are to

- Achieve the required dynamic range
- Have amplifiers in adjacent paths track each other in amplitude and phase
- For active transmit antennas, limit the generation of intermodulation products while retaining an acceptable efficiency.

All carriers may be present in each power amplifier, which typically is a solid-state power amplifier (SSPA), and strict requirements to the linearity apply. This limits the amplifier efficiency achievable even though advanced linearization techniques are used. In contrast, passive antennas are often used in systems where the total frequency bandwidth is divided into channels, and the power amplification takes place channel by channel with at most very few carriers present in a channel. Then, the linearity requirements are less and the power amplification can be carried out at a much higher efficiency. In satellite communications, highly efficient traveling-wave tube amplifiers (TWTAs) are still being used, in particular with geostationary satellites at C and Ku band and above. One drawback of the channelized system is that output multiplexers (OMUXs) are required to combine the channels before the antenna beam ports. The insertion loss of the OMUX and the transmission lines required must be included when active and passive antenna

where a 4-by-4 MPA:

systems are compared. Nevertheless, channelized systems with passive antennas remain—since their introduction with Intelsat IV in 1971—popular with satellite operators as a satellite channel or transponder is a convenient unit to lease to service providers short of leasing the full satellite.

Satellites in low Earth orbits like Globalstar and Iridium at L and S bands often use active direct radiating arrays [18,19]. The mechanically steerable electronically zooming Ku-band antennas foreseen for Skybridge would keep the cell lattice fixed on Earth during the pass of the satellite [20]. The Globalstar and Iridium cell lattices move with the satellite requiring more handovers between beams. Lier and Jacomb-Hood [21] advocated active phased arrays for geostationary C- and Ku-band satellites. The active array allows more a compact low-power BFN technology with variable MMIC (microwave monolithic integrated circuit) and MEMS (microelectromechanical system) components. Figure 3 and 4 show a diagram and a photo of the Ku-band active Tx array BFN for the French Stentor technology satellite program. The photo shows the three beam ports, some MMICs, and some of the 48 output ports.

The SSPAs are located on the lower face of the radiating panel close to the radiating elements. In an active multibeam transmit antenna it is desirable to operate all power amplifiers at nominal power under all beam loading conditions to achieve optimum efficiency and minimize insertion phase variations. For multibeam transmit reflector antennas, this has led to the development of the *semiaactive antenna systems* or multiport antenna systems described by Roederer [22]. The feed array elements are not directly connected to power amplifiers, but separated from them by Butler matrix-type networks as indicated in Fig. 2. Typically 4×4 or 8×8 Butler matrices are used. The output (Butler) networks (ONETs) are always

required and must have low loss. The input (Butler) networks (INETs) are optional. By controlling the phases of the low-level equal-amplitude signals at the power amplifier inputs, the output power can be directed to the selected feeds to generate multiple pencil or contoured beams. DBF makes these beams reconfigurable.

Passive antenna technology is still very useful, in particular for geostationary satellite systems at C and Ku band and above, where wide frequency bands are used. An ultimate simple multibeam reflector antenna concept requiring no BFNs has become popular for Ka-band applications with each beam in a lattice as shown in Fig. 1c generated by a single feed; the feeds are distributed

Figure 4. Stentor Ku-band active Tx array BFN with three fully reconfigurable beams over 48 output ports. (Courtesy of Alcatel Space.)

among three to four offset reflectors increasing the feed diameter by a factor of $\sqrt{3} - \sqrt{4}$, compared to the single-reflector case. The larger feed provides acceptable values of beam crossover losses and spillover losses [23].

In the general case each beam requires a BFN to excite a cluster of feeds. Many different BFN technologies are available such as rectangular waveguide, rectangular coaxial line, stripline, and microstrip. The main requirements are that it should be possible to make couplers and other components, the losses should be low for a passive antenna, the BFN must be able to handle the power required, the BFN must be stable with temperature, and the mass and volume must be acceptable. Waveguide is generally used at Ku band and above, and TEM line at C band and below. The literature on components in these technologies is very extensive, and excellent CAD software is available. Uher et al. [24] have published a book dedicated to waveguide BFN components. *Multipaction* and *passive intermodulation* (PIM) must be addressed in any high-power feed system—passive or active. *Electrostatic discharge* (ESD) may be a problem on a more general level. Consult Kitsuregawa's book [12] and other sources available. Otherwise, no fundamental problem should exist for fixed passive BFNs where array elements are used by only a single beam. The case where many array elements are used by more than one beam in the same polarization is the subject of the next section.

Antennas with *reconfigurable beams* where the BFN includes variable components have attracted much attention. This is an area where active antenna systems have considerable advantages over passive antenna systems. The active antenna performs the beamforming at low power levels, and compact MMIC or MEMS components or DBF technology can be used. A reconfigurable passive antenna must incorporate variable BFN components in the BFN at high power level on transmit and low loss on both transmit and receive. For passive antenna like the DSCS III lens antennas, Ricardi [9] discusses BFNs with ferrite circulator switches and variable ferrite phase shifters and power dividers. Attempts to transform the ferrite

technology to civilian applications have not been satisfactory. The ACTS 30- and 20-GHz Cassegrain reflector antenna systems use BFNs with latching ferrite waveguide switches to implement hopping spot beams [25]. The ACTS antenna subsystem is also unique by the high reflector surface accuracy (0.075 mm RMS for the 20-GHz 3.3-m main reflector) to implement frequency reuse by sidelobe isolation in the Ka band and the polarization sensitive subreflector systems to implement frequency reuse by polarization isolation. International satellites since Intelsat V have implemented reconfigurability by electromechanical coaxial or waveguide switches in the BFN. Kobayashi et al. [26] further developed the switched reconfigurability concept by combining small fixed sub-BFNs by switch couplers on the beam port side. The concept requires a minimum of variable BFN components and has been used on more recent satellites; see Bornemann et al. [27] and Paus et al. [28] for examples. Figure 5 illustrates an international communication satellite with reconfigurable coverages where the two hemi beams in the one hand of polarization are fixed, but the zone beams in the other hand of polarization may be changed by switches. This allows a satellite to be reconfigured for operation in different ocean regions. The BFNs are arranged in different layers of TEM line networks behind the feed array as indicated on the right side of the figure. Figure 6 shows one of the network layers and Fig. 7, a complete antenna system including BFNs, feed array, and reflector tested in a large compact range.

With satellite lifetimes of 13 years and more, reliability and availability are key issues. Variable BFN components and in particular active components are of concern. It is common practice to require redundancy for active components such as LNAs, SSPAs, and TWTAs. Similar concerns apply to mobile base station antenna systems as their complexity increases. During winter in cold climates, access may be difficult for long periods or even relatively short outages may be unacceptable. There is a large cost incentive in reducing the amount of maintenance required for a large number of widely dispersed base stations.

4. ORTHOGONAL BEAMS

The problem of forming simultaneous multiple beams from a common aperture has received considerable interest. Much of the work considered arrays and in particular linear arrays and aimed at determining properties and limitations of the multibeam antenna networks assumed to be passive and their impact on the antenna performance. Many of the findings also apply to reflector antennas where the space feed mechanism may be viewed as a generalized network. One important antenna inefficiency to be added for reflectors is the feed array spillover loss. As already discussed, active antennas can overcome some of the inefficiencies of passive antennas, but at some cost.

Much of the work was carried out very early and is published in papers from 1961 and 1962. Shelton and Kelleher [29] found that the best multibeam pattern

Figure 7. International C-band Tx hemizone antenna system mounted on a satellite mockup during compact range tests. (Courtesy of EADS Astrium.)

configuration for a linear array of N elements occurs when the beams are equally spaced and the number of beams is equal to the number of elements. A scattering matrix analysis showed that the antenna network is lossless for only uniform illumination. Allen [30] extended the analysis and showed that unless one is willing to accept losses in addition to the normal Ohmic losses, the *complex array factor* of the beams must be mutually orthogonal over a period of the array factor. Kahn and Kurss [31] further extended the work demonstrating that the lossless network of the linear multibeam array results in some unique features; if the N beams shall be similar, the angular spacing between the beams is fixed. If the beams are not required to be similar, aperture illuminations will still have uniform phase progressions, but sinusoidal and cosinusoidal amplitude tapers generated by superposition of uniform distributions are possible.

White [32] showed that in a lossless passive antenna radiating multiple beams from a common aperture, the beams must be orthogonal in space so that the radiation pattern and the crossover levels cannot be specified independently. This result applies both to array antennas and to reflector antennas. White presented as examples 1D patterns from uniform, cosine, and cosine-squared distributions of width D . The beams for uniform distribution and sidelobe level 13.2 dB must be spaced λ/D in $u = \sin \theta$ space to be orthogonal with a crossover level of 3.9 dB. With cosine illumination, the beams with sidelobe level 23.0 dB must be spaced $2\lambda/D$, and the crossover level must be 9.5 dB. With cosine-squared distribution and 31.5 dB peak sidelobe level, the beam spacing must be $3\lambda/D$ and the crossover level must be only 15.4 dB. If one is forced to reduce the spacing to obtain satisfactory crossovers, the beams couple and the network will be lossy. White proposed three methods for solving this problem:

1. Split aperture decoupling
2. Resistive circuit decoupling
3. Active circuit decoupling

These solutions remain valid. Dividing the beams between several apertures is the solution being adapted in Ka-band satellite multibeam antenna systems with beams generated by single feeds distributed between three to four reflectors as described by Rao [23]. White proposed a decoupling networks with 3-dB hybrids and matched loads. For a 2D lattice of beams with cosine illumination and λ/D spacing with 2.1 dB crossover in the principal planes and 4.2 dB crossover in the diagonal plane, one-fourth of the power is radiated and three-fourths dissipated. For the cosine-squared illumination in both planes, only $\frac{9}{64}$ th of the power is radiated for the λ/D spacing. An active antenna with the amplification taking place at the array element before the resistive network overcomes these losses. On transmit, they occur at low level, and on receive, they do not affect the sensitivity.

4.1. The Stein Limit

Stein [33] quantified the effect of nonorthogonal beams and determined a fundamental limitation—the *Stein*

limit—of the maximum efficiency possible of an MBA. Stein considered a linear passive MBA network with M ports generating M beams. If the k th beam port is excited with a signal of unity power and all other beam ports terminated by matched loads, the complex vector far field is given by

$$\mathbf{E}_k(\theta, \phi) = q_k \mathbf{R}_k(\theta, \phi) \frac{e^{-jkr}}{r}$$

Here $\mathbf{R}_k(\theta, \phi)$ is termed the k th beam pattern and normalized such that

$$\int_{\Omega} \mathbf{R}_k^*(\theta, \phi) \cdot \mathbf{R}_k(\theta, \phi) d\Omega = 1$$

Then the total radiated power of the k th beam is

$$P_k = \int_{\Omega} r^2 \mathbf{E}_k^*(\theta, \phi) \cdot \mathbf{E}_k(\theta, \phi) d\Omega = |q_k|^2$$

With unit power incident, $|q_k|^2$ represents the radiation efficiency of the k th beam, and $1 - |q_k|^2$ network losses and power reflected back at all the beam ports. Given the M beam patterns, Stein defined as a measure of the beam overlaps the set of beam coupling factors

$$\beta_{kj} = \int_{\Omega} \mathbf{R}_k^*(\theta, \phi) \cdot \mathbf{R}_j(\theta, \phi) d\Omega$$

Here $\beta_{kk} = 1$ from the normalization, and also $\beta_{kj} = \beta_{jk}^*$ and $|\beta_{jk}| \leq 1$. Stein pointed out that the beam coupling factors do not define beam coupling simply in terms of overlap of the amplitude patterns. The fact that the beam patterns are complex-valued can be extremely important since variations in phase in the product being integrated can cause the integral to vanish even though the amplitude patterns may be identical. One such instance can occur when the locations on the radiating structure of the major currents exciting two beams are sufficiently disjoint. If a set of currents gives rise to a beam $\mathbf{R}_k(\theta, \phi)$ and this set of currents is translated the distance d , the new beam will have the form $\mathbf{R}_k(\theta, \phi) \exp(jkd \sin \psi)$, where ψ is the angle between the observation direction and the direction of translation. Another example is that of a “dual-mode antenna” where the phase patterns of two beams with overlapping amplitude patterns vary differently to make the integral vanish.

When all beam ports are excited with input signals x_k , the total radiated power is

$$P_{\text{rad}} = \sum_{k=1}^M \sum_{j=1}^M x_k^* q_k^* \beta_{kj} q_j x_j$$

Stein’s limit, based on the Hermitian and positive semi-definite properties of the matrix with elements $\Gamma_{kj} = q_k^* \beta_{kj} q_j$, states that the largest eigenvalue of this matrix cannot exceed unity: $\max \gamma_k \leq 1$.

Stein provided several examples. A simple and important result is obtained for the case when all beams have

equal radiation efficiencies, $q_k = q$ for all k . Then the eigenvalues of the matrix with elements Γ_{kj} are linearly related to the eigenvalues of the beam coupling matrix with elements β_{kj} by $\gamma_k = |q|^2 \beta_k$, and the Stein limit becomes $|q|^2 \leq 1/\max \beta_k$. Thus, the limitation on the radiation efficiency is determined directly from the beam overlap via the beam coupling matrix, independent of the MBA network. Since for all diagonal elements $\beta_{kk} = 1$, the sum of the diagonal elements (the trace of the matrix) is M . For any Hermitian matrix the sum of the eigenvalues equals the trace of the matrix. Thus, the largest eigenvalue must be equal to or exceed unity and $|q|^2 \leq 1$ with $|q|^2 = 1$ possible only if all eigenvalues are equal. This requires that all off-diagonal elements β_{kj} vanish, or that all beams be mutually orthogonal as previously pointed out by Allen and White. With two beams with equal radiation efficiencies, the eigenvalues are $\beta_{1,2} = 1 \pm \beta_{12}$ and the upper bound of the radiation efficiencies is for $\text{Re}(\beta_{12}) > 0$

$$|q|^2 \leq \frac{1}{1 + \beta_{12}}$$

The beam coupling factor for a uniformly illuminated line source of width D is

$$\beta_{12} = \text{sinc} \frac{\pi D(u_1 - u_2)}{\lambda}$$

Both Mailloux [9] and Hansen [4] provide more examples of beam coupling factors and further discussion. The beam coupling factor integral over the far field can be replaced by a summation of array excitation for omnidirectional array elements. Quite different beam overlap factors can be obtained for beams that differ only in their sidelobe structure, but have almost identical mainlobes. The same apply to the phase patterns that are seldom specified in a design. Most of the information on beam coupling factors applies to cases with a constant pattern phase.

4.2. MBA Network Realization

More recently DuFort [34,35] addressed the problem of finding a passive BFN that will realize the Stein limit. The first paper investigated the formation from a large linear array of a large number of identical low sidelobe beams in the Butler matrix directions with λ/D spacing, but with tapered distribution as considered previously by White. DuFort derived a simplified version of Stein’s limit for this case: “The maximum efficiency possible is the ratio of the average to the peak value of the aperture power distribution.” The network synthesis is based on Butler matrix networks with weights (attenuators and phase shifters) placed between the outputs of the Butler matrix and the array elements. The basic Butler matrix consists of 3-dB hybrid couplers and phase shifts and produces orthogonal beams with uniform excitations spaced $U = \lambda/D$ apart. Such beams and networks were considered by others [29,30,32] as discussed above. Figure 8 outlines an 8×8 Butler matrix network. The literature on Butler matrices

Figure 8. An 8×8 Butler matrix network with 3-dB hybrid couplers and phase shifts in degrees.

is very extensive [4,9,36]. DuFort showed that the optimum Stein limit efficiency can be achieved by placing attenuators in the array aperture. The network implements the optimum efficiency of $\frac{1}{2}$ for the cosine distribution in the 1D array as does White's network with hybrids and matched loads on the input of the orthogonal matrix network. In an alternative synthesis, DuFort placed the control elements on the input of the Butler matrix. This is advantageous when the number of beams is less than the number of array elements as in a limited scan case—in particular when an active antenna is used to compensate the beam coupling losses. A design with two types of 1–3 power dividers so that each beam uses three adjacent Butler matrix beams realizes a cosine squared on a pedestal with the optimum efficiency $|q|^2 = ((2+a)^2 + 2)/(4+a)^2$, where a is the pedestal height. For the case of no pedestal, DuFort's network achieves the optimum efficiency of $\frac{3}{8}$ for the linear array, as does White's two-stage network. The extension to Taylor n -bar distributions is more difficult and does not yield optimum results.

The second paper by DuFort [35] generalized the synthesis procedure. The desired complex radiation patterns or aperture distributions shall be specified, but can be arbitrary. The analysis leading to Klein's limit is extended into a synthesis procedure for the case of the general linear array. The analysis uses a weighted correlation matrix derived from the excitations specified over N array elements for M beams and specified weights for the efficiencies. The beam with the best efficiency is numbered one, and the others are allowed relative degraded efficiencies. Thus, DuFort's correlation matrix is a hybrid between Stein's beam coupling matrix with elements β_{kj} and the matrix with elements $\Gamma_{kj} = q_k^* \beta_{kj} q_j$ modified by the complex beam efficiency factors q_k . The synthesis is formulated in terms of the M eigenvalues λ_m and eigenvectors Ψ_m of the correlation matrix. The syn-

thesis procedure is expressed as a product of three matrices \mathcal{E} , \mathcal{T} and \mathcal{U}^\dagger , where the superscript \dagger denotes a conjugate transpose matrix. The \mathcal{E} matrix is an $M \times N$ matrix derived from the specified excitations, the efficiency weights, and the correlation matrix eigenvectors and eigenvalues. The \mathcal{T} matrix is an $M \times M$ diagonal matrix with elements $\sqrt{\lambda_m/\lambda_1}$. The \mathcal{U} matrix is an $M \times M$ diagonal matrix whose columns are the eigenvectors Ψ_m . The overall network is composed of three subnetworks—one subnetwork for each of the three matrices. The operation of the \mathcal{T} network may be performed by attenuators $\sqrt{\lambda_m/\lambda_1}$ between the input ports of the \mathcal{E} network closest to the array elements and the output ports of the \mathcal{U}^\dagger network. DuFort proposed to synthesize the \mathcal{E} and the \mathcal{U}^\dagger networks as Blass matrix networks and provided a synthesis procedure.

Figure 9 illustrates a *Blass matrix network* with eight feed ports and three beam ports. The network consists of directional couplers and phase shifters. Each beam is formed by a series-fed network. If the couplers have good isolation, the network for the beam closest to the array elements can be designed independent of the other beams. Other beams have spurious excitations due to the networks in front of them. For small coupling values, the magnitude of the spurious beams is reduced. The network suffers from losses in the loads terminating each line depending on how large coupling values are allowed at the end of the lines. The network can incorporate true time delays so that the beams will not squint with frequency as opposed to Butler matrix networks. See Butler [36], Hansen [4], and Mailloux [9] for further information on the network.

While DuFort had mainly radar applications as in Fig. 1a in mind, Wood [37] considered a satellite mobile application with beams in a hexagonal lattice as in Fig. 1c. Wood provided a simple formula to estimate the MBA orthogonality loss. A direct radiating array with N array elements provides M beams with array excitations c_j^i for

Figure 9. Blass matrix network with eight feed ports and three beam ports.

Table 3. Average Efficiency η_{MBA} and Network Efficiency η_{BFN} versus Aperture Dimension D and Crossover Level for Blass Matrix Network

D (λ)	Crossover Level (dB)	η_{MBA} (dB)	η_{BFN} (dB)	Largest Coupling (dB)
7.7	2.9	-4.1	-4.4	2.8
9.0	4.0	-3.3	-3.5	0.8
10.3	5.4	-2.5	-2.8	1.3
12.9	8.9	-1.4	-1.6	2.3

the j th element and the i th beam. By comparing the total array input power for the case where a beam is radiated at the time to the case where all beams are radiated simultaneously, Wood proposed the *MBA average efficiency*

$$\eta_{\text{MBA}} = \frac{\sum_{i=1}^M \sum_{j=1}^N c_j^i c_j^{i*}}{\max \sum_{i=1}^M \sum_{k=1}^M \sum_{j=1}^N c_j^i c_j^{k*}}$$

with a ‘‘cophasal beam’’ condition to maximize the denominator. A direct radiating array with 19 rectangular radiating elements in a hexagonal lattice with a Blass matrix network as in Fig. 9 is required to generate seven beams in a hexagonal lattice. Networks were designed for a 6.8 dB amplitude taper and a range of array aperture sizes. Table 3 summarizes the results comparing versus maximum aperture dimension D and crossover level the orthogonality loss predicted by the average efficiency η_{MBA} with the network efficiency η_{BFN} derived from the power dumped in the line terminations. The table also lists the largest coupling value in the networks and indicates that the networks are 0.2–0.3 dB less efficient than predicted by η_{MBA} . Wood attributed this difference to be representative of networks that avoid the 0 dB coupling limit and require the same total load power for each beam. Because of asymmetries in the beam overlap and in the network itself, it may be necessary to have a different total load power for each beam if the average efficiency η_{MBA} is to be achieved. Varying the aperture taper from 0 to -9.5 dB for the 10.3λ aperture increases the crossover level from 6.2 to 4.9 dB and improves the first sidelobe from 14.8 to 23.9 dB below peak, but also degrades η_{MBA} from -0.1 to -3.4 dB. The change in edge taper and sidelobe level degrades the networks efficiency by 3.3 dB even though the crossover level is improved only by 1.3 dB. In addition, the aperture efficiency is reduced by 0.5 dB.

Wood compared the array antenna with a 10.3λ -diameter offset reflector with seven feeds to generate the seven beams using one feed per beam. For the reflector antenna, the orthogonality loss mechanism is the spillover that occurs when part of the feed radiation is not intercepted by the reflector. The reflector antenna provided a crossover level of 6.4 dB and a spillover loss of 2.2 dB. This may be compared by the orthogonality loss of 2.0 dB derived from η_{MBA} for the 19-element array with the same edge taper.

4.3. Quasiorthogonal Beams

We assume an array-fed reflector antenna system with a network generating excitations sets for M beams over

N feeds. The excitation sets are given by vectors $\mathbf{c}^i = (c_1^i, \dots, c_N^i)$ for $i = 1, \dots, M$, where the excitations are normalized to unity power (i.e., $\sum_{j=1}^N c_j^i c_j^{i*} = 1$). If the network exists and is reciprocal and all ports are matched and isolated on both the feed and beam port side, the scattering matrix would take the form

$$\begin{pmatrix} b_1 \\ \vdots \\ b_N \\ b_{N+1} \\ \vdots \\ b_{N+M} \end{pmatrix} = \begin{pmatrix} 0 & \cdots & 0 & c_1^1 & \cdots & c_N^1 \\ \vdots & & \vdots & \vdots & & \vdots \\ 0 & \cdots & 0 & c_1^N & \cdots & c_N^N \\ c_1^1 & \cdots & c_N^1 & 0 & \cdots & 0 \\ \vdots & & \vdots & \vdots & & \vdots \\ c_1^M & \cdots & c_N^M & 0 & \cdots & 0 \end{pmatrix} \begin{pmatrix} a_1 \\ \vdots \\ a_N \\ a_{N+1} \\ \vdots \\ a_{N+M} \end{pmatrix}$$

where the port numbering begins on the feed port side. The specified excitation sets may have been determined by excitation optimizations separate for each beam and will then act as a reference solution for the multibeam antenna system. Depending on the specified excitation sets, the scattering matrix may not be realizable. If so, this will be corrected in an iterative procedure that changes the excitation sets as discussed below. For now we assume that received signals specified by the vector $(c_1^{i*}, \dots, c_N^{i*})$ equal to the complex conjugated i th excitation set are input on the feed ports. Then, the signal output on the k th beam port is

$$b_{N+k}^i = \sum_{j=1}^N c_j^k c_j^{i*}$$

For a lossless orthogonal network $b_{N+i}^i = 1$ and $b_{N+k}^i = 0$ for $k \neq i$. For a nonorthogonal network, the power $|b_{N+i}^i|^2$ represents the desired signal while the other power terms $|b_{N+k}^i|^2$ represent beam coupling losses due to the nonorthogonality of the network. This beam coupling loss (BCL) may be expressed by a set of beam port efficiencies. For the i th beam port we obtain the efficiency

$$\eta_{\text{BCL}}^i = \frac{|b_{N+i}^i|^2}{\sum_{k=1}^M |b_{N+k}^i|^2}$$

The procedure is repeated for all beam ports applying each time the appropriate complex-conjugated excitation set. For two identical excitation sets, $b_{N+1}^1 = b_{N+2}^1 = b_{N+1}^2 = b_{N+2}^2$, and the beam coupling loss is 3 dB. The expression for η_{BCL}^i is an alternative to Wood’s *MBA average efficiency*, but it provides an efficiency for each beam port rather than the average efficiency.

If the beam port efficiencies η_{BCL}^i are applied to the appropriate excitation sets in an iterative multibeam excitation optimization, the beam coupling loss will be traded off in the pattern optimization to achieve the best overall performance. A good starting point is the excitations derived for the case where the beams are provided by dedicated antennas. The *quasiorthogonal excitations* may be most useful when only a few feeds are shared between the beams and some losses can be tolerated. Unfortunately

there is no direct way of synthesizing the corresponding quasiorthogonal network apart from following the procedures outlined by DuFort and Wood. The network synthesis problem is addressed again at the end of the next section.

4.4. Dual- and Multimode Antennas

Previously, communications satellite contoured-beam reflector antenna systems were often so-called *dual-mode antennas* providing two identical beams in the same polarization—one beam used by the even numbered channels and the other by the odd numbered channels to relax the output multiplexer requirements. The Arabsat C-band transmit antenna described by Han and Hwang [13] is an example of a dual-mode antenna. Figure 10 outlines the principles of the antenna BFN with a 2–4 dual-mode converter with the even- and the odd-mode input ports and four sub-BFNs to connect to 13 circular waveguide feeds. The dual-mode converter consists of four quadrature hybrids and linelengths to provide the even- and the odd-mode excitation sets. The Arabsat BFN was implemented in barline technology (air stripline with solid conductor) and used “ratrace” couplers and not branchline couplers as indicated in the figure. The Arabsat BFN was divided into four network layers with the two layers closest to the feeds containing the four sub-BFNs for each of the two hands of circular polarization. The two last layers contain the dual-mode converters—one layer for each polarization. The connections between the layers eliminate the crossing lines in Fig. 10.

The sub-BFNs reduce the complexity of the dual-mode converter. The design of a general 2–13 converter is difficult, and the network will large requiring 23 hybrid

couplers with many paths through the network between the input and the output ports. The pathlengths must be approximately equal if the network is to operate over any significant bandwidth. A dual- or multimode converter synthesis procedure exists, but it provides a single-frequency design with no control of the coupling factors and the linelengths. The 2–4 converter with four hybrids is popular as it often provides a good tradeoff between performance and complexity. A more general converter is obtained by replacing the crossing lines between the four hybrids by a fifth hybrid—in particular if the coupling factors and linelengths are optimized as part of the excitation optimization. Then, the dual-mode converter usually has almost no impact on antenna performance. Sometimes 2–3 converters with only three hybrids are used providing sub-BFN excitations with phase offsets similar to $(\pm 0^\circ, \pm 60^\circ, \pm 120^\circ)$ often resulting in noticeable pattern degradations. A single hybrid is the ultimate simple dual-mode converter, but with phase offsets similar to $(\pm 0^\circ, \pm 90^\circ)$ at the two output ports and often unacceptable pattern degradations.

For linearly polarized antennas, the circular waveguide feeds are often replaced by larger rectangular waveguide feeds. This may replace a sub-BFN and several small feed with a single large feed, or at least significantly reduce the number of feeds per sub-BFN.

Another application of dual- or multimode antenna systems is to provide overlapping regional beams as in the case of the MSAT mobile communication satellite, which has six beams over North America and Hawaii. Four of the beams overlap and use three 2–3 mode converters to share feeds between adjacent beams [38]. A more complex scenario with four overlapping “linguistic” beams tailored to language zones in central parts of Europe was considered

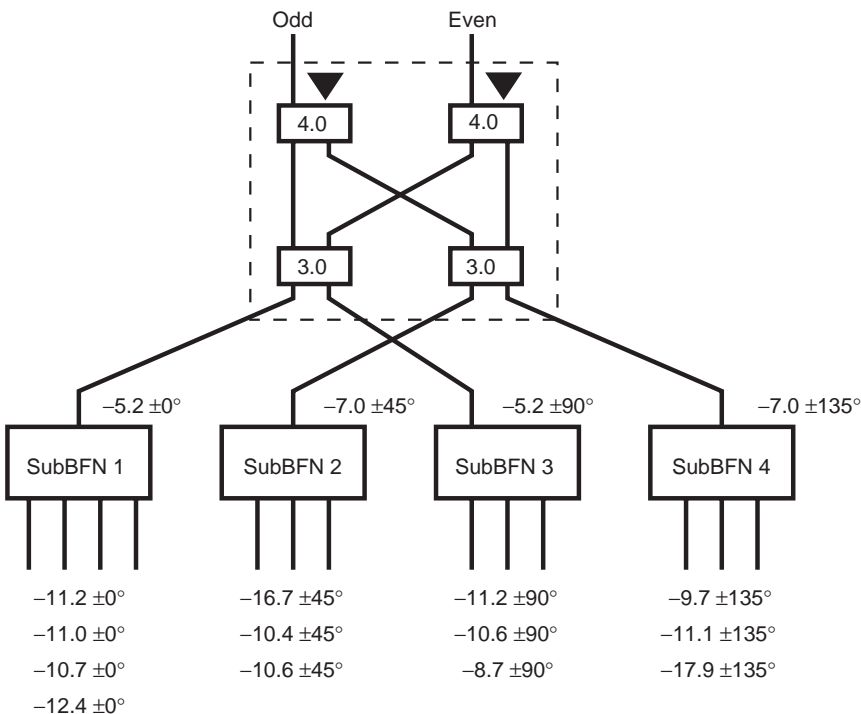

Figure 10. Dual-mode BFN with 2–4 dual-mode converter and 4 sub-BFNs connected to 13 feeds. The figure shows the coupling factors of the dual-mode converter hybrid couplers in decibels and the excitations of the two modes in decibels and degrees at the outputs of the dual-mode converter and of the sub-BFNs.

by LaFlame et al. [39]. This system required one 4–4, one 3–4, and one 2–3 mode converter. The 4–4 and 3–4 mode converters are complex and cause significant pattern degradations compared to the case with dedicated antennas for each beam.

Several approaches are available for synthesizing a dual- or multimode antenna. In one approach, the excitations for the overlapping beams are optimized applying orthogonality constraints, similar to $\sum_{j=1}^N c_j^k c_j^{i*} = 0$ for $k \neq i$ in the previous section between the excitations of the i th and the k th beams. Applying an orthogonality constraint directly to determine an excitation may not be the best approach. LaFlame et al. [39] use the orthogonality constraint indirectly by at each step in the iterative excitation optimization to improve only the beam with the worst performance and modify the other beams so that they remain orthogonal. Alternatively, the orthogonality condition may be applied “softly” via the *quasiorthogonal excitations* and *beam port efficiencies* η_{BCL}^i defined in the previous section. In any case, the excitation optimization should include sub-BFN arrangements adopted to simplify the network. Finally, a BFN must be found to realize the optimized excitation sets. There is no unique solution to this problem and typically the synthesis is carried out at a single frequency. Available synthesis methods progress as the Blass matrix network and Ruggerini’s *diagonalization BFN* [40] along similar lines. First a network of hybrid couplers and phase shifts is set up for the first beam. Then a network is set up for the next beam behind the first network. The second network attaches to the unused hybrid coupler ports of the first network and is determined such that it realizes the desired excitations at the feed ports in the presence of the network in front. The procedure is repeated for any remaining beam.

The synthesized network may be overly sensitive to component tolerances and bandwidth effects. A second synthesis approach is to derive as simply as possible approximate excitation sets, such as by a *quasiorthogonal excitation* optimization preferably identifying the most promising sub-BFN arrangement. Then, a template network is set up for the dual- or multimode part of the network and the component values are optimized using suitable models for the to fit the sub-BFN excitations found in the previous step. For a complex scenario like the MSAT scenario, several mode converting networks or matrices may have to be defined. When suitable mode converting networks with sufficient bandwidth have been identified, their network models are input and optimized in an overall excitations operating on the network component variables and any other excitations to determine the overall best antenna performance in terms of minimum coverage area directivity, sidelobe isolation, and other parameters versus antenna size and complexity.

5. OFFSET REFLECTORS

The offset paraboloidal reflector has emerged as the most popular quasioptic system used in multibeam antennas to reduce the size and the complexity of the array and the BFN for applications with a limited field of view as in the

case of geostationary satellites. The offset reflector is preferred to the center-fed reflector as the blockage by the feed array and its support is eliminated, and the interaction between the reflector and the feeds is reduced. The price paid is a more complex structure, where the reflector asymmetry generates a cross-polarization component for linearly polarized feeds or a small beam squint away from the offset plane for circularly polarized feeds—to the left for right-hand circular polarization and to the right for left-hand circular polarization when looking down the range.

As the array antenna far field is the Fourier transform of the array aperture field, the reflector far field is essentially the double Fourier transform or a replica of the feed array aperture field apart from near-field effects, scan degradations and a filtering of the feed array angular spectrum by the reflector aperture. While the beamsteering in the array is carried out by phase control, the beamsteering in the reflector is done by amplitude control and only the feeds in the vicinity of the image in the focal plane of a beam contribute to the beam. Thus, beams that do not overlap will tend to use feeds in spatially separated regions of the reflector focal plane. Beams away from the boresight suffer from scan degradations, which ultimately limit the angular region over which a reflector can be used. Increasing the focal length to aperture diameter (f/D) ratio reduces the scan degradations.

5.1. Multibeam Reflector Antenna Design

Book chapters by Rusch et al. [11] and Rahmat-Samii [41] provide information on the design and analysis of reflector antenna systems. The TICRA GRASP8/GRASP8W software [42] has become the industry standard for reflector antenna analysis. A number of simple beam models and design rules are available for the initial multibeam reflector antenna tradeoff and layout [6,7,23,43,44]. A brief summary is presented below.

We consider the offset paraboloidal reflector in Fig. 11 with aperture diameter D and focal length f . A number of

Figure 11. Side and front views of offset reflector with focus at F , apex at O , and $x_f y_f$ focal plane.

feeds placed in the tilted focal plane $x_f y_f$ each generates a pencil beam. If the maximum scan in the direction of the feed array is θ_{scan} and the ray from the lower edge of the reflector must clear the feed array by the angle θ_{clear} , the *reflector clearance* or offset must be

$$d_c = 2f \tan \frac{\theta_{\text{scan}} + \theta_{\text{clear}}}{2}$$

Different choices exist for the orientation of the feed array in the offset reflector. Mittra et al. [45] showed that the phase distortions of scanned feeds are minimized if the feed array points toward the reflector surface point whose projection into a plane perpendicular to the paraboloid axis is the center of the projected aperture. This provides the feed tilt angle

$$\delta = \arctan \left(\frac{d_1}{f - d_1^2/(4f)} \right)$$

Here we assume that the feed tilt angle is equal to the offset angle θ_o bisecting the angle subtended by the upper and lower reflector edges seen from the focus. This minimizes the spillover loss for the on-axis beam and slightly reduces cross-polarization effects. The offset angle and the subtended semiangle θ^* are determined from the offset height and aperture diameter (or vice versa) by

$$d_c = 2f \tan \frac{\theta_o - \theta^*}{2}$$

$$D + d_c = 2f \tan \frac{\theta_o + \theta^*}{2}$$

For an f/D ratio of 1 and an offset as large as $d_c/D = 0.5$, the angle δ is equal to 53.1° while θ_o and θ^* are 50.9° and 22.8° , respectively.

A feed element located at (x_j, y_j) in the focal plane gives rise to a pencil beam at (u_j, v_j) in antenna uv coordinates where

$$u_j = -\frac{B_{\text{df}} x_j}{f + d_1^2/4f} \pm \frac{\lambda \sin(\theta_o)}{4\pi f}$$

$$v_j = \frac{B_{\text{df}} y_j}{f + d_1^2/4f}$$

Here B_{df} is the *beam deviation factor* and d_1 the offset of the reflector center from the paraboloid axis. The denominator $f + d_1^2/(4f)$ is the distance from the focal point to the reflector center and acts as the “effective” focal length of the offset reflector. The second term on the right-hand side of the equation for u_j is the circular polarization beam squint. The upper sign applies for right-hand circular polarization and the lower sign, for left-hand circular polarization. No beam squint occurs for linear polarization where the term is omitted.

The beam deviation factor B_{df} depends on the aperture illumination $f(\rho)$. It may be derived from the expression

$$B_{\text{df}} = \frac{\int_0^a f(\rho)/(1 + (\rho/2f)^2)\rho^3 d\rho}{\int_0^a f(\rho)\rho^3 d\rho}$$

Table 4. Beam Deviation Factor B_{df} versus f/D Ratio for Uniform Illumination

f/D	0.7	1.0	1.3	1.6
B_{df}	0.922	0.960	0.976	0.984

derived by Ruze [46] under the condition of small feed displacements. The beam deviation factors derived for a center-fed reflector may be applied for an offset reflector if a larger “effective” focal length is used for the offset reflector as in the expressions above relating the feed location (x_j, y_j) and the beam location (u_j, v_j) . Rusch et al. [11] propose a slightly different “effective” focal length. For uniform illumination, the closed-form expression

$$B_{\text{df}} = 32 \left(\frac{f}{D} \right)^4 \left[\left(\frac{D}{f} \right)^2 - 16 \ln \left(1 + \frac{(D/f)^2}{16} \right) \right]$$

or ... $\frac{1}{16} \left(\frac{D}{f} \right)^2 \dots$

is obtained. Table 4 lists a few values of B_{df} versus f/D .

The *feed spillover* is important for multibeam reflector antennas as it must be traded off with the crossover loss between adjacent beams. For a Gaussian feed pattern with a half 10-dB feed pattern beamwidth θ_{10} , the *spillover loss* in dB is

$$L_{\text{spillover}} = 10 \log(1 - 10^{-(\theta^*/\theta_{10})^2})$$

As a beam is scanned away from the antenna boresight, a gain loss and a beam widening occur due to phase errors over the reflector aperture. The scan degradations depend for a given scan angle θ_{scan} on the D/λ ratio, the f/D ratio, the offset angle θ_o , and the aperture illumination. Following Dragone [47] and expanding the aperture phase errors in a power series and neglecting terms of order higher than 3, one obtains for the first-order *scan loss* in decibels due to *coma*, *astigmatism*, and an aberration with three periods in ϕ

$$L_{\text{scan loss}} \approx L_{\text{coma}} + L_{\text{astigmatism}} + L_3$$

where

$$L_{\text{coma}} = A(\alpha) \left[\frac{D}{\lambda} \left(\frac{D}{f} \right)^2 \sin \theta_{\text{scan}} \right]^2$$

$$L_{\text{astigmatism}} = B(\alpha) \left[\frac{DD}{\lambda f} \tan \frac{\theta_o}{2} \sin \theta_{\text{scan}} \right]^2$$

$$L_3 = C(\alpha) \left[\frac{D}{\lambda} \left(\frac{D}{f} \tan \frac{\theta_o}{2} \right)^2 \sin \theta_{\text{scan}} \right]^2$$

Table 5 provides expressions for $A(\alpha)$, $B(\alpha)$, and $C(\alpha)$ and numerical values versus edge taper for the aperture distribution $\alpha + (1 - \alpha)(1 - (\rho/a)^2)$. The expressions are approximate and neglect the dependence of the scan loss on the scan direction. A beam scanned away from the feed array suffers a higher scan loss than does a beam scanned

Table 5. Expressions and Numerical Values of Scan Loss Factors versus Aperture Taper for $\alpha + (1 - \alpha)(1 - (\rho/a)^2)$ Distribution

Factor	Expression	13 dB	10 dB	0 dB
$A(\alpha)$	$\frac{\pi^2}{2^{10}3 \ln 10} \frac{1 + 6\alpha + 3\alpha^2}{(1 + \alpha)(1 + 2\alpha)}$	0.001963	0.002076	0.002325
$B(\alpha)$	$\frac{5\pi^2}{2^5 3 \ln 10} \frac{1 + 3\alpha}{1 + \alpha}$	0.3048	0.3305	0.4464
$C(\alpha)$	$\frac{\pi^2}{2^9 \ln 10} \frac{1 + 4\alpha}{1 + \alpha}$	0.01296	0.01441	0.02093

toward the feed array. Nevertheless, the expressions indicate the impact of the antenna parameters on the scan loss and show that the astigmatism is most important for practical antenna geometries. A physical optics reflector antenna analysis program should be used to establish the actual antenna performance, and the expressions should be used only for qualitative comparisons. The scan loss is not a loss in radiated power as the BFN loss and the spill-over loss. It represents a loss in the resolution of the reflector due to the widening of the beams with increasing scan angle. The scan loss of the center-fed reflector is for the same aperture diameter, f/D ratio, and aperture illumination order of magnitude less than that of the offset reflector. The dominant scan aberration of the center-fed reflector is coma, which has a minor impact on the scan loss and mainly degrades the sidelobe performance. As the total scan loss is determined by a combination of coma, higher-order astigmatism, and spherical aberration, no simple expression exists for the scan loss of the center-fed reflector. Coma and astigmatism have ray optical interpretations; coma is related to the region on the far-field sphere with one or more rays from the feed reflected in the reflector surface. Similarly, astigmatism is related to the region with caustic effects where four edge-diffracted rays occur [48]. This observation provides an alternative explanation of why astigmatism for an off-axis feed is stronger in the offset reflector with its elliptical rim than in the center-fed reflector, where caustic phenomena occupy much smaller regions of the far-field sphere. It also indicates that surface shaping is not likely to reduce the astigmatism for the offset reflector. A dual-offset reflector with conic or shaped surfaces is required to improve the scan performance. Dual-offset reflectors with conic surfaces are discussed in Section 5.3 of this article. Albertsen et al. [49] compare different surface shaping techniques of dual-offset reflector antennas for improving the scan performance.

A beam generated by a single large feed in an offset reflector will suffer from significant degradations if scanned a sufficiently large number of beamwidths. Lam et al. [50] show that by replacing the single large feed by a cluster of smaller feeds with optimized excitations, the scan degradations may be reduced considerably. For an offset 108λ reflector scanned 10 beamwidth, the optimum directivity by a 7-element cluster and a 19-element cluster is respectively 8 and 12 dB higher than that of a single feed. When the feed cluster spacing is larger than 1λ , the

directivity found by conjugate field matching is similar to that found by optimization. For contoured beams generated by feed clusters, the excitation optimization may also partially compensate the scan aberrations.

5.2. Cross-Polarization Effects

We have already encountered Adatia and Rudge's [51] approximate formula for the circular polarization beam squint in the offset reflector

$$\psi_s = \pm \arcsin\left(\frac{\lambda \sin(\theta_o)}{4\pi f}\right)$$

stated to be accurate within 1.0% of the half-power beamwidth. The beam squint is to the left for right-hand circular polarization and to the right for left-hand circular polarization.

For linear polarization, each feed generates two cross-polar lobes, one on either side of the copolar beam center in directions perpendicular to the offset plane. Jacobsen's "reflector transformation" [52] gives for the ratio of the peak cross-polarization level (Cross-pol_{\max}) to peak copolarization level (Copol_{\max}) for a uniformly illuminated aperture

$$\frac{\text{Cross-pol}_{\max}}{\text{Copol}_{\max}} \approx 0.36\theta^* \tan\left(\frac{\theta_o}{2}\right)$$

The values $\theta_o = 35.23^\circ$ for the offset angle and $\theta^* = 23.23^\circ$ for the semiangle subtended by the reflector rim give a ratio of -27.2 dB. A similar expression, but with 0.36 replaced by 0.4 and θ^* by half the 10 dB feed beamwidth, was derived by Gans and Semplak [53] for reflector aperture fields (and far fields for the feed beamwidth small compared to θ^*). The cross-polar maxima occur about $0.73 \lambda/D$ radians from the copolar beam center and have opposite phases in phase quadrature with the copolar pattern. Several methods exist for reducing this cross-polarization, including

- Long f/D ratio and small offset angle,
- Dual-gridded reflector with polarization sensitive grid on the front shell and separate feed arrays for the two orthogonal linear polarizations (e.g., see Raab [54])
- Trimode feed horn including TM_{11} and TE_{21} mode as proposed by Rudge and Adatia [55]
- Feed array aligned with the paraboloid axis and the array factor squinted toward the offset reflector as proposed by Jacobsen [52]
- Planar polarization screen between the feed arrays and the reflector with either a parallel wire grid forming the angle $\theta_o/2$ with the xy plane as proposed by Chu [56] or a curved wire grid with more degrees of freedom for the screen tilt angle as proposed by Dragone [57]
- Cross-polarization cancellation between adjacent array feed elements with similar excitations as discussed by Balling et al. [58]

- Compensated dual-offset reflector with conic surfaces as discussed in the next section
- Dual-offset reflector with shaped surfaces to achieve a circular or elliptical beam with low cross-polarization as described by several authors [59–62]
- Dual-gridded subreflector with a polarization-sensitive grid on the front shell and a solid main reflector, and separate feed arrays for the two orthogonal linear polarizations as in the case of the ACTS 30 and 20 GHz Cassegrain reflector antenna systems [25]

5.3. Compensated Dual-Offset Reflectors

The scan degradations and the high cross-polarization levels for linear polarization of the offset reflector are reduced by a compensated dual-offset reflector antenna system. Tanaka and Mizusawa [63] established a condition that eliminates the linear polarization cross-polarization due to the reflector offset by adjusting the angles γ between the subreflector and the main reflector axis and ψ between the feed and the subreflector indicated for the offset Cassegrain and Gregorian systems in Fig. 12. A dual-offset reflector may with some limitations be represented by its *equivalent paraboloid*. The offset angle of the equivalent paraboloidal reflector is

$$\tan \frac{\theta_{o,eq}}{2} = \frac{e \sin((\psi - \gamma)/2) + \sin((\psi + \gamma)/2)}{e \cos((\psi - \gamma)/2) + \cos((\psi + \gamma)/2)}$$

where e is the eccentricity of the subreflector hyperboloid or ellipsoid. The equivalent offset angle $\theta_{o,eq}$ can take on any value, including zero. The condition $\theta_{o,eq} = 0$, which eliminates the cross-polarization and as shown by Dragone [47] most first-order scan aberrations including astigmatism, corresponds to a rotationally symmetric

equivalent paraboloid. The condition may be expressed as

$$\tan \psi = \frac{(1 - e^2) \sin \gamma}{(1 + e^2) \cos \gamma - 2e}$$

or in Adatia's [51] simplified form

$$\tan \frac{\psi}{2} = M \tan \frac{\gamma}{2}$$

where $M = (e + 1)/(e - 1)$ is the subreflector magnification. This condition is sometimes referred to as the *Mizugutch condition* as the paper by Tanaka and Mizusawa was not initially noticed outside Japan. Mizugutch et al. [59] spread the result and also present compact dual-offset reflector antenna systems with shaped surfaces for low cross-polarization, but allowing the feed axis to be kept parallel to the main reflector axis. Kitsuregawa and Mizugutch use notations that differ from Adatia's notation adopted in this article. Kitsuregawa uses angles $\alpha = \gamma$ and $\beta = \psi + \gamma$ with an eccentricity that changes sign for hyperboloidal and ellipsoidal and for concave and convex subreflectors. Mizugutch uses angles $\alpha = \psi$ and $\beta = \gamma$. In this article, the eccentricity is always positive, but the angles and the subreflector magnification may be negative. (An exception occurs for Cassegrain systems that use the concave branch of the hyperboloid. They are discussed below and require that the sign of the eccentricity in the formulas above be changed.) The Gregorian antenna in Fig. 12 has γ positive and ψ negative, whereas both angles are positive for the Cassegrain antenna. The Gregorian subreflector and main reflector are offset in opposite directions, making the Gregorian antenna more compact than the Cassegrain antenna. A main drawback of the Gregorian geometry is the scattering and spillover from the upper subreflector edge affecting the antenna far field close to the antenna boresight.

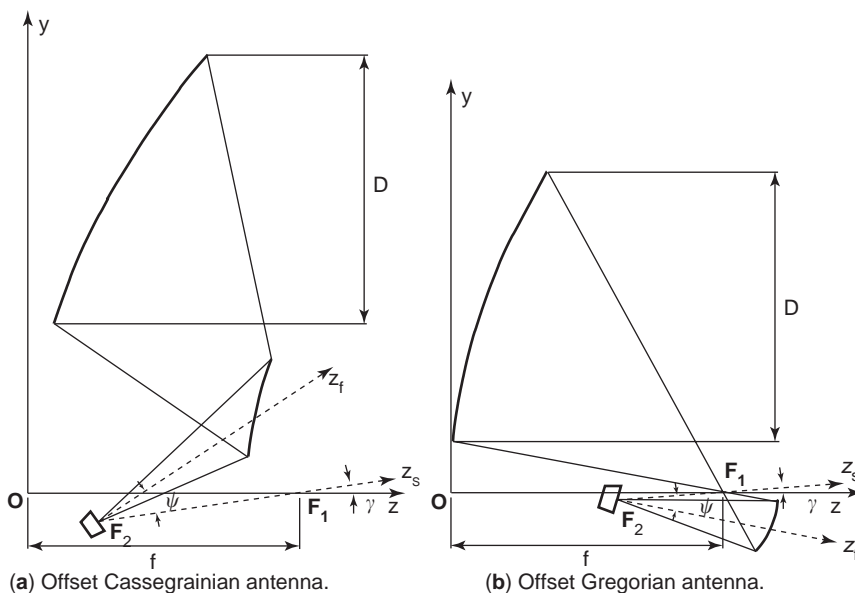

Figure 12. Compensated offset Cassegrain and Gregorian reflector antenna systems with $f/D = 1$ for main reflector: (a) Cassegrain system with $M = 3$, $\gamma = 8.45^\circ$, and $\psi = 25.00^\circ$; (b) Gregorian system with $M = -3$, $\gamma = 6.04^\circ$, and $\psi = -18.00^\circ$.

Alternatively, the subreflector magnification may be defined as the ratio of the equivalent paraboloid focal length to the main reflector focal length

$$M_{\text{eq}} = \frac{f_{\text{eq}}}{f} = \frac{e^2 - 1}{e^2 - 2e \cos \gamma + 1}$$

which differs from M for $\gamma \neq 0$.

The equivalent paraboloid is useful mainly for evaluating the case where the feed is placed at the focus and for determining in a first approximation the relation between feed positions in the focal plane and beam directions. The equivalent paraboloid should not be used to determine the scan degradations. For the offset Cassegrain and Gregorian systems in Fig. 12, rays for scanned beams will miss the small sub-reflectors. It is necessary to increase the subreflector size and the reflector offsets to prevent blockage and spillover. As described by Kitsuregawa [12], the subreflector and the feed array for scan angles as large as $\pm 10^\circ$ will be several times larger than the main reflector for a Cassegrain system. A Gregorian system can be more compact, but the subreflector will still be large. For both offset Cassegrain and Gregorian systems, the feed arrays cannot be planar for large scan angles. Rusch et al. [64] have evaluated the accuracy of the equivalent paraboloid for predicting the performance of offset Cassegrain and Gregorian antennas with a main reflector diameter of 100λ , subreflector diameter of about 20λ , main reflector f/D ratio of 0.625, subreflector magnifications of about 3 and -3 , and a feed taper of -10 dB toward the subreflector rim. For this case with no subreflector oversizing and the feed placed at the hyperboloid/ellipsoid focus, the subreflector diffraction causes a copolar loss of about 0.5 dB. The copolar sidelobes agree fairly well down to 30 dB below peak. Whereas the equivalent paraboloid predicts zero cross-polarization, the dual-reflector analyses predicts peak levels of about 32 and 38 dB below copolar peak for the Casse-

grain and the Gregorian antenna, respectively. Under scanned conditions, the agreement between the equivalent paraboloid and the dual-reflector analyses deteriorates rapidly. There are significant copolar differences for one beamwidth of scan, and gross differences at two and four beamwidths of scan. Thus, extreme care must be taken when applying the equivalent paraboloid under scanned conditions as would be required for multibeam antennas.

While classical offset Cassegrain and Gregorian systems can provide adequate performance for at least 10–12 beamwidths of scan within a $\pm 4^\circ$ field of view, the *front-fed offset Cassegrain* (FFOC) and *side-fed offset Cassegrain* (SFOC) in Fig. 13 are good candidates for applications with scan angles as large as $\pm 10^\circ$. For these systems, the subreflector is the concave branch of the hyperboloid with the magnification $M = (e - 1)/(e + 1)$ less than one. The feed arrays can be planar and will be smaller than for the classical offset Cassegrain and Gregorian systems. The subreflector size is comparable to that of the main reflector, but in particular the front-fed configuration allows a compact arrangement. Both the FFOC and the SFOC have unique scan properties due to the large focal length of the main reflector. The configurations seem to have been identified first by Tanaka and Mizusawa [63] and considered later by Dragone [65,66]. Makino et al. [67] and Jørgensen et al. [68] provided the extension to $\pm 10^\circ$ scan angles for the FFOC and the SFOC, respectively. The performance of the FFOC was experimentally validated and compared with that of an classical offset Gregorian with a large oversized subreflector.

For a 120λ main reflector aperture and 10° (17 beamwidths) scan, the SFOC scan loss is 2.1 dB in the worst direction, which is better than that of the offset Gregorian by 3 dB. The maximum linear polarization crosspolarization level of the SFOC is -38.0 dB calculated and -34.0 dB measured compared to -23 dB for the offset Gregorian. The feed horn provides a reflector edge level for the center beam of -15 dB and the feed used in the

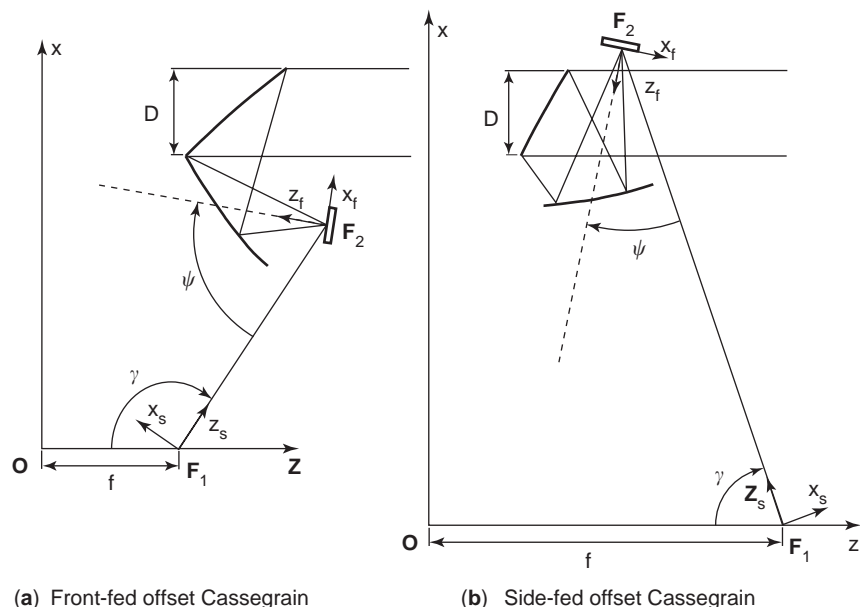

Figure 13. Offset Cassegrain antenna systems: (a) front-fed offset Cassegrain with $M = 0.344$, $\gamma = -123.61^\circ$, and $\psi = -65.37^\circ$; (b) side-fed offset Cassegrain with $M = 0.383$, $\gamma = -70.00^\circ$, and $\psi = -30.00^\circ$.

Table 6. Predicted Performance of the FFOC and SFOC Antenna Systems with 120λ Main Reflector Aperture

Scan Direction	Directivity (dBi)	Change (dB)	Sidelobe (dB)	Cross-polarization (dB)
<i>Side-Fed Offset Cassegrain</i>				
On axis	46.88	—	−18.50	−48.68
10° downward	46.52	0.36	−6.89	−38.06
10° upward	43.04	3.84	−14.80	−35.52
10° sideward	46.05	0.83	−12.42	−37.40
<i>Front-Fed Offset Cassegrain</i>				
On axis	46.42	—	−18.41	−54.78
10° downward	46.83	−0.41	−13.55	−40.20
10° upward	45.05	1.37	−15.67	−37.49
10° sideward	46.20	0.22	−15.95	−41.56

experiment had a cross-polarization level of about −40 dB. The FFOC performs even better with its larger main reflector f/D ratio. Table 6 compares the calculated FFOC and SFOC performance for the on-axis beam and the 10° beams scanned upward, sideward, and downward for 1.8λ feeds in the FFOC and 2.1λ feeds in the SFOC. For each case, Table 6 lists the peak directivity, the change in peak directivity from the on-axis beam, the peak sidelobe level, and the peak cross-polarization level.

The small feeds provide crossover levels close to 3 dB and would be used in a feed array where feeds are combined with BFNs to provide multiple contoured beams. Then, the high spillover losses of 4–5 dB on the feed element level would be reduced. The SFOC and FFOC provide a very high performance comparable to the copolar performance of single-offset reflectors with f/D ratios of about 2.6 and 5.6, respectively. Increasing the reflector diameter to 240λ and 480λ will increase the scan losses, which then may be reduced by optimizing the reflector surface shapes.

Only a limited number of FFOC and SFOC applications have been reported. The capability has so far exceeded the demand. Chandler et al. [69] proposed using four FFOCs in the Ka band to provide global multibeam coverage from a geostationary satellite using one feed per beam. While the SFOC may be applied in the same role [70], its main use has been for high-performance compact antenna test ranges as described by Dudok [71]. The excellent scan performance, low cross-polarization, and low diffraction in the large subreflector make the FFOC an excellent choice for this application, where it allows a large quiet zone to be implemented.

MULTICONDUCTOR TRANSMISSION LINES

J. A. BRANDÃO FARIA
 Instituto Superior Técnico
 Lisbon, Portugal

1. INTRODUCTION

An important electrical engineering theme, the topic of wave propagation phenomena in multiconductor transmission lines (MTL) has been receiving attention since 1930 [1,2]. Interest in such a topic pervades many different areas where high-frequency regimes come into play, namely, powerline transients and powerline communications,

crosstalk and electromagnetic compatibility problems, electronic and microelectronic design, and packaging, as well as, naturally, in RF and microwave engineering.

In recent times the subject of multiconductor transmission lines has been growing in importance, particular attention being paid to the computation of the propagation characteristics of printed-circuit boards, high-speed interconnects, microstrip lines, and other components, with numerous applications in VLSI, MMICs, impedance-matching networks, pulseshaping devices, filters, and other microwave structures.

For an exact evaluation of transmission-line traveling-wave solutions, hybrid-mode full-wave analysis is often required. Nevertheless, quasistatic approaches based on transverse electromagnetic (TEM) parameters are ordinarily used. The latter yield very good results provided that two basic assumptions are fulfilled; the system's transverse dimensions are small compared to the operating wavelengths (higher-order modes excluded), and the longitudinal electromagnetic field components (due to system losses and dielectric inhomogeneity) are very small compared to the transverse ones. These assumptions are employed throughout this article, enabling the consistent use of such concepts as voltages and currents.

2. VOLTAGES AND CURRENTS IN MTLs

A multiconductor transmission line is defined by a set of $n + 1$ conductors running parallel to a longitudinal axis (z axis). Among the system conductors one of them is ordinarily chosen for reference (ground conductor, conductor 0).

Conductor voltages and conductor currents are defined at transverse planes (z constant). A function of t and z , conductor k voltage is defined as the line integral of the electric field vector \mathbf{E} from conductor k to conductor 0, the integration path \mathbf{s} lying on the z plane

$$v_k(z, t) = \int_{k0} \mathbf{E}(x, y, z, t) \cdot d\mathbf{s}, \quad \text{for } k = 1, 2, \dots, n \quad (1)$$

A function of t and z , conductor- k current is defined as the surface integral of the current density \mathbf{J}_k flowing in the conductor through its own cross section S_k , or, which is equivalent, the line integral of the magnetic field vector \mathbf{H} along an arbitrary closed path \mathbf{s}_k encircling the conductor, but, again, lying on the transverse plane

$$\begin{aligned} i_k(z, t) &= \int_{S_k} \mathbf{J}_k \cdot \mathbf{u}_z dS \\ &= \oint_{\mathbf{s}_k} \mathbf{H}(x, y, z, t) \cdot d\mathbf{s}, \quad \text{for } k = 1, 2, \dots, n \end{aligned} \quad (2)$$

where \mathbf{u}_z denotes the unit vector in the direction of the positive z axis (reference direction for positive currents).

The current intensity i_0 flowing in the reference conductor is not an independent variable, for it is related to

MULTICONDUCTOR TRANSMISSION LINES

J. A. BRANDÃO FARIA
Instituto Superior Técnico
Lisbon, Portugal

1. INTRODUCTION

An important electrical engineering theme, the topic of wave propagation phenomena in multiconductor transmission lines (MTL) has been receiving attention since 1930 [1,2]. Interest in such a topic pervades many different areas where high-frequency regimes come into play, namely, powerline transients and powerline communications,

crosstalk and electromagnetic compatibility problems, electronic and microelectronic design, and packaging, as well as, naturally, in RF and microwave engineering.

In recent times the subject of multiconductor transmission lines has been growing in importance, particular attention being paid to the computation of the propagation characteristics of printed-circuit boards, high-speed interconnects, microstrip lines, and other components, with numerous applications in VLSI, MMICs, impedance-matching networks, pulseshaping devices, filters, and other microwave structures.

For an exact evaluation of transmission-line traveling-wave solutions, hybrid-mode full-wave analysis is often required. Nevertheless, quasistatic approaches based on transverse electromagnetic (TEM) parameters are ordinarily used. The latter yield very good results provided that two basic assumptions are fulfilled; the system's transverse dimensions are small compared to the operating wavelengths (higher-order modes excluded), and the longitudinal electromagnetic field components (due to system losses and dielectric inhomogeneity) are very small compared to the transverse ones. These assumptions are employed throughout this article, enabling the consistent use of such concepts as voltages and currents.

2. VOLTAGES AND CURRENTS IN MTLs

A multiconductor transmission line is defined by a set of $n + 1$ conductors running parallel to a longitudinal axis (z axis). Among the system conductors one of them is ordinarily chosen for reference (ground conductor, conductor 0).

Conductor voltages and conductor currents are defined at transverse planes (z constant). A function of t and z , conductor k voltage is defined as the line integral of the electric field vector \mathbf{E} from conductor k to conductor 0, the integration path \mathbf{s} lying on the z plane

$$v_k(z, t) = \int_{k0} \mathbf{E}(x, y, z, t) \cdot d\mathbf{s}, \quad \text{for } k = 1, 2, \dots, n \quad (1)$$

A function of t and z , conductor- k current is defined as the surface integral of the current density \mathbf{J}_k flowing in the conductor through its own cross section S_k , or, which is equivalent, the line integral of the magnetic field vector \mathbf{H} along an arbitrary closed path \mathbf{s}_k encircling the conductor, but, again, lying on the transverse plane

$$\begin{aligned} i_k(z, t) &= \int_{S_k} \mathbf{J}_k \cdot \mathbf{u}_z dS \\ &= \oint_{\mathbf{s}_k} \mathbf{H}(x, y, z, t) \cdot d\mathbf{s}, \quad \text{for } k = 1, 2, \dots, n \end{aligned} \quad (2)$$

where \mathbf{u}_z denotes the unit vector in the direction of the positive z axis (reference direction for positive currents).

The current intensity i_0 flowing in the reference conductor is not an independent variable, for it is related to

the remaining conductor currents through

$$i_0(z, t) = \int_{S_0} \mathbf{J}_0 \cdot \mathbf{u}_z dS = - \sum_{k=1}^n i_k(z, t) \quad (3)$$

3. TIME-DOMAIN EQUATIONS FOR LOSSLESS LINES

The application of Maxwell’s equations in integral form to the conductors of a loss-free multiconductor transmission-line structure of arbitrary small length yields [3,4]

$$\oint_{s_k} \mathbf{E} \cdot d\mathbf{s} = - \frac{\partial}{\partial t} \psi_k \rightarrow \frac{\partial}{\partial z} v_k(z, t) = - \sum_{j=1}^n L_{kj} \frac{\partial}{\partial t} i_j(z, t) \quad (4)$$

$$\int_{Sv_k} \mathbf{J} \cdot \mathbf{n}_e dS = - \frac{\partial}{\partial t} q_k \rightarrow \frac{\partial}{\partial z} i_k(z, t) = - \sum_{j=1}^n C_{kj} \frac{\partial}{\partial t} v_j(z, t) \quad (5)$$

where the per unit length external inductances L_{kj} (H/m) and the per unit length capacitances C_{kj} (F/m) take into account the distributed effects of magnetic and electric coupling among system conductors, respectively. These key parameters, which depend on the properties (permittivity ϵ and permeability μ) of the dielectric media that surrounds the conductors, are intrinsic to the geometry of the line configuration. Except for very simple cases, as, for example, MTLs comprising thin circular conductors, the evaluation of L_{kj} and C_{kj} generally requires the utilization of rather elaborated semianalytical or numerical techniques, [4].

By introducing two column vectors $\mathbf{v}(z, t)$ and $\mathbf{i}(z, t)$, that respectively gather all the conductor voltages and all the conductor currents,

$$\mathbf{v}(z, t) = \begin{bmatrix} v_1(z, t) \\ \vdots \\ v_k(z, t) \\ \vdots \\ v_n(z, t) \end{bmatrix}; \quad \mathbf{i}(z, t) = \begin{bmatrix} i_1(z, t) \\ \vdots \\ i_k(z, t) \\ \vdots \\ i_n(z, t) \end{bmatrix}$$

equations (4) and (5) can be written compactly in a convenient matrix form as

$$\frac{\partial \mathbf{v}}{\partial z} = - \mathbf{L}_e \frac{\partial \mathbf{i}}{\partial t}; \quad \frac{\partial \mathbf{i}}{\partial z} = - \mathbf{C} \frac{\partial \mathbf{v}}{\partial t} \quad (6)$$

where \mathbf{L}_e and \mathbf{C} are $n \times n$ matrices whose entries are the parameters L_{kj} and C_{kj} referred to above.

The per unit length external inductance and capacitance matrices in (6) are, both them, real symmetric positive-definite matrices [3,4].

In the particular case of MTLs with conductors surrounded by a homogeneous dielectric medium the matrix

pair \mathbf{L}_e and \mathbf{C} is related through

$$\mathbf{L}_e \mathbf{C} = \mathbf{C} \mathbf{L}_e = \mu \epsilon \mathbf{1} \quad (7)$$

where $\mathbf{1}$ is the $n \times n$ identity matrix (ones along the main diagonal).

If the cross section of the transmission line varies along the longitudinal coordinate z , or if μ or ϵ are functions of z , then the MTL will be classified as a nonuniform line. In such cases the inductance and capacitance matrices appearing in (6) and (7) become functions of z , $\mathbf{L}_e = \mathbf{L}_e(z)$ and $\mathbf{C} = \mathbf{C}(z)$.

The coupled pair of fundamental equations in (6) can be transformed in two other equations, one for \mathbf{v} and another for \mathbf{i} . By differentiating both sides of the two equations in (6) in order to z , one will get

$$\frac{\partial^2 \mathbf{v}}{\partial z^2} - \frac{d\mathbf{L}_e}{dz} \mathbf{L}_e^{-1} \frac{\partial \mathbf{v}}{\partial z} = \mathbf{L}_e \mathbf{C} \frac{\partial^2 \mathbf{v}}{\partial t^2} \quad (8)$$

$$\frac{\partial^2 \mathbf{i}}{\partial z^2} - \frac{d\mathbf{C}}{dz} \mathbf{C}^{-1} \frac{\partial \mathbf{i}}{\partial z} = \mathbf{C} \mathbf{L}_e \frac{\partial^2 \mathbf{i}}{\partial t^2} \quad (9)$$

The preceding results greatly simplify when uniform lines are considered since the terms involving $d\mathbf{L}_e/dz$ and $d\mathbf{C}/dz$ vanish. Further simplification arises in the case of MTLs with a homogeneous dielectric medium:

$$\frac{\partial^2 \mathbf{v}}{\partial z^2} = \mu \epsilon \frac{\partial^2 \mathbf{v}}{\partial t^2} \quad (10)$$

$$\frac{\partial^2 \mathbf{i}}{\partial z^2} = \mu \epsilon \frac{\partial^2 \mathbf{i}}{\partial t^2} \quad (11)$$

From (10) and (11) one immediately sees that line voltages and line currents obey the standard wave equation; the wave propagation velocity, common to all voltages and currents, given by $(\mu \epsilon)^{-1/2}$.

4. FREQUENCY-DOMAIN EQUATIONS FOR MTLs

The transmission-line equations presented in the preceding section are particularized now for the situation of time-harmonic fields, where all voltages and currents are assumed to vary sinusoidally in time with a given angular frequency ω . In order to exemplify the notation we write conductor k ’s voltage as

$$v_k(z, t) = V_k(z) \cos(\omega t + \phi_k(z)) = \text{Re}\{\bar{V}_k(z) e^{+j\omega t}\}$$

$$\bar{V}_k(z) = V_k(z) e^{j\phi_k(z)}$$

where \bar{V}_k is the complex amplitude associated with voltage v_k . This complex time-invariant quantity contains information about the magnitude V_k and phase angle ϕ_k of voltage v_k , both of which may vary along the line longitudinal coordinate z .

The consideration of time-harmonic regimes has two main advantages. On one hand, a great deal of simplification arises in the writing and solving of the transmission-line equations, since the time variable t disappears.

On the other hand, it easily allows for the incorporation of line losses (an important issue that cannot be dealt with in the framework of a pure time-domain formalism [5]).

The pair of equations in (6) for lossless MTLs translates to the frequency domain as

$$\frac{d}{dz}\bar{\mathbf{V}} = -j\omega\mathbf{L}_e\bar{\mathbf{I}} \quad (12)$$

$$\frac{d}{dz}\bar{\mathbf{I}} = -j\omega\mathbf{C}\bar{\mathbf{V}} \quad (13)$$

Generalization of these results to include conductor losses and dielectric losses is now possible by adding to the right-hand side of both equations new corrective terms as follows

$$\frac{d}{dz}\bar{\mathbf{V}} = -(\bar{\mathbf{Z}}_s + j\omega\mathbf{L}_e)\bar{\mathbf{I}} \quad (14)$$

$$\frac{d}{dz}\bar{\mathbf{I}} = -(\mathbf{G} + j\omega\mathbf{C})\bar{\mathbf{V}} \quad (15)$$

where $\bar{\mathbf{Z}}_s$ is the surface impedance matrix per unit length. The entries of this complex symmetric square matrix of order n are evaluated with the help of skin effect theory. By breaking down $\bar{\mathbf{Z}}_s$ into its real and imaginary parts, one finds

$$\bar{\mathbf{Z}}_s = \mathbf{R} + j\omega\mathbf{L}_i \quad (16)$$

where \mathbf{R} is the per unit length resistance matrix associated with line conductors finite conductivity, and \mathbf{L}_i is the per unit length internal inductance matrix associated with magnetic energy storage inside line conductors. For millimeter-wave and microwave applications, where the conductor skin effect penetration depth is of the order of micrometers, the frequency dependence of \mathbf{R} and \mathbf{L}_i is approximately of the type

$$\mathbf{R}(\omega) \propto \omega^{1/2}, \quad \mathbf{L}_i(\omega) \propto \omega^{-1/2}$$

In (15), \mathbf{G} denotes the per unit length conductance matrix, which is associated with dielectric media imperfections (conduction and polarization losses).

If we now define the longitudinal impedance matrix $\bar{\mathbf{Z}}$ (Ω/m) and the transverse admittance matrix $\bar{\mathbf{Y}}$ (S/m) such that

$$\bar{\mathbf{Z}} = \bar{\mathbf{Z}}_s + j\omega\mathbf{L}_e = \mathbf{R} + j\omega(\underbrace{\mathbf{L}_e + \mathbf{L}_i}_{\mathbf{L}}) \quad (17)$$

$$\bar{\mathbf{Y}} = \mathbf{G} + j\omega\mathbf{C} \quad (18)$$

we may rewrite (14) and (15) in the form

$$\frac{d}{dz}\bar{\mathbf{V}}(z) = -\bar{\mathbf{Z}}(\omega)\bar{\mathbf{I}}(z) \quad (19)$$

$$\frac{d}{dz}\bar{\mathbf{I}}(z) = -\bar{\mathbf{Y}}(\omega)\bar{\mathbf{V}}(z) \quad (20)$$

For the general case of nonuniform MTLs where $\bar{\mathbf{Z}}$ and $\bar{\mathbf{Y}}$ are functions of z , we obtain, in correspondence with (8) and (9)

$$\frac{d^2\bar{\mathbf{V}}}{dz^2} - \frac{d\bar{\mathbf{Z}}}{dz}\bar{\mathbf{Z}}^{-1}\frac{d\bar{\mathbf{V}}}{dz} = \bar{\mathbf{Z}}\bar{\mathbf{Y}}\bar{\mathbf{V}} \quad (21)$$

$$\frac{d^2\bar{\mathbf{I}}}{dz^2} - \frac{d\bar{\mathbf{Y}}}{dz}\bar{\mathbf{Y}}^{-1}\frac{d\bar{\mathbf{I}}}{dz} = \bar{\mathbf{Y}}\bar{\mathbf{Z}}\bar{\mathbf{I}} \quad (22)$$

From now on, throughout the remaining of this article, in order to alleviate the notation, we will drop the overbars indicating complex quantities.

5. SOLUTION OF TRANSMISSION-LINE EQUATIONS: MODAL DECOUPLING

Finding a solution to the frequency-domain transmission-line (TL) equations in (21) and (22) is a task that generally will require numerical integration techniques. However, a common procedure that is often used to analyze nonuniform MTLs consists in segmenting the global structure into a number of small longitudinal sections, each of which is a uniform MTL where \mathbf{Z} and \mathbf{Y} are assigned constant values, [3,4,6].

For the case of uniform line sections the set of equations in (21) and (22) reduces to a set of linear differential equations with constant coefficients

$$\frac{d^2\mathbf{V}}{dz^2} = \mathbf{Z}\mathbf{Y}\mathbf{V} \quad (23)$$

$$\frac{d^2\mathbf{I}}{dz^2} = \mathbf{Y}\mathbf{Z}\mathbf{I} \quad (24)$$

The much simpler equations in (23) and (24) have analytical solutions that ordinarily take the form of a superposition of natural modes of propagation involving exponential functions on z , [3,4,7–10], that is

$$\mathbf{V}(z) = \begin{bmatrix} V_1(z) \\ \vdots \\ V_k(z) \\ \vdots \\ V_n(z) \end{bmatrix} = \mathbf{T}\hat{\mathbf{V}}(z) \quad (25)$$

$$= \sum_{j=1}^n \mathbf{t}_j(\hat{\mathbf{V}}_j^{(f)} e^{-\gamma_j z} + \hat{\mathbf{V}}_j^{(b)} e^{+\gamma_j z})$$

$$\mathbf{I}(z) = \begin{bmatrix} I_1(z) \\ \vdots \\ I_k(z) \\ \vdots \\ I_n(z) \end{bmatrix} = \mathbf{W}\hat{\mathbf{I}}(z) \tag{26}$$

$$= \sum_{j=1}^n \mathbf{w}_j \hat{Y} w_j (\hat{\mathbf{V}}_j^{(f)} e^{-\gamma_j z} - \hat{\mathbf{V}}_j^{(b)} e^{+\gamma_j z})$$

where the complex amplitudes of the modal voltages $\hat{\mathbf{V}}_j^{(f)}$ and $\hat{\mathbf{V}}_j^{(b)}$ concerning the forward- and backward-propagating waves are determined upon consideration of boundary conditions. In (25), vector \mathbf{t}_j denotes the j th column of matrix \mathbf{T} ; likewise, in (26), vector \mathbf{w}_j denotes the j th column of matrix \mathbf{W} .

Voltages in the natural domain \mathbf{V} and voltages in the modal domain $\hat{\mathbf{V}}$, in (25), are related among them through a suitably chosen transformation matrix \mathbf{T} , which has the property of assuring the decoupling of the equation set defined in (23). Similarly, currents in the natural domain \mathbf{I} and currents in the modal domain $\hat{\mathbf{I}}$, in (26), are related among them through a suitably chosen transformation matrix \mathbf{W} , which has the property of assuring the decoupling of the equation set defined in (24):

$$\frac{d^2 \hat{\mathbf{V}}}{dz^2} = (\mathbf{T}^{-1} \mathbf{Z} \mathbf{Y} \mathbf{T}) \hat{\mathbf{V}} \tag{27}$$

$$\frac{d^2 \hat{\mathbf{I}}}{dz^2} = (\mathbf{W}^{-1} \mathbf{Y} \mathbf{Z} \mathbf{W}) \hat{\mathbf{I}} \tag{28}$$

For effective decoupling of equations to take place, the matrix products in parentheses must yield diagonal matrices. Since \mathbf{Z} and \mathbf{Y} are both symmetric matrices, we must find

$$\mathbf{T}^{-1} \mathbf{Z} \mathbf{Y} \mathbf{T} = \underbrace{\mathbf{T}^t}_{\mathbf{W}^{-1}} (\mathbf{Y} \mathbf{Z}) \underbrace{\mathbf{T}^{-1t}}_{\mathbf{W}} = \gamma^2$$

$$= \begin{bmatrix} \gamma_1^2 & & & & \\ & \ddots & & & \\ & & \gamma_j^2 & & \\ & & & \ddots & \\ & & & & \gamma_n^2 \end{bmatrix} \tag{29}$$

where superscript t denotes transposition.

From (29) we see that the transformation matrix for voltages and the transformation matrix for currents are not independent. Apart from an arbitrary normalizing matrix, these transformations are related to each other through

$$\mathbf{T}^t = \mathbf{W}^{-1} \tag{30}$$

Substituting (29) into (27) and (28) we find, for $j = 1, \dots, n$

$$\frac{d^2}{dz^2} \begin{Bmatrix} \hat{\mathbf{V}}_j \\ \hat{\mathbf{I}}_j \end{Bmatrix} = \gamma_j^2 \begin{Bmatrix} \hat{\mathbf{V}}_j \\ \hat{\mathbf{I}}_j \end{Bmatrix} \tag{31}$$

The solution of (31), concerning the modal voltage $\hat{\mathbf{V}}_j(z)$ and modal current $\hat{\mathbf{I}}_j(z)$ pertaining to mode j , can be put in the standard form of a sum of forward (f) and backward (b) propagating waves

$$\hat{\mathbf{V}}_j(z) = \hat{\mathbf{V}}_j^{(f)} e^{-\gamma_j z} + \hat{\mathbf{V}}_j^{(b)} e^{+\gamma_j z} \tag{32}$$

$$\hat{\mathbf{I}}_j(z) = \hat{Y} w_j (\hat{\mathbf{V}}_j^{(f)} e^{-\gamma_j z} - \hat{\mathbf{V}}_j^{(b)} e^{+\gamma_j z}) \tag{33}$$

where $\gamma_j = \alpha_j + j\beta_j$ stands for the propagation constant of mode j (α_j is the attenuation constant and β_j is the phase constant), and $\hat{Y} w_j$ stands for the characteristic wave admittance of mode j .

It should be stressed that, as a result of the frequency dependence of \mathbf{Z} and \mathbf{Y} , the transformation matrices \mathbf{T} and \mathbf{W} , as well as the diagonal matrices containing the propagation constants and characteristic wave admittances, all are, in general, frequency-dependent matrices. For the case of uniform MTLs such a dependence on the frequency is a smooth one.

The transformation matrix \mathbf{T} required to convert voltages from the natural domain to the modal domain is composed of n linearly independent column vectors (the eigenvectors of $\mathbf{Z} \mathbf{Y}$):

$$(\mathbf{Z} \mathbf{Y}) \mathbf{t}_j = (\gamma_j^2) \mathbf{t}_j \tag{34}$$

From a physical point of view, the entries of vector \mathbf{t}_j provide information about the voltages distribution among the conductors of the MTL when only mode j is present; likewise, the entries of vector \mathbf{w}_j provide information about the currents distribution among the conductors of the MTL when only mode j is present.

The diagonal matrix of characteristic wave admittances that we have referred to before

$$\hat{\mathbf{Y}}_W = \begin{bmatrix} \hat{Y} w_1 & & & & \\ & \ddots & & & \\ & & \hat{Y} w_j & & \\ & & & \ddots & \\ & & & & \hat{Y} w_n \end{bmatrix}$$

relates modal voltages to modal currents through

$$\hat{\mathbf{I}}^{(f)} = +\hat{Y}_W \hat{\mathbf{V}}^{(f)}, \quad \hat{\mathbf{I}}^{(b)} = -\hat{Y}_W \hat{\mathbf{V}}^{(b)} \quad (35)$$

The diagonal matrix \hat{Y}_W is determined from (19), or from (20), by imposing $\mathbf{V} = \mathbf{T}\hat{\mathbf{V}}$ and $\mathbf{I} = \mathbf{W}\hat{\mathbf{I}}$:

$$\frac{d\hat{\mathbf{V}}}{dz} = -\mathbf{T}^{-1}\mathbf{Z}\mathbf{W}\hat{\mathbf{I}}, \quad \frac{d\hat{\mathbf{I}}}{dz} = -\mathbf{W}^{-1}\mathbf{Y}\mathbf{T}\hat{\mathbf{V}}$$

Using (30), and taking into account the exponential dependence on $\pm\gamma z$ exhibited by the modal waves in $\hat{\mathbf{V}}(z)$ and $\hat{\mathbf{I}}(z)$ we find

$$\hat{Y}_W = \mathbf{T}'\mathbf{Z}^{-1}\mathbf{T}\gamma = \mathbf{T}'\mathbf{Y}\mathbf{T}\gamma^{-1} \quad (36)$$

Before we continue discussing the solution of the TL equations, an important subtle point must be addressed concerning the diagonalization of the \mathbf{ZY} matrix product, a key step that lies at the heart of the modal decoupling procedure—see (29) and (34).

We want to emphasize that despite the peculiar physical properties of \mathbf{Z} and \mathbf{Y} , no absolute aprioristic guarantees can be given of the success of the diagonalization operation in (29). Abnormal situations exist [3,11], which lead to singular transformation matrices \mathbf{T} , revealing a failure in the process of finding a complete set of n linearly independent eigenvectors \mathbf{t}_j . Such a failure is not of numerical or computational nature but is intrinsic to the constitution of the \mathbf{ZY} matrix itself.

Those abnormal cases—which fortunately are very rare—occur whenever \mathbf{ZY} is an irregular degenerate matrix [3] (a necessary, but not sufficient, condition for this to happen is that multiple eigenvalues γ are present). In such circumstances the solution to the problem involves the consideration of Jordan normal forms and modal groups [3,12]. The type of solution for line voltages and line currents can then include contributions of the type

$$(a_0 + a_1\gamma z + a_2(\gamma z)^2 + \cdots + a_{m-1}(\gamma z)^{m-1})e^{\pm\gamma z}$$

where γ is an irregular eigenvalue of order m , with $m \leq n$.

6. TRANSMISSION MATRIX OF UNIFORM MTLs

The results given in (25) and (26) allow the evaluation of MTL voltages and currents at any specific cross section z , thus enabling voltage and current variations to be followed along the entire length of the line section. In many applications this detailed knowledge is not necessary, as one may be concerned with voltages and currents only at the input and output terminals of the line. In this case the MTL structure is viewed as a blackbox, a $2n$ -port network whose internal constitution is not of concern.

In this section we obtain the transmission matrix (ABCD matrix) that characterizes a uniform MTL of

length ℓ :

$$\begin{bmatrix} \mathbf{V}_{\text{in}} \\ \mathbf{I}_{\text{in}} \end{bmatrix} = \underbrace{\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix}}_{\Phi} \begin{bmatrix} \mathbf{V}_{\text{out}} \\ \mathbf{I}_{\text{out}} \end{bmatrix} \quad (37)$$

The results in (25) and (26) can be rewritten in the form

$$\mathbf{V}(z) = \mathbf{T}e^{-\gamma z}\mathbf{T}^{-1}\mathbf{T}\hat{\mathbf{V}}^{(f)} + \mathbf{T}e^{+\gamma z}\mathbf{T}^{-1}\mathbf{T}\hat{\mathbf{V}}^{(b)} \quad (38)$$

$$\mathbf{I}(z) = (\mathbf{W}\hat{Y}_W\mathbf{T}^{-1})(\mathbf{T}e^{-\gamma z}\mathbf{T}^{-1}\mathbf{T}\hat{\mathbf{V}}^{(f)} - \mathbf{T}e^{+\gamma z}\mathbf{T}^{-1}\mathbf{T}\hat{\mathbf{V}}^{(b)}) \quad (39)$$

where the leading factor in the right hand side of (39)—a symmetric matrix—is the characteristic wave admittance matrix in natural coordinates

$$\mathbf{Y}_W = \mathbf{W}\hat{Y}_W\mathbf{T}^{-1} = \mathbf{Z}^{-1}\mathbf{T}\mathbf{Y}\mathbf{T}^{-1} = \mathbf{Y}\mathbf{T}\mathbf{T}^{-1} \quad (40)$$

where

$$\mathbf{T} = \mathbf{T}\gamma\mathbf{T}^{-1} = \text{SQRT}(\mathbf{ZY}) \quad (41)$$

It is also convenient to define the characteristic wave impedance matrix in natural coordinates, the inverse of \mathbf{Y}_W ,

$$\mathbf{Z}_W = \mathbf{Y}_W^{-1}$$

Imposition of the boundary conditions at $z=0$, $\mathbf{V}(0) = \mathbf{V}_{\text{in}}$ and $\mathbf{I}(0) = \mathbf{I}_{\text{in}}$, in (38) and (39), allow the determination of $\hat{\mathbf{V}}^{(f)}$ and $\hat{\mathbf{V}}^{(b)}$:

$$\hat{\mathbf{V}}^{(f)} = \frac{1}{2}(\mathbf{V}_{\text{in}} + \mathbf{Z}_W\mathbf{I}_{\text{in}}), \quad \hat{\mathbf{V}}^{(b)} = \frac{1}{2}(\mathbf{V}_{\text{in}} - \mathbf{Z}_W\mathbf{I}_{\text{in}})$$

Retrosubstitution of $\hat{\mathbf{V}}^{(f)}$ and $\hat{\mathbf{V}}^{(b)}$ into (38) and (39), followed by particularization for $z = \ell$, finally yields

$$\mathbf{V}_{\text{in}} = \text{COSH}(\Gamma\ell)\mathbf{V}_{\text{out}} + \text{SINH}(\Gamma\ell)\mathbf{Z}_W\mathbf{I}_{\text{out}} \quad (42)$$

$$\mathbf{I}_{\text{in}} = \mathbf{Y}_W \text{SINH}(\Gamma\ell)\mathbf{V}_{\text{out}} + \mathbf{Y}_W \text{COSH}(\Gamma\ell)\mathbf{Z}_W\mathbf{I}_{\text{out}} \quad (43)$$

where

$$\text{COSH}(\Gamma\ell) = \mathbf{T}(\cosh \gamma\ell)\mathbf{T}^{-1} \quad (44)$$

$$\text{SINH}(\Gamma\ell) = \mathbf{T}(\sinh \gamma\ell)\mathbf{T}^{-1}$$

Comparison established between (37) and (42), (43) permits identification of the submatrices \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} that define the constitution of the transmission matrix Φ :

$$\mathbf{A} = \text{COSH}(\Gamma\ell) \quad (45)$$

$$\mathbf{B} = \mathbf{B}^\ell = \text{SINH}(\Gamma\ell)\mathbf{Z}_W \quad (46)$$

$$\mathbf{C} = \mathbf{C}^\ell = \mathbf{Y}_W \text{SINH}(\Gamma\ell) \quad (47)$$

$$\mathbf{D} = \mathbf{A}^\ell = \mathbf{Y}_W \text{COSH}(\Gamma\ell)\mathbf{Z}_W \quad (48)$$

We have shown above how the transmission matrix Φ can be obtained using previous knowledge of the transformation matrices and modal propagation parameters. The inverse problem poses no special difficulties, [3]; transformation matrices and modal propagation parameters are obtained straightforwardly from Φ with the help of (45)–(48).

7. TRANSMISSION MATRIX OF NONUNIFORM MTLs

The transmission matrix of a nonuniform MTL structure, characterized by per unit length longitudinal impedance and transverse admittance matrices $Z(z)$ and $Y(z)$ that vary along the line, can be analytically determined using various approaches.

It can be obtained by modeling the global structure as a cascade of many small uniform sections, after which the global Φ matrix is determined by multiplying the transmission matrices of the individual sections [3,4]

$$\Phi = \Phi_1 \Phi_2 \dots \Phi_k \dots \Phi_N \tag{49}$$

where N is the number of uniform sections into which the structure has been broken.

Alternatively, the A , B , C , and D submatrices can be evaluated by iterative numerical integration of transmission-line equations provided that both $Z(z)$ and $Y(z)$ are prespecified known functions of z , [13]. In fact, from (19) and (20)

$$\frac{d}{dz} \begin{bmatrix} \mathbf{V}(z) \\ \mathbf{I}(z) \end{bmatrix} = - \begin{bmatrix} \mathbf{Z}(z) & 0 \\ 0 & \mathbf{Y}(z) \end{bmatrix} \begin{bmatrix} \mathbf{I}(z) \\ \mathbf{V}(z) \end{bmatrix}$$

together with

$$\begin{bmatrix} \mathbf{V}_{in} \\ \mathbf{I}_{in} \end{bmatrix} = \begin{bmatrix} \mathbf{A}(z) & \mathbf{B}(z) \\ \mathbf{C}(z) & \mathbf{D}(z) \end{bmatrix} \begin{bmatrix} \mathbf{V}(z) \\ \mathbf{I}(z) \end{bmatrix}$$

leads to the problem of iteratively solving

$$\frac{d}{dz} \begin{bmatrix} \mathbf{A}(z) & \mathbf{B}(z) \\ \mathbf{C}(z) & \mathbf{D}(z) \end{bmatrix} = \begin{bmatrix} \mathbf{B}(z)\mathbf{Y}(z) & \mathbf{A}(z)\mathbf{Z}(z) \\ \mathbf{D}(z)\mathbf{Y}(z) & \mathbf{C}(z)\mathbf{Z}(z) \end{bmatrix}$$

Starting with the initial values $\mathbf{A}(0) = \mathbf{D}(0) = \mathbf{1}$, and $\mathbf{B}(0) = \mathbf{C}(0) = \mathbf{0}$, the process ends at $z = \ell$, yielding

$$\mathbf{A} = \mathbf{A}(\ell), \quad \mathbf{B} = \mathbf{B}(\ell), \quad \mathbf{C} = \mathbf{C}(\ell), \quad \mathbf{D} = \mathbf{D}(\ell)$$

Regardless of which technique is used, one will end up with a formulation as in (37):

$$\begin{bmatrix} \mathbf{V}_{in} \\ \mathbf{I}_{in} \end{bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{V}_{out} \\ \mathbf{I}_{out} \end{bmatrix} \tag{50}$$

However, for the general case of nonuniform MTLs, the submatrices A , B , C , and D no longer satisfy the very peculiar properties in (45)–(48), as now, in general, $\mathbf{A} \neq \mathbf{D}^t$, $\mathbf{B} \neq \mathbf{B}^t$, and $\mathbf{C} \neq \mathbf{C}^t$.

As shown elsewhere [14,15], the transmission matrix properties for nonuniform MTLs are

$$\mathbf{A}\mathbf{B}^t - \mathbf{B}\mathbf{A}^t = \mathbf{B}^t\mathbf{D} - \mathbf{D}^t\mathbf{B} = \mathbf{D}\mathbf{C}^t - \mathbf{C}\mathbf{D}^t = \mathbf{C}^t\mathbf{A} - \mathbf{A}^t\mathbf{C} = \mathbf{0} \tag{51}$$

$$\mathbf{A}\mathbf{D}^t - \mathbf{B}\mathbf{C}^t = \mathbf{D}^t\mathbf{A} - \mathbf{B}^t\mathbf{C} = \mathbf{1} \tag{52}$$

$$\det \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} = \mathbf{1} \tag{53}$$

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{D} & -\mathbf{C} \\ -\mathbf{B} & \mathbf{A} \end{bmatrix}^t \tag{54}$$

As we will see next, by using suitable modal transformations defined at both the input and output terminals of the MTL structure, all submatrices A , B , C , and D can be brought into diagonal form. This allows the n -coupled MTL system to be broken down into a set of n uncoupled nonuniform single lines, whose modal parameters—propagation constants, characteristic forward-wave admittances, and characteristic backward-wave admittances—are easily determined.

The natural domain matrix equation in (50) is transformed into the modal domain as

$$\begin{bmatrix} \hat{\mathbf{V}}_{in} \\ \hat{\mathbf{I}}_{in} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{A}} & \hat{\mathbf{B}} \\ \hat{\mathbf{C}} & \hat{\mathbf{D}} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{V}}_{out} \\ \hat{\mathbf{I}}_{out} \end{bmatrix} \tag{55}$$

where, according to our notation, quantities with a “hat” sign denote modal quantities.

The relationship between modal and natural domain quantities (voltages and currents) is defined through

$$\begin{aligned} \mathbf{V}_{in} &= \mathbf{T}_{in} \hat{\mathbf{V}}_{in}, \quad \hat{\mathbf{I}}_{in} = \mathbf{T}_{in}^t \mathbf{I}_{in} \\ \mathbf{V}_{out} &= \mathbf{T}_{out} \hat{\mathbf{V}}_{out}, \quad \hat{\mathbf{I}}_{out} = \mathbf{T}_{out}^t \mathbf{I}_{out} \end{aligned} \tag{56}$$

The diagonal modal matrices $\hat{\mathbf{A}}$, $\hat{\mathbf{B}}$, $\hat{\mathbf{C}}$ and $\hat{\mathbf{D}}$ in (55) are obtained from the corresponding ones in (50) through

$$\hat{\mathbf{A}} = \mathbf{T}_{in}^{-1} \mathbf{A} \mathbf{T}_{out} = \begin{bmatrix} \hat{a}_1 & & & & \\ & \ddots & & & \\ & & \hat{a}_j & & \\ & & & \ddots & \\ & & & & \hat{a}_n \end{bmatrix} \tag{57}$$

$$\hat{\mathbf{B}} = \mathbf{T}_{in}^{-1} \mathbf{B} \mathbf{T}_{out}^{-1t} = \begin{bmatrix} \hat{b}_1 & & & & \\ & \ddots & & & \\ & & \hat{b}_j & & \\ & & & \ddots & \\ & & & & \hat{b}_n \end{bmatrix} \tag{58}$$

$$\hat{\mathbf{C}} = \mathbf{T}_{\text{in}}^t \mathbf{C} \mathbf{T}_{\text{out}} = \begin{bmatrix} \hat{c}_1 & & & & \\ & \ddots & & & \\ & & \hat{c}_j & & \\ & & & \ddots & \\ & & & & \hat{c}_n \end{bmatrix} \quad (59)$$

$$\hat{\mathbf{D}} = \mathbf{T}_{\text{in}}^t \mathbf{D} \mathbf{T}_{\text{out}}^{-1t} = \begin{bmatrix} \hat{d}_1 & & & & \\ & \ddots & & & \\ & & \hat{d}_j & & \\ & & & \ddots & \\ & & & & \hat{d}_n \end{bmatrix} \quad (60)$$

where $\hat{a}_j \hat{d}_j - \hat{b}_j \hat{c}_j = 1$, for $j = 1 \dots n$.

The transformation matrices \mathbf{T}_{in} and \mathbf{T}_{out} , which apply respectively to the input and output terminals of the non-uniform MTL, are in general different from each other. They may happen to coincide only in very special cases, when certain symmetries exist (as always occurs with uniform lines).

Matrix \mathbf{T}_{in} is a similarity transformation that simultaneously brings $\mathbf{B}\mathbf{C}^t$ and $\mathbf{A}\mathbf{D}^t$ into diagonal form. Likewise, matrix \mathbf{T}_{out} is a similarity transformation that simultaneously brings $\mathbf{B}^t\mathbf{C}$ and $\mathbf{D}^t\mathbf{A}$ into diagonal form [16]:

$$\mathbf{T}_{\text{in}}^{-1}(\mathbf{B}\mathbf{C}^t)\mathbf{T}_{\text{in}} = \mathbf{T}_{\text{out}}^{-1}(\mathbf{B}^t\mathbf{C})\mathbf{T}_{\text{out}} = \hat{\mathbf{B}}\hat{\mathbf{C}} \quad (61)$$

$$\mathbf{T}_{\text{in}}^{-1}(\mathbf{A}\mathbf{D}^t)\mathbf{T}_{\text{in}} = \mathbf{T}_{\text{out}}^{-1}(\mathbf{D}^t\mathbf{A})\mathbf{T}_{\text{out}} = \hat{\mathbf{A}}\hat{\mathbf{D}} \quad (62)$$

The propagation parameters for mode j are determined using the information in (57)–(60) concerning the matrix entries \hat{a}_j , \hat{b}_j , \hat{c}_j , and \hat{d}_j , [16]:

Propagation constant $\gamma_j = \alpha_j + j\beta_j$:

$$\cosh(\gamma_j \ell) = \frac{\hat{a}_j + \hat{d}_j}{2} \quad (63)$$

Characteristic forward-wave modal admittance:

$$\hat{Y}w_j^{(f)} = \frac{e^{+\gamma_j \ell} - \hat{a}_j}{\hat{b}_j} = \frac{\hat{c}_j}{e^{+\gamma_j \ell} - \hat{d}_j} \quad (64)$$

Characteristic backward-wave modal admittance:

$$\hat{Y}w_j^{(b)} = \frac{\hat{a}_j - e^{-\gamma_j \ell}}{\hat{b}_j} = \frac{\hat{c}_j}{\hat{d}_j - e^{-\gamma_j \ell}} \quad (65)$$

It should be noted that, contrary to what happens with uniform MTLs, the characteristic forward- and backward-

wave modal admittances do not ordinarily coincide with each other when nonuniform structures are considered. Also, the propagation parameters, and transformation matrices characterizing nonuniform MTLs do not exhibit a smooth dependence on the frequency, as sharp variations are observed at the vicinity of certain critical frequencies, depending on the length of the TL structure [17].

MULTIMODE EQUIVALENT NETWORK REPRESENTATIONS

MARCO GUGLIELMI
European Space Research and
Technology Centre
Noordwijk, The Netherlands

1. INTRODUCTION

The research carried out at the Radiation Laboratory of the Massachusetts Institute of Technology during World War II had a profound effect on the state of the art in the electromagnetic analysis of waveguide junctions and discontinuities [1,2].

One of the reasons for this significant effect was the use of *transmission-line formalism* to represent waveguide modes, and *single-mode equivalent circuits* to describe waveguide discontinuities (and junctions) as simple lumped circuit elements [3–5]. Following this approach, electromagnetic field problems could be solved by engineers with simple calculations based on network theory, while the development of the equivalent circuits themselves was carried out by researchers in the field. Engineers could then rapidly and effectively concentrate on the development of microwave equipment. As a result of this pioneering work, a number of equivalent network representations for a variety of waveguide discontinuities and junctions were then collected in the *Waveguide Handbook* [6].

Although single-mode equivalent networks are still extremely valuable tools, they do suffer from limitations that restrict their applicability. One of the most basic restrictions comes from the fact that they represent *distributed* discontinuities in terms of lumped elements as seen from the fundamental mode of the waveguide and therefore cannot account for *higher-order mode* interactions. If the *distance* between discontinuities is not sufficiently large, the higher-order mode interactions cannot be neglected and single-mode equivalent network representations are no longer valid.

Modern microwave and millimeter-wave equipment require extreme miniaturization of all components. Single-mode equivalent circuits must, therefore, be replaced by more advanced *multimode* representations that can correctly account for all higher-order mode interactions.

The objective of this article is to describe the basic theoretical steps leading to the formulation of multimode equivalent network representation of waveguide junctions. Both planar and arbitrary junctions are treated, progressing from the basic formulation to the formal solution of the relevant integral equations.

This article is intended as a guide to the development of practical solutions and can be of interest to both researchers and engineers in the microwave and millimeter-wave areas.

2. PLANAR JUNCTIONS

The problem under investigation is the planar junction between two arbitrary waveguides, as shown in Fig. 1. To

Figure 1. Planar junction between two arbitrary waveguides.

analyze this discontinuity, two formulations are possible, one leading to a multimode impedance and the other leading to a multimode admittance representation [7]. In this article, however, we will describe only the impedance formulation because of its superior computational performance [7].

The starting point is the imposition of the boundary conditions at the junction ($z = 0$ in Fig. 1), namely

$$\sum_{n=1}^{\infty} I_n^{(1)} \mathbf{h}_n^{(1)} = \sum_{n=1}^{\infty} I_n^{(2)} \mathbf{h}_n^{(2)} \quad (1)$$

where the index n covers both $TE_{m,n}$ and $TM_{m,n}$ modes, and where the superscripts (1) and (2) refer to regions (1) and (2) in Fig. 1. To proceed, we then separate the *accessible* from the *localized* modes by writing

$$\begin{aligned} \sum_{n=1}^{N^{(1)}} I_n^{(1)} \mathbf{h}_n^{(1)} - \sum_{n=N^{(1)}+1}^{\infty} V_n^{(1)} Y_n^{(1)} \mathbf{h}_n^{(1)} &= \sum_{n=1}^{N^{(2)}} I_n^{(2)} \mathbf{h}_n^{(2)} \\ &+ \sum_{n=N^{(2)}+1}^{\infty} V_n^{(2)} Y_n^{(2)} \mathbf{h}_n^{(2)} \end{aligned} \quad (2)$$

where $Y_n^{(\delta)}$ is the modal admittance. The next step is to add and subtract to (2)

$$\sum_{n=1}^{N^{(1)}} V_n^{(1)} \hat{Y}_n^{(1)} \mathbf{h}_n^{(1)} + \sum_{n=1}^{N^{(2)}} V_n^{(2)} \hat{Y}_n^{(2)} \mathbf{h}_n^{(2)} \quad (3)$$

where $\hat{Y}_n^{(\delta)}$ is defined as

$$\hat{Y}_n^{(\delta)} = (\hat{Z}_n^{(\delta)})^{-1} = \lim_{n \rightarrow \infty} Y_n^{(\delta)} = \begin{cases} \frac{-j|k_{t,n}^{(\delta)}|}{\omega\mu} & \text{for TE} \\ \frac{\omega\epsilon}{-j|k_{t,n}^{(\delta)}|} & \text{for TM} \end{cases} \quad (4)$$

The next step is to redefine the modal currents according to

$$\tilde{I}_n^{(1)} = I_n^{(1)} + V_n^{(1)} \hat{Y}_n^{(1)} \quad (5)$$

$$\tilde{I}_n^{(2)} = I_n^{(2)} - V_n^{(2)} \hat{Y}_n^{(2)} \quad (6)$$

so that (2) becomes

$$\begin{aligned} \sum_{n=1}^{N^{(1)}} \bar{\mathbf{I}}_n^{(1)} \mathbf{h}_n^{(1)} - \sum_{n=1}^{N^{(2)}} \bar{\mathbf{I}}_n^{(2)} \mathbf{h}_n^{(2)} &= \sum_{n=1}^{N^{(1)}} V_n^{(1)} \hat{\mathbf{Y}}_n^{(1)} \mathbf{h}_n^{(1)} \\ &+ \sum_{n=N^{(1)}+1}^{\infty} V_n^{(1)} Y_n^{(1)} \mathbf{h}_n^{(1)} + \sum_{n=1}^{N^{(2)}} V_n^{(2)} \hat{\mathbf{Y}}_n^{(2)} \mathbf{h}_n^{(2)} \\ &+ \sum_{n=N^{(2)}+1}^{\infty} V_n^{(2)} Y_n^{(2)} \mathbf{h}_n^{(2)} \end{aligned} \quad (7)$$

We now use the definition of modal voltage and write

$$V_n^{(\delta)} = \int_{cs} (\mathbf{u}_z \times \mathbf{E}) \cdot \mathbf{h}_n^{(\delta)*} ds' \quad (8)$$

where the electric field in the aperture ($\mathbf{u}_z \times \mathbf{E}$) can now be written as a linear combination of the *incident* accessible modes only (the modes that carry energy from one discontinuity to another)

$$(\mathbf{z}_0 \times \mathbf{E}) = \sum_{n=1}^{N^{(1)}} \bar{\mathbf{I}}_n^{(1)} \mathbf{M}_n^{(1)} - \sum_{n=1}^{N^{(2)}} \bar{\mathbf{I}}_n^{(2)} \mathbf{M}_n^{(2)} \quad (9)$$

This expression can now be substituted into (8) and (7), finally obtaining the integral equation

$$\begin{aligned} \mathbf{h}_n^{(\delta)} &= \int_{cs} \mathbf{M}_n^{(\delta)} \cdot \left[\sum_{m=1}^{N^{(1)}} \hat{\mathbf{Y}}_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} \right. \\ &+ \sum_{m=N^{(1)}+1}^{\infty} Y_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} \\ &+ \sum_{m=1}^{N^{(2)}} \hat{\mathbf{Y}}_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \\ &\left. + \sum_{m=N^{(2)}+1}^{\infty} Y_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \right] ds' \end{aligned} \quad (10)$$

The formulation is now concluded by recalling (8) and (9), to write

$$V_m^{(\gamma)} = \sum_{n=1}^{N^{(1)}} \bar{\mathbf{I}}_n^{(1)} \mathbf{z}_{m,n}^{(\gamma,1)} - \sum_{n=1}^{N^{(2)}} \bar{\mathbf{I}}_n^{(2)} \mathbf{z}_{m,n}^{(\gamma,2)} \quad (11)$$

where

$$\mathbf{z}_{m,n}^{(\gamma,\delta)} = \int_{cs} \mathbf{M}_n^{(\delta)} \cdot \mathbf{h}_m^{(\gamma)*} ds' \quad (12)$$

Equations (10) and (12) complete the formal solution of the problem in Fig. 1 in terms of the *finite* impedance multimode equivalent network shown in Fig. 2.

It is important to note that although the network representation derived involves only a limited number of accessible modes, the formulation described is rigorous in

Figure 2. Multimode equivalent network representation of the waveguide step in Fig. 1.

principle since no approximations have been introduced. What needs to be done in practice in order to ensure accurate results is to explicitly include enough higher-order modes to correctly model the higher-order mode interactions between cascaded junctions.

Particularly simple equivalent network representations can be obtained for rectangular waveguide devices involving only inductive or capacitive discontinuities [8,9].

2.1. Offset and Multiple Discontinuities

The formulation described in the previous section is valid if the waveguide in region (2) is completely contained in the cross section of waveguide (1). The case shown in Fig. 3, however, can also be treated by using as basis functions for the method of moments (MoM) solution of (10) the mode functions of a waveguide with cross section equal to the common aperture. Furthermore, the same formulation can also be used if more than two waveguides are connected to each other, as in the case shown in Fig. 4 [10]. The only modification that is required is to define the unknown function $\mathbf{M}_n^{(\delta)}(s')$, and all the integrations, over the union of all of the common apertures AP :

$$AP = \bigcup_{q=2}^{NWG} ap^{(q)} \quad (13)$$

Figure 3. Offset waveguide step.

Figure 4. Multiple-aperture planar waveguide junction.

Taking this into account, we can write directly

$$\mathbf{h}_n^{(\delta)} u^{(\delta)} = \int_{AP} \mathbf{M}_n^{(\delta)} \cdot \sum_{q=1}^{NWG} \left[\sum_{m=1}^{N^{(q)}} \hat{Y}_m^{(q)} \mathbf{h}_m^{(q)} u^{(q)} \mathbf{h}_m^{(q)*} u^{(q)} + \sum_{m=N^{(q)}+1}^{\infty} Y_m^{(q)} \mathbf{h}_m^{(q)} u^{(q)} \mathbf{h}_m^{(q)*} u^{(q)} \right] ds' \quad (14)$$

$$\mathbf{z}_{m,n}^{(\gamma,\delta)} = \int_{AP} \mathbf{M}_n^{(\delta)} \cdot \mathbf{h}_m^{(\gamma)*} u^{(\gamma)} ds' \quad (15)$$

where NWG indicates the number of waveguides involved in the step, and the function $u^{(\delta)}(s)$ is denned as

$$u^{(\delta)} = \begin{cases} 1 & \text{for } s \in ap^{(\delta)} \\ 0 & \text{for } s \ni ap^{(\delta)} \end{cases} \quad (16)$$

The equivalent network obtained in this case is shown in Fig. 5. Once again, particularly simple representations can be obtained for inductive or capacitive multiple apertures in rectangular waveguide [10]

3. ARBITRARY WAVEGUIDE JUNCTIONS

The theory presented up to now is applicable to planar junctions where two or more waveguides are connected together at a planar interface that is orthogonal to the

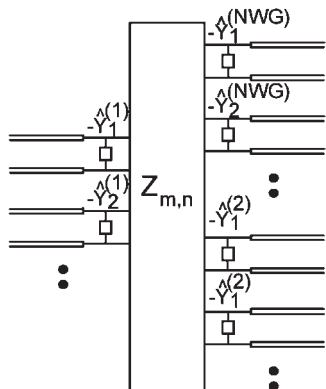

Figure 5. Multimode equivalent network for a multiple-aperture planar waveguide junction.

Figure 6. Waveguides joined by an arbitrarily shaped cavity.

propagation direction of the waveguides. Planar junctions of this type indeed cover the majority of engineering applications. However, an additional, more general type of junction is needed in order to cover *all* possible applications, namely, a junction where the connection between the waveguides is achieved with the help of a cavity, as shown in Fig. 6 [11]. The multimode equivalent network representation of this type of junction can be obtained with a simple modification of the formulation presented for the planar case. To start, we write the general expression of the magnetic field in the cavity based on Huygens' principle [12–14]

$$\mathbf{H}^{(c)}(\mathbf{r}) = \int_{(S)} \mathbf{G}^{(c)}(\mathbf{r}|\mathbf{r}') \mathbf{M}(\mathbf{r}') dS' \quad (17)$$

where

$$\mathbf{M}(\mathbf{r}) = \mathbf{n}(\mathbf{r}) \times \mathbf{E}^{(c)}(\mathbf{r}) \quad (18)$$

represents the magnetic currents in the apertures, the vector \mathbf{n} is directed outward from the cavity, and

$$\mathbf{G}^{(c)}(\mathbf{r}|\mathbf{r}') = j\omega\epsilon_0 \sum_{n=1}^{+\infty} \frac{\mathbf{h}_n^{(c)}(\mathbf{r}) \mathbf{h}_n^{(c)}(\mathbf{r}')}{k_0^2 - k_n^2} + \frac{j}{\omega\mu_0} \sum_{n=1}^{+\infty} \mathbf{g}_n^{(c)}(\mathbf{r}) \mathbf{g}_n^{(c)}(\mathbf{r}') \quad (19)$$

is the cavity's Green function described by solenoidal $\mathbf{h}_n^{(c)}$ and irrotational $\mathbf{g}_n^{(c)}$ modes [15].

Similar to what we did for the planar case, we now separate the modal expansion of the magnetic field in the ports in accessible ($I_k^{(\mu)}$) and localized ($Y_k^{(\mu)} V_k^{(\mu)}$) modes

$$\mathbf{H}^{(WG)}(\mathbf{r}) = \sum_{\mu=1}^N \sum_{k=1}^{N^{(\mu)}} I_k^{(\mu)} \mathbf{h}_k^{(\mu)}(\mathbf{r}) \delta_k^{(\mu)}(\mathbf{r}) + \sum_{\mu=1}^N \sum_{k=N^{(\mu)}+1}^{+\infty} Y_k^{(\mu)} V_k^{(\mu)} \mathbf{h}_k^{(\mu)}(\mathbf{r}) \delta_k^{(\mu)}(\mathbf{r}) \quad (20)$$

with

$$V_k^{(\mu)} = \int_{(S_{(\mu)})} \mathbf{h}_k^{(\mu)*}(\mathbf{r}) \mathbf{M}(\mathbf{r}) dS \quad (21)$$

and

$$\delta_k^{(\mu)}(\mathbf{r}) = \begin{cases} 1 & \text{if } \mathbf{r} \in S_{(\mu)} \\ 0 & \text{elsewhere} \end{cases} \quad (22)$$

where $Y_k^{(\mu)}$ denotes the characteristic admittance of mode k in port μ .

Applying the boundary condition of the magnetic field in the apertures, we find

$$\begin{aligned} & \sum_{\mu=1}^N \sum_{k=1}^{N^{(\mu)}} I_k^{(\mu)} \mathbf{h}_k^{(\mu)}(\mathbf{r}) \delta_k^{(\mu)}(\mathbf{r}) \\ &= \int_{(S)} [\mathbf{G}^{(\text{WG})}(\mathbf{r}|\mathbf{r}') + \mathbf{G}^{(c)}(\mathbf{r}|\mathbf{r}')] \mathbf{M}(\mathbf{r}') dS' \end{aligned} \quad (23)$$

with

$$\begin{aligned} & \mathbf{G}^{(\text{WG})}(\mathbf{r}|\mathbf{r}') \\ &= \sum_{\mu=1}^N \sum_{k=N^{(\mu)}+1}^{+\infty} Y_k^{(\mu)} \delta_k^{(\mu)}(\mathbf{r}) \mathbf{h}_k^{(\mu)}(\mathbf{r}) \mathbf{h}_k^{(\mu)*}(\mathbf{r}') \delta_k^{(\mu)}(\mathbf{r}') \end{aligned} \quad (24)$$

To continue, it is now again possible to model the magnetic current in the apertures as linear combination of the *incident* modes

$$\mathbf{M}(\mathbf{r}) = \sum_{v=1}^N \sum_{k=1}^{N^{(v)}} I_k^{(v)} \mathcal{M}_k^{(v)}(\mathbf{r}) \delta_k^{(v)}(\mathbf{r}) \quad (25)$$

leading to an integral equation for the new unknowns $\mathcal{M}_k^{(v)}$

$$\begin{aligned} \mathbf{h}_k^{(v)}(\mathbf{r}) &= \int_{(S)} [\mathbf{G}^{(\text{WG})}(\mathbf{r}|\mathbf{r}') \\ &+ \mathbf{G}^{(c)}(\mathbf{r}|\mathbf{r}')] \mathcal{M}_k^{(v)}(\mathbf{r}') dS' \end{aligned} \quad (26)$$

We complete the formulation by combining (21) and (25), and writing

$$V_k^{(\mu)} = \sum_{v=1}^N \sum_{l=1}^{N^{(v)}} \mathbf{Z}_{k,l}^{(\mu,v)} I_l^{(v)} \quad (27)$$

where

$$\mathbf{Z}_{k,l}^{(\mu,v)} = \int_{(S_{(\mu)})} \mathbf{h}_k^{(\mu)}(\mathbf{r}') M_l^{(v)}(\mathbf{r}') dS \quad (28)$$

is the generic expression for the elements of the multi-mode impedance representation of the cavity in terms of *accessible* modes only. The network representation shown

in Fig. 5 for the multiaperture case is directly applicable to this case as well.

It is important to note also in this case that the formulation is rigorous since no approximations have been introduced. The network representation will provide accurate results as long as enough higher-order modes are included to account for interactions between adjacent junctions in the waveguide arms.

4. FREQUENCY DEPENDENCE TREATMENT

To use the equivalent network representations derived, we must first solve the relevant fundamental integral equations. To this end, a convenient procedure, based on the method of moments, will be shown in a later section. One aspect, however, that deserves further attention is the frequency dependence of the kernel of the integral equations. The more complex the frequency dependence is, the longer will be the computing time required since the solution must be obtained for each point in frequency. In this section we describe a procedure that can be effectively used to greatly simplify the frequency dependence, thus reducing very substantially the computational effort required.

4.1. Planar Junction

For the case of the planar junction, we write

$$\begin{aligned} \mathbf{K}(s, s') &= \\ & \left[\sum_{m=1}^{N^{(1)}} \hat{Y}_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} + \sum_{m=N^{(1)}+1}^{\infty} Y_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} \right. \\ & \left. + \sum_{m=1}^{N^{(2)}} \hat{Y}_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} + \sum_{m=N^{(2)}+1}^{\infty} Y_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \right] \end{aligned} \quad (29)$$

We then add and subtract the complement to infinity of the terms in (3), obtaining

$$\begin{aligned} \mathbf{K}(s, s') &= \left[\sum_{m=1}^{\infty} \hat{Y}_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} + \sum_{m=1}^{\infty} \hat{Y}_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \right. \\ & - \sum_{m=N^{(1)}+1}^{\infty} \hat{Y}_m^{(1)} \left(1 - \frac{Y_m^{(1)}}{\hat{Y}_m^{(1)}} \right) \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} \\ & \left. - \sum_{m=N^{(2)}+1}^{\infty} \hat{Y}_m^{(2)} \left(1 - \frac{Y_m^{(2)}}{\hat{Y}_m^{(2)}} \right) \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \right] \end{aligned} \quad (30)$$

With this procedure, the first two terms of (30) become static, while for the other two we can write

$$\lim_{m \rightarrow \infty} \left(1 - \frac{Y_m^{(\delta)}}{\hat{Y}_m^{(\delta)}} \right) = 0 \quad (31)$$

obtaining

$$\left(1 - \frac{\mathbf{Y}_m^{(\delta)}}{\hat{\mathbf{Y}}_m^{(\delta)}}\right) \simeq \sum_{p=1}^P B_{(2p)} \left(\frac{k_0}{k_{t,m}^{(\delta)}}\right)^{(2p)} \quad (32)$$

The expressions for the coefficient B_p can be found in Table 1.

Collecting all together, we have

$$\begin{aligned} \mathbf{K}(s, s') &= \hat{\mathbf{K}}(s, s') \\ &- \sum_{p=1}^P (k_0)^{2p} \hat{\mathbf{K}}_{2p}(s, s') \end{aligned} \quad (33)$$

where

$$\hat{\mathbf{K}}(s, s') = \sum_{m=1}^{\infty} \hat{\mathbf{Y}}_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} + \sum_{m=1}^{\infty} \hat{\mathbf{Y}}_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \quad (34)$$

$$\begin{aligned} \hat{\mathbf{K}}_p(s, s') &= \sum_{m=N^{(1)}+1}^{\infty} \frac{B_{2p}}{(k_{t,m}^{(1)})^p} \hat{\mathbf{Y}}_m^{(1)} \mathbf{h}_m^{(1)} \mathbf{h}_m^{(1)*} \\ &+ \sum_{m=N^{(2)}+1}^{\infty} \frac{B_{2p}}{(k_{t,m}^{(2)})^p} \hat{\mathbf{Y}}_m^{(2)} \mathbf{h}_m^{(2)} \mathbf{h}_m^{(2)*} \end{aligned} \quad (35)$$

The result of this manipulation is that all the summations involved in the computation of the kernel are now frequency-independent, and need be computed only once outside the frequency loop.

4.2. Arbitrary Junction

Similar to what we have done for the planar discontinuity case, we will now simplify the frequency dependence of the integral equation in (26). To do so, we first divide the first part of (19) into two series, obtaining

$$\begin{aligned} &\sum_{n=1}^{+\infty} \frac{\mathbf{h}_n^{(c)}(\mathbf{r}) \mathbf{h}_n^{(c)}(\mathbf{r}')}{k_0^2 - k_n^2} \\ &= \sum_{n=1}^{N_0} \frac{\mathbf{h}_n^{(c)}(\mathbf{r}) \mathbf{h}_n^{(c)}(\mathbf{r}')}{k_0^2 - k_n^2} + \sum_{l=0}^{L_0} (k_0)^{2l} \\ &\times \sum_{n=N_0+1}^{+\infty} \frac{a_{l,n}}{(k_n^{(2l+1)})^2} \mathbf{h}_n^{(c)}(\mathbf{r}) \mathbf{h}_n^{(c)}(\mathbf{r}') \end{aligned} \quad (36)$$

where the second part includes the Taylor expansion of

$$\frac{1}{k_0^2 - k_n^2} = \sum_{l=0}^{L_0} a_{2l,n} (k_0)^{2l} \quad (37)$$

where $a_{2l,n} = -1$ for all l .

The upper summation limit N_0 has to be chosen such that $k_{N_0} > k_{\max}$ with $k_{\max} = 2\pi f_{\max}/c_0$ when f_{\max} denotes the maximum frequency that is used in the simulation. For all $k_n > k_{N_0+1}$, the term $1/(k_0^2 - k_n^2)$ is a well-behaved function that has no poles and can therefore be expanded

Table 1. TE and TM Expansion Coefficients B_p

P	TE	TM
2	$\frac{1}{2}$	$\frac{1}{2}$
4	$\frac{1}{8}$	$\frac{3}{8}$
6	$\frac{1}{16}$	$\frac{5}{16}$
8	$\frac{5}{128}$	$\frac{35}{128}$
10	$\frac{7}{256}$	$\frac{63}{256}$

into a rapidly converging Taylor series. The second series in the Taylor expansion term of (36), namely

$$\sum_{n=N_0+1}^{+\infty} a_{l,n} \mathbf{h}_n^{(c)}(\mathbf{r}) \mathbf{h}_n^{(c)*}(\mathbf{r}') \quad (38)$$

can be summed up after applying a method of moments on (26) to solve for the unknowns $\mathcal{M}_k^{(v)}$, so that for the frequency-dependent evaluation we only need to compute the outer series over l in (36).

The remaining portion of the kernel of (26), namely $\mathbf{G}^{(\text{WG})}$, can be treated as already shown for the planar junction case.

5. METHOD OF MOMENTS SOLUTION OF THE INTEGRAL EQUATION

The integral equations in (10), (14), and (26), must be solved before the equivalent network representations can be used. This can be easily done by using the method of moments (MoM), thereby effectively reducing the solution of a field problem to the solution of a linear system [16].

Since the application of the method of moments is essentially identical in all cases, we will outline here only the case of the planar junction. The procedure begins by rewriting the kernel (10) in the form

$$\begin{aligned} &\mathbf{h}_n^{(\delta)} \\ &= \int_{\text{cs}} M_n^{(\delta)} \cdot \left[\sum_{\gamma=1}^2 \sum_{m=1}^{\text{NKER}} \hat{\mathbf{Y}}_m^{(\gamma)} \mathbf{h}_m^{(\gamma)} \mathbf{h}_m^{(\gamma)*} \right. \\ &\quad \left. - \sum_{p=1}^P (k_0)^{2p} \left(\sum_{\gamma=1}^2 \sum_{m=N^{(\gamma)}+1}^{\text{NKER}} \frac{B_{2p}}{(k_{t,m}^{(\gamma)})^{2p}} \hat{\mathbf{Y}}_m^{(\gamma)} \mathbf{h}_m^{(\gamma)} \mathbf{h}_m^{(\gamma)*} \right) \right] ds' \end{aligned} \quad (39)$$

To implement the MoM solution of the integral equation, we first expand the unknown function using as the basis function the modes of the smallest waveguide

$$\mathbf{M}_n^{(\delta)} = \sum_{i=1}^{\text{NFUN}} \alpha_{i,n}^{(\delta)} \cdot \mathbf{h}_i^{(2)} \quad (40)$$

The integral equation is then reduced to a linear system by using Galerkin's procedure, thus obtaining

$$\sigma_{n,p}^{(\delta)} = \sum_{i=1}^{\text{NFUN}} \eta_{p,i} \alpha_{i,n}^{(\delta)} \quad (41)$$

where

$$\sigma_{n,p}^{(\delta)} = \int_{\text{cs}} \mathbf{h}_n^{(\delta)} \cdot \mathbf{h}_p^{(2)*} ds \quad (42)$$

and

$$\begin{aligned} & \eta_{p,i} \\ &= \sum_{\gamma=1}^2 \sum_{m=1}^{\text{NKER}} \hat{\mathbf{Y}}_m^{(\gamma)} \sigma_{m,p}^{(\gamma)} \sigma_{m,i}^{(\gamma)} \\ & - \sum_{p=1}^P (k_0)^{2p} \left(\sum_{\gamma=1}^2 \sum_{m=N^{(\gamma)}+1}^{\text{NKER}} \frac{B_{2p}}{(k_{t,m}^{(\gamma)})^{2p}} \right) \\ & \times \hat{\mathbf{Y}}_m^{(\gamma)} \sigma_{m,p}^{(\delta)} \sigma_{i,m}^{(\delta)} \end{aligned} \quad (43)$$

The formulation described is completely general and can therefore be used for any two-dimensional waveguide step for which we can compute the coupling integrals in (42). Once the solution of the system (41) is obtained, we can easily compute the impedance matrix, obtaining

$$\mathbf{Z}_{m,n}^{(\gamma,\delta)} = \sum_{i=1}^{\text{NFUN}} \alpha_{i,n}^{(\delta)} \sigma_{m,i}^{(\gamma)} \quad (44)$$

In the solution procedure outlined, all infinite sums are truncated to a finite number of terms. The relevant parameters are NFUN and NKER. Their values affect the accuracy of the solution. For most engineering applications, sufficient accuracy is obtained with NKER=400 and NFUN = $2N^{(\delta)}$. The number of modes $N^{(\delta)}$, on the other hand, depends on how close to each other the discontinuities are located in the actual waveguide device. An important feature of this approach is that the relative number of modes (modal ratios) chosen on each side of a step in the final network representation does not affect the final result. In fact, by increasing the total number of modes, the solution converges to the same result independently from the modal ratios.

The implementation of the solution procedure just described requires the computation of the coupling integrals in (42). This calculation can be carried out very efficiently for junctions involving canonical waveguide shapes (e.g., rectangular, circular, elliptical, coaxial) for which the modes are known in analytical form. The same consideration applies to arbitrary junctions involving resonators for which modes are known in analytical form (cubic, cylindrical, etc.). The procedure outlined, however, can also be used for junctions involving arbitrarily shaped waveguides or resonators for which we can compute the required coupling integrals [17].

6. APPLICATIONS

Following our theory, the first step in the analysis of any passive waveguide component is the decomposition of the component itself into a number of "uniform waveguide sections." The junctions between all the uniform waveguide sections—namely, the discontinuities—are then analyzed and characterized in terms of the multimode impedance matrix in Fig. 2, where the elements of $\mathbf{Z}_{m,n}$ are given by the theory discussed in this article. The next step is then to represent also the sections of uniform waveguide in terms of a multimode impedance matrix whose elements are given by simple network calculations (see, e.g., Ref. 6 or 17). The global equivalent network of the passive component can then be easily assembled by interconnecting the individual multimode impedance networks. In mathematical terms, what we obtain at the end of this process is a linear system with a sparse, block coefficient matrix containing all the separate multimode impedance matrices needed to represent the device under analysis [17]. The system thus obtained can then be easily inverted and the global electrical performance computed.

It is important to note that the process just described is inherently modular and is therefore very suitable for the development of advanced full-wave electromagnetic simulation programs. In the following sections we describe a few specific applications to show the very high level of accuracy that can indeed be achieved.

6.1. Inductive Filter

Microwave filters are among the most commonly used passive microwave components for both ground and space applications. One of the simplest and most commonly used microwave filter structures is the classic inductive filter in rectangular waveguides. In this class of filters, lengths of uniform rectangular waveguides are separated by thick inductive irises. The lengths of the waveguide act as resonators, and the inductive irises couple the energy from one resonator to the other. This type of structure is ideally suited for the application of the theory described in this article [8]. Figure 7 describes the structure of a five-pole filter that has been designed using software based on the

Figure 7. Classic inductive filter in rectangular waveguide.

Figure 8. Measured and simulated performances of the inductive filter in rectangular waveguide.

theory described. Figure 8 shows a comparison between measured and simulated performances. As we can see, the agreement is indeed very good.

One important feature of this class of filters is that, using modern, high-accuracy manufacturing techniques, they can be realized without the need for any postmanufacture adjustment, or tuning, thereby greatly reducing the global cost of the filter.

6.2. Dual-Mode Inductive Filter

The next application we discuss is an inductive dual-mode filter. The difference between this structure and the previous one is that each physical cavity (a length of uniform waveguide) is used electrically 2 times. This particular feature allows for the implementation of advanced filter transfer functions that cannot be realized with the classic configuration [18]. Figure 9 shows the structure of an inductive dual-mode filter, while Fig. 10 shows the comparison between simulation and measurement.

6.3. Triple-Mode Filter

A further advancement with respect to the dual-mode filter described in the previous section is the triple-mode

Figure 10. Measured (thick) and simulated performances of the dual-mode inductive filter in rectangular waveguide.

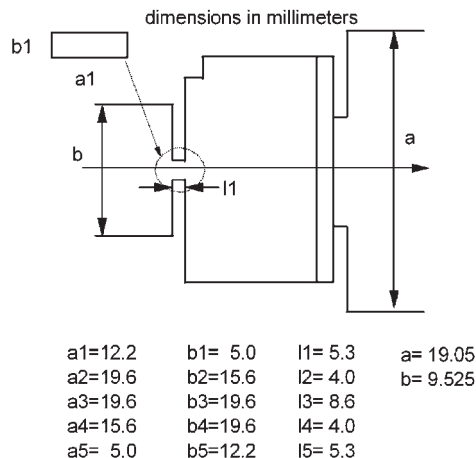

Figure 11. Longitudinal section of triple-mode filter in rectangular waveguide.

Figure 9. Dual-mode inductive filter in rectangular waveguide.

Figure 12. Simulated performance for triple-mode filter in rectangular waveguide compared with simulation from commercial finite-element software (thick).

filter. In this case, as the term *triple* indicates, the same physical cavity is used 3 times electrically. The result is an extremely compact filter that can be used to implement very selective filter transfer functions [19]. Figure 11 shows the structure of the filter, while Fig. 12 shows the comparison between the simulation based on the theory described in this article and the simulated response obtained using commercial finite-element software.

6.4. Waveguide Twist

Another type of passive microwave device that is sometimes required is the waveguide twist. A waveguide twist is needed whenever the polarization direction of a rectangular waveguide needs to be rotated. The structure shown in Fig. 13 can be effectively used to introduce a 90° rotation. Figure 14 shows a comparison between measured and simulated performances [20].

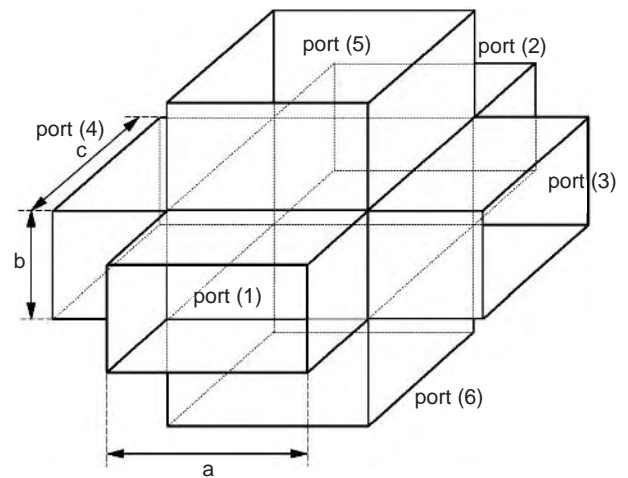

Figure 15. Cubic junction in rectangular waveguide.

Figure 16. Measured versus simulated (dotted line) performances of a cubic junction in rectangular waveguide.

Figure 17. Measured versus simulated (dotted line) performances of a cubic junction in rectangular waveguide.

6.5. Cubic Junction

All the application examples reported so far have dealt with devices composed of cascaded uniform waveguide sections requiring the analysis of planar waveguide junctions. In the article, however, we have also discussed the theory of arbitrary waveguide junctions. As a last example, therefore, we now describe the analysis of the cubic junction shown in Fig. 15. This junction is particularly useful because it can be used to build very complex devices such as diplexers and output multiplexers where two or more microwave filters are combined in a single waveguide output. The comparison between measurements and simulation for this device is shown in Figs. 16 and 17 [11]. As we can see, very good agreement between simulation and measurements has indeed been achieved.

7. CONCLUSION

The multimode equivalent network representations described in this article can be used to analyze *all* waveguide junction problems of practical interest for microwave and millimeter-wave engineering applications. The formulations presented effectively reduce complex field problems to the computation of coupling integrals between the modes of the waveguides involved in the junctions, and to the solution of simple linear systems.

The theory presented in this article has a wide application scope, is rigorous, and leads to highly efficient numerical implementations. It constitutes, therefore, a very solid theoretical foundation for the development of advanced electromagnetic simulation programs needed for the analysis and design of modern complex waveguide devices and subsystems.

Acknowledgment

The author would like to acknowledge the contributions of the many graduate and postdoctoral students who contributed to the development and validation of the formulations described in this article. In particular, the author

would like to acknowledge the efforts and dedication of Alejandro Alvarez, Vicente Boria, Giampiero Gerini, Giorgio Gheri, Benito Gimeno, Gianluca Lastoria, Michael Mattes, and Antonio Panariello.

MULTIPLE ACCESS SCHEMES

MOSHE SIDI
Technion—Israel Institute of
Technology

Communication channels are major components of computer communication networks. They provide the physical mediums over which signals representing data are transmitted from one node of the network to another node. Communication channels can be classified into two main categories: point-to-point channels and shared channels. Typically, the backbone of wide-area networks (WAN) consists of point-to-point channels, whereas local-area networks (LAN) use shared channels.

Point-to-point channels are dedicated to connecting a pair of nodes of the network. They are usually used in fixed topology networks, and their cost depends on many parameters such as distance and bandwidth. An important characteristic of these channels is that nodes do not interfere with each other; in other words, transmissions between a pair of nodes has no effect on the transmissions between another pair of nodes, even if a node is common to the two pairs.

Shared channels are used when point-to point channels are not economical or not available or when dynamic topologies are preferable. In a shared channel, called also a broadcast channel, several nodes can potentially transmit and/or receive messages at the same time. Shared channels appear naturally in radio networks, satellite networks, and some local area networks (e.g., Ethernet). Their deployment is usually easier than point-to-point channels. An important characteristic of shared channels is that transmissions of different nodes interfere with each other; specifically, one transmission coinciding in time with another may cause none of them to be received. This means that the success of transmission between a pair of nodes is no longer independent of other transmissions.

To have successful transmissions in shared channels, interference must be avoided or at least controlled. The channel allocation among the competing nodes is critical for proper operation of the network. This article focuses on access schemes to such channels known as multiple access schemes. These schemes are nothing more than channel allocation rules that determine who goes next on the channel, aiming at some desirable network performance characteristics. Multiple-access schemes belong to a sublayer of the data link layer called the medium access control layer (MAC), which is especially important in LANs.

Multiple access schemes are natural not only in communication systems but also in many other systems such as computer systems, storage facilities, or servers of any kind, where resources are shared by a number of nodes. In this article we address mainly shared communication channels.

One way to classify multiple access schemes is according to the level of contention that is allowed among the nodes of the network. On the one hand, there are the conflict-free schemes that ensures that each transmission is successful, namely, it will not be interfered with by any other transmission. On the other hand, there are the contention-based schemes that do not guarantee that a transmission will be successful, namely, it might be interfered with by another transmission.

Conflict-free transmissions can be achieved by allocating the shared channel in an adaptive or nonadaptive (static) manner. Two common static allocations are the time-division multiple access (TDMA), where the entire available bandwidth is allocated to a single node for a fraction of the time, and the frequency-division multiple access (FDMA), where a fraction of the available bandwidth is allocated to a single node for all the time. Adaptive allocations are usually based on demands so that nodes that are idle use only little of the shared channel, leaving the majority of their share to other more active nodes. Adaptive allocations can be done by various reservation schemes using either central or distributed network control. Polling algorithms illustrate central control, whereas ring networks generally use distributed control based on token-passing mechanisms. It is important to note that idle nodes consume their portion of the shared channel when conflict-free schemes are used. The aggregate channel portion of idle nodes becomes significant when the number of potential nodes in the system is very large to the extent that conflict-free schemes might become impractical.

When contention-based schemes are used, it is essential to devise algorithms that resolve conflicts when they occur, so that messages are eventually transmitted successfully. Conflict resolution algorithms can be either adaptive or nonadaptive (static). Static resolution can be deterministic using some fixed priority that is assigned to the nodes, or it can be probabilistic when the transmission schedule for interfered nodes is chosen from a fixed distribution as is done in Aloha-type schemes and the various versions of carrier-sensing multiple-access (CSMA) schemes. Adaptive resolution attempt to track the system evolution and exploit the available information. For example, resolution can be based on time of arrival, giving highest (or lowest) priority to the oldest message in the system as is done in some tree-based algorithms. Alternatively, resolution can be probabilistic but such that the statistics change dynamically according to the extent of the interference. This category includes estimating the multiplicity of the interfering nodes and the exponential backoff scheme of the Ethernet standard. Note that when the population of potential nodes in the system increases beyond a certain amount and conflict-free schemes are useless, contention-based protocols are the only possible solution.

The goal of this article is to survey typical examples of multiple access schemes. These examples include TDMA, FDMA, Aloha, polling, and tree-based schemes. The allocated space for the topic of multiple access schemes in the encyclopedia (which is yet another shared resource) is just too tiny to include all the ingenious multiple access schemes that have been designed by researchers over the years. Interested readers should refer to books on the subject (e.g., Rom and Sidi [23], Hammond and O'Reilly [22], and to the international journals that have published papers on the subject).

1. BASIC MODEL

When multiple-access schemes are devised, a collection of nodes that communicate with each other or with a central node via a single shared channel is considered. In general, the ability of a node to hear the transmission of another node depends on the transmission power used, on the distance between the two nodes, and on the sensitivity of the receiver at the receiving node. We assume single-hop topologies in which all nodes hear one another, and whenever messages are transmitted successfully they arrive at their destinations.

The shared channel is the medium through which data are transferred from their sources to their destinations. The total transmission rate possible in the channel is C bits/s. We consider an errorless collision channel. Collision is a situation in which, at the receiver, two or more transmissions overlap in time wholly or partially. A collision channel is one in which all the colliding transmissions are not received correctly and must be retransmitted until they are received correctly. We assume that nodes can detect collisions. The channel is errorless in the sense that a single transmission heard at a node always received correctly. Other possible channels include the noisy channel in which errors may occur even if only a single transmission is heard at a node; furthermore, the channel may be such that errors between successive transmissions are not independent. Another channel type is the capture channel in which one or more of the colliding transmissions captures the receiver and can be received correctly. Yet another case is a channel in which coding is used so that even if transmissions collide the receiver can still decode some or all of the transmitted information.

The basic unit of data generated by a node is a message. It is possible, though, that because of its length, a message cannot be transmitted in a single transmission and must therefore be broken into smaller units called packets, each of which can be transmitted in a single channel access. A message consists of an integral number of packets, although the number of packets in a message can vary randomly. Packet size is measured by the time required to transmit the packet after access to the channel has been granted. Typically, all packets are of equal size, say, L bits.

The number of nodes that share the channel is denoted by M . When M becomes very large, the population of nodes is referred to as infinite population. Only contention-based schemes can cope with an infinite node population. The aggregate arrival process of new packets is assumed to be

Poisson with rate Λ packets/s. When the population is finite, the arrival rate to each node is $\lambda = \Lambda/M$ packets/s.

Nodes are generally not assumed to be synchronized and are capable of accessing and transmitting their messages on the shared channel at any time. Another important class of systems is that of slotted systems in which there is a global clock that marks discrete intervals of time called slots whose length is usually the time required to transmit a packet (i.e., $T=L/C$ s). In these systems, transmissions of packets start only at slot starts. The slot length is therefore $T=L/C$ s. Other operations, such as determining activities on the channel, can be done at any time.

In some models, nodes can tell if the shared channel is in use before trying to use it. If the channel is sensed as busy, no node will attempt to use it until it goes idle in order to reduce interference. Naturally, additional hardware is required at each node to implement the sensing ability. In other models, nodes cannot sense the channel before trying to use it. They just go ahead and transmit according to their access scheme. Only later can they determine whether the transmission was successful via the feedback mechanism. Feedback in general is the information available to the nodes regarding activities on the shared channel at prior times. This information can be obtained by listening to the channel, or by explicit acknowledgment messages sent by the receiving node. For every scheme, there exist some instants of time (typically slot boundaries or end of transmissions) in which feedback information is available. Common feedback information indicates whether a message was successfully transmitted or a collision took place or the channel was idle. Feedback mechanisms do not consume the shared channel sources because they usually use a different channel or are able to determine the feedback locally. Other feedback variations include indication of the exact or the estimated number of colliding transmission, or providing uncertain feedback (e.g., in the case of a noisy channel).

The important performance measures of multiple-access schemes are their throughput and delay. The throughput of the channel is the aggregate average amount of data that is transported successfully through the channel in a unit of time. The throughput equals the fraction of time in which the channel is engaged in the successful transmission of node data and will be denoted by S , and it is obvious that $S \leq 1$. In conflict-free access schemes, the throughput is also the total or offered load on the shared channel. However, in contention-based access schemes, the offered load on the shared channel includes transmissions of new packets as well as retransmissions of packets that collide with each other. The offered load is denoted by g (measured in packets per second) and, obviously, $g \geq \Lambda$. The normalized offered load [i.e., the rate (per packet transmission time) packets are transmitted on the channel] is denoted by $G = g \cdot T$ and, obviously, $G \geq S$.

Delay is the time from the moment a message is generated until it arrives successfully across the shared channel. Here one must distinguish between the node and the system measures because it is possible that the average delay measured for the entire system does not necessarily reflect the average delay experienced by any of the nodes.

In “fair” or homogeneous systems, we expect these to be almost identical. The average delay is denoted by D seconds, and its normalized version, grouped into units of packet transmission times, is denoted by \mathcal{D} (i.e., $\mathcal{D} = D/T = D \cdot C/L$).

Another important performance criterion is system stability. Unfortunately, some schemes’ characteristics may be such that some message generation rates, even smaller than the maximal transmission rate in the channel, cannot be sustained by the system for a long time. Evaluation of those input rates for which the system remains stable is therefore essential.

1.1. Ideal Access Scheme

Before introducing the various multiple-access schemes, let us consider an ideal scheme to use the shared channel. Ideally, transfer of the channel from one node to another can be accomplished instantaneously, without cost. Furthermore, whenever a node has data to transmit, some ingenious central controller knows this instantaneously and assigns the channel to that node in case the channel is idle. If the channel is busy, packets that arrive at the nodes are queued. For our purposes, the order in which packets of different nodes are served is not important. The performance of the ideal scheme serves as a bound to what can be expected from any practical access scheme.

The way the ideal scheme operates is identical to the operation of a single queue that is served by a single server, because packets do not interfere and because no time is wasted in transferring the channel use from one node to another. Because arrivals of new packets are according to a Poisson process and time is slotted, the performance of the ideal scheme is that of an $M/D/1$ queue. The throughput of an $M/D/1$ queue is just the utilization factor of the server as long as $S < 1$ (the stability condition), and it equals the offered load, in other words

$$S = G = \lambda T = \frac{\lambda \cdot M \cdot L}{C} \tag{1}$$

The normalized average delay of an $M/D/1$ queue is given by (as long as $S < 1$)

$$\mathcal{D} = 1 + \frac{S}{2(1 - S)} = \frac{2 - S}{2(1 - S)} \tag{2}$$

The Unit in the expression \mathcal{D} is the normalized transmission time of a packet, whereas $S/[2(1 - S)]$ is the normalized waiting time of a packet until being transmitted.

No access scheme can achieve throughput higher than S given in Eq. (1), and no access scheme can provide normalized average delays lower than \mathcal{D} given in Eq. (2). These quantities will serve as yardsticks in the sequel.

2. CONFLICT-FREE SCHEMES

Conflict-free schemes are designed to ensure that a transmission, whenever made, is not interfered with by any other transmission and is therefore successful. This is achieved by allocating the channel to the nodes without

any overlap between the portions of the channel allocated to different nodes. An important advantage of conflict-free access protocols in the ability to ensure fairness among nodes and the ability to control the packet delay—a feature that may be essential in real-time applications.

We consider both fixed-assignment schemes and dynamic schemes that guarantee no conflicts. In fixed-assignment schemes the channel allocation is predetermined (typically at network design time) and is independent of the demands of the nodes in the network. The most well-known fixed-assignment schemes are the frequency-division multiple access and the time-division multiple access. For both FDMA and TDMA, no overhead, in the form of control messages, is incurred. However, because of the static and fixed assignment, parts of the channel might be idle even though some nodes have data to transmit. Dynamic channel allocation schemes attempt to overcome this drawback by changing the channel allocation based on the current demands of the nodes. These schemes use some kind of reservation strategies based on either centralized or distributed polling.

2.1. Fixed Assignment

Both FDMA and TDMA are the oldest and most understood access schemes, widely used in practice. They are the most common implementation of fixed-assignment schemes.

With FDMA the entire available frequency band is divided into bands, each of which is used by a single node. Every node is therefore equipped with a transmitter for a given, predetermined frequency band and a receiver for each band (which can be implemented as a single receiver for the entire range with a bank of bandpass filters for the individual bands). With TDMA the time axis is divided into timeslots, preassigned to the different nodes. Every node is allowed to transmit freely during the slot assigned to it; that is, during the assigned slot the entire shared channel is devoted to that node. The slot assignments follow a predetermined pattern that repeats itself periodically; each such period is called a frame. In most TDMA implementations, every node has exactly one slot in every frame.

The main advantage of both FDMA and TDMA is that each transmission is guaranteed to be successful and no control messages are required. An additional advantage of FDMA is its simplicity—it does not require any coordination or synchronization among the nodes because each can use its own frequency band without interference. However, both FDMA and TDMA are wasteful, especially when the load is momentarily uneven, because when one node is idle, its share of the channel cannot be used by other nodes. Another drawback of FDMA and TDMA is that they are not flexible; adding a new node to the network requires equipment or software modification in every other node. In addition, both waste some portion of the channel to ensure no overlap (either in time or in bandwidth) in the transmissions of different nodes. FDMA uses guardbands between the subchannels, and TDMA uses guard times to separate the nodes.

Neglecting the channel waste resulting from guardbands or times, the throughput of FDMA and TDMA is

identical to that of the idealized schemes, because packets are never transmitted more than once. Therefore, we have for both

$$S = G = \Lambda T = \frac{\lambda \cdot M \cdot L}{C}$$

The delay characteristics of FDMA and TDMA are different. With FDMA the transmission rate of each node is C/M bps; therefore, the time to transmit a packet is $M \cdot L/C$ seconds. Each node can be modeled as an $M/D/1$ queue with arrival rate $\lambda = \Lambda/M$ and service time $M \cdot L/C$. The normalized average delay is therefore

$$\mathcal{D} = M \left[1 + \frac{S}{2(1-S)} \right] = M \frac{2-S}{2(1-S)}$$

which is M times larger than the normalized average delay of the ideal scheme.

With TDMA the transmission rate of each node is C bps, and the time to transmit a packet is L/C seconds. Each node can be modeled as an $M/D/1$ queue with arrival rate $\lambda = \Lambda/M$, but service is granted to the node only once a frame, namely every $M \cdot L/C$ seconds. The normalized average delay is therefore

$$\mathcal{D} = 1 + \frac{M}{2(1-S)}$$

Comparing the throughput delay characteristics of FDMA and TDMA, we note that

$$\mathcal{D}_{\text{FDMA}} = \mathcal{D}_{\text{TDMA}} + \frac{M}{2} - 1$$

We thus conclude that for any reasonable parameters, the TDMA-normalized average delay is always less than that of FDMA and the difference grows linearly with the number of nodes and is independent of the load. The difference stems from the fact that the actual transmission of a packet in TDMA takes only a single slot, whereas in FDMA it lasts the equivalent of an entire frame. This difference is somewhat offset by the fact that a packet arriving at an empty node may need to wait until the proper slot when a TDMA scheme is employed, whereas in FDMA transmission starts right away. It must be remembered, though, that at high throughput the dominant factor in the normalized average delay is inversely proportional to $(1-S)$ in both TDMA and FDMA; therefore, the ratio of the normalized average delays between the two schemes approaches unity when the load increases. Figure 1 depicts the delay throughput characteristics for TDMA and FDMA and the ideal access scheme for 50 users.

2.1.1. Further Reading. Many texts treating FDMA and TDMA are available [e.g.1,2] A good analysis of TDMA and FDMA can be found in Ref. 3. A sample path comparison between FDMA and TDMA schemes is carried out in Ref. 4 where it is shown that TDMA is better than FDMA not just on the average. A TDMA scheme in which the packets of each node are serviced according to a priority

Figure 1. TDMA and FDMA performance.

rule is analyzed by De Moraes and Rubin [5]. The question of optimal allocation of slots to the nodes in generalized TDMA (in which a node can have more than one slot in a frame) is addressed in Itai and Rosberg [6], where the throughput of the network is maximized (assuming single buffers for each node), Hofri and Rosberg [7] where the expected packet delay in the network is minimized. Message delay (as opposed to packet delay) for generalized TDMA is analyzed by Rom and Sidi [8].

2.2. Dynamic Assignment

Static conflict-free protocols such as FDMA and TDMA schemes do not use the shared channel very efficiently, especially when the network is lightly loaded or when the loads of different nodes are asymmetric. The static and fixed assignment in these schemes cause portions of the channel to remain idle even though some nodes have data to transmit. Dynamic channel allocation schemes are designed to overcome this drawback. With dynamic allocation strategies, the channel allocation changes with time and is based on current (and possibly changing) demands of the various nodes. The better and more responsive use of the shared channel achieved with dynamic schemes does not come for free; it requires control overhead that is unnecessary with fixed-assignment schemes and consumes a portion of the channel.

To ensure conflict-free operation, it is necessary to reach an agreement among the nodes on who transmits in a given slot. This agreement entails collecting information as to which nodes have packets to transmit and an arbitration scheme that selects one of these nodes to transmit in the slot. Both the information collection and the arbitration can be achieved using centralized control or distributed control.

A representation example of schemes that use centralized control are polling schemes. The basic feature of polling schemes is the operation of a central controller that polls the nodes of the network in some predetermined

order (the most common is round-robin) to provide access to the shared channel. When a node is polled and has packets to transmit, it uses the whole shared channel to transmit its backlogged packets. With an exhaustive policy, the node empties its backlog completely, whereas with a gated policy it transmits only those packets that reside in its queue on the polling instant. The last transmitted packet contains an indication that the central controller can poll the next node. If a polled node does not have packets to transmit, the next node is polled. In between polls, nodes accumulate the arriving packets in their queues and do not transmit until polled.

The control overhead of polling schemes is a result of the time required to switch from one node to the next. The switching time, denoted by w , includes all the time necessary to transfer the poll (channel propagation delay, transmission time of polling and response packets, etc.). We let $\hat{w} = w/T$ denote the normalized switching time.

The throughput of a polling scheme is identical to that of an ideal scheme and is given by Eq. (1). The normalized average delay is given by

$$\mathcal{D} = 1 + \frac{S}{2(1-S)} + \frac{M\hat{w}(1-S/M)}{2(1-S)}$$

We note that the first two terms are just the normalized average delay of the ideal scheme and the third term reflects the overhead resulting from the switching times from one node to the next.

As an example of a distributed dynamic conflict-free scheme, we use the minislotted alternating priority (MSAP) scheme [9]. The MSAP scheme allows the nodes to determine in a distributed manner the order in which they'll use the shared channel, assuming the nodes are ordered according to some priority rule. Either the priority rule can be static or it can change in a round-robin manner in each slot.

MSAP is based on distributed reservations. To describe its operation, we need to define the slot structure. Let τ (seconds) denote the maximum system propagation delay, that is, the longest time it takes for a signal emitted at one end of the network to reach the other end. The quantity τ plays a crucial role in multiple-access schemes. Its normalized version is denoted by $a = \tau/T$. Let every slot consist of initial $M - 1$ reservation minislots, each of duration T , followed by another minislot. Only those nodes wishing to transmit in a slot take any action: a node that does not wish to transmit in a given slot remains quiet for the entire slot duration. Given that every node wishing to transmit knows its own priority, they behave as follows. If the node of the highest priority wishes to transmit in this slot, then it starts immediately. Its transmission consists of an unmodulated carrier for a duration of $M - 1$ minislots followed by a packet of duration T . A node of the i th priority ($2 \leq i \leq M$) wishing to transmit in this slot will do so only if the first $i - 1$ minislots are idle. In this case, it will transmit $M - i$ minislots of unmodulated carrier followed by a packet of duration T . The specific choice of the minislot duration ensures that when a given node transmits in a minislot all other nodes know it by the end of that minislot

allowing them to react appropriately. The additional minislot at the end allows the data signals to reach every node of the network. This is needed to ensure that all start synchronized in the next slot, as required by the reservation scheme.

The fraction of slots in which transmissions take place is ΛT . Because a fraction of $M\tau/(T + M\tau)$ of every slot is overhead, we conclude that the throughput of this scheme is

$$S = \Lambda T \frac{T}{T + M\tau} = \Lambda T \frac{1}{1 + Ma}$$

The normalized average delay is obtained by using standard analysis of priority queues, and it is given by

$$\mathcal{D} = (1 + Ma) \left\{ 1 + \frac{1}{2[1 - (1 + Ma)S]} \right\}$$

Figure 2 depicts the delay-throughput characteristics for the dynamic access schemes for 50 users.

2.2.1. Further Reading. The variants of polling schemes are numerous. Reference 10 contains the analysis of most of the basic schemes with a long list of reference that is complemented in Ref. 11. In Ref. 12 more advanced schemes are described along with some optimization considerations in the operations of polling schemes, such as the determination of the poll order of the nodes.

The MSAP scheme described previously represents an entire family of schemes that guarantees conflict-free transmissions using distributed reservation. All these schemes have a sequence of preceding bits serving to reserve or announce upcoming transmissions (this is known as the reservation preamble). In MSAP there are $M - 1$ such bits for every transmitted packet. An improvement to the MSAP scheme is the bit-map protocol described by Tanenbaum [13]. The idea is to use a single reservation preamble to schedule more than a single transmission;

Figure 2. Dynamic access.

using the fact that all participating nodes are aware of the reservations made in the preamble. The bit-map scheme requires synchronization among the nodes that is somewhat more sophisticated than the MSAP scheme, but the overhead paid per transmitted packet is less than the overhead for MSAP. Another variation of a reservation scheme has been described by Roberts [14]. There, every node can make a reservation in every minislot of the reservation preamble, and if the reservation remains uncontested, that reserving node will transmit. If there is a collision in the reservation minislot, all nodes but the "owner" of that minislot will abstain from transmission. Altogether, this is a standard TDMA with idle slots made available to be grabbed by others. Several additional reservation and TDMA schemes are also analyzed by Rubin [4]. One of the most efficient reservation schemes is the broadcast recognition access method (BRAM) [15]. This is essentially a combination between the bit-map and the MSAP schemes. As with MSAP, a reservation preamble serves to reserve the channel for a single node, but unlike the MSAP, the reservation preamble does not necessarily contain all $M-1$ minislots. The idea is that nodes start their transmission with a staggered delay not before they ensure that another transmission is not ongoing (Kleinrock and Scholl [9] also refer to a similar scheme). Under heavy load BRAM reduced to regular TDMA.

3. CONTENTION-BASED SCHEMES

With the conflict-free schemes discussed earlier, every scheduled transmission is guaranteed to succeed. With contention-based schemes success of a transmission is not guaranteed in advance because whenever two or more nodes are transmitting on the shared channel simultaneously, a collision occurs and the data cannot be received correctly. This being the case, packets may have to be transmitted and retransmitted until eventually they are correctly received. Transmission scheduling is therefore the focal concern of contention-based schemes.

3.1. Pure and Slotted Aloha

The Aloha family of schemes is probably the richest family of multiple-access protocols. First of all, its popularity is the result of seniority because it was the first contention-based scheme introduced [16]. Second, many of these schemes are so simple that their implementation is straightforward. Many local-area networks of today implement some sophisticated variants of this family of schemes.

The pure Aloha scheme is the basic scheme in the family and it is very simple [16]. It states that a newly generated packet is transmitted immediately on generation, hoping for no interference by others. If two or more nodes transmit so that their packets overlap (even partially) in time, interference results, and the transmissions are unsuccessful. In this case every colliding node, independently of the others, schedules its retransmission to a random time in the future. This randomness is required to ensure that the same set of packets does not continue to collide indefinitely.

The Aloha scheme is very well suited to bursty traffic because a node does not hold the shared channel when it has no packets to transmit. The drawback of this scheme is that network performance deteriorates significantly as a result of excessive collisions at medium and high traffic intensities. The Aloha scheme is a completely distributed scheme that allows every node to operate independently of the others.

The exact characterization of the offered load to the channel for the pure Aloha scheme is extremely complicated. To overcome this complexity, it is standard to assume that the offered load forms a Poisson process (with rate g , of course). This flawed assumption is an approximation (as has been shown by simulation) that simplifies the analysis of Aloha-type schemes considerably and provides some initial intuitive understanding of the ALOHA scheme. Consider a packet (new or retransmitted) whose transmission starts at time t . This packet will be successful if no other packet is transmitted in the interval $(t - T, t + T)$ (this period of duration $2T$ is called the vulnerable period). The probability of this happening, that is, the probability of success P_s is the probability that no packet is transmitted in an interval of length $2T$. Because the transmission points correspond to a Poisson process, we have

$$P_s = e^{-2gT}$$

Now, packets are scheduled at a rate of g per second, of which only a fraction P_s are successful. Thus, the rate of successfully transmitted packets is gP_s . When a packet is successful, the channel carries useful information for a period of T seconds; in any other case, it carries no useful information at all. Because the throughput is the fraction of time that useful information is carried on the shared channel, we have

$$S = gTe^{-2gT} = Ge^{-2G}$$

This relation between S and G is typical to many Aloha-type schemes. For small values of G (light load), the throughput is approximately the offered load. For large values of G (heavy load), the throughput decreases rapidly because of excessive amount of collisions. For pure Aloha we note that for $G = \frac{1}{2}$, S takes on its maximal value of $1/2e \approx 0.18$. This value is referred to as the capacity of the pure Aloha channel. Figure 3 depicts the load throughput characteristics for the Aloha-type schemes.

We recall that for a system to be stable the long-term rate of input must equal the long-term rate of output meaning that stability requires $S = \Lambda T$. Larger values of Λ clearly cannot result in stable operation. Note, however, that even for smaller values of Λ there are two values of G to which it corresponds—one larger and one smaller than $\frac{1}{2}$. The smaller one is (conditionally) stable, whereas the other one is conditionally unstable, meaning that if the offered load increases beyond that point the system will continue to drift to higher load and lower throughput. Thus, without additional measures of control, the stable throughput of pure Aloha is 0 [17]. It is appropriate to note

Figure 3. Throughput of Aloha and slotted Aloha.

that this theoretical instability is rarely a severe problem in real systems, where the long-term load, including, of course, the “off-hours” load, is fairly small, although temporary problems may occur.

The delay characteristic of the Aloha scheme can be approximated as follows. For each packet, the average number of transmission attempts until the packet is transmitted successfully is $G/S = e^{2G}$. Thus, the average number of unsuccessful transmission attempts is $G/S - 1 = e^{2G} - 1$. If a collision occurs, the node reschedules the colliding packet for some random time in the future. Let the average rescheduling time be B (seconds). Each successful transmission attempt requires T seconds and each unsuccessful transmission attempt requires $T + B$ seconds on the average. Therefore, the average delay is given by

$$\begin{aligned}
 D &= T + (G/S - 1)(T + B) \\
 &= T + (e^{2G} - 1)(T + B)
 \end{aligned}
 \tag{3}$$

and in a normalized form

$$\mathcal{D} = 1 + (e^{2G} - 1)(1 + B/T)$$

With pure Aloha, even if the overlap in time between two transmitted packets is very tiny, both packets are destroyed. The slotted Aloha variation overcomes this drawback, and it is simply pure Aloha with a slotted channel. Thus, two (or more) packets can either overlap completely or do not overlap at all, and the vulnerable period is reduced to a single slot. In other words, a slot will be successful if and only if exactly one packet is transmitted in that slot. Therefore

$$S = gTe^{-gT} = Ge^{-G}$$

This relation is very similar to that of pure Aloha, except of increased throughput. Channel capacity is $1/e \approx 0.36$

and is achieved at $G = 1$. These results were first derived by Roberts [14]. Similar to the pure Aloha scheme, the normalized average delay for the slotted Aloha scheme is

$$\mathcal{D} = 1 + (e^G - 1)(1 + B/T)$$

3.2. Carrier-Sensing Protocols

The Aloha schemes exhibit fairly poor performance, which can be attributed to the “impolite” behavior of the nodes, namely, whenever one has a packet to transmit it does so without consideration of others. It is clear that in a shared environment even little consideration can benefit all. Consider a listen-be-fore-talk behavior wherein every node, before attempting any transmission, listens whether somebody else is already using the channel. If this is the case, the node will refrain from transmission to the benefit of all; its packet will clearly not be successful if transmitted; furthermore, disturbing another node will cause the currently transmitted packet to be retransmitted, possibly disturbing yet another packet.

The process of listening to the shared channel is not that demanding. Every node is equipped with a receiver anyway, and every node can monitor the channel because it is shared. Moreover, to detect another node’s transmission does not require receiving the information; it suffices to sense the carrier that is present when signals are transmitted. The carrier-sensing family of schemes is characterized by sensing the carrier and deciding according to it whether another transmission is ongoing.

Carrier sensing does not yield conflict-free operation. Suppose that the channel has been idle for a while and that two nodes concurrently generate a packet. Each will sense the channel, discover that it is idle, and transmit the packet to result in a collision. “Concurrently” here does not really mean at the very same time; if one node starts transmitting it takes some time for the signal to propagate and arrive at the other node. Hence concurrently actually means within a time window of duration equal to signal propagation time. The maximum propagation time in the network is τ , and its normalized version is a , an important parameter that affects the performance of carrier sensing schemes. The larger this quantity is, collisions are more likely and the performance becomes worse.

All the carrier sensing multiple access schemes share the same philosophy: when a node generates a new packet, the channel is sensed, and if found idle the packet is transmitted without further ado. When a collision takes place, every transmitting node reschedules a retransmission of the collided packet to some other time in the future (chosen with some randomization to avoid repeated collisions) at which time the same operation is repeated. The variations on the CSMA scheme are caused by the behavior of nodes that wish to transmit and find (by sensing) the channel busy. Most of the basic variations were introduced and analyzed by Kleinrock and Tobagi [18–20].

In the nonpersistent versions of CSMA (NP-CSMA) a node that generated a packet and found the channel busy refrains from transmitting the packet and behaves exactly as if its packet collided [i.e., it schedules (randomly) the

retransmission of the packet to some time in the future]. With NP-CSMA, there are situations in which the channel is idle although one or more nodes have packets to transmit. The 1-persistent CSMA (1P-CSMA) is an alternative to NP-CSMA because it avoids such situations by being a bit more greedy. This is achieved by applying the following rule. A node that senses the channel and finds it busy persists to wait and transmits as soon as the channel becomes idle. Consequently, the channel is always used if there is a node with a packet. With the 1-persistent scheme, a collision may occur not only because of nonzero propagation delays but also when two nodes become ready to transmit in the middle of another node's transmission. In this case, both nodes will wait until that transmission ends and will begin transmission simultaneously, resulting in a collision.

For slotted operation, CSMA schemes use time slot of duration τ seconds, which is usually much smaller than the slot size of duration T seconds, used with slotted Aloha. However, like slotted Aloha, all nodes using slotted CSMA schemes are forced to start transmission at the beginning of a slot.

Beside the ability to sense the carrier, some local-area networks (such as Ethernet) have an additional feature, namely, that nodes can detect interference among several transmissions (including their own) while transmission is in progress and abort transmission of their collided packets. If this can be done sufficiently fast, then the duration of an unsuccessful transmission would be shorter than that of a successful one, thus improving the performance of the scheme. Together with carrier sensing, this produces a variation of CSMA that is known as CSMA/CD (carrier sensing multiple access with collision detection). The operation of all CSMA/CD schemes is identical to the operation of the corresponding CSMA schemes, except that if a collision is detected during transmission, the transmission is aborted and the packet is scheduled for transmission at some later time. For Ethernet networks this random delay is doubled (at most 16 times) each time the packet collides—a scheme known as binary exponential backoff. To ensure that all network nodes indeed detect a collision when it occurs, a consensus reinforcement procedure is used. This procedure is manifested by jamming the channel with a collision signal for a duration of τ_{cr} seconds, which is usually much larger than the time necessary to detect a collision. We let $\gamma = \tau_{cr}/\tau$.

The analysis of the throughput of CSMA schemes is rather complicated. It is based on computations of average lengths of idle and transmission periods. For NP-CSMA, we have

$$S = \frac{gTe^{-g\tau}}{g(T + 2\pi) + e^{-g\tau}} = \frac{Ge^{-aG}}{G(1 + 2a) + e^{-aG}}$$

For slotted NP-CSMA, we have

$$S = \frac{aGe^{-aG}}{1 - e^{-aG} + a}$$

For 1P-CSMA, we have

$$S = \frac{gTe^{-g(T+2\tau)}[1 + gT + g\tau(1 + gT + g\tau/2)]}{g(T + 2\tau) - (1 - e^{-g\tau}) + 1 + g\tau e^{-gT + \tau}}$$

$$= \frac{Ge^{-G(1+2a)}[1 + G + aG(1 + G + aG/2)]}{G(1 + 2a) - (1 - e^{-aG}) + (1 + aG)e^{-G(1+a)}}$$

For slotted 1P-CSMA, we have

$$S = \frac{Ge^{-G(1+2a)(1+a-e^{-aG})}}{(1+a)(1 - e^{-aG}) + ae^{-G(1+a)}}$$

For nonpersistent CSMA/CD, we have

$$S = \frac{Ge^{-aG}}{Ge^{-aG} + \gamma aG(1 - e^{-aG}) + 2aG(1 - e^{-aG}) + 2 - e^{-aG}}$$

For slotted nonpersistent CSMA/CD, we have

$$S = \frac{Ge^{-aG}}{Ge^{-aG} + \gamma aG(1 - e^{-aG} - aGe^{-aG}) + (2 - e^{-aG} - aGe^{-aG})}$$

Figure 4 depicts the load throughput characteristics for the CSMA-type schemes.

3.2.1. Further Reading. Numerous variations on the environment under which the Aloha and CSMA schemes operate have been addressed in the literature (see, e.g., Refs. 3, 13, and 21–23). For instance, various packet length distributions were considered by Abramson [24] and Ferguson [25] for Aloha and by Tobagi and Hunt [26] and for CSMA.

The assumption that, whenever two or more packets overlap at the receiver, all packets are lost is overly pessimistic. In radio networks the receiver might correctly receive a packet despite the fact that it is time overlapping

Figure 4. Throughput of CSMA versions.

with other transmitted packets. This phenomenon is known as capture and it can happen as a result of various characteristics of radio systems. Most studies [27,28] considered power capture (the phenomenon whereby the strongest of several transmitted signals is correctly received at the receiver). Thus, if a single high-powered packet is transmitted, then it is correctly received regardless of other transmissions. Hence, channel use increases.

Reservation schemes that allow contentions are designed to have the advantages of both the Aloha and the TDMA approaches. Examples of reservation schemes appear in Ref. 29, where the knowledge of the number of users is needed, or in Refs. 14 and 30, where they do not require this knowledge. Approximate analysis of a reservation Aloha protocol can be found in Lam [31].

Approximate analysis of the delay was presented by Ferguson [32] for Aloha and by Beurman and Coyle [33] for CSMA schemes. Instability issues of the Aloha protocol were first identified by Carleial and Hellman [34] and Lam and Kleinrock [35]. Later, similar issues were identified for the CSMA family of protocols by Tobagi and Kleinrock [20].

4. COLLISION RESOLUTION SCHEMES

The original Aloha scheme and its CSMA derivatives are inherently unstable in the absence of some external control. Looking into the philosophy behind the schemes, it is obvious that there is no sincere attempts to resolve collisions among packets as soon as they occur. Instead, the attempts to resolve collisions are always deferred to the future, with the hope that things will then work out, somehow, but they never do.

Another type of contention-based schemes with a different philosophy are collision resolution schemes (CRSs). In these schemes the efforts are concentrated on resolving collisions as soon as they occur. Moreover, in most versions of these schemes, new packets that arrive to the network are inhibited from being transmitted while the resolutions of collisions is in progress. This ensures that if the rate of arrival of new packets to the system is smaller than the rate at which collisions can be resolved (the maximal rate of departing packets—throughput), then the system is stable. The basic idea behind these schemes is to exploit in a more sophisticated manner the feedback information that is available to the nodes in order to control the retransmission process so that collisions are resolved more efficiently.

The most basic collision resolution scheme is called the binary-tree CRS (or binary-tree scheme) and was proposed by Capetanakis [36], Hayes [37], and Tsybakov and Mikhailov [38]. According to this schemes, when a collision occurs, in slot k , say, all nodes that are not involved in the collision wait until the collision is resolved. The nodes involved in the collision split randomly into two subsets, by (for instance) each flipping a coin. The nodes in the first subset, those that flopped 0, retransmit in slot $k+1$, whereas those that flipped 1 wait until all those that flipped 0 transmit their packets successfully. If slot $k+1$ is either idle or contains a successful transmission, the

nodes of the second subset (those that flipped 1) retransmit in slot $k+2$. If slot $k+1$ contains another collision, then the procedure is repeated (i.e., the nodes whose packets collided in slot $k+1$ flip a coin again and operate according to the outcome of the coin flipping, and so on). A node having a packet that collided (at least once) is backlogged.

The operation of the scheme can also be described by a binary tree in which every vertex corresponds to a time-slot. The root of the tree corresponds to the slot of the original collision. Each vertex of the tree also designates a subset (perhaps empty) of backlogged nodes. Vertices whose subsets contain at least two nodes indicate collisions and have two outgoing branches, corresponding to the splitting of the subset into two new subsets. Vertices corresponding to empty subsets or subsets containing one node are leaves of the tree and indicate an idle slot and a successful slot, respectively. For instance, consider a collision that occurs in slot 1. At this point it is neither known how many nodes nor who are the nodes that collided in this slot. Each of the colliding nodes flip a coin, and those that flipped 0 transmit in slot 2. By the rules of the scheme, no newly arrived packet is transmitted while the resolution of a collision is in progress, so that only nodes that collided in slot 1 and flipped 0 transmit in slot 2. Another collision occurs in slot 2, and the nodes involved in that collision flip a coin again. In this example, all the colliding nodes of slot 2 flipped 1 and therefore slot 3 is idle. The nodes that flipped 1 in slot 2 transmit again in slot 4, resulting in another collision and forcing the nodes involved in it to flip a coin once more. One node flips 0 and transmits (successfully) in slot 5, causing all nodes that flipped 1 in slot 4 to transmit in slot 6. In this example, there is one such node, and therefore slot 6 is a successful one. Now that the collision among all nodes that flipped 0 in slot 1 has been resolved, the nodes that flipped 1 in that slot transmit (in slot 7). Another collision occurs, and the nodes involved in it flip a coin. Another collision is observed in slot 8, meaning that at least two nodes flipped 0 in slot 7. The nodes that collided in slot 8 flip a coin and, as it happens, there is a single node that flipped 0, and it transmits (successfully) in slot 9. Then, in slot 10, transmit the nodes that flipped 1 in slot 8. There is only one such node, and its transmission is, of course, successful. Finally, the nodes that flipped 1 in slot 7 must transmit in slot 11. In this example, there is no such node; hence slot 11 is idle, completing the resolution of the collision that occurred in slot 7 and, at the same time, the one in the first slot.

It is clear from this example that each node, including those that are not involved in the collision, can construct the binary tree by following the feedback signals corresponding to each slot, thus knowing exactly when the collision is resolved. A collision is resolved when the nodes of the network know that all packets involved in the collision have been transmitted successfully. The time interval starting with the original collision (if any) and ending when this collision is resolved is called collision resolution interval (CRI). In the preceding example the length of the CRI is 11 slots.

The binary-tree protocol dictates how to resolve collisions after they occur. To complete the description of the

protocol, one must specify when newly generated packets are transmitted for the first time. One alternative, which is assumed all along (known as the obvious-access scheme), is that new packets are inhibited from being transmitted while a resolution of a collision is in progress. That is, packets that arrive to the system while a resolution of a collision is in progress, wait until the collision is resolved, at which time they are transmitted. In the example above all new packets arriving to the system during slots 1 through 11 are transmitted for the first time in slot 12.

Let L_n be the expected length of a CRI that starts with the transmission of n packets. From the operation of the scheme, it is clear that as long as the arrival rate of new packets into the system is smaller than the ratio n/L_n (for large n), the system is stable. When fair coins are used for splitting the users upon collisions, one can show that for every n

$$L_n \leq 2.886n + 1$$

yielding stable system for arrival rates that are smaller than 0.346.

The performance of the binary-tree protocol can be improved in two ways. The first is to speed up the collision resolution process by avoiding certain, avoidable, collisions. The second is based on the observation that collisions among a small number of packets are resolved more efficiently than collisions among a large number of packets. Therefore, if most CRIs start with a small number of packets, the performance of the protocol is expected to improve.

Consider again the example above. In slots 2 and 3 a collision is followed by an idle slot. This implies that in slot 2 all users (and there were at least two of them) flipped 1. The binary-tree protocol dictates that these users must transmit in slot 4, although it is obvious that this will generate a collision than can be avoided. The modified binary-tree protocol was suggested by Massey [39], and it eliminates such avoidable collisions by letting the users that flipped 1 in slot 2 in the preceding example, flip coins before transmitting in slot 4. Consequently, the slot in which an avoidable collision would occur is saved. In this case, fair coins yield a stable system for arrival rates smaller than 0.375, and biased coins increase this number up to 0.381.

When the obvious access is employed, it is very likely that a CRI will start with a collision among a large number of packets when the previous CRI was long. When the system operates near its maximal throughput, most CRIs are long; hence collisions among a large number of packets must be resolved frequently, yielding nonefficient operation. Ideally, if it were possible to start each CRI with the transmission of exactly one packet, the throughput of the system would have been 1. Because this is not possible, one should try to design the system so that in most cases a CRI starts with the transmission of about one packet. There are several ways to achieve this goal by determining a first-time transmission rule (i.e., when packets are transmitted for the first time). One way, suggested by Capetanakis [36], is to have an estimate on the number of

packets that arrived in the previous CRI and divide them into smaller groups, each having an expected number of packets on the order of one and handling each group separately. Another way, known as the epoch mechanism has been suggested by Gallager [40] and Tsybakov and Mikhailov [41]. According to this mechanism, time is divided into consecutive epochs each of length Δ slots. The i th arrival epoch is the time interval $[i\Delta, (i+1)\Delta]$. Packets that arrive during the i th arrival epoch are transmitted for the first time in the first slot after the collision among packets that arrived during the $(i-1)$ st arrival epoch is resolved. The parameter Δ is chosen to optimize the performance of the system. When $\Delta = 2.68$, the system is stable for arrival rates up to 0.429 if slots of sure collisions are not saved, and up to 0.462 if they are. A final enhancement of the epoch mechanism is to start a new epoch each time a collision is followed by two successful transmissions. This guarantees that each CRI will start with an optimal number of packets, and it yields the highest stable throughput known for multiple access systems—0.487.

4.1. Further Reading

Numerous variations of the environment under which collision resolution protocols operate have been addressed in the literature and excellent surveys on the subject appear in Refs. 42 and 43. Books by Bertsekas and Gallager [21] and Rom and Sidi [23] are also excellent sources on collision resolution protocols. Considerable effort has been spent on finding upper bounds to the maximum throughput that can be achieved in an infinite population model with Poisson arrivals and ternary feedback. The best upper bound known to date is 0.568 and is the work of Tsybakov and Likhanov [44]. Practical multiple access communication systems are prone to various types of errors. Collision resolution protocols that operate in the presence of noise errors, erasures, and captures have been studied in Refs. 45–49. Collision resolution protocols yielding high throughputs for general arrival processes (even if their statistics are unknown) were developed by Cidon and Sidi [50] and Greenberg et al. [51]. The expected packet delay of the binary-tree protocol has been derived by Fayolle et al. [52] and Tsybakov and Mikhailov [38]. Bounds on the expected packet delay of the algorithm with the epoch mechanism have been obtained in Refs. 41 and 53, and bounds on the packet delay distribution have been obtained in Refs. 54 and 55.

MULTIPLEXERS

RAAFAT R. MANSOUR
 University of Waterloo
 Waterloo, Ontario, Canada

1. INTRODUCTION

Multiplexers are used in communication system applications where there is a need to divide a wideband signal into a number of narrowband signals (channels). They are also employed to provide the opposite function, by combining several narrowband channels into a single wideband channel. Multiplexers are therefore known as *channelizers* or *combiners*. They find widespread use in many applications such as satellite payloads, wireless systems, and electronic warfare (EW) systems.

A two-channel version of the multiplexer is usually referred to as a *diplexer*, which is a component used in almost every communication wireless system. Figure 1 illustrates a simplified block diagram of the front end of a cellular base station. The purpose of the receive filter is to reject the out-of-band interference prior to low-noise

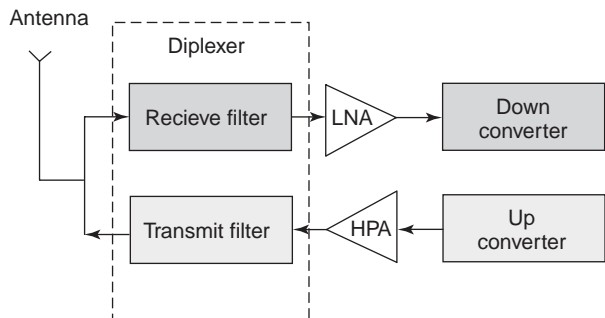

Figure 1. A simplified block diagram of the front end in base stations.

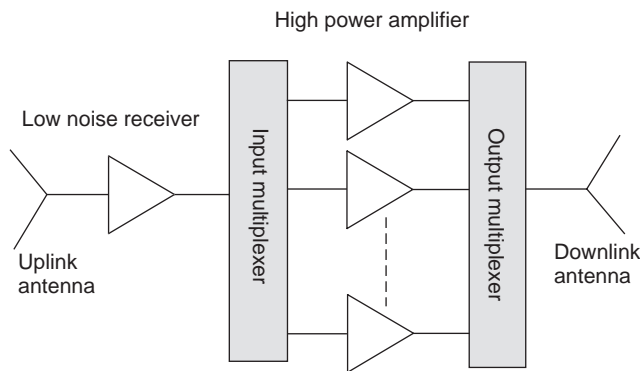

Figure 2. A simplified block diagram of a satellite payload.

amplification and downconversion. The transmit filter is used primarily to limit the out-of-band signals generated by the transmit portion of the base station. The transmit filter must have a very high level of rejection in the receive band in order to eliminate the possibility of intermodulation products being fed into the receiver through the common antenna. The receive and transmit filters are combined in the form of a diplexer to allow the receive and transmit functions to be used through a common antenna.

In satellite payloads, the input/output multiplexers are considered key components that determine the performance of the overall payload. Figure 2 illustrates a simplified block diagram of a conventional satellite payload system. It consists of receive/transmit antenna, low-noise receiver, input and output multiplexers and high-power amplifiers (HPAs). The payload acts basically as an orbiting repeater that receives, amplifies, and transmits. The practical constraints on high-power amplifiers require channelization of the received signal into a number of RF channels through the use of input multiplexers. The relatively narrowband channels are then amplified separately using high-power amplifiers and then recombined through the use of an output multiplexer for transmission back to ground. The typical number of filters for input multiplexers ranges from 36–60 filters, while the number of RF filters in output multiplexers typically ranges from 6 to 24 channels.

Multiplexers may also be used in wireless applications where the base station may need to transmit various frequency channels in different directions by using directive antennas. In this case, a multiplexer would be needed to separate the overall band transmitted into channels radiated in various directions. Another possible application of multiplexers in wireless base stations is in cases where the base station provides service to a number of independent operators who are licensed to operate only in specific channels within the band covered by the base station.

In EW systems, multiplexers may be used to construct switched filterbanks, which are essential building blocks in wideband receivers that operate in a hostile dense signal environment. In this case, switches are integrated with a multiplexer to allow the selection of a particular channel, allowing effectively the realization of a tunable filter with a variable bandwidth and a variable center frequency.

Figure 3. A diplexer implemented using the 90° hybrid approach.

2. DIPLEXER/DUPLEXER CONFIGURATIONS

The terms *diplexer* and *duplexer* have been used interchangeably by RF engineers for many years. The prefix “Di” is defined as twice or double, while the prefix “Du” is defined as two or dual. The term “Plex” is generated from the Latin word *plexus*, which means an interwoven combination of parts or elements. Thus, there is no basic difference in the meaning of the two terms. Traditionally, the term *duplexer* is used where the transmit and receive functions are combined in a single unit. A duplexer may be configured by coupling separate transmit and receive filters via a circulator or a switch or as an integrated unit with one common transmit/receive port as shown in Fig. 1. On the other hand, a diplexer is referred to as a unit that separates a composite signal into two separate channels. However, in view of IEEE publications on the subject since the early 1980s, one can clearly see that the two terms are often used interchangeably to describe the general case where the receive signal is isolated from transmit signal. In this article, we will use the term diplexer.

A simple form of a diplexer is shown in Fig. 3. It consists of two 90° hybrids and two identical filters. The filters are designed to operate within the receive band with enough isolation to reject the transmit band. The diplexer allows the use of one antenna for the receive (Rx) and transmit (Tx) signals. In view of the scattering matrix of the 90° hybrid [1], one can readily show that the signal received from the antenna port will be sent to the receive port while the signal from the transmit port will be reflected from the filters and will be directed to the antenna port. This diplexer configuration is bulky, requiring the use of two hybrids. However, it offers design simplicity and higher power handling capability.

Another approach to realize the diplexer is to use one filter for the receive channel and another one for the transmit channel. The two filters are then combined using a T junction. Figure 4a illustrates two coaxial filters combined together by a wire T junction, while Fig. 4b shows two iris waveguide bandpass filters combined together by a waveguide T junction. The interaction between the two filters in this case is very strong, requiring that the phase at the junction arms to be adjusted to make sure that the receive and transmit signals are integrated properly. In some applications such as radar systems, the receive and transmit signals do not exist simultaneously. In this case, a fast switch is used to replace the T junction, allowing the antenna to be connected to either the receive or the transmit circuits.

In diplexer applications, the insertion loss of the receive filter is an important factor since it contributes directly to the overall noise figure of the receiver that follows the diplexer. The insertion loss of the transmit filter is equally important since it impacts the power transmitted and the efficiency of the transmit system. A tradeoff exists among the loss, rejection and size of the filter. A high rejection, with a little effect on insertion loss and size, can be achieved by allocating several attenuation poles (rejection) in the appropriate band to increase the filter rejection. Typically, the insertion loss of the 90° hybrid approach is slightly higher than that of the T-junction combining approach. However, the 90° hybrid approach offers a higher power-handling capability. The reason is that the power-handling capability of the T-junction approach is determined by the power-handling capability of the transmit filter, while that of the hybrid approach is determined by the power handling capability of the 90° hybrid. Because of the buildup of energy inside the resonators, filters typically have less power-handling capability in comparison with 90° hybrids.

3. MULTIPLEXER CONFIGURATIONS

Since the early 1970s, several multiplexer configurations have been reported in the literature [2–17]. The most commonly used configurations are, hybrid-coupled multiplexers, directional filter multiplexers, circulator-coupled multiplexers, and manifold-coupled multiplexers. A summary of the advantages and disadvantages of these multiplexer configurations is given in Table 1 [9].

Figure 4. (a) A diplexer implemented using two coaxial filters and a wire T junction; (b) a diplexer implemented using two waveguide iris filters and T waveguide junction.

Table 1. A comparison between various multiplexer configurations

Manifold Multiplexer	Circulator Coupled MUX	Directional Filter MUX	Hybrid Coupled MUX
<i>Advantages</i>			
Requires one filter per channel	Requires one filter per channel	Requires one filter per channel	Amenable to modular concept
Most compact design	Simple to tune—no interaction between channel filters	Simple to tune—no interaction between channel filters	Simple to tune—no interaction between channel filters
Optimum if all present and future channels are assigned and installed at same time	Amenable to a modular concept	Amenable to modular concept	Total power in transmission modes as well as reflection mode is divided by the hybrid so that only 50% of the power is incident on each filter; power handling is thus increased and susceptibility to voltage breakdown is reduced
<i>Disadvantages</i>			
Tuning of the multiplexer can be time-consuming and expensive	Signals must pass in succession through circulators, incurring a loss per trip	Restricted to realize all-pole functions such as Butterworth and Chebyshev	Two identical filters and two hybrids are required for each channel
Not amenable to a flexible frequency plan; i.e., change of a channel frequency will require a new multiplexer design	Low-loss, high-power ferrite circulators are expensive	Difficult to realize bandwidths greater than 1%	Linewidths between hybrids and filters require precise balancing to preserve circuit directivity
	Higher level of passive intermodulation products than other configurations		The physical size and weight of the multiplexer is greater than other approaches

3.1. Hybrid-Coupled Approach

Figure 5 shows a layout of a hybrid-coupled multiplexer. Each channel consists of two identical filters and two identical 90° hybrids. The main advantage of the hybrid-coupled approach is that it is amenable to a modular concept minimizing the interaction between the channel filters. It also allows the integration of additional channels at a later date without disrupting the existing multiplexer design, which is a requirement in some systems. Another key advantage of this approach is that only half of the input power goes through each filter. Thus the filter design can be relaxed when using this type of multiplexer in high-power applications. Multiplexers employing this approach, however, have a relatively larger size since they require the use of two filters and two hybrids per channel. Another design consideration of such multiplexers is the phase deviation between the two filter paths that the two signals undergo before they add constructively at the

Figure 5. Layout of a hybrid-coupled multiplexer.

channel output. The structure therefore must be fabricated with tight tolerances to minimize the phase deviation, particularly in planar circuit applications where it is difficult to use tuning elements to balance the two paths.

3.2. Circulator-Coupled Approach

Each channel in this case consists of a channel-dropping circulator and one filter as shown in Fig. 6. This circulator-coupled approach has the same advantages as the hybrid-coupled approach in terms of amenability to modular integration and ease of design and assembly. The insertion loss of the first channel is the sum of the insertion loss of the channel filter as well as the insertion loss of the circulator. The subsequent channels exhibit a relatively higher loss due to the insertion loss incurred during each trip through the channel dropping circulators. Figure 7 shows a photo of a four-channel multiplexer employing four channel filters [14]. It consists of a stack of four circulators connected to stack of four filters by cables.

Figure 6. A circulator-coupled multiplexer.

Figure 7. A four-channel circulator-coupled multiplexer [14].

3.3. Directional Filter Approach

Figure 8 illustrates a layout of a multiplexer realized by connecting directional filters in series. A directional filter is a four-port device where one port is terminated in a load. The other three ports of the directional filter essentially act as a circulator connected to a bandpass filter. Power incident at one port emerges at the second port with a bandpass frequency response, while the reflected power from the filter emerges at the third port. Directional filters, however, do not require the use of ferrite circulators. Figures 9a and 9b illustrate two possible approaches for realizing directional filters in waveguide and microstrip respectively [2]. The waveguide directional filter is realized by coupling rectangular waveguides operating in TE₁₀ modes to a circular waveguide filter operating in TE₁₁ modes. The microstrip version consists of one wavelength ring resonators coupled to one another and to two transmission lines. This multiplexing approach has the same advantages as the hybrid-coupled and circulator-coupled approaches. It is however limited to narrowband applications.

3.4. Manifold-Coupled Approach

The manifold-coupled approach shown in Fig. 10 is viewed as the optimum choice as far as miniaturization and absolute insertion loss are concerned. However, since interaction between filters on the manifold must be taken into account, manifold-coupled multiplexers are not amenable to a flexible frequency plan. Any changes in one of the channels will require a new multiplexer design. Moreover, as the number of channels increases, this approach becomes more difficult to implement. The manifold coupled multiplexer shown in Fig. 10 acts as a channelizer. It should be mentioned that the same configuration can be used as a combiner. Figure 11 is a photo of a four-channel multiplexer employing a waveguide manifold and four

Figure 9. (a) A waveguide directional filter; (b) a microstrip directional filter.

dual-mode circular waveguide filters. The same figure also shows a miniature multiplexer employing a coaxial manifold and superconductive filters [17]. The manifold-coupled concept can be implemented as well in planar circuits as shown in Fig. 12, where three microstrip filters are integrated with a microstrip manifold [14]. In this particular case, one of the channels is connected directly to the manifold.

4. MULTIPLEXER DESIGN

The design of circulator-coupled multiplexers and hybrid-coupled multiplexers basically reduces down to the design of the individual channel filters. The same can be also stated for directional filter multiplexers. However, for the manifold-coupled multiplexer the interaction between the channel filters has to be taken into consideration over the whole band of operation. Manifold-coupled multiplexers can be built with non-contiguous channels where there is a frequency guardband between the channels. For such multiplexers, channel interaction is less and, as a consequence, their design and implementation is easier. However, in order to fully utilize the frequency spectrum, multiplexers are usually built with contiguous channels where there is a crossover between the adjacent channels at the 3-dB levels. The interaction between the channels for the contiguous case is obviously much stronger than the noncontiguous case, and the design of the channel filters must include the loading effects from adjacent channels as well as the loading effects of the manifold itself.

In designing manifold-coupled multiplexers, one can start with doubly terminated filters or singly terminated

Figure 8. A directional filter multiplexer.

Figure 10. A manifold-coupled multiplexer.

Figure 11. A C-band four-channel waveguide multiplexer in comparison with a four-channel multiplexer implemented using superconductor technology [17].

filters. Doubly terminated filters are generally used when designing noncontiguous multiplexers, whereas singly terminated filters are used for contiguous multiplexers. The doubly terminated filters are standalone filters, which are designed to terminate in loads at both ends. The singly terminated filters are synthesized to have a load only at one end and will only function as a filter if placed on the manifold. While several synthesis techniques have been published on the design manifold-coupled multiplexers [2–6], the focus since the early 1990s has been on the use of computer optimization.

To illustrate the design concept of manifold-coupled multiplexers, we consider the generalized filter network shown in Fig. 13, which is represented by a coupling matrix in the form

$$M = \begin{bmatrix} M_{11} & M_{12} & \dots & M_{1n} \\ M_{21} & M_{22} & \dots & M_{2n} \\ \vdots & & & \vdots \\ M_{n1} & M_{n2} & \dots & M_{nn} \end{bmatrix} \quad (1)$$

Figure 12. A three-channel multiplexer [14].

Figure 13. Coupling matrix representation of microwave filters.

where M_{ij} represents the coupling between resonators i and j . The diagonal elements relate to the resonance frequencies of the individual resonators and are zeros in the case of synchronously tuned filters. Following the analysis described in Ref. 18, one can obtain the scattering parameters of the filter in terms of coupling elements:

$$S_{21} = -2j\sqrt{R_1 R_2} [A^{-1}]_{n1} \quad (2)$$

$$S_{11} = 1 + 2jR_1 [A^{-1}]_{11} \quad (3)$$

where

$$A = \lambda I - jR + M \quad (4)$$

$$\lambda = \frac{f_0}{BW} \left(\frac{f}{f_0} - \frac{f_0}{f} \right) \quad (5)$$

where I is the identity matrix and R is a matrix with all elements zero, except $R_{11} = R_1$ and $R_{nn} = R_2$.

Consider the N -channel multiplexer shown in Fig. 14. The manifold consists of N T junctions connected in cascade and is terminated by a short circuit. The filters are spaced on the manifold and by $L(1), L(2), L(3) \dots L(N)$ and are placed away from the T junction by $W(1), W(2), W(3) \dots W(N)$ as shown in Fig. 14. With the knowledge of the scattering matrix of the T junction and the scattering matrices of the individual filters, one can use the generalized multiport technique given in Ref. 19, to calculate the overall scattering matrix of the multiplexer. Alternatively, the Y -parameter analysis given in Ref. 7 can be used to calculate the overall scattering matrix of the

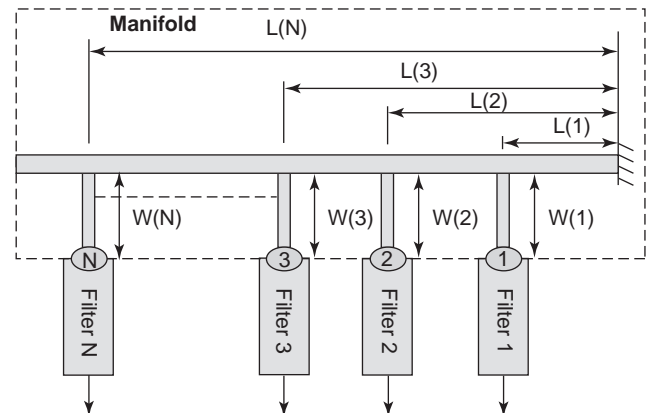

Figure 14. A layout of manifold-coupled multiplexer having N channels.

multiplexer. Our design objective is to find the manifold physical dimensions $L(1), L(2), L(3) \cdots L(N)$ and $W(1), W(2), W(3) \cdots W(N)$, as well as the coupling matrix of each of the N filters.

4.1. Noncontiguous Band Multiplexer

The design steps for the noncontiguous multiplexer given in this article are similar to those reported in Ref. 7, they can be summarized as follows:

Step 1 (Initial Dimensions). A good starting point for the noncontiguous manifold coupled multiplexer is to use doubly terminated filters; that is, the individual filters are designed as “standalone” filters to meet the bandwidth and return loss requirements. The coupling matrices for these filters can then be synthesized using Ref. 18. Equations (2)–(5) can then be used to calculate the scattering matrices of the filters.

Let $W(1) = W(2) = W(3) \cdots W(N) = W_0$ where W_0 is the minimum spacing that would allow the physical implementation of the channel filters on the manifold. Set $W_0 = 0$, if the channel filters can be attached directly to the manifold. Place the filters on the manifold such that the lowest frequency filter is closer to the short-circuited end of the manifold. Set the initial spacings L values according to:

$$L(0) = 0, L(k) - L(k - 1) = \lambda_{gk} / 2 \quad (6)$$

for $k = 1, 2, \dots, N$

where λ_{gk} is the guide wavelength at the center frequency f_{0k} of filter k .

Step 2 (Multiplexer Response). Using the given filter spacings L and the scattering matrices of the standalone filters, compute the frequency response of the multiplexer

by applying the generalized multiport analysis given in Ref. 19. If the multiplexer response meets the requirement, the design is complete and obviously nothing else needs to be done. Otherwise, find the filter j that satisfies the following:

$$|\rho(f_{0j})| = \max |\rho(f_{0k})| \text{ for } k = 1, 2, \dots, N \quad (7)$$

The filter j is basically the filter that has the worst return loss at the center frequency.

Step 3 (Filter Allocation). Change the spacing $L(j)$ of the filter according to the following rule. The filter is moved closer to the short circuit if a better return loss occurs at a frequency lower than midband frequency, and vice versa. The rule can be written as

$$\text{If } |\rho(f_{0j} - \Delta)| < |\rho(f_{0j})|, \text{ then} \quad (8)$$

$$L(j) = L(j) + \lambda_{gj} [1 - \lambda_1 / \lambda_{gj}]$$

$$\text{If } |\rho(f_{0j} + \Delta)| < |\rho(f_{0j})|, \text{ then} \quad (9)$$

$$L(j) = L(j) + \lambda_{gj} [1 - \lambda_2 / \lambda_{gj}]$$

where λ_1 and λ_2 are the guide wavelengths calculated at $(f_{0j} - \Delta)$ and $(f_{0j} + \Delta)$, respectively, and Δ is the filter bandwidth [7].

Step 4 (Iterations). Repeat steps 2 and 3 for a number of iterations. Typically this process converges, quickly leading to a multiplexer response with well-defined channels but with an input/output return loss that is the range of 8–12 dB (Fig. 15).

Step 5 (Multiplexer Optimization). The multiplexer performance can be improved by applying computer optimization. The optimization variables in this case would be

Figure 15. The performance of a 16-channel noncontiguous multiplexer designed using doubly terminated filters. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 16. The optimized performance of a 20-channel contiguous multiplexer. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$L(1), L(2), \dots, L(N)$ as well as $W(1)W(2), \dots, W(N)$. Typically, such a process leads to a multiplexer response that is very close to the optimum solution. Figure 16 shows a typical response of a noncontiguous three-channel multiplexer designed by using doubly terminated filters.

Step 6 (Multiplexer Fine Tuning). Fine tuning of the multiplexer requires optimization of all manifold physical dimensions L s and G s as well as the first few coupling elements of the filters (R_1, M_{12}). The initial values for the optimization variables could be the L and W values obtained from step 5 and the coupling matrices of the doubly terminated filters.

Step 7 (Overall Multiplexer Physical Dimensions). Once the optimized filter coupling elements are determined, the filter physical dimensions can be readily obtained. The problem reduces basically to the physical realization of filters for a given coupling matrix. An example for such realization is given in Refs. 21–23 for dielectric resonator filters.

The multiplexer design can certainly be achieved by skipping steps 2–4 and only applying steps 1, 5, 6, and 7, that is, to rely completely on computer optimization to achieve the goal. We have included steps 2–4 to illustrate that a reasonable performance in the case of noncontiguous multiplexers can be obtained by simply using manual tuning (on the computer) of the manifold spacings.

4.2. Design of Contiguous Band Multiplexers

The use of doubly terminated filters for the contiguous band multiplexer with an initial spacing of $\lambda/2$ does not usually lead to an acceptable response that can be reasonably tuned manually as the case of noncontiguous multiplexers. Two options can be followed in this case:

Option 1. Use doubly terminated filters and rely on computer optimization for both rough tuning and fine tuning. In some cases, it may be difficult to optimize the multiplexer since the starting point is usually far away from the final solution. In addition, it may lead to an inferior design in terms of group delay and loss variations. This design approach however may converge to the optimum solution by intelligently selecting the parameters to be optimized.

Option 2. Use singly terminated filter designs based on the synthesis procedure given in Ref. 20 or Refs. 2–6. Then use computer optimization to fine-tune the filter coupling elements as well as manifold physical dimensions. Figure 16 shows the performance of a 20-channel contiguous multiplexer [24] designed using option 2.

A detailed description of a design procedure for contiguous-band multiplexers is given in Ref. 25.

1. INTRODUCTION

The multiresolution time-domain (MRTD) scheme is a time-domain Maxwell solver based on electromagnetic field expansions in terms of scaling and wavelet functions [1,2], and has been extensively applied to various electromagnetic engineering applications [1–13]. The technique promises to significantly reduce the requirements on computational space and CPU time while at the same time it presents a unified field expansion structure that includes the finite-difference time-domain (FDTD) method and its higher-order versions. The MRTD scheme has been successfully applied to the analysis of fundamental guided-wave structures, microwave devices, scattering targets, and antenna applications. However, there are challenging issues that often hinder the implementation of the MRTD scheme for practical applications. For example, we cannot truncate a perfectly electric conducting (PEC) boundary by specifying a tangential electric field to zero for shielded structures, due to the coupling between cells resulting from high-order expansions of fields; another difficulty is that the orthogonal relations among scaling and wavelet basis functions are corrupted in an inhomogeneous region. This leads to great complexities when deriving field update equations for a structure with different materials that must be systematically solved in order to develop a generalized Maxwell MRTD solver.

In this article we begin by reviewing the foundation of the MRTD scheme—the multiresolution analysis (MRA), and then exploring the properties of the scaling functions and wavelets [14–28]. Also, we demonstrate the applications of the MRTD technique by analyzing a transverse electromagnetic (TEM) wave propagation in a dielectric layered stratified space and an integrated microwave circuit, which can be extended to solve electromagnetic engineering problems of general nature.

2. MULTIRESOLUTION ANALYSIS

This section will briefly present the fundamental concepts of the MRA, which serves as the conceptual foundation for the MRTD. To better understand the basic concept behind the definition of the MRA, we start by analyzing the structure of an electromagnetic field signal. In general, such a signal can be viewed as a composition of a smooth background embellished by fluctuation noises or details. The distinction between the smooth part and the details is

determined by the level of resolution. Therefore, at a given resolution level, a signal can be approximated by ignoring all the effects of fluctuations above that level. To better approximate the signal, we can progressively increase resolution levels and thus successively add finer detail to a coarse description of the signal. Eventually, when the resolution goes to infinity, we represent the original signal without any approximation error.

We can formulate the intuitive description above more precisely as follows. The resolution level, labeled by an integer s , has a corresponding scale set to 2^{-s} . The approximation of a signal $f(t)$ at level s is denoted by $f_s(t)$. When we increase the level to $s + 1$, we need to add the details, denoted by $d_s(t)$, to the signal at this new level in order to obtain the modified approximation, that is, $f_{s+1}(t) = f_s(t) + d_s(t)$. By repeating this procedure, we can recover the original signal $f(t)$ at infinity:

$$f(t) = f_s(t) + \sum_{k=s}^{\infty} d_k(t) \tag{1}$$

From a global perspective of the signal space, (1) indicates that we need to consider two sequences of subspaces $\{W_s\}$ and $\{V_s\}$, such that every $f(t)$ can be approximated at the resolution level $s + 1$ with $f_s(t)$ in the scale space V_s and $d_s(t)$ in the detail space W_s . Those subspaces will be the basic objects in our definition.

Our signal space is now considered as the space of square-integrable functions. Here we define a sequence of the resolution levels labeled by integers such that all details of signals on scales smaller than 2^{-s} will be ignored at the level s . Also, we define V_s as the subspace of the functions that contain the signal information down to the scale 2^{-s} . Formally, an MRA is just a sequence of V_s , which satisfies certain mathematical conditions.

Instead of beginning with a formal definition of MRA, we will first explain the meanings behind those fundamental conditions. We will clarify five fundamental properties that an MRA should possess.

2.1. Subspace Structure

The subspaces V_s should be constructed in a nested structure; information at the resolution level s is necessarily included in information at a higher resolution level; therefore, $V_s \subset V_{s+1}$ for all s . The difference between $f_{s+1}(t)$ and $f_s(t)$, denoted by $d_s(t) = f_{s+1}(t) - f_s(t)$, is the additional information on scales between 2^{-s} and $2^{-(s+1)}$. Since the best approximation in terms of V_s is given by the projection of the function onto V_s , we may expect that $d_s(t) \perp f_s(t)$. Accordingly, we can decompose the subspace V_{s+1} as $V_{s+1} = V_s \oplus W_s$, where W_s is the detail space at the resolution level s and is orthogonal to V_s , specifically, $W_s \perp V_s$. Repeating the decomposition, we obtain

$$V_{s+1} = W_s \oplus V_s = W_s \oplus W_{s-1} \oplus V_{s-1} = \dots = W_s \oplus W_{s-1} \oplus W_{s-2} \oplus \dots \oplus W_{s-s'} \oplus V_{s-s'} \tag{2}$$

These subspaces are mutually orthogonal. In fact, since $W_s \perp V_s$, we see that W_s is orthogonal to any subspace of V_s .

Since for $s' < s$, both $V_{s'}$ and $W_{s'}$ are contained in V_s and we thus have $W_s \perp V_{s'}$, and $W_s \perp W_{s'}$ when $s \neq s'$. In other words, any two detail spaces at different resolutions are orthogonal, and the detail space W_s is orthogonal to an approximation space $V_{s'}$ only when the detail space is at a higher resolution level.

2.2. Resolution of Functions

In the MRA, we describe all square-integrable functions at the finest resolution and only the zero function at the coarsest level. More precisely, as the resolution increases, we include an increasing number of details. As the resolution goes to infinity, the approximation can approach any original signal in the entire initial space $L^2(R)$. In other words, $\lim_{s \rightarrow \infty} V_s = \cup_s V_s$ should be dense in $L^2(R)$. On the other hand, as the resolution gets coarser, we remove more and more details of the signal. When $s \rightarrow -\infty$, only constant functions survive. Since functions have to be square-integrable, the zero function will be the only one left, that is, $\lim_{s \rightarrow -\infty} V_s = \cap_s V_s = \{0\}$.

2.3. Dilation of Function

This scale or dilation invariance of the space V_s is an important feature of the MRA. More explicitly, all V_s should be scaled versions of the central space V_0 . In fact, if a function $f(t)$ is in the space V_s , then $f(t)$ contains no details or fluctuations of scales smaller than 2^{-s} . Since $f(2t)$ is a function obtained from $f(t)$ with a squeezing factor of 2, it contains no details at scales smaller than $2^{-(s+1)}$. Therefore, $f(2t)$ is in V_{s+1} . Conversely, if $f(2t)$ is in V_{s+1} , then, by similar reasoning, $f(t)$ is in the space V_s . Therefore, $f(t) \in V_s \Leftrightarrow f(2t) \in V_{s+1}$.

2.4. Translation of Function

The translation or shift invariance of the space V_s is another important feature of the MRA. If we have a function $f(t) \in V_0$ and define $T_k f(t) = f(t - k)$, where $k \in Z$, then it is clear that the resolution level of $T_k f(t)$ should not change at all. Therefore, we require that V_0 be integral translation-invariant, that is, $T_k(V_0) \subset V_0$ for every integer k . Note that these properties yield the following result—if $f(t) \in V_0$, then $f(2^j t - k) \in V_j$ for all $k \in Z$.

2.5. Scaling Basis Functions

The final and the most important property we describe is the existence of a function ϕ whose set of integral translations forms a Riesz basis of the space V_0 [27]. The scale invariance condition then implies that $\{\phi(2t - k)\}_{k \in Z}$ forms a Riesz basis of V_1 . More generally, if we define $\phi_{s,k}(t) = 2^{s/2} \phi(2^s t - k)$, then $\{\phi_{s,k}(t)\}_{k \in Z}$ forms a Riesz basis of V_s . The function ϕ , which generates basis functions for all V_s , is called a *scaling function* of the MRA. This key feature is similar to the function $e^{j\omega t}$ that we use in Fourier analysis, where $e^{j\omega t}$ is the only function needed to generate an orthonormal basis.

On the basis of the preceding discussion, we now give the formal definition as follows. An MRA in $L^2(R)$ is

defined as a set of closed subspace V_s with $s \in \mathbb{Z}$ such that

1. $\dots \subset V_{-1} \subset V_0 \subset V_1 \subset \dots \subset L^2(\mathbb{R})$, that is, $V_s \subset V_{s+1}$ for all $s \in \mathbb{Z}$.
2. $\bigcap_{s=-\infty}^{+\infty} V_s = \{0\}$ and $\bigcup_{s=-\infty}^{+\infty} V_s$ is dense in $L^2(\mathbb{R})$.
3. $f(t) \in V_s$ if and only if $f(2t) \in V_{s+1}$.
4. If $f(t) \in V_0$, then $f(t-k) \in V_0$.
5. There exists a function $\phi(t) \in V_0$, called a *scaling function*, such that the set $\{\phi(t-k) | k \in \mathbb{Z}\}$ is a Riesz basis of V_0 .

If a scaling function actually generates an orthonormal basis, then we refer it to as an *orthonormal* scaling function. While the orthonormal bases are desirable, the orthogonality will strictly limit the possible scaling functions that we can use in practice. Therefore, a generalized orthonormal basis in the definition offers us greater flexibility. On the other hand, we can almost always use an orthogonalization procedure to produce an orthonormal scaling function from a Riesz scaling function, such that they generate the same V_s .

3. SCALING FUNCTIONS AND WAVELETS

The function $\phi(t)$ in the MRA definition is also called a father scaling function, as it generates bases for all V_s . In fact, based on the properties of the MRA, the sequence $\{\phi_{s,l}(t) = 2^{s/2} \phi(2^s t - l) | l \in \mathbb{Z}\}$ forms a Riesz basis of V_s for all s . It is clear from the definition that the scaling function plays a key role in MRA applications.

Since V_0 is contained in V_1 , we can represent $\phi(t)$ as a linear combination of the Riesz basis of V_1 :

$$\phi(t) = \sqrt{2} \sum_l h_l \phi(2t - l) \tag{3}$$

This is often called the “refinement” equation or the “dilation” equation. It plays a very important role in both the MRA theory and its applications. For example, it provides a way to construct fast algorithms to evaluate a scaling function at dyadic points [28]. This is often enough in many applications and is particularly useful when we do not know the scaling function itself explicitly.

On the other hand, when an orthonormal scaling function $\phi(t)$ is given, then the values of h_l can be easily found as follows:

$$\begin{aligned} & \sqrt{2} \int_{-\infty}^{+\infty} \phi(t) \phi^*(2t - n) dt \\ &= 2 \sum_l \int_{-\infty}^{+\infty} h_l \phi(2t - l) \phi^*(2t - n) dt \\ &= 2 \int_{-\infty}^{+\infty} h_n \phi(2t - n) \phi^*(2t - n) dt \\ &= \int_{-\infty}^{+\infty} h_n \phi(x) \phi^*(x) dx \\ &= h_n \end{aligned} \tag{4}$$

Since $V_s \subset V_{s+1}$, we may decompose V_{s+1} by $V_{s+1} = V_s \oplus W_s$. Recursive applications of this relation lead to

$$V_0 \oplus \sum_{s=0}^n W_s = \bigoplus_{s=-\infty}^n W_s = V_{n+1}, \text{ and } \bigoplus_{s=-\infty}^{+\infty} W_s = L^2 \tag{5}$$

Note that such W_s is not unique unless we require W_s to be the orthogonal complement space of V_s in V_{s+1} . We will assume that this is the case; that is, $W_s \perp V_s$, unless stated otherwise. This relation is referred to as an *orthogonal MRA* in some references where a general W_s is desired, although the terminology may be misleading as it does not require the scaling function of $W_s \perp V_s$ to generate orthogonal bases. However, it does imply that all W_s 's are mutually orthogonal as discussed before.

A function $\psi(t) \in W_0$ is called a *wavelet* (or *semiorthogonal wavelet*) of the MRA if the sequence $\{\psi_l(t) = \psi(t-l) | l \in \mathbb{Z}\}$ forms a Riesz basis of W_0 . It is called an *orthonormal wavelet* if the wavelet actually generates an orthonormal basis. Similar to $\phi(t)$, the function $\psi(t)$ is also called a “mother wavelet,” as $\psi(t)$ generates $\{\psi_{s,l} | l \in \mathbb{Z}\}$ to form Riesz bases for all W_s , where $\psi_{s,l}(t) = 2^{s/2} \psi(2^s t - l)$. Furthermore, since all W_s values are mutually orthogonal, the union of their Riesz bases, namely, $\{\psi_{s,l} | s, l \in \mathbb{Z}\}$, forms a Riesz basis of the whole space L^2 . In fact, it is often called a *semi-orthogonal basis* since $\psi_{s,l}(t) \perp \psi_{r,k}(t)$ for $s \neq r$. Once again, note that in general it is not necessary that the associated scaling function and wavelet be orthonormal, only $W_s \perp V_s$ and all W_s values are mutually orthogonal.

Since W_0 is contained in V_1 , the mother wavelet $\psi(t)$ can also be represented as a linear combination of the Riesz basis of V_1 :

$$\psi(t) = \sqrt{2} \sum_l g_l \phi(2t - l) \in V_1 \tag{6}$$

We call this the *wavelet equation*. Again, this equation plays a key role in wavelet construction, especially when it is used together with the refinement equation (3). Together (3) and (6) are often called *two-scale relations*.

We now turn to the question of how to generate a mother wavelet mathematically for a given MRA. Notice that existence of $\psi(t)$ is neither required nor guaranteed by the definition of the MRA; however, there is a procedure for producing an associated wavelet for a given $\phi(t)$. For example, if $\phi(t)$ is orthonormal, then $\psi(t)$ can be constructed using (6), as we can take $g_l = (-1)^l h_{1-l}^*$ in this case, where the values of h_k are the coefficients in the refinement equation (3). Note that $\psi(t)$ may not be uniquely generated in this manner.

4. TEM WAVE PROPAGATION

4.1. MRTD Modeling of TEM Wave Propagation

Based on the concepts of the MRA developed above, this section will demonstrate the principal procedure of the MRTD by analyzing a TEM wave propagation in a dielectric-layered space along the x (horizontal) axis. We consider an electromagnetic plane wave propagating

along the x direction and use a set of generalized formulations that include both the MRTD region and the anisotropic perfectly matched layers (APML) absorbing region [29–33]. We can then simplify the Maxwell equations as

$$\frac{\partial H_z}{\partial x} = -j\omega s_x D_y \tag{7}$$

$$D_y = \epsilon E_y \tag{8}$$

$$\frac{\partial E_y}{\partial x} = -j\omega\mu_0 s_x H_z \tag{9}$$

with

$$s_x = \begin{cases} 1 + \frac{\sigma_x}{j\omega\epsilon_0} & \text{in APML regions} \\ 1 & \text{in a non-APML region } (\sigma_x = 0) \end{cases} \tag{10}$$

where σ_x is the APML electric conductivity, and the permittivity ϵ is given as

$$\epsilon = \epsilon_0 \epsilon_y(x) = \begin{cases} \epsilon_0 \epsilon_y & \text{in the dielectric regions} \\ \epsilon_0 & \text{elsewhere} \end{cases} \tag{11}$$

Next, we expand the electromagnetic fields as follows:

$$\begin{aligned} E_y(x, t) = & \sum_{i,n=-\infty}^{+\infty} \left[\phi_y E_i^n \phi_i(x) \right. \\ & + \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} \psi_{yl}^s E_{i+2^{-s}(l+1/2)}^n \\ & \left. \times \psi_{s,i+2^{-s}(l+1/2)}(x) \right] h^n(t) \end{aligned} \tag{12}$$

$$\begin{aligned} D_y(x, t) = & \sum_{i,n=-\infty}^{+\infty} \left[\phi_y D_i^n \phi_i(x) \right. \\ & + \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} \psi_{yl}^s D_{i+2^{-s}(l+1/2)}^n \\ & \left. \times \psi_{s,i+2^{-s}(l+1/2)}(x) \right] h^n(t) \end{aligned} \tag{13}$$

$$\begin{aligned} H_z(x, t) = & \sum_{i,n=-\infty}^{+\infty} \left[\phi_z H_{i+1/2}^{n+1/2} \phi_i(x) \right. \\ & + \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} \psi_{zl}^s H_{i-1/2+2^{-s}(l+1/2)}^{n+1/2} \\ & \left. \times \psi_{s,i-1/2+2^{-s}(l+1/2)}(x) \right] h^{n+1/2}(t) \end{aligned} \tag{14}$$

where $\phi_y E_i^n$, $\psi_{yl}^s E_{i+2^{-s}(l+1/2)}^n$, $\phi_z H_{i+1/2}^{n+1/2}$, and $\psi_{zl}^s H_{i-1/2+2^{-s}(l+1/2)}^{n+1/2}$, are the field expansion coefficients in terms of scaling and wavelet functions. The basis functions $\phi(x)$, $\psi(x)$, $\psi_s(x)$, and $h(t)$ are, respectively, the Battle-Lemarie scaling, mother wavelet, s th-level wavelet,

and time rectangle pulse functions. The Fourier-transformed versions of the basis functions can be expressed as

$$\tilde{\phi}(\omega) = \left(\frac{\sin \frac{\omega}{2}}{\frac{\omega}{2}} \right)^4 \tag{15a}$$

$$\times \frac{1}{\sqrt{\left(1 - \frac{4}{3} \sin^2 \frac{\omega}{2} + \frac{2}{5} \sin^4 \frac{\omega}{2} - \frac{4}{315} \sin^6 \frac{\omega}{2} \right)}}$$

$$\tilde{\psi}(\omega) = e^{j(\omega/2)} \frac{\tilde{\phi}(\omega + 2\pi)}{\tilde{\phi}\left(\frac{\omega}{2} + \pi\right)} \tilde{\phi}\frac{\omega}{2} \tag{15b}$$

$$\tilde{\psi}_s(\omega) = e^{j(\omega/2)} \frac{\tilde{\phi}_s(\omega + 2\pi)}{\tilde{\phi}_s\left(\frac{\omega}{2} + \pi\right)} \tilde{\phi}_s\left(\frac{\omega}{2}\right) \tag{15c}$$

$$\tilde{\psi}_{s,i}(\omega) = 2^{(s/2)} \cdot e^{-j\omega 2^{-s}i} \cdot \tilde{\psi}(2^{-s}\omega) \tag{15d}$$

In order to illustrate their localized supports in both the space and frequency domains, the scaling functions $\phi(x)$ and $\tilde{\phi}(\omega)$, and the wavelet functions $\psi(x)$, $\psi_1(x)$, $\tilde{\psi}(\omega)$, and $\tilde{\psi}_1(\omega)$, have been, respectively, plotted in Figs. 1 and 2.

The orthogonal relations for the rectangular time pulse, scaling, and wavelet functions can be expressed as follows

$$\int_{-\infty}^{\infty} h^n(t) h^{n'}(t) dt = \delta_{n,n'} \Delta t \tag{16}$$

$$\int_{-\infty}^{\infty} \phi_i(x) \phi_{i'}(x) dx = \delta_{i,i'} \Delta x \tag{17}$$

$$\int_{-\infty}^{\infty} \psi_i^{s,l}(x) \psi_{i'}^{s',l'}(x) dx = \delta_{s,s'} \delta_{l,l'} \delta_{i,i'} \Delta x \tag{18}$$

where $\delta_{i,i'}$ is the Krönecker symbol representing unity when $i=i'$ and zero otherwise. To derive the MRTD update equations, we have to apply some intricate integral relations, which are summarized in the following:

$$\int_{-\infty}^{+\infty} \phi_i(x) \frac{\partial}{\partial x} \phi_{i'+(1/2)}(x) dx = \sum_{v=-\infty}^{+\infty} a(v) \delta_{i',i+v} \tag{19a}$$

$$a(v) = \frac{1}{\pi} \int_0^{+\infty} \left| \hat{\phi}(\omega) \right|^2 \omega \sin \left[\left(v + \frac{1}{2} \right) \omega \right] d\omega \tag{19b}$$

$$\int_{-\infty}^{+\infty} \phi_{j+(1/2)}(y) \frac{\partial \psi_{s,j'+2^{-s}(l+1/2)}(y)}{\partial y} dy \tag{20a}$$

$$= \sum_{v=-\infty}^{+\infty} d_{s,l}(v) \delta_{j',j+v}$$

$$\begin{aligned} d_{s,l}(v) = & \frac{1}{\pi} \int_0^{+\infty} \hat{\phi}(\omega) |\hat{\psi}_s(\omega)| \omega \\ & \times \sin \left[\omega \left(v - \frac{1}{2} + \frac{l}{2^s} + \frac{1}{2^{s+1}} \right) \right] d\omega \end{aligned} \tag{20b}$$

Figure 1. The cubic spline Battle-Lemarie scaling function in the (a) space domain and (b) spectral domain.

$$\int_{-\infty}^{+\infty} \psi_{s,j-(1/2)+2^{-s}[l+(1/2)]}(y) \frac{\partial \phi_{j'}(y)}{\partial y} dy = \sum_{v=-\infty}^{v=+\infty} c_{s,l}(v) \delta_{j',j+v} \quad (21a)$$

$$c_{s,l}(v) = \frac{1}{\pi} \int_0^{\infty} \hat{\phi}(\omega) |\hat{\psi}_s(\omega)| \omega \times \sin \left[\omega \left(v + \frac{1}{2} - \frac{l}{2^s} - \frac{1}{2^{s+1}} \right) \right] d\omega \quad (21b)$$

$$\int_{+\infty}^{+\infty} \psi_{s,i-(1/2)+2^{-s}[l+(1/2)]}(x) \times \frac{\partial \psi_{s,i'+2^{-s}'[l'+(1/2)]}(x)}{\partial x} dx = \sum_{v=-\infty}^{+\infty} b_{l',l}^{s,s'}(v) \delta_{i',i+v} \quad (22a)$$

Figure 2. The cubic spline Battle-Lemarie wavelet functions with $s=0$ and $s=1$ in the (a) space domain and (b) spectral domain.

$$b_{l',l}^{s,s'}(v) = \frac{1}{\pi} \int_0^{\infty} |\tilde{\psi}_s(\omega)| |\tilde{\psi}_{s'}(\omega)| \omega \times \sin \left[\omega \left(v + \frac{1}{2} + \frac{l'}{2^{s'}} - \frac{l}{2^s} + \frac{1}{2^{s'+1}} - \frac{1}{2^{s+1}} \right) \right] d\omega \quad (22b)$$

Because of the localized nature of the Battle-Lemarie scaling and wavelet functions, the values of $a(v)$, $b_{l',l}^{s,s'}(v)$, $c_{s,l}(v)$, and $d_{s,l}(v)$ appearing in the equations above decrease exponentially with an increase in the absolute value of v . Although the summation index v in, (19a), (20a), and (21a) spans from positive to negative infinity, it is usually sufficient to truncate it at v_{\max} ($|v| \leq v_{\max}$; $v_{\max} = 9$), due to the fast convergent property of the scaling and wavelet functions. In addition, the symmetry of the coefficients, namely, $a(-1-v) = -a(v)$, $b_{l',l}^{s,s'}(-1-v) = -b_{l',l}^{s,s'}(v)$, $c_{s,l}(v) = c_{s,l}(v)$, and $d_{s,l}(v) = -d_{s,l}(v)$, can reduce the computational workload even more significantly in field update

equations. The values of $\alpha(v)$, $c_{0,0}(v)$, and $b_{0,0}^{0,0}(v)$ are listed in Ref. 2. The values of $d_{s,l}(v)$, $c_{s,l}(v)$, and $b_{l,l}^{s,s}(v)$ ($s = 1$) are summarized in Tables 1 and 2.

In these tables, we note that $b_{0,0}^{1,1}(v) = -b_{0,0}^{1,1}(v-1)$, if $v < 0$; $b_{0,1}^{1,1}(v) = -b_{0,1}^{1,1}(v-2)$, if $v < -1$; $b_{1,0}^{1,0}(v) = b_{0,0}^{0,1}(v)$; $b_{1,0}^{1,1}(v) = b_{0,1}^{1,1}(v)$, and $b_{1,1}^{1,1}(v) = b_{0,0}^{1,1}(v)$ for all values of v .

Substituting the field expansion in (12) through (14) into the governing equations (7) and (9), and applying Galerkin's method by using a scaling or wavelet function as a test function, we can derive time-domain update equations as follows:

$$\begin{aligned} \phi_y D_i^{n+1} &= \left(\frac{1 - \frac{\sigma_x \Delta t}{2\epsilon_0}}{1 + \frac{\sigma_x \Delta t}{2\epsilon_0}} \right) \\ &\times \phi_y D_i^n - \frac{1}{\left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0}\right)} \left(\sum_{v=-9}^{+8} \alpha(v) \phi_z H_{i+v+(1/2)}^{n+(1/2)} \right) \end{aligned} \quad (23)$$

$$\begin{aligned} &+ \left. \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} \sum_{v=-9}^{+9} d_{s,l}(v) \psi_z^s H_{[i-(1/2)+v]+2^{-s}[l+(1/2)]}^{n+(1/2)} \right) \frac{\Delta t}{\Delta x} \\ \psi_y^s D_{i+2^{-s}[l+(1/2)]}^{n+1} &= \left(\frac{1 - \frac{\sigma_x \Delta t}{2\epsilon_0}}{1 + \frac{\sigma_x \Delta t}{2\epsilon_0}} \right) \\ &\times \psi_y^s D_{i+2^{-s}[l+(1/2)]}^n - \frac{1}{\left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0}\right)} \end{aligned} \quad (24)$$

$$\begin{aligned} &\times \left(\sum_{v=-9}^{+9} c_{s,l}(v) \phi_z H_{i+v+(1/2)}^{n+(1/2)} \right) \\ &+ \sum_{s'=0}^{s_{\max}} \sum_{l'=0}^{2^{s'}-1} \sum_{v=-9}^{+9} b_{l',l'}^{s,s'}(v) \\ &\times \psi_z^s H_{[i+(1/2)+v]+2^{-s'}[l'+(1/2)]}^{n+(1/2)} \right) \frac{\Delta t}{\Delta x} \end{aligned}$$

$$\begin{aligned} \phi_z H_{i+(1/2)}^{n+(1/2)} &= \left(\frac{1 - \frac{\sigma_x \Delta t}{2\epsilon_0}}{1 + \frac{\sigma_x \Delta t}{2\epsilon_0}} \right) \phi_z H_{i+(1/2)}^{n-(1/2)} \\ &- \frac{1}{\mu_0 \left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0}\right)} \left(\sum_{v=-9}^{+8} \alpha(v) \phi_y E_{i+v+1}^n \right) \\ &+ \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} \sum_{v=-\infty}^{+\infty} d_{s,l}(v) \\ &\times \psi_y^s E_{i+v+2^{-s}[l+(1/2)]}^n \left) \frac{\Delta t}{\Delta x} \end{aligned} \quad (25)$$

$$\begin{aligned} \psi_z^s H_{i-(1/2)+2^{-s}[l+(1/2)]}^{n+(1/2)} &= \left(\frac{1 - \frac{\sigma_x \Delta t}{2\epsilon_0}}{1 + \frac{\sigma_x \Delta t}{2\epsilon_0}} \right) \psi_z^s H_{i+(1/2)+2^{-s}[l+(1/2)]}^{n-(1/2)} \\ &- \frac{1}{\mu_0 \left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0}\right)} \left(\sum_{v=-\infty}^{v=+\infty} c_{s,l}(v) \phi_y E_{i+v}^n \right) \\ &+ \sum_{s'=0}^{s_{\max}} \sum_{l'=0}^{2^{s'}-1} \sum_{v=-\infty}^{v=+\infty} b_{l',l'}^{s,s'} \psi_z^{s'} E_{i+v+2^{-s'}[l'+(1/2)]}^n \left) \frac{\Delta t}{\Delta x} \end{aligned} \quad (26)$$

These update equations are valid in all regions including both the APML and normal MRTD regions. We can easily obtain the update equations in a non-APML region by simply setting $\sigma_x \equiv 0$, ($s_x(x) \equiv 1$) in (23)-(26).

To further solve for the update equations for E fields, we apply the same discretization procedure for (8) and obtain

$$\epsilon_0 \sum_{i'=-\infty}^{+\infty} \left[(\epsilon_y^{\phi,\phi})_{i',i} \phi_y E_{i'}^n \right. \quad (27)$$

$$\begin{aligned} &+ \left. \sum_{s=0}^{s_{\max}} \sum_{l=0}^{2^s-1} (\epsilon_y^{\psi,\psi})_{i',i} \psi_y^s E_{i'+2^{-s}[l+(1/2)]}^n \right] = \phi_y D_i^n \\ \epsilon_0 \sum_{i'=-\infty}^{+\infty} \left[(\epsilon_y^{\psi,\phi})_{i,i'} \phi_y E_{i'}^n \right. \\ &+ \left. \sum_{s'=0}^{s_{\max}} \sum_{l'=0}^{2^{s'}-1} (\epsilon_{l,l'}^{s,s'} \psi_y^s)_{i,i'} \psi_y^{s'} E_{i'+2^{-s'}[l'+(1/2)]}^n \right] \\ &= \psi_y^s D_{i+2^{-s}[l+(1/2)]}^n \end{aligned} \quad (28)$$

with the dielectric-related coefficients defined as

$$\begin{aligned} (\epsilon_y^{\phi,\phi})_{i',i} &= \frac{1}{\Delta x} \int_{-\infty}^{+\infty} \epsilon_y(x) \phi_{i'}(x) \phi_i(x) dx \\ &= \delta_{i,i'} + \sum_{\alpha=0}^{\alpha_0} (\epsilon_y^\alpha - 1) \frac{1}{\Delta x} \int_{x_1}^{x_2} \phi_{i'}(x) \phi_i(x) dx \end{aligned} \quad (29a)$$

 \end{aligned} \tag{29d}$$

where α_0 is the total number of dielectric regions and x_1^α and x_2^α are the beginning and end positions of the α th dielectric region.

For the sake of computational efficiency and simplicity, we expand all field quantities in terms of scaling functions for an entire computational region; we also expand wavelets with levels 0 and 1 in an extended discontinuity subregion where discontinuities exist and fields change dramatically. For example, for the α th dielectric region $[x_1^\alpha, x_2^\alpha] = [i_1 \Delta x, i_2 \Delta x]$ in a multilayer dielectric system we can truncate the wavelet expansions in the extended discontinuity subregion, $[(i_1 - M) \Delta x, (i_2 + M) \Delta x]$, by taking into account the stencil effect of the scaling and wavelet functions, where M is an adjustable integer dependent on accuracy requirements. The simplest choice is $M = 0$ for the crudest approximation. It is seldom necessary to set $M > 9$ because of the local support of scaling and wavelet functions. The value of M is usually designated by a suitable value to ensure enough accuracy, and in this research we set $M = 9$. Thus, we can rewrite the update equations (27) and (28) in matrix form

$$\begin{bmatrix} [\phi_y \mathbf{E}_i^n] \\ [\psi_{y0} \mathbf{E}_{i+(1/2)}^n] \\ [\psi_{y1} \mathbf{E}_{i+(1/4)}^n] \\ [\psi_{y1} \mathbf{E}_{i+(3/4)}^n] \end{bmatrix} = \frac{1}{\varepsilon_0} \sum_{i'=i_1-M}^{i_2+M} \begin{bmatrix} [{}^0 \varepsilon_{i,i'}^{\phi,\phi}] & [{}^0 \varepsilon_{i,i'+(1/2)}^{\phi,\psi}] & [{}^0 \varepsilon_{i,i'+(1/4)}^{\phi,\psi}] & [{}^1 \varepsilon_{i,i'+(3/4)}^{\phi,\psi}] \\ [{}^0 \varepsilon_{i+(1/2),i'}^{\psi,\phi}] & [{}^0 \varepsilon_{i+(1/2),i'+(1/2)}^{\psi,\psi}] & [{}^0 \varepsilon_{i+(1/2),i'+(1/4)}^{\psi,\psi}] & [{}^0 \varepsilon_{i+(1/2),i'+(3/4)}^{\psi,\psi}] \\ [{}^1 \varepsilon_{i+(1/4),i'}^{\psi,\phi}] & [{}^1 \varepsilon_{i+(1/4),i'+(1/2)}^{\psi,\psi}] & [{}^1 \varepsilon_{i+(1/4),i'+(1/4)}^{\psi,\psi}] & [{}^1 \varepsilon_{i+(1/4),i'+(3/4)}^{\psi,\psi}] \\ [{}^1 \varepsilon_{i+(3/4),i'}^{\psi,\phi}] & [{}^1 \varepsilon_{i+(3/4),i'+(1/2)}^{\psi,\psi}] & [{}^1 \varepsilon_{i+(3/4),i'+(1/4)}^{\psi,\psi}] & [{}^1 \varepsilon_{i+(3/4),i'+(3/4)}^{\psi,\psi}] \end{bmatrix}^{-1} \begin{bmatrix} [\phi_y \mathbf{D}_{i'}^n] \\ [\psi_{y0} \mathbf{D}_{i'+(1/2)}^n] \\ [\psi_{y0} \mathbf{D}_{i'+(1/4)}^n] \\ [\psi_{y1} \mathbf{D}_{i'+(3/4)}^n] \end{bmatrix} \tag{30}$$

where the coefficient matrix $[\epsilon_{i,i'}^{\phi,\phi}]$, for example, is given as follows

$$[\epsilon_{i,i'}^{\phi,\phi}] = \begin{bmatrix} (\epsilon_y^{\phi,\phi})_{i_1-M,i_1-M} & (\epsilon_y^{\phi,\phi})_{i_1-M,i_1-M+1} & \cdots & (\epsilon_y^{\phi,\phi})_{i_1-M,i_2+M-1} & (\epsilon_y^{\phi,\phi})_{i_1-M,i_2+M} \\ (\epsilon_y^{\phi,\phi})_{i_1-M+1,i_1-M} & (\epsilon_y^{\phi,\phi})_{i_1-M+1,i_1-M+1} & \cdots & (\epsilon_y^{\phi,\phi})_{i_1-M+1,i_2+M-1} & (\epsilon_y^{\phi,\phi})_{i_1-M+1,i_2+M} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ (\epsilon_y^{\phi,\phi})_{i_2+M-1,i_1-M} & (\epsilon_y^{\phi,\phi})_{i_2+M-1,i_1-M+1} & \cdots & (\epsilon_y^{\phi,\phi})_{i_2+M-1,i_2+M-1} & (\epsilon_y^{\phi,\phi})_{i_2+M-1,i_2+M} \\ (\epsilon_y^{\phi,\phi})_{i_2+M,i_1-M} & (\epsilon_y^{\phi,\phi})_{i_2+M,i_1-M+1} & \cdots & (\epsilon_y^{\phi,\phi})_{i_2+M,i_2+M-1} & (\epsilon_y^{\phi,\phi})_{i_2+M,i_2+M} \end{bmatrix} \quad (31a)$$

and $[\phi_y E_{i'}^n]$ is expressed as

$$[\phi_y E_{i'}^n]^T = [\phi_y E_{i_1-M}^n \quad \phi_y E_{i_1-M+1}^n \quad \cdots \quad \phi_y E_{i_2+M-1}^n \quad \phi_y E_{i_2+M}^n]^T \quad (31b)$$

As seen from Eq. (30), the fields at discrete points are coupled, and we have to update them by solving a matrix equation with dimensions of $4(i_2 - i_1 + 2M) \times 4(i_2 - i_1 + 2M)$ at each timestep. Note that all elements in the coefficient matrix (30) are constants for a specified system and that its elements can be calculated and stored in a constant array. Thus, we can update the E fields in (30) by simply performing a matrix multiplication if the inverse matrix of the coefficient matrix in (30) is saved as a constant matrix. Also note that the crudest approximation is to make the diagonal approximation and then (30) using the leapfrog update equations similar to those in the FDTD algorithm.

As shown in Fig. 3, we employ an APML to truncate both the entire computational domain for scaling functions (APML_s) and the internal extended discontinuity subregions (APML_w). To ensure adequate wave absorption in the x direction, we usually

choose the behavior of the APML conductivity σ_x as

$$\sigma_x = \sigma_{\max} \left| \frac{x - x_0}{d} \right|^\alpha \quad (32)$$

where x_0 is a starting position of the APML region in the x direction, d is the thickness of the APML region, and α is the power of the polynomial with the value of 2. The constant σ_{\max} is determined by the designated reflection coefficient for a wave to be normally incident on the APML wall

$$\sigma_{\max} = -\frac{\epsilon_0 v (\alpha + 1)}{2d} \ln(R(0)) \quad (33)$$

where v is the speed of electromagnetic wave propagation and $R(0)$ is the designated coefficient with normal incidence, here assuming $R(0) = 1.0 \times 10^{-8}$.

4.2. Application Results

As shown in Fig. 3, a plane TEM transient pulse, generated by exciting the E_y field, is incident on a dielectric slab characterized with the relative permittivity $\epsilon_y = 4$ and width $d = 9$ cm. The entire computational domain contains 100 cells with a cell size of $\Delta x = 7.5$ mm. The fields expanded with the scaling functions in the entire computational region are terminated by an APML at the two

Figure 3. A TEM_x wave incident on a dielectric slab, where d is the width of the dielectric slab and d_0 is the extended dielectric region.

Table 3. Discretization in MRTD and FDTD Methods

	Δx (mm)	Δt (ps)	N_x (cell)	$N_{\text{PML},s}$ (cell)	$N_{\text{PML},w}$ (cells)
FDTD	1.5	2.5	512	N/A	N/A
S-MRTD	7.5	1.0	100	8	N/A
SW-MRTD ($s=0$)	7.5	1.0	100	8	5
SW-MRTD ($s=1$)	7.5	5.55	100	8	5

ends of the region, while those expanded with the wavelet expansion functions are defined only in the extended discontinuity subregion truncated with an APML_w . We observe excellent agreement among the results derived from the finite-difference time-domain (FDTD) method, the scaling function-based MRTD (S-MRTD), the scaling and wavelet function-based MRTD (SW-MRTD), and the analytic results. Table 3 lists the space and time discretization values of the system for the MRTD and FDTD computations.

It is found that the contribution to field magnitude from wavelets is much lower than that of scaling functions, and this is the reason why we only expand wavelets in an extended discontinuity region. In Figs. 4a and 4b, we present the reflection coefficients for a dielectric-layer system calculated by using the FDTD, S-MRTD, and SW-MRTD ($s=0,1$) methods. We observe excellent agreement between the results. We find that the SW-MRTD with $s=1$ shows the best accuracy with the relative error of 0.07% calculated at the peak as shown in Fig. 4b, and that the FDTD is the worst-case scenario with the relative error of 0.6% with respect to the analytic solution.

5. ANALYSIS OF MICROWAVE CIRCUITS

5.1. MRTD Modeling

In this section we study a generalized microwave circuit problem. For simplicity, we expand the electromagnetic fields only in terms of the Battle-Lemarie scaling function and ignore wavelet expansions. The governing equations thus include the pair of Maxwell two-curl equations

$$\nabla \times \vec{H} = \frac{\partial \vec{D}}{\partial t} \quad (34)$$

$$\nabla \times \vec{E} = -\mu_0 \frac{\partial \vec{H}}{\partial t} \quad (35)$$

and the defined constitutive relation relating the \vec{E} and \vec{D} fields:

$$\frac{\partial \vec{D}}{\partial t} = \bar{\sigma} \cdot \vec{E} + \epsilon_0 \bar{\epsilon}_r \cdot \frac{\partial \vec{E}}{\partial t} \quad (36)$$

For generality, we represent the relative permittivity and the conductivity as a diagonal tensor. Note that the printed planar microstrip circuits usually are inhomogeneous in the vertical direction (y axis) but homogenous in horizontal directions (x and z axes). Thus, the elements of the relative permittivity and conductivity can be ex-

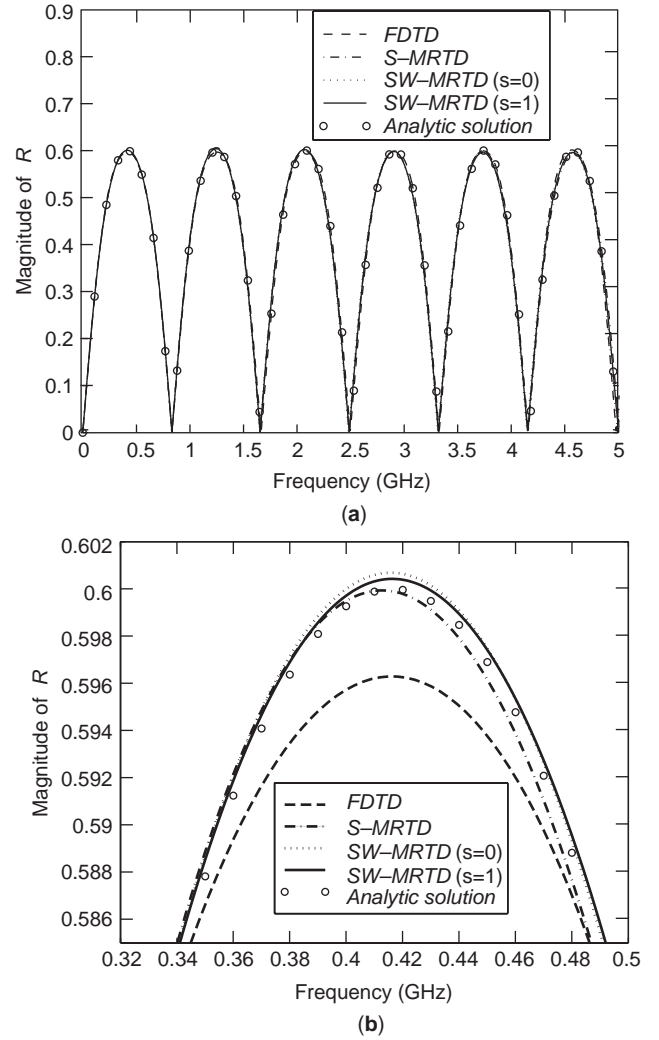

Figure 4. Magnitude of reflection coefficient R for a dielectric-layer slab system versus frequency ($d=9$ cm, $\epsilon_r=4.0$): (a) full frequency bandwidth of interest; (b) enlarged frequency response.

pressed as $\epsilon_i = \epsilon_i(y)$ ($i=x,y,z$) and $\sigma_i(x,y,z) = \sigma_\infty(x \in [x_1, x_2], y \in [y_1, y_2], z \in [z_1, z_2])$.

Next, we expand all the electric and magnetic field quantities in terms of the cubic spline Battle-Lemarie scaling function $\phi(x)$ in space and the rectangular pulse function $h(t)$ in time. For instance, all the x components of fields can be expressed as follows:

$$D_x(r, t) = \sum_{n,i,j,k=-\infty}^{+\infty} \phi_x D_{i+(1/2),j,k}^n \phi_{i+(1/2)}(x) \times \phi_j(y) \phi_k(z) h_n(t) \quad (37)$$

$$E_x(r, t) = \sum_{n,i,j,k=-\infty}^{+\infty} \phi_x E_{i+(1/2),j,k}^n \phi_{i+(1/2)}(x) \times \phi_j(y) \phi_k(z) h_n(t) \quad (38)$$

$$H_x(r, t) = \sum_{n,i,j,k=-\infty}^{+\infty} \phi_x H_{i,j+(1/2),k+(1/2)}^{n+(1/2)} \phi_i(x) \phi_{j+(1/2)}(y) \times \phi_{k+(1/2)}(z) h_{n+(1/2)}(t) \quad (39)$$

$$B_x(r, t) = \sum_{n,i,j,k=-\infty}^{+\infty} \phi_x B_{i,j+(1/2),k+(1/2)}^{n+(1/2)} \phi_i(x) \phi_{j+(1/2)}(y) \times \phi_{k+(1/2)}(z) h_{n+(1/2)}(t) \quad (40)$$

Note that both the electric fields E_x and D_x as well as the magnetic fields H_x and B_x are sampled at the same space points and time positions, respectively. Substituting the field expansions into Maxwell equations and applying the Galerkin's method, we obtain a set of field update equations. Typically, their x components read

$$\begin{aligned} \phi_x D_{i+(1/2),j,k}^{n+1} &= \phi_x D_{i+(1/2),j,k}^n \\ &+ \sum_m a(m) \left[\phi_z H_{i+(1/2),j+m+(1/2),k}^{n+(1/2)} \frac{\Delta t}{\Delta y} \right. \\ &\left. - \phi_y H_{i+(1/2),j,k+m+(1/2)}^{n+(1/2)} \frac{\Delta t}{\Delta z} \right] \end{aligned} \quad (41)$$

$$\begin{aligned} \phi_x H_{i,j+(1/2),k+(1/2)}^{n+(1/2)} &= \phi_x H_{i,j+(1/2),k+(1/2)}^{n-(1/2)} \\ &+ \frac{1}{\mu_0} \sum_m a(m) \left[\phi_y E_{i,j+(1/2),k+m+1}^{n+1} \frac{\Delta t}{\Delta z} \right. \\ &\left. - \phi_z E_{i,j+m+1,k+(1/2)}^{n+1} \frac{\Delta t}{\Delta y} \right] \end{aligned} \quad (42)$$

where the expansion coefficient $a(m)$ is as defined in (19). Note that the update equations so derived still retain the form of an explicit leapfrogging scheme similar to that of the FDTD, although they are more complex.

The microstrip line printed on a grounded dielectric substrate is a fundamental structure in planar printed millimeter-wave integrated circuits (MICs). We will derive the update equations for this type of MIC. For simplicity, both the printed microstrip-type circuits and the ground plane are assumed to be PECs, and infinitesimally thin as well.

In order to take into account of the coupling between cells in implementing the high-order expansions in the MRTD applications, we apply an image technique to truncate the PEC ground plane as shown in Fig. 5 [2,33]. Note that an imaginary image region must be constructed for PEC boundary truncation to account for the field contribution from the image structure although it would not require any additional computer resources.

Next, we consider a microstrip structure, in which a PEC strip and a dielectric substrate are defined inside the computational domain. We would like to point out that derived update equations such as (41) and (42) will not be sufficient to update fields in an inhomogeneous region, where the computational domain contains different materials, such as a PEC strip and a substrate. An additional update equation, including material parameters, must be derived from the constitutive relation. By expanding the

Figure 5. Computational domain for a grounded open microstrip-type structure using the MRTD scheme.

fields, substituting them into (36), and using Galerkin's method, we can obtain new update equations whose x -component relation reads

$$\begin{aligned} (\phi_x D_{i+(1/2),j,k}^{n+1} - \phi_x D_{i+(1/2),j,k}^n) &= \sum_{i',j',k'=-\infty}^{\infty} (\sigma_x)_{ii',jj',kk'} \frac{\Delta t}{2} (\phi_x E_{i'+(1/2),j',k'}^{n+1} + \phi_x E_{i'+(1/2),j',k'}^n) \\ &+ \epsilon_0 \sum_{j'=-\infty}^{\infty} (\epsilon_x)_{jj'} (\phi_x E_{i+(1/2),j',k}^{n+1} - \phi_x E_{i+(1/2),j',k}^n) \end{aligned} \quad (43)$$

where the coefficient $(\epsilon_x)_{jj'}$, defined as the element of the equivalent relative permittivity in the MRTD domain, is expressed as

$$\begin{aligned} (\epsilon_x)_{jj'} &= \frac{1}{\Delta y} \int_{-\infty}^{+\infty} \phi_j(y) \epsilon_x(y) \phi_{j'}(y) dy \\ &= \frac{1}{\Delta y} \int_{-\infty}^{+\infty} \phi \left(\frac{y}{\Delta y} - j \right) \epsilon_x(y) \phi \left(\frac{y}{\Delta y} - j' \right) dy \quad (44a) \\ &= \int_{-\infty}^{+\infty} \phi(y-j) \epsilon_x(y \Delta y) \phi(y-j') dy \end{aligned}$$

Similarly, the coefficient $(\sigma_x)_{ii',jj',kk'}$ is given as follows: is given as follows:

$$\begin{aligned} (\sigma_x)_{ii',jj',kk'} &= \frac{1}{\Delta x \Delta y \Delta z} \iiint_{\infty} \phi_{i+(1/2)}(x) \phi_{i'+(1/2)}(x) \phi_j(y) \\ &\times \phi_{j'}(y) \phi_k(z) \phi_{k'}(z) \sigma_x dx dy dz \\ &= \sigma_{\infty} \left(\int_{x_1}^{x_2} \phi_{i+(1/2)}(x) \phi_{i'+(1/2)}(x) \frac{dx}{\Delta x} \right) \\ &\times \left(\int_{y_1}^{y_2} \phi_j(y) \phi_{j'}(y) \frac{dy}{\Delta y} \right) \left(\int_{z_1}^{z_2} \phi_k(z) \phi_{k'}(z) \frac{dz}{\Delta z} \right) \\ &= \sigma_{\infty} \alpha_{i+(1/2),i'+(1/2)} \beta_{j,j'} \gamma_{k,k'} \end{aligned} \quad (44b)$$

In view of the localized feature of the basis functions, we have used a diagonal approximation in evaluating $a_{x,x'}$ ($\alpha = \alpha, \beta, \gamma; \chi = i + \frac{1}{2}j, k$); namely, we have replaced $\alpha_{i+(1/2),i' + (1/2)}\beta_{j,j'}\gamma_{k,k'}$ with $\alpha_{i+(1/2),i' + (1/2)}\beta_{j,j'}\gamma_{k,k'}\delta_{i,i'}\delta_{j,j'}\delta_{k,k'}$ in deriving update equations. Thus, (43) now becomes

$$\begin{aligned} & (\phi_x D_{i+(1/2),j,k}^{n+1} - \phi_x D_{i+(1/2),j,k}^n) \\ &= \left(\frac{\sigma_\infty \alpha_{i,i} \beta_{j,j} \gamma_{k,k} \Delta t}{2} \right) (\phi_x E_{i+(1/2),j,k}^{n+1} + \phi_x E_{i+(1/2),j,k}^n) \\ &+ \varepsilon_0 \sum_{j'=-\infty}^{\infty} (\varepsilon_x)_{j,j'} (\phi_x E_{i+(1/2),j',k}^{n+1} - \phi_x E_{i+(1/2),j',k}^n) \end{aligned} \quad (45)$$

where $\delta_{i,i'}$ is the Kronecker symbol representing unity when $i=i'$ otherwise zero. Furthermore, when the PEC strip is infinitesimally thin at the gridpoint j_0 , $\beta_{j,j}$ can be simply written as $\beta_{j,j}\delta_{j,j_0}$.

For an open grounded planar structure as shown in Fig. 5, all grids in the original region along the y direction are defined in the region $[0, N_y]$. Note that the summation index j' in (45) spans the original structure as well as all the image regions. However, all the image field quantities can be expressed in terms of fields in the original region bounded by $[0, N_y]$. According to the image principle [31], a tangential E field in the image region (parallel to the PEC ground plane) is oddly symmetric to its original field, while a tangential H field in the image region is evenly symmetric to its mirror field. Thus the summation (45) degenerates into a simpler form as

$$\begin{aligned} & (\phi_x D_{i+(1/2),j,k}^{n+1} - \phi_x D_{i+(1/2),j,k}^n) \\ &= \left(\frac{\sigma_\infty \alpha_{i,i} \beta_{j,j} \gamma_{k,k} \Delta t}{2} \right) \delta_{j,j_0} (\phi_x E_{i+(1/2),j,k}^{n+1} + \phi_x E_{i+(1/2),j,k}^n) \\ &+ \varepsilon_0 \sum_{j'=0}^{N_y} (\varepsilon_x^*)_{j,j'} (\phi_x E_{i+(1/2),j',k}^{n+1} - \phi_x E_{i+(1/2),j',k}^n) \end{aligned} \quad (46)$$

with

$$\sum_{j'=0}^{N_y} (\varepsilon_x^*)_{j,j'} = \sum_{j'=0}^{N_y} (\varepsilon_x)_{j,j'} - \sum_{j'=-N_y}^{-1} (\varepsilon_x)_{j,j'} \quad (47)$$

where the first term corresponds to the original circuits and the second one results from its image structure.

By taking the inverse operation of the equation in (46), we can obtain the update equation for the x -component of the E fields as follows:

$$\begin{aligned} \phi_x E_{i+(1/2),j,k}^{n+1} &= \sum_{j'=0}^{N_y} [A]_{j,j'} \phi_x E_{i+(1/2),j',k}^n \\ &+ \frac{1}{\varepsilon_0} \sum_{j'=0}^{N_y} [B]_{j,j'} (\phi_x D_{i+(1/2),j',k}^{n+1} \\ &- \phi_x D_{i+(1/2),j',k}^n) \end{aligned} \quad (48)$$

where the matrices $[A]$ and $[B]$ are given by

$$[A] = \left[[e_x^*]_{j,j'} + \frac{\sigma_\infty \alpha_{i,i} \beta_{j,j} \gamma_{k,k} \Delta t}{2\varepsilon_0} \delta_{j,j_0} \right]^{-1} \cdot \left[[e_x^*]_{j,j'} - \frac{\sigma_\infty \alpha_{i,i} \beta_{j,j} \gamma_{k,k} \Delta t}{2\varepsilon_0} \delta_{j,j_0} \right] \quad (49a)$$

$$[B] = \left[[e_x^*]_{j,j'} + \frac{\sigma_\infty \alpha_{i,i} \beta_{j,j} \gamma_{k,k} \Delta t}{2\varepsilon_0} \delta_{j,j_0} \right]^{-1} \quad (49b)$$

In common with the approach typically employed in the FDTD method, the MRTD algorithm can also accommodate different material parameters in the update equations for inhomogeneous computational regions, as is evident from the expressions given in (48) and (49).

5.2. APML Modeling

To truncate the computational domain, we apply an APML that incorporates the MRTD field expansions. For the sake of generality, we represent the relative permittivity and permeability as a diagonal tensor. Then, in a generalized APML medium, the Maxwell equations in the frequency domain become

$$\nabla \times \vec{H} = j\omega\varepsilon_0 \bar{\varepsilon} \cdot \vec{E} \quad (50)$$

$$\nabla \times \vec{E} = -j\omega\mu_0 \bar{\mu} \cdot \vec{H} \quad (51)$$

where the APML constitutive parameter matrix can be represented as

$$\bar{\varepsilon} = \begin{bmatrix} s_x^{-1} s_y s_z & 0 & 0 \\ 0 & s_x s_y^{-1} s_z & 0 \\ 0 & 0 & s_x s_y s_z^{-1} \end{bmatrix} \quad (52a)$$

with

$$s_\alpha = 1 + \frac{\sigma_\alpha}{j\omega\varepsilon_0} \quad (\alpha = x, y, z) \quad (52b)$$

By using the generalized differential matrix operators [34], the Maxwell equation can thus be written in matrix form for the APML region:

$$\begin{bmatrix} 0 & -\partial_z & \partial_y \\ \partial_z & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} = j\omega\varepsilon_0 \varepsilon_r \begin{bmatrix} s_y s_z s_x^{-1} & 0 & 0 \\ 0 & s_x s_z s_y^{-1} & 0 \\ 0 & 0 & s_x s_y s_z^{-1} \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (53)$$

$$\begin{bmatrix} 0 & -\partial_z & \partial_y \\ \partial_z & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} = -j\omega\mu_0 \begin{bmatrix} s_y s_z s_x^{-1} & 0 & 0 \\ 0 & s_x s_z s_y^{-1} & 0 \\ 0 & 0 & s_x s_y s_z^{-1} \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} \quad (54)$$

Note that s_x, s_y, s_z are parameters associated with wave attenuation in the x, y, z directions, respectively. Usually an APML region consists of a number of subregions, including APML faces, edges, and corners. As the most generalized case, we consider an APML corner where a wave is absorbed in all (x, y, z) directions. Since the three components of the E fields are similar, we need only to illustrate the x component.

Because of the reciprocal relation of $s_x(\alpha = x, y, z)$ appearing in Eqs. (53) and (54), we have to adopt a two-step approach by defining an electric flux density:

$$D_x = \left(\frac{1 + (\sigma_y/j\omega\epsilon_0)}{1 + (\sigma_x/j\omega\epsilon_0)} \right) \epsilon_0 \epsilon_r(y) E_x \quad (55)$$

With the frequency-time converter, $j\omega \Leftrightarrow (\partial/\partial t)$, we can convert (55) and the first equation of (53) into the time domain:

$$\frac{\partial D_x}{\partial t} + \frac{\sigma_z}{\epsilon_0} D_x = \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} \quad (56)$$

$$\epsilon_0 \epsilon_r \frac{\partial E_x}{\partial t} + \epsilon_0 \frac{\sigma_y}{\epsilon_0} E_x = \frac{\partial D_x}{\partial t} + \frac{\sigma_x}{\epsilon_0} D_x \quad (57)$$

By expanding all the fields in terms of the scaling functions in space and rectangular pulse function in time, substituting them into (56), (57), and then employing the Galerkin method, we can derive their corresponding update equations:

$$\begin{aligned} \phi_x D_{i+(1/2),j,k}^{n+1} &= \left(\frac{1 - (\sigma_z \Delta t / 2\epsilon_0)}{1 + (\sigma_z \Delta t / 2\epsilon_0)} \right) \phi_x D_{i+(1/2),j,k}^n \\ &+ \left(\frac{1}{1 + (\sigma_z \Delta t / 2\epsilon_0)} \right) \sum_m a(m) \\ &\times \left(\phi_z H_{i+(1/2),j+m+(1/2),k}^{n+(1/2)} \frac{\Delta t}{\Delta y} \right. \\ &\left. - \phi_y H_{i+(1/2),j,k+m+(1/2)}^{n+(1/2)} \frac{\Delta t}{\Delta z} \right) \end{aligned} \quad (58)$$

$$\begin{aligned} \phi_x E_{i+(1/2),j,k}^{n+1} &= \left(\frac{1 - (\sigma_y \Delta t / 2\epsilon_0)}{1 + (\sigma_y \Delta t / 2\epsilon_0)} \right) \phi_x E_{i+(1/2),j,k}^n \\ &+ \frac{1}{\epsilon_0} \left(\frac{1}{1 + (\sigma_y \Delta t / 2\epsilon_0)} \right) \sum_{j'=0}^{N_y} ([\epsilon_x^*]^{-1})_{j,j'} \\ &\times \left[\left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0} \right) \phi_x D_{i+(1/2),j',k}^{n+1} \right. \\ &\left. - \left(1 - \frac{\sigma_x \Delta t}{2\epsilon_0} \right) \phi_x D_{i+(1/2),j',k}^n \right] \end{aligned} \quad (59)$$

Following the same procedure developed above, we can also obtain magnetic field equations in the frequency and time domains, whose x components read

$$B_x = \left(\frac{1 + (\sigma_y/j\omega\epsilon_0)}{1 + (\sigma_x/j\omega\epsilon_0)} \right) \mu_0 \mu_r H_x \quad (60)$$

$$-\frac{\partial B_x}{\partial t} - \frac{\sigma_z}{\epsilon_0} B_x = \frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} \quad (61)$$

$$\mu_0 \mu_r \frac{\partial H_x}{\partial t} + \mu_0 \frac{\sigma_y}{\epsilon_0} H_x = \frac{\partial B_x}{\partial t} + \frac{\sigma_x}{\epsilon_0} B_x \quad (62)$$

Their associated/update equations now become

$$\begin{aligned} \phi_x B_{i,j+(1/2),k+(1/2)}^{n+(1/2)} &= \left(\frac{1 - (\sigma_z \Delta t / 2\epsilon_0)}{1 + (\sigma_z \Delta t / 2\epsilon_0)} \right) \phi_x B_{i,j+(1/2),k+(1/2)}^{n-(1/2)} \\ &+ \left(\frac{1}{1 + (\sigma_z \Delta t / 2\epsilon_0)} \right) \sum_m a(m) \\ &\times \left(\phi_y E_{i,j+(1/2),k+m+1}^n \frac{\Delta t}{\Delta z} \right. \\ &\left. - \phi_z H_{i,j+m+1,k+(1/2)}^n \frac{\Delta t}{\Delta y} \right) \end{aligned} \quad (63)$$

$$\begin{aligned} \phi_x H_{i,j+(1/2),k+(1/2)}^{n+(1/2)} &= \left(\frac{1 - (\sigma_y \Delta t / 2\epsilon_0)}{1 + (\sigma_y \Delta t / 2\epsilon_0)} \right) \phi_x H_{i,j+(1/2),k+(1/2)}^{n-(1/2)} \\ &+ \frac{1}{\mu_0 \mu_r} \left(\frac{1}{1 + (\sigma_y \Delta t / 2\epsilon_0)} \right) \\ &\times \left[\left(1 + \frac{\sigma_x \Delta t}{2\epsilon_0} \right) \phi_x B_{i,j+(1/2),k+(1/2)}^{n+(1/2)} \right. \\ &\left. - \left(1 - \frac{\sigma_x \Delta t}{2\epsilon_0} \right) \phi_x B_{i,j+(1/2),k+(1/2)}^{n-(1/2)} \right] \end{aligned} \quad (64)$$

We can derive the remaining MRTD update equations in the same manner for all the APML-face, edge, and corner regions.

5.3. Extraction of MIC characteristics

Most of the MIC characteristics can be extracted from the time or frequency domain voltages and currents. Since the time-domain-updated quantities in the MRTD do not

Figure 6. The integral paths C and L for the time-domain voltage and the current of a microstrip line.

represent fields but only the field expansion coefficients, we must first construct the total fields from these coefficients. For instance, the time-domain voltage for a microstrip line can be solved, as shown in Fig. 6, by taking an integration of E_y from the ground plane to the strip along an integral path L with the specified values of x_0 and z_0 . The time-domain voltage is then given as

$$\begin{aligned}
 V &= - \int_0^h E_y(x_0, y, z_0, t_0) dy \\
 &= - \sum_{l=0}^{N_s} \int_{l\Delta y}^{(l+1)\Delta y} \left[\iiint E_y(x, y, z, t) \delta(x - x_0) \right. \\
 &\quad \left. \times \delta(z - z_0) \delta(t - t_0) dx dz dt \right] dy \\
 &= - \sum_{l=0}^{N_s} \left[\int_{l\Delta y}^{(l+1)\Delta y} \sum_{i,j,k=-\infty}^{+\infty} \phi_y E_{i_0-i_j+(1/2),k_0-k}^n \phi(i) \phi(k) \right. \\
 &\quad \left. \times \phi_{j+(1/2)}(y) dy \right] \\
 &= - \sum_{l=0}^{N_s} \left[\sum_{i,j,k=-\infty}^{+\infty} \phi_y E_{i_0-i_j+l+(1/2),k}^n \phi(i) \phi(k) b(j) \Delta y \right]
 \end{aligned} \tag{65}$$

with

$$b(j) = \int_{-1/2}^{1/2} \phi(y-j) dy \tag{66}$$

where N_s is the number of cells counted from the ground plane to the PEC strip and $h = N_s \Delta y$. Note that the summation indices i, j, k must span all the real and image regions.

Similarly, we can solve the time-domain current by integrating the magnetic field intensity surrounding the strip along an enclosed contour C as shown in Fig. 6, and

described below

$$\begin{aligned}
 I &= \oint_C \vec{H} \cdot d\vec{l} \\
 &= \left[\int_{[i_1-(1/2)]\Delta x}^{[i_1+(1/2)]\Delta x} H_x(x, y_1, z_0, t_0) dx + \dots \right. \\
 &\quad \left. + \int_{[j_2-(1/2)]\Delta x}^{[j_2+(1/2)]\Delta x} H_x(x, y_1, z_0, t_0) dx \right] \\
 &\quad - \left[\int_{[i_1-(1/2)]\Delta x}^{[i_1+(1/2)]\Delta x} H_x(x, y_2, z_0, t_0) dx + \dots \right. \\
 &\quad \left. + \int_{[j_2-(1/2)]\Delta x}^{[j_2+(1/2)]\Delta x} H_x(x, y_2, z_0, t_0) dx \right] \\
 &\quad + \left[- \int_{[j_0-(1/2)]\Delta y}^{[j_0+(1/2)]\Delta y} H_y(x_1, y, z_0, t_0) dy \right. \\
 &\quad \left. + \int_{[j_0-(1/2)]\Delta y}^{[j_0+(1/2)]\Delta y} H_y(x_2, y, z_0, t_0) dy \right]
 \end{aligned} \tag{67}$$

where the first integration can be derived as

$$\begin{aligned}
 &\int_{[i_1-(1/2)]\Delta x}^{[i_1+(1/2)]\Delta x} H_x(x, y_1, z_0, t_0) dx \\
 &= \int_{[i_1-(1/2)]\Delta x}^{[i_1+(1/2)]\Delta x} \left[\iiint H_x(x, y, z, t) \delta(y - y_1) \right. \\
 &\quad \left. \times \delta(z - z_0) \delta(t - t_0) dy dz dt \right] dx \\
 &= \int_{[i_1-(1/2)]\Delta x}^{[i_1+(1/2)]\Delta x} \sum_{i,j,k=-\infty}^{+\infty} \phi_k H_{i_1-j,k_0-k}^{n+(1/2)} \phi(j) \phi(k) \phi_i(x) dx \\
 &= \sum_{i,j,k=-\infty}^{+\infty} \phi_k H_{i_1+i_{j_1-j},k_0-k}^{n+(1/2)} \phi(j) \phi(k) b(i)
 \end{aligned} \tag{68}$$

We finally have the time-domain current as follows:

$$\begin{aligned}
 I &= \sum_{l=i_1}^{i_2} \left[\sum_{i,j,k=-\infty}^{+\infty} (\phi_x H_{l+i_{j_1-j},k_0-k}^{n+(1/2)} \right. \\
 &\quad \left. - \phi_x H_{l+i_{j_2-j},k_0-k}^{n+(1/2)}) \phi(j) \phi(k) b(i) \right] \\
 &\quad + \sum_{i,j,k=-\infty}^{+\infty} [(\phi_y H_{i_2-i_{j_0+j},k_0-k}^{n+(1/2)} \\
 &\quad - \phi_y H_{i_1-i_{j_0+j},k_0-k}^{n+(1/2)}) \phi(i) \phi(k) b(j)]
 \end{aligned} \tag{69}$$

The two most important characteristics for a transmission line are the effective dielectric constant $\epsilon_{r,\text{eff}}$ and characteristic impedance Z_0 . The effective dielectric constant $\epsilon_{r,\text{eff}}$

defined as

$$\varepsilon_{r,\text{eff}}(\omega) = \frac{\beta^2(\omega)}{\omega^2 \varepsilon_0 \mu_0} \quad (70)$$

with

$$\beta(\omega) = \frac{1}{(z_j - z_i)} \text{angle} \left(\frac{\text{FFT}[V(z_i, t)]}{\text{FFT}[V(z_j, t)]} \right) \quad (71)$$

where z_i and z_j are two points along the transmission line separated by a distance $(z_j - z_i)$ and FFT denotes the fast Fourier transform to the time-domain voltage signals, $V(z_i, t)$ and $V(z_j, t)$. We find that it is not always necessary to extract the propagation characteristics using a post-processing algorithm [35] when the APMLs are used for mesh truncation.

Subsequently, the characteristic impedance Z_0 is calculated from

$$Z_0 = \frac{\text{FFT}\{V(z_i, t)\}}{\text{FFT}\{I(z_i, t)\}} \quad (72)$$

Apparently, both the time-domain voltages and currents can be solved at a specified position z_i , as mentioned previously.

On the basis of the defined voltage signals at each port, we can solve for the scattering parameters for a multiport

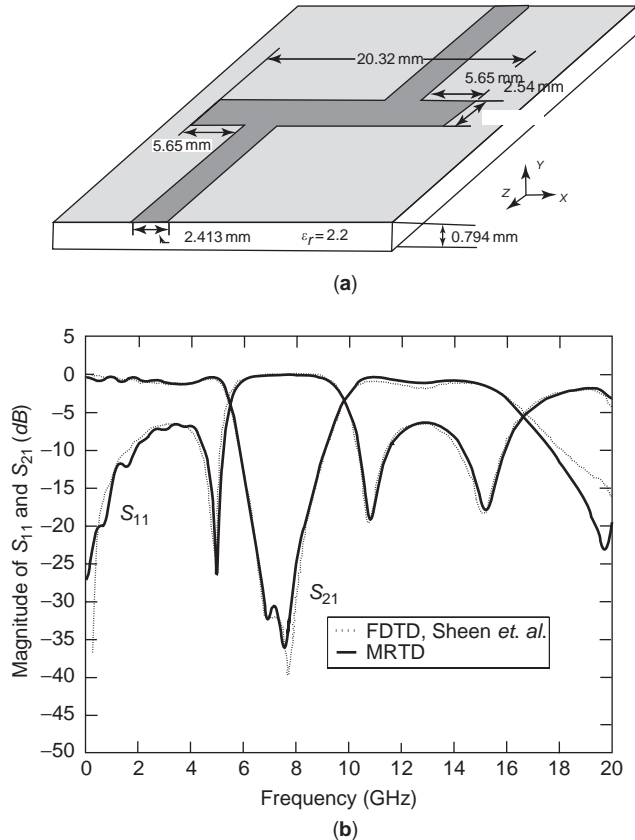

Figure 7. (a) Geometry and dimensions for a microstrip lowpass filter; (b) magnitudes of the S parameters S_{11} and S_{21} .

Table 4. Spatial and Time Discretization for a Microstrip Lowpass Filter

Discretization	MRTD	FDTD
Δx (mm)	0.8128	0.4064
Δy (mm)	0.3970	0.2650

Δt (ps)	0.3996	0.4410
$N_x \times N_y \times N_z$	$45 \times 10 \times 45$	$80 \times 16 \times 100$
VDR		15.82%
CPU time (s)	3553.77	19782.42c
TDR		17.96%

millimeter-wave integrated circuit. The scattering matrix coefficients in the frequency domain for a multiport system are defined as

$$[V]^- = [S][V]^+ \quad (73)$$

where $[V]^-$ and $[V]^+$ are the reflected and incident voltage vectors, respectively, and $[S]$ denotes the scattering matrix [36]. An arbitrary element on the scattering matrix S_{ij} can be derived from

$$S_{ij} = \frac{\text{FFT}\{V_i^-(t)\} \sqrt{Z_{0j}}}{\text{FFT}\{V_j^+(t)\} \sqrt{Z_{0i}}} \quad (74)$$

where $V_i^-(t)$ and $V_j^+(t)$ are the reflected and incident voltage signals defined at ports i and j , respectively and $\sqrt{Z_{0i}}$ and $\sqrt{Z_{0j}}$ are their corresponding characteristic impedance values at these two ports.

5.4. Application Results

Next we apply the developed MRTD technique to analyze a microstrip lowpass filter as shown in Fig. 7a. Six- and four-layer APMLs are used for termination of computational domain along the direction of wave propagation and other open walls; the image technique is employed for the ground plane termination.

The computational volume is discretized into $45 \times 10 \times 45$ cells as given in Table 4. The central strip segment is specified with the area of $25\Delta x \times 3\Delta z$, and the time update is terminated at $N_t = 4000$. We observe good agreement within a wide frequency range between the results of the scattering parameters derived from the MRTD and FDTD approaches [37], as seen in Fig. 7b. However, the MRTD approach requires much less computational CPU time (3,553.77 s) compared to that of the FDTD (19,782.42 s). A 333 MHz, a 128 M RAM Pentium II-MAX PC Compatible is used for all computations. The computational volume difference ratio (VDR) and CPU time difference ratio (TDR) between the MRTD scheme and the FDTD method are 15.82% and 17.96%, respectively.

6. CONCLUSIONS

In this article, we have introduced the fundamental concepts of MRA, scaling functions, and wavelets. On the basis of these concepts, we have developed a cubic spline

Battle–Lemarie scaling and wavelet function–based MRTD scheme, in conjunction with an APMML absorption boundary condition and an image technique, for generalized electromagnetic engineering applications. We have demonstrated the applications of the MRTD scheme by analyzing a TEM wave propagation in a dielectric-layered space and a microstrip lowpass filter. It is found that the developed MRTD scheme is highly efficient for all cases investigated and requires only a fraction of computational space and CPU time that are used in the FDTD techniques at the price of complexity in mathematical modeling. References 1–13 are on MRTD, Refs. 14–28 are on MRA, Refs. 29–33 are on APMML, and Refs. 34–37 are general.

Acknowledgment

The authors would like to thank Dr. Xian Wu for his comments and suggestions for the theory part of scaling functions and wavelets and Ms. Lori Donath for her great editing assistance.

NEGATIVE RESISTANCE

CLIFFORD A. KING
KWOK K. NG
Lucent Technologies

Resistance is the measure of allowed current passing through a component when a terminal voltage is applied. Ohm's law defines that the resistance is the ratio of the applied voltage to the resulting current:

$$R = \frac{V}{I} \quad (1)$$

This simple I - V relationship is shown in Fig. 1a. Sometimes a component deviates from having a linear relationship, resulting in a nonlinear curve. An example of a rectifier is shown in Fig. 1b. Such resistance is referred to as being nonlinear, as opposed to linear. It is also helpful to distinguish the static resistance (V/I) from the dynamic resistance or differential resistance (the slope of the I - V curve as dV/dI). So in a linear resistor, the static resistance is the same as the dynamic resistance ($V/I = dV/dI$), whereas in a nonlinear resistor, $V/I \neq dV/dI$.

It is understood that the term negative resistance refers to the dynamic characteristic, that is, the slope of the I - V curve (dV/dI) is negative. Notice that in the example of a common negative resistance (Fig. 1c), only dV/dI is negative, but the static resistance is always positive. That is why negative resistance and negative differential resistance are used interchangeably. Negative resistance can also be classified into two shapes: (1) N-shape negative resistance, as shown in Fig. 1c; and (2) S-shape negative resistance, as shown in Fig. 1d. The S-shape negative resistance is typical behavior of a switch.

Most of the devices exhibiting negative resistance have two terminals, but there are also devices with three or more terminals. An example is thyristor. The function of the extra terminal is to control the shape of the I - V characteristics between the two terminals that carry the majority of the current. Specifically, for the S-shape curve shown in Fig. 1d, the triggering (breakover) voltage or current before negative resistance sets in can be varied.

There is yet another group of devices where the negative resistance does not come from a negative slope in the I - V curve. In these devices, when an AC voltage is applied, the resulting AC current is not in phase with the applied voltage. The majority of this phase delay comes from the transit time of charge which is generated within the device and subsequently travels to the boundaries of the devices and to the terminals. For this reason, these devices are called transit-time devices. The phase relationship between the applied voltage and the resulting current is shown in Fig. 1e. The unique feature is that when the small-signal voltage is positive, the small-signal current is negative, giving rise to negative AC power

absorbed. So this type of negative resistance comes from \vec{V}/\vec{I} being negative, as opposed to dV/dI being negative. It is worthwhile to mention that both inductor and capacitor cause a phase shift between the AC voltage and current. The crucial requirement here is that in order to have net AC power gain, a phase shift or more than 90° is necessary, which is not achievable with either a capacitor or an inductor.

In the following sections, the negative resistance devices originating from dV/dI being negative are discussed, followed by their applications. Finally, similar discussions on the transit-time devices are presented.

1. TUNNEL DIODE

Tunneling is a quantum-mechanical process whereby electrons with insufficient energy to surmount a thin energy barrier tunnel directly through it. In a semiconductor p-n junction, significant tunneling occurs when both sides of the junction are heavily doped so that the depletion region (energy barrier) is thin. Also, since the tunneling process requires conservation of energy, the tunnel diode (Esaki diode) is fabricated such that both sides of the junction are degenerately doped so that states of equal energy exist on both sides of the junction (in the conduction and valence bands). Figure 2a illustrates the situation under low forward bias where the bottom of the conduction band on the n side and the top of the valence band on the p side overlap and significant tunneling occurs. At higher bias, the overlap becomes smaller and the tunneling current decreases, thereby producing the negative differential resistance (NDR) feature mentioned earlier. Eventually, at still higher forward voltages, when the overlap disappears as in Fig. 2b, the normal diffusion current becomes dominant and the current increases with bias once again. A useful figure of merit for NDR devices is the peak-to-valley ratio, which is a measure of the ratio of the peak current obtained just before the onset of NDR (point *B* in Fig. 1c) to the minimum current at the termination of the NDR region (point *C* in Fig. 1c). Peak-to-valley ratios of 3 to 20 are typical for semiconductor tunnel diodes.

2. RESONANT TUNNELING STRUCTURES

A semiconductor quantum well is a structure formed when materials with either a conduction or valence band discontinuity are joined such that the discontinuity creates a potential well. For example, a well formed in the conduction band is accomplished by sandwiching a layer of high-electron-affinity material in between layers of lower-electron-affinity material. The conduction band discontinuity serves as the barrier in the well. In the case of a resonant tunneling structure, the quantum well exists between two very thin, low electron affinity layers that have a large discontinuity and serve as the well barrier.

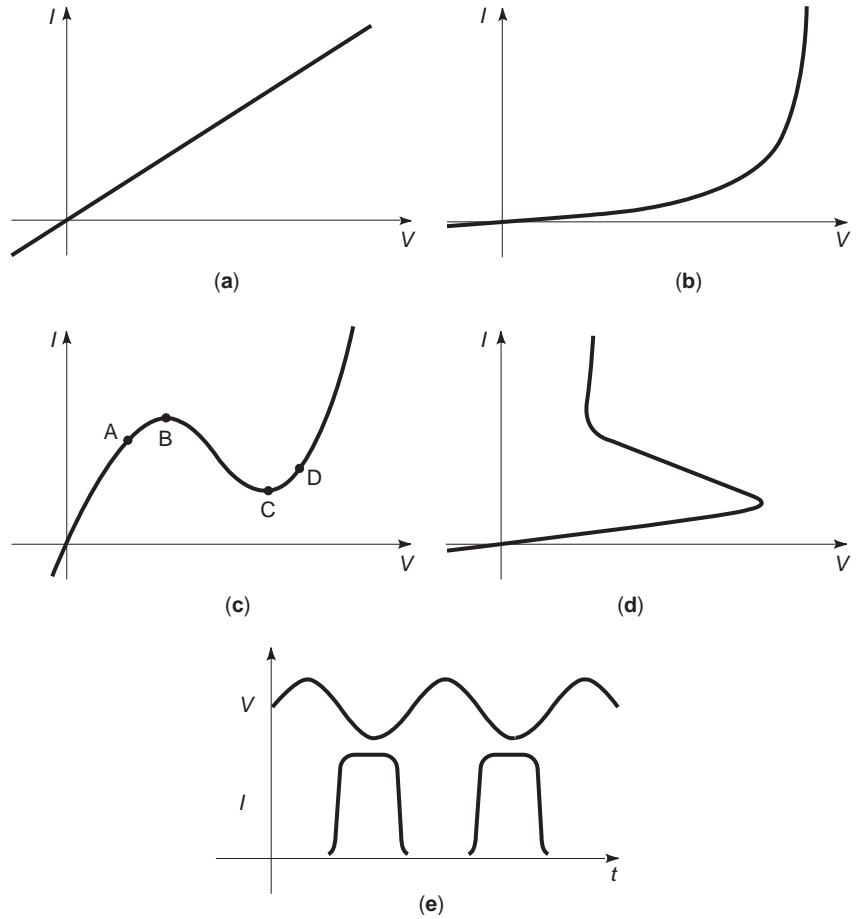

Figure 1. I - V relationship showing (a) linear resistance, (b) nonlinear resistance, (c) N-shape differential negative resistance, and (d) S-shape negative differential resistance; (e) in a transit-time device, negative resistance comes from the phase difference between terminal voltage and current.

Figure 2. Band diagram showing how forward bias voltage affects the tunneling current in a tunnel diode. In (a), the junction is slightly forward biased so that there is still an overlap of states at the same energy in the conduction and valence bands. In (b), the forward bias is sufficient to remove the overlap and the current consists of carriers which surmount the barrier (diffusion current).

For example, in the GaAs/AlGaAs system, as shown in the inset of Fig. 3, the GaAs serves as the quantum well and the outside contact regions, while the barriers are made from AlGaAs. As the well is made thin, the continuum of states in the conduction band become discrete levels of subbands according to the following expression

$$E_n - E_C = \frac{h^2 n^2}{8m^* W^2}, \quad n = 1, 2, 3 \dots \quad (2)$$

where E_C is the conduction band edge, h is Planck's constant, m^* is the effective mass, and W is the thickness of the well. The band diagram of Fig. 3 shows how significant current flows only when E_C of the contact region aligns with the first subband energy. As the bias is further increased, the tunnel current diminishes, leading to a decrease in total current and thus an NDR region in the I - V characteristic. Depending on the depth of the well (height of the barriers), tunneling through higher subband energies can also occur, leading to additional NDR regions.

A resonant tunneling bipolar transistor (RTBT) results when the quantum well is placed within the emitter or base of a bipolar transistor. A resonant tunneling hot-electron transistor (RHET) has a similar structure without the emitter-base p-n junction. The advantages of such three-terminal structures are that the negative resistance

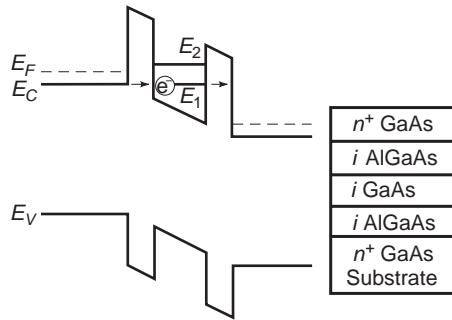

Figure 3. Band diagram of a resonant tunneling diode under bias conditions such that the conduction band edge aligns with the first subband level E_1 , causing a tunneling current to flow. The layer structure is shown in the inset.

is tunable by the base bias, and the output is isolated from the input.

3. SEMICONDUCTOR SWITCHES

A thyristor is a four-layer Si device consisting of an n-p-n-p structure. The structure is called a silicon controlled rectifier (SCR) when a gate contact is made to the middle p region, as shown in the inset of Fig. 4. As positive voltage is applied to the anode, a small reverse bias current flows until either the depletion regions of the central junctions join (a condition known as punchthrough), or avalanche multiplication occurs at the reverse biased junction. Beyond this “breakover voltage” (V_{BO}), a large current flows and the voltage across the device drops. An S-shape negative resistance region arises in this device as it switches from the high-impedance forward-blocking state to the low-impedance on state. With positive gate current, the breakover voltage is lowered, which is the mechanism used to trigger the device into the on state. Once the SCR

Figure 4. SCR current-voltage characteristics illustrating how positive gate current lowers the breakover voltage. The device structure is shown in the inset.

is switched on, an applied bias lower than the holding voltage (V_H) will turn the device off.

Other semiconductor switches which possess S-shape negative-resistance regions similar to the thyristor are the metal insulator semiconductor switch (MISS) and the planar doped barrier switch [1].

4. GUNN EFFECT AND THE TRANSFERRED ELECTRON DEVICE

The transferred electron device directly exploits a particular material property of semiconductors like GaAs and InP, which have lower mobility satellite valleys to which electrons transfer at high applied electric fields. A uniformly doped length of these materials display normal positive ohmic characteristics for low fields, but for applied voltages that cause the electric field to exceed some critical field a reduction in the current results, as more electrons are transferred to the low-mobility satellite valley. The critical electric field for GaAs is 3.2 kV/cm and 10.5 kV/cm for InP. This process of intervalley scattering can create instabilities within the semiconducting material with sufficient applied bias, which gives rise to microwave oscillations. The occurrence of these oscillations is known as the Gunn effect, named for its first observer.

The transferred-electron device (TED) or Gunn diode is simply composed of a length of material with two contacts on the ends. Planar structures grown on semiinsulating substrates are also possible. The essence of operation of the TED lies with the generation of a charge accumulation region within the device. Once an adequate bias is applied across the length of the device, an accumulation region will form in an area where there may be a crystal defect or a difference in doping—something that causes the electric field to be slightly larger than in the rest of the device. Once the fields in this region is sufficiently large to possess a negative differential mobility, a space charge instability will form and grow (either as a simple accumulation of electrons or a dipole consisting of electrons and ionized donors). Once the field in this unstable region rises above the point where it possesses a negative differential mobility, the dipole ceases to grow (matures) and continues to travel along the length of the device with the saturated drift velocity (v_{sat}). The result is charge pulses that arrive at the anode with a period of L/v_{sat} , where L is the length of the device. The transferred electron device is widely used as oscillator for 1–100-GHz applications.

5. REAL-SPACE TRANSFER DEVICES

Real-space transfer is similar to the Gunn effect described above, except that electrons are transferred to a lower-mobility material in real space at high fields rather than being transferred in momentum space. Unlike the Gunn effect, however, either electrons or holes can be transferred. In its most common implementation, a heterojunction barrier (e.g., AlGaAs/GaAs) and modulation doping form the basis of the structure. At low fields, carriers confined in the low-bandgap material flow from one contact to the other exhibiting normal ohmic behavior. At sufficiently

high bias, some carriers gain enough energy to surmount the barrier into the low-mobility, high-bandgap material. This transfer lowers the effective mobility and decreases the total current, which gives rise to an NDR region.

The charge injection transistor (CHINT) or negative-resistance field-effect transistor (NERFET) is a three-terminal device utilizing real-space transfer. The structure used in the Si/SiGe system is illustrated in Fig. 5. A lightly doped channel of low-bandgap material (SiGe) exists between source and drain. A barrier between the collector and the channel is formed by a layer of undoped Si, which has a larger bandgap than the SiGe. The inset of Fig. 5. illustrates the band structure of the CHINT device perpendicular to the channel. As voltage is applied between the source and drain, the carriers present in the channel produce a current flow just as in a normal FET. As the bias increases and the field across the channel increases, some carriers gain sufficient energy to surmount the barrier and are collected by the collector. This siphoning of carriers by the collector causes the total drain current to decrease with increasing drain voltage producing an NDR characteristic.

6. APPLICATIONS

The most common uses of negative resistance are for circuit applications in oscillators, amplifiers, memory, and active filters. An oscillator is made by combining a negative-resistance device together with a tuned *RLC* circuit so that the net resistance becomes zero. (The majority of *R* comes from parasitics.) The frequency of the oscillations is determined by the *LC* of the circuit. The series connection of a normal resistance and a negative resistance provides a simple example of a negative-resistance amplifier. By connecting a negative resistance (*-r*) in series with a normal resistor (*R*) as in Fig. 6a, and

Figure 6. A simple negative-resistance amplifier is shown in (a), while (b) exhibits the use of a bistable negative-resistance device as a memory element.

taking the output across the normal resistor, the voltage ratio becomes

$$\frac{V_{out}}{V_{in}} = \frac{R}{R + (-r)} \tag{3}$$

which produces a voltage gain. Active filters for use on monolithic microwave integrated circuits (MMIC) are greatly improved with the use of a negative resistance to compensate for losses in inductors, transmission lines, and lossy dielectrics. In these filters, the negative resistance is combined with the *L* and *C* components to increase the overall quality factor (*Q*), which leads to a sharper cutoff at the frequency band edges. Memory circuits using negative resistance exploit the fact that these devices exhibit bistable behavior. Figure 6b shows an elemental memory circuit with a negative-resistance device loaded with a resistor *R* from a supply voltage *V_{DD}*. The *I-V* curve of Fig. 1c shows the two staple states, *A* and *D*, possible for a given load line. By forcing the voltage across the negative resistance device high or low, the circuit is forced to one or the other of the stable states.

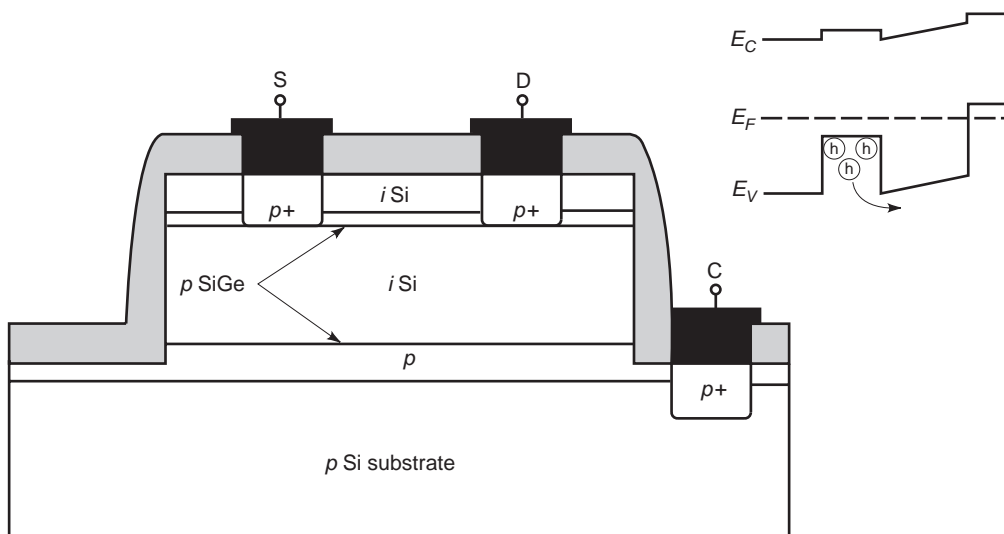

Figure 5. Charge injection transistor (CHINT) device structure for the Si/SiGe materials system. The top channel consists of small bandgap SiGe separated from the collector by an undoped Si barrier region. The inset schematically exhibits the device band diagram in the direction perpendicular to the channel.

Figure 7. Structure of an IMPATT diode.

7. TRANSIT-TIME DEVICES

In a transit-time device, there are two important mechanisms. The first is the generation and buildup of charge within the device, followed by transit of these charges across the length of the device. Although the transit of charge is quite similar for different transit-time devices, the generation or injection of charge is quite different among them. These mechanisms include avalanche multiplication, thermionic emission, and tunneling. The most popular device among them is the IMPATT (impact ionization avalanche transit-time) diode. This discussion will be confined to the operation of the IMPATT diode. Other transit-time devices are BARITT (barrier injection transit-time) diode, TRAPATT (trapped-plasma avalanche-triggered transit) diode, DOVATT (double-velocity avalanche transit-time) diode, MITATT (mixed-tunnel-avalanche transit-time) diode, DOVETT (double-velocity transit-time) diode, TUNNETT (tunnel injection transit-time) diode, and QWITT (quantum-well injection transit-time) diode. Brief discussions on each of these can be found in Ref. 1.

An IMPATT diode can be realized by different physical structures. All of these are variations of a p-n junction. The most common is called the Read diode and is shown in Fig. 7. Common semiconductor materials are Si and GaAs. Here the p-n junction provides a high field for avalanche multiplication, and the large intrinsic layer is the region

where transit time is originated. The DC characteristics are shown in Fig. 8a. Notice that in the I - V curve, there is no region where the slope is negative. During operation, the diode is reverse biased with a DC value near the breakdown (V_{BD}), so that a small AC signal will drive it into avalanche multiplication. Referring again to Fig. 1e, the delay of current with respect to the voltage comes from two components. The first is the time it requires to build up the charge internally. The second is the transit time across this intrinsic region. This charge buildup time is a characteristic of avalanche multiplication, and it is absent in other injection mechanisms such as tunnelling and thermionic emission. That is why the IMPATT diode is more efficient in power generation compared with, for example, a BARITT diode. After the charge is generated, it traverses the intrinsic region with saturation velocity (v_{sat}). During the time of this transit, there is a continuous terminal current of magnitude

$$J = \frac{Q_A v_{sat}}{L} \quad (4)$$

where Q_A is the charge per area (cross-sectional) and L is the region of the intrinsic layer. The magnitude of Q_A is related to the magnitude and frequency of the AC signal and detailed derivation is beyond the scope of this article. Assuming that the transit time dominates the phase delay, the frequency of operation is given by

$$f = \frac{v_{sat}}{2L} \quad (5)$$

since the duration of the current pulse corresponds to the transit time of the charge packet, and this current pulse is roughly half of the cycle.

The main application of a transit-time diode is microwave generation in the 3–300 GHz range. The transit-time devices are the most efficient microwave oscillators in this frequency range. Usually a transit-time device is a discrete component and it is mounted in a resonator cavity. When a DC bias is applied to the device, an AC output is produced. Applications of these oscillators are in radar

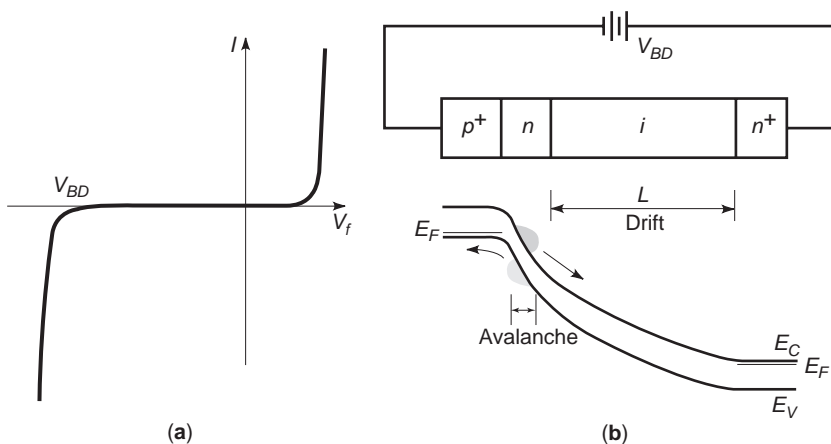

Figure 8. (a) The I - V curve of an IMPATT diode does not process a negative slope; (b) schematic diagram showing where the charge is generated (in this case by avalanche multiplication), and the region of charge transit.

systems and alarm systems. In high-power oscillators, a good heat sink is crucial.

1. INTRODUCTION

Neural networks, also called *artificial neural networks* (ANNs), are information processing systems whose design was inspired by the studies of the ability of the human brain to learn from observations and to generalize by abstraction [1]. The fact that neural networks can be trained to learn arbitrary nonlinear input–output relationships from corresponding data has resulted in their use in a number of areas such as pattern recognition, speech processing, control, and biomedical engineering. In RF and microwave areas, ANN has been used to model passive and active devices to enhance circuit design. Neural networks can be trained using measured or simulated microwave device data, such as electromagnetic (EM) data for passive components and physics data for active devices. The trained neural networks become models of microwave devices and can be used in place of CPU-intensive EM/physics models to significantly speed up circuit design, while maintaining EM/physics-level accuracies. ANN-based modeling has been used to model a variety of passive and active components on both device and circuit levels [2]. ANN models can be realized in both frequency-domain and time-domain formats, compatible with the framework of existing CAD tools, including component’s geometric and physical parameters as optimization variables. ANN-based microwave models can be a pure neural network, or a knowledge-based neural network in which RF/microwave information is utilized together with neural networks.

The ANN modeling approach generally involves the following steps: (1) selecting appropriate ANN structure, (2) data generation and preprocessing, (3) ANN model training, (4) plugging the resultant neural model into a circuit simulator, and (5) simulation, optimization, and circuit design using ANN models. Each of these steps is elaborated in subsequent sections.

2. NEURAL NETWORK STRUCTURES

We describe neural network structural issues to better understand what neural networks are and why they have the ability to represent RF and microwave component behaviors. We study neural networks from the external input–output point of view, and also from the internal neuron information processing point of view. The most popularly used neural network structure, namely, the multilayer perceptron, is described in detail. The effects of structural issues on modeling accuracy are discussed.

2.1. Basic Components

A typical neural network structure has two types of basic components, namely, the processing elements and the interconnections between them [1]. The processing elements are called *neurons*, and the connections between the neurons are known as *links* or *synapses*. Every link has a corresponding weight parameter associated with it. Each neuron receives stimuli from other neurons connected to it, processes the information, and produces an output. Neurons that receive stimuli from outside the network are called *input neurons*; neurons whose outputs are externally used are called *output neurons*. Neurons that receive stimuli from other neurons and whose outputs are stimuli for other neurons in the network are known as *hidden neurons*. Different neural network structures can be constructed by using different types of neurons and by connecting them differently.

2.2. Neural Networks versus Conventional Modeling

The neural network approach can be compared with conventional approaches for a better understanding. The first approach is the detailed modeling approach (e.g., EM-based models for passive components and physics-based models for active devices), where the model is defined by a well-established theory. The detailed models are accurate but could be computationally expensive. The second approach is an approximate modeling approach, which uses either empirical or equivalent-circuit-based models for passive and active components. Evaluation of approximate models is much faster than that of the detailed models. However, the models are limited in terms of accuracy and input parameter range over which they can be accurate. Neural network approach is a new type of modeling approach where the model can be developed by learning from detailed (accurate) data of the RF/microwave component. After training, the neural network becomes a fast and accurate model representing the original component behaviors.

2.3. Multilayer Perceptrons Neural Network

2.3.1. Structure and Notation. Multilayer perceptrons (MLPs) is a popularly used neural network structure. In the MLP neural network, the neurons are grouped into layers. Let the total number of layers be L . The first layer is the input layer, the L th layer is the output layer, and layers 2 through $L - 1$ are hidden layers, as shown in Fig. 1.

Figure 1. Multilayer perceptrons neural network structure. Typically, an MLP network consists of an input layer, one or more hidden layers, and an output layer. (Reprinted with permission from Ref. 1: Q. J. Zhang and K. C. Gupta, *Neural Networks for RF and Microwave Design*, Artech House Publishers, Norwood, MA, USA, 2000; www.artechhouse.com.)

2.3.2. Anatomy of Neurons. In the MLP network, each neuron processes the stimuli (inputs) received from other neurons. The process is done through a function called *activation function* in the neuron, and the processed information becomes the output of the neuron. Let z_i^l be the output of i th neuron of the l th layer, and let N_l be the number of neurons in the l th layer. Every neuron in the l th layer receives stimuli from the neurons of $l-1$ th layer: $z_1^{l-1}, z_2^{l-1}, \dots, z_{N_{l-1}}^{l-1}$. A typical i th neuron in the l th layer processes this information in two steps:

1. Each input is multiplied by the corresponding weight parameter, and the products are added to produce a weighted sum γ_i^l

$$\gamma_i^l = \sum_{j=0}^{N_{l-1}} w_{ij}^l z_j^{l-1} \quad (1)$$

where $w_{ij}^l, j > 0$, represent the weight of the link between j th neuron of the $(l-1)$ th layer and the i th neuron of the l th layer and w_{i0}^l represents the bias for the i th neuron of the l th layer.

2. The weighted sum in (1) is used to activate the neuron's activation function $\sigma(\cdot)$ to produce the final output of the neuron: $z_i^l = \sigma(\gamma_i^l)$. This output can, in turn, become the stimulus to neurons in the $(l+1)$ th

layer. The most commonly used hidden neuron activation function is the sigmoid function given by

$$\sigma(\gamma) = \frac{1}{1 + e^{-\gamma}} \quad (2)$$

Other functions that can also be used include the arc-tangent function and the hyperbolic tangent function. All these are smooth switch functions that are bounded, continuous, monotonic, and continuously differentiable. Input neurons use a relay activation function and simply relay the external stimuli to the hidden-layer neurons, $z_i^1 = x_i$, where x_i represents the i th external input to the MLP, $i = 1, 2, \dots, N_1$. In the case of neural networks for RF/microwave design, where the purpose is to model continuous electrical parameters instead of a binary relationship, a linear activation function can be used for output neurons. This makes it easier for the model to be trained since, according to the universal approximation theorem [3], a single layer of sigmoid functions in the hidden layer is sufficient to model the nonlinear input-output relationships. The linear activation function is defined as

$$\sigma(\gamma) = \gamma = \sum_{j=0}^{N_{l-1}} w_{ij}^l z_j^{l-1} \quad (3)$$

2.3.3. Feedforward Computation. Neural network feedforward computation is a process used to compute the output vector $\mathbf{y} = [y_1 \ y_2 \ \dots \ y_{N_y}]^T$ from the input vector $\mathbf{x} = [x_1 \ x_2 \ \dots \ x_{N_x}]^T$ and the weight vector \mathbf{w} , where N_x and N_y are numbers of external inputs and outputs of the MLP, respectively. Feedforward computation is useful not only during neural network training but also during the usage of the trained neural model. The external inputs are applied to the input neurons (i.e., the first layer) and the outputs from the input neurons are fed to the hidden neurons of the second layer. Continuing this way, the outputs of $(L-1)$ th-layer neurons are fed to the output-layer neurons (i.e., L th layer). During feedforward computation, neural network weights \mathbf{w} remain fixed. The computation is given by

$$z_i^1 = x_i, \quad i = 1, 2, \dots, N_1, \quad N_x = N_1 \quad (4)$$

$$z_i^l = \sigma \left(\sum_{j=0}^{N_{l-1}} w_{ij}^l z_j^{l-1} \right), \quad (5)$$

$$i = 1, 2, \dots, N_l, \quad l = 2, 3, \dots, L$$

$$y_i = z_i^L, \quad i = 1, 2, \dots, N_L, \quad N_y = N_L \quad (6)$$

Figure 2 shows physical representations of microstrip-line (passive) and FET (active) devices along with their corresponding neural models clearly showing choice of model inputs and outputs.

2.3.4. Speed and Accuracy of ANN Models. It may be noted that the simple formulas in (4)–(6) are now intended

Figure 2. Physical models of (a) FET and (b) a microstrip line along with corresponding neural models.

for use as RF/microwave component models. It is evident that computation of these formulas is much easier than is numerical solution of theoretical EM or physics equations. This is why neural network models are much faster than detailed numerical models of RF/microwave components. The question of how such simple formulas for neural network can represent complicated behaviors can be answered by the universal approximation theorem.

The universal approximation theorem [3] states that there always exists a three-layer MLP neural network that can approximate any arbitrary, nonlinear, continuous, multidimensional function to any desired accuracy. This forms a theoretical basis for employing neural networks to approximate RF/microwave behaviors, which are functions of physical/geometric/bias parameters. MLP neural networks are distributed models; that is, no single neuron can produce the overall x - y relationship. For a given x , some neurons are switched to ON state, some are in OFF state, and others are in transition. This combination of neuron switching states enables the MLP to represent a given nonlinear input-output mapping. During the training process, the MLP weight parameters are adjusted, and at the end of training, they encode the component information from the corresponding x - y training data.

2.4. Other Neural Network Configurations

In addition to MLP, there are other ANN structures, such as radial basis function (RBF) networks, wavelet networks, and recurrent networks. In order to select a neural network structure for a given application, one starts by identifying the nature of the x - y relationship. Nondynamic modeling problems (or problems converted from dynamic to nondynamic using methods such as harmonic balance) can be solved using MLP, RBF, and wavelet

networks [1]. The most popular choice is the MLP. RBF and wavelet networks can be used when the problem exhibits highly nonlinear and localized phenomena (e.g., sharp variations). Time-domain dynamic behavior of nonlinear devices or circuits can be represented using recurrent neural networks (RNNs) [4] and dynamic neural networks (DNN) [5]. One of the most recent research directions in the area of microwave-oriented ANN structures is the knowledge-based network [6], which combines existing engineering knowledge (e.g., empirical equations and equivalent-circuit models) with neural networks.

3. ANN TRAINING

3.1. Defining ANN Inputs and Outputs

The first step toward developing a neural model is the identification of inputs (x) and outputs (y). Determination of the output parameters is based on the objectives of the neural network model. For example, real and imaginary parts of S parameters can be selected as outputs for passive component models, and currents and charges can be used for large-signal device models. Neural model input parameters are those device/circuit parameters (e.g., geometric, physical, bias, frequency) that affect the output parameter values.

3.2. Data Generation and Preprocessing

In this step, x - y sample pairs are generated using either simulation or measurement. The generated sample pairs could be divided into three sets, namely, training data, validation data, and test data. Training data is utilized to guide the training process, i.e., to update the neural network weight parameters during training. Validation data is used to monitor the quality of the neural network model during training and to determine stop criteria for the training process. Test data is used to independently examine the final quality of the trained neural model in terms of accuracy and generalization capability.

Scaling of data may also improve the training efficiency. Linear scaling of data can provide balance between different inputs (or outputs) whose values are different by orders of magnitude. Another scaling method is the logarithmic scaling, which can be applied to outputs with large variations in order to provide a balance between small and large values of the same output.

3.3. Formulation of Training Process

The most important step in neural model development is the neural network training. Let d_k be the k th sample of y in training data. We define neural network training error as

$$E_{T_r}(\mathbf{w}) = \frac{1}{2} \sum_{k \in T_r} \sum_{j=1}^{N_y} |y_j(\mathbf{x}_k, \mathbf{w}) - d_{jk}|^2 \tag{7}$$

where d_{jk} is the j th element of d_k , $y_j(\mathbf{x}_k, \mathbf{w})$ is the j th neural network output for input \mathbf{x}_k , T_r is the index set of all training data, and \mathbf{w} is the vector of neural network weight parameters.

The purpose of neural network training, in basic terms, is to adjust \mathbf{w} such that the error function $E_{T_r}(\mathbf{w})$ is minimized. Since $E_{T_r}(\mathbf{w})$ is a nonlinear function of the adjustable (i.e., trainable) weight parameters \mathbf{w} , iterative algorithms are often used to explore the \mathbf{w} space efficiently, beginning with an initialized value of \mathbf{w} and then iteratively updating it.

Neural network training algorithms commonly used in RF/microwave applications include gradient-based training techniques such as backpropagation, conjugate-gradient, and quasi-Newton methods. Global optimization methods such as simulated annealing and genetic algorithms can be used for increased quality of neural network training but at the cost of increased training time.

Neural network training process can be categorized into sample-by-sample training and batch-mode training. In sample-by-sample training also called *online training*, \mathbf{w} is updated each time a training sample is presented to the network. In batch-mode training, also known as *offline training*, \mathbf{w} is updated after each epoch, where an *epoch* is defined as a stage of training process that involves presentation of all the training data to the neural network once. The batch-mode training is more efficient because neural network weight update is done by considering errors in the entire training data. In the RF/microwave case, the data, which come from measurement or simulations, are typically offline so that batch data are available for training. Hence in RF/microwave modeling, batch-mode training is usually employed. A flowchart summarizing major steps in neural network training and testing is shown in Fig. 3 [7].

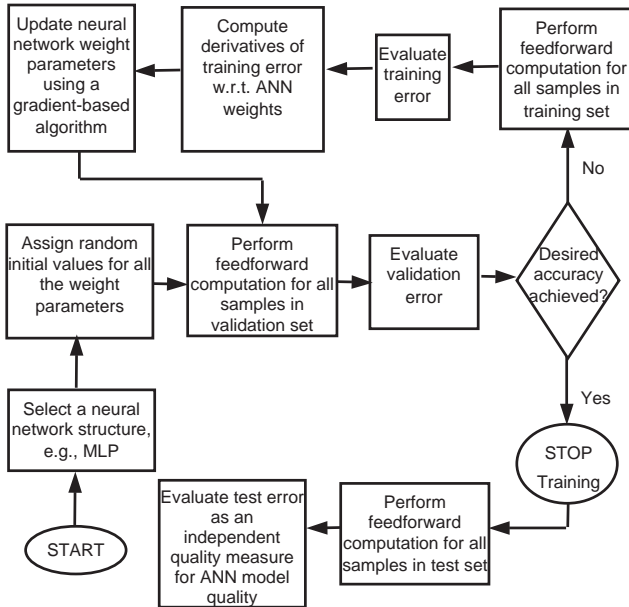

Figure 3. Flowchart demonstrating neural network training, neural model testing, and use of training, validation, and test datasets in ANN model development. (© 2003 IEEE, reprinted from Ref. 7 with permission from IEEE.)

3.4. Overlearning and Underlearning

The ability of a neural network to estimate output \mathbf{y}_k accurately when presented with input \mathbf{x}_k that is never seen during training (i.e., $k \notin T_r$) is called *generalization ability*. Let \hat{E}_V represent the validation error defined similarly to \hat{E}_{T_r} of (7) except that the dataset represents validation data instead of training data T_r . *Good learning* of a neural network is achieved when both training error (\hat{E}_{T_r}) and validation error (\hat{E}_V) have small values (e.g., 0.50%) and are close to each other. The ANN exhibits *overlearning* when it memorizes the training data but cannot generalize well (i.e., \hat{E}_{T_r} is small but $\hat{E}_V \gg \hat{E}_{T_r}$). Remedies for overlearning are, deleting a certain number of hidden neurons or adding more samples to the training data. The neural network exhibits *underlearning* when it has difficulties in learning the training data itself (i.e., $\hat{E}_{T_r} \gg 0$). Possible remedies are to add more hidden neurons or perturbing the current solution \mathbf{w} to escape from a local minimum of $E_{T_r}(\mathbf{w})$ and then continue training.

The automatic model generation (AMG) algorithm [8] automatically performs the model development process, including data generation with adaptive data sampling algorithm, training ANN, and determining the optimal number of hidden neurons by examining over- and underlearning. In this way, ANN models can be developed with minimum manual effort.

4. EM-ORIENTED NEURAL MODELING

4.1. Frequency-Domain Modeling

A frequency-domain neural model can represent Y or S parameters of a passive component with the speed of empirical models but with accuracy near detailed EM models [1]. Let \mathbf{x} represent an N_x vector containing the variables and \mathbf{y} represent an N_y vector containing the outputs (responses) of a passive component. For example, \mathbf{x} could contain geometric parameters such as length (L_R) and width (W_R) of an embedded resistor and signal frequency ω , and \mathbf{y} could contain corresponding Y or S parameters, as shown in Fig. 4.

Let \mathbf{f} represent a detailed EM relationship between \mathbf{x} and \mathbf{y}

$$\mathbf{y} = \mathbf{f}(\mathbf{x}) \quad (8)$$

to be modeled by a neural network. In general, \mathbf{f} can be accessible to microwave engineers in the form of a *data generator*:

$$\mathbf{d} = \mathbf{d}(\mathbf{x}) \quad (9)$$

For a given input \mathbf{x} , data generator $\mathbf{d}(\mathbf{x})$ can be used to compute and/or measure the outputs \mathbf{d} of the original problem. Data generation involves repetitive use of the data generator to obtain sample pairs $(\mathbf{x}_k, \mathbf{d}_k)$, where k is the sample index. These sample pairs are divided into training sets and test sets. The purpose of neural network

Figure 4. Geometric structure of embedded resistor and its neural model showing choice of inputs and outputs for the neural model.

modeling is to develop a fast neural model

$$y = f_{ANN}(x, w) \tag{10}$$

that accurately represents $f(x)$. Here, f_{ANN} is a neural network trained to learn samples of $f(x)$ from training data (x_k, d_k) , $k \in T_r$, and w is ANN weight vector. The trained fast neural model f_{ANN} can be used in place of CPU-intensive EM simulator during frequency-domain simulation and optimization.

4.2. Time-Domain Modeling

Time-domain models are important for CAD applications such as minimization of signal delay and crosstalk in high-speed VLSI interconnects. There is a need for time-domain models that include detailed EM effects. A time-domain neural model provides current/voltage relationships of a given passive component and their dependence on the component’s geometric parameters and time (t).

In a time-domain modeling approach, ANN can be used to provide coefficient values of the time-domain responses. Figure 5 explains the typical time-domain modeling approach.

For example, in the state space equation–neural network (SSE-NN) method [9], the frequency-domain and time-domain relations are given as follows:

$$H_{ij} = Y_{ij}(s) = \frac{b_0 + b_1s + \dots + b_{n-1}s^{n-1} + b_ns^n}{a_0 + a_1s + \dots + a_{n-1}s^{n-1} + s^n} \tag{11}$$

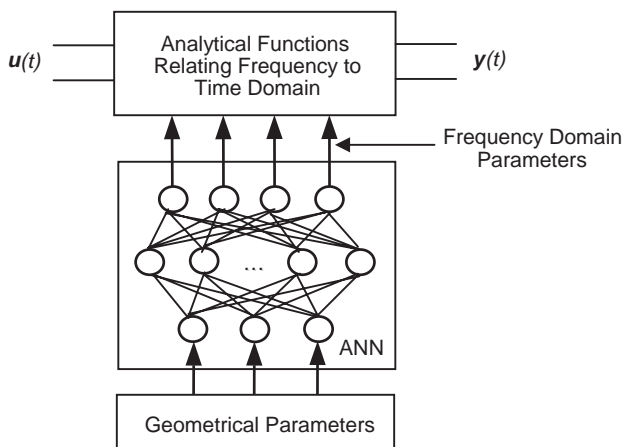

Figure 5. Time-domain EM-based ANN modeling approach.

This equation represents the Y-parameter transfer function between ports i and j of the EM structure. Here, s is the complex frequency and n represents the effective order of high-frequency behaviors of the passive component. The coefficients a_k , $k = 0, 1, \dots, n - 1$, and b_k , $k = 0, 1, \dots, n$ are related to physical/geometric parameters of the EM problem through an ANN. Following this, state space equations are used to express the time-domain responses as

$$\begin{cases} \dot{v}(t) = Av(t) + Bu(t) \\ i(t) = Cv(t) + Du(t) \end{cases} \tag{12}$$

where matrices A , B , C , and D are obtained by arranging the coefficients (i.e., the a and b values) estimated by ANN into a format specific to our choice of the transfer functions [9]; $v(t)$ represents state variables or voltages, and $u(t)$ and $i(t)$ are input voltage and output current waveforms, respectively. In summary, Eqs. (11) and (12) combined with a MLP form an EM based time-domain SSE-NN model of the passive component under consideration.

5. KNOWLEDGE-BASED NEURAL NETWORKS

The knowledge-based neural network (KBNN) approaches exploit the available microwave information in the form of empirical or equivalent-circuit models together with the neural models to develop fast and accurate hybrid EM-ANN models. The use of knowledge in neural networks helps reduce the amount of training data needed and enhance the extrapolation capability of the model. Here we summarize some of the major techniques developed to reduce the need for expensive data.

5.1. Difference Method (DM)

In this method, an ANN is trained to ascertain the difference between detailed EM data (obtained from simulator or measurements) and approximate model (equivalent-circuit and empirical relations) outputs [10]. The final model performs addition of equivalent-model output and the ANN output.

5.2. Knowledge-Based Neural Networks (KBNNs)

In this method, microwave knowledge in the form of empirical functions or analytical approximations is embedded into the neural network internal structure [6].

KBNN also accommodates multiple knowledge formulas in different regions of the parameter space using region definition neurons.

5.3. Prior Knowledge Input (PKI) Method

In this method, the empirical model outputs are used as inputs to the neural network model, in addition to the original problem inputs. In this case, the input–output mapping to be learnt by neural network is between the outputs of existing approximate model and the original problem [11].

5.4. Space-Mapped Neural Networks (SMNNs)

The SMNN concept divides the modeling problem into coarse-model part (empirical models) and fine-model part (EM or physics models). ANN is used to map the input parameters of the fine model into those of the coarse model. In this way, the coarse model aims to provide finer outputs by using suitably modified inputs with the help of mapping [12].

5.5. Equivalent Circuit–State Space Equation–Neural Networks (EC–SSE–NNs)

The difference between the equivalent-circuit model and actual EM data is represented by a state space model, and the state space model in turn is related to physical/geometric parameters by ANN. The final model output is the sum of approximated output of equivalent circuit and difference provided by the state space model. This technique is suitable for time-domain applications.

6. MODELING OF NONLINEAR RF/MICROWAVE DEVICES

For general nonlinear modeling problems, relationships between inputs and outputs of nonlinear circuits are not algebraic; they are related by differential equations. To model such relationships, two different categories of ANN-based approaches exist. The first category uses a combination of circuit and ANN models, where we rely on the circuit to define the dynamics and the ANN to define the nonlinearity. The second category uses dynamic or recurrent neural networks to directly represent the entire model, including both dynamic effect and nonlinearity. In the second category, we have a continuous time-domain formulation called *dynamic neural networks* (DNN) and a discrete time-domain formulation called recurrent neural networks (RNN).

6.1. Combined Circuit/ANN Approach for Nonlinear Device Modeling

In this approach, we use a known equivalent-circuit topology, but the nonlinear algebraic functions needed to describe the nonlinearities in the circuit branches are achieved by ANN. Figure 6 shows an FET model [13], where the function of the drain current with respect to gate and drain voltages is represented by an ANN. To train this model using DC and small-signal device data, an adjoint neural network [13] method can be used, which allows the ANN to learn the required derivative information between input and output neurons.

Figure 6. Neuron-based model of an FET where the nonlinear algebraic functions for current and charge are replaced by ANNs.

6.2. Continuous Time-Domain DNN Modeling

The DNN approach can be explained from the block schematic in Fig. 7. Let \mathbf{u} and \mathbf{y} be vectors of the input and the output signals of the nonlinear circuit, respectively. Let $\mathbf{y}^{(i)}(t) = d^i \mathbf{y}(t) / dt^i$ and $\mathbf{u}^{(j)}(t) = d^j \mathbf{u}(t) / dt^j$ represent the i th-order derivative of $\mathbf{y}(t)$ and the j th-order derivative of $\mathbf{u}(t)$ with respect to t , respectively. Let f_{ANN} represent a static multilayer perceptron (MLP) neural network. DNN is formulated as a reduced order representation of the original circuit [5]

$$\mathbf{y}^{(n)}(t) = f_{\text{ANN}}(\mathbf{y}(t), \mathbf{y}^{(1)}(t), \dots, \mathbf{y}^{(n-1)}(t), \mathbf{u}(t), \mathbf{u}^{(1)}(t), \dots, \mathbf{u}^{(n)}(t)) \quad (13)$$

where n is the effective order of the reduced model, $n < N_S$, and N_S is the order of the original nonlinear circuit. In this formulation, the signal flow from f_{ANN} input to output resembles differentiation; hence the model is referred to as a *differential dynamic neural network* (DDNN). In the integral DNN (IDNN) approach, the input–output relationship is reorganized as follows:

$$\mathbf{y}(t) = f_{\text{ANN}}(\mathbf{y}^{(1)}(t), \dots, \mathbf{y}^{(n)}(t), \mathbf{u}(t), \mathbf{u}^{(1)}(t), \dots, \mathbf{u}^{(n)}(t)) \quad (14)$$

Here the signal flow from f_{ANN} input to output resembles integration, as such the model is called *integral DNN* (IDNN).

Figure 7. Dynamic neural network (DNN) for nonlinear circuit modeling in continuous time domain.

These two different formulations, DDNN and IDNN, are complementary formats of DNN and together form the DNN family. They can be used to represent the nonlinear microwave circuit behavior and can be used as models for high-level circuit and system design.

6.3. Discrete Time-Domain RNN Modeling

Recurrent neural networks (RNNs) are a special type of neural network with feedback from output to input and are capable of learning and then representing dynamic system behavior [4]. The nonlinear circuit modeling approach in discrete time domain using RNN is illustrated in Fig. 8. In order to derive a macromodel representing a nonlinear dynamic relationship, we first reformulate the original relationship in the discrete time domain with specific sampling rate into an input–output formulation as

$$\mathbf{y}(k) = \mathbf{g}(\mathbf{y}(k-1), \dots, \mathbf{y}(k-M_y), \mathbf{u}(k-1), \dots, \mathbf{u}(k-M_u), \mathbf{p}) \quad (15)$$

where k is the time index in the discrete time domain, $\mathbf{y}(k)$ is a simplified notation for $\mathbf{y}(k\tau)$, $\mathbf{u}(k)$ is a simplified notation for $\mathbf{u}(k\tau)$, τ is the time sampling interval, and \mathbf{g} is set of nonlinear functions. The terms \mathbf{y} , \mathbf{u} , and \mathbf{p} are vectors of output and input signals and circuit parameters, respectively. The number of delays M_y and M_u , of \mathbf{y} and \mathbf{u} , respectively, represent effective order of original nonlinear circuit as seen from input–output data. In the RNN approach, we use a neural network such as the MLP to represent the nonlinear function \mathbf{g} of (15). Furthermore, we use a reduced order representation such that M_y and M_u of (15) is replaced by n . In this way, the order of the RNN model is n , which can be much less than the order of the original circuit.

The input layer of the MLP contains buffered history of the circuit input and output signals, and the circuit parameter. Input and output waveforms of the original circuit are used as training data for RNN, which is trained by the backpropagation through time (BPTT) method.

Figure 8. Recurrent neural network (RNN) for nonlinear circuit modeling in discrete time domain.

RNNs can be used to learn dynamics in both transient and steady-state stages [4].

7. USE OF ANN FOR CIRCUIT OPTIMIZATION

The trained ANN models for RF/microwave components can be used in circuit design and optimization [14]. If the ANN models have been trained from original EM/physics data, the use of such ANN models instead of original EM/physics models helps improve design speed while maintaining accuracy. To achieve this, the trained neural models are first incorporated into circuit simulators. An ANN model can be connected to other ANN models or any other models in the simulator to form a high-level circuit. During simulation, the circuit simulator passes input variables such as frequency and the physical parameters of a component to the ANN model, the ANN model then computes and returns the corresponding outputs of the neural network back to the simulator.

In case of knowledge-based ANN models, the knowledge part itself is usually already compatible with circuit simulator while the ANN part and its interaction with knowledge part can be incorporated into circuit simulator as functions of its weight parameters. While plugging DNN models, the dynamics can be represented by an equivalent circuit [5]. The combined circuit and ANN for such nonlinear models can then be implemented similarly to those of knowledge-based models.

Once the models are incorporated into the circuit environment, the device they represent can be optimized along with rest of the circuit with the model parameters as optimization variables. This approach allows the neural network inputs \mathbf{x} as optimization variables, for instance, physical/geometric parameters of the device or circuit. The performance optimization problem can be stated as minimization of errors between circuit responses and design specifications subject to electrical or physical/geometric constraints on the circuit elements.

Neural-network-based microwave optimization is especially significant for computationally expensive design tasks. It addresses the combined challenges due to (1) computational expenses of evaluating EM/physics effects in circuit components, (2) the size and complexities in today's RF/microwave circuits where the EM effects are present in many components at various levels of the design hierarchy, and (3) the need to repetitively vary physical/geometric parameters and re-evaluate EM/physics behaviors of all the components during design optimization. The use of neural network models helps to significantly accelerate EM/physics-based optimization.

NOISE AND INTERFERENCE MODELING

GEOFFREY C. ORSAK
Southern Methodist University

Noise and interference are inevitable realities of collecting data or taking measurements in the real world. In some cases, the noise level may be so insignificant as to allow the engineer to ignore its effects. However, this situation generally occurs only in very controlled circumstances, such as those in the laboratory or when signal powers are exceptionally large relative to the noise.

Unfortunately, it is more generally the case that the noise and interference cannot be ignored. Rather, design and analysis must be done with careful attention to the corruptive effects of these disturbances. One way to ensure an effective final design is to have accurate models of the noise components of the signals of interest. Examples of the impact of high and low levels of noise on the observation of a sinusoid are shown in Fig. 1.

Modeling these effects can range from being relatively straightforward to being rather difficult if not impossible. To assist in this endeavor, it is the purpose of this article to describe various methods of characterizing noise and interference signals and to elaborate on some of the most popular models in practice today.

1. STATISTICAL DESCRIPTIONS OF NOISE

Because of its random nature, characterizing noise necessarily requires a variety of statistical methods. For applications involving the observation of continuous time or sampled signals, the most complete statistical description of the noise process is the so-called joint distribution of the process [1]. Throughout this article we will denote an arbitrary noise or interference signal by $x(t)$.

Definition 1. The n th-order joint distribution of $x(t)$, denoted $F_x(\mathbf{x}; \mathbf{t})$, is given by

$$F_x(\mathbf{x}; \mathbf{t}) = \Pr[x(t_1) \leq x_1, x(t_2) \leq x_2, \dots, x(t_n) \leq x_n] \quad (1)$$

where the length n vectors \mathbf{x} and \mathbf{t} represent the collections $\{x_1, x_2, \dots, x_n\}$ and $\{t_1, t_2, \dots, t_n\}$, respectively, and where, for example, $\Pr[x(t_1) \leq x_1]$ is the probability that the signal $x(t)$ at time t_1 is less than the constant x_1 . For $F_x(\mathbf{x}; \mathbf{t})$ to be completely defined, it must be computed for all collections of times t_1, t_2, \dots, t_n , vectors \mathbf{x} , and all integer values of n .

In modeling noise, one often wishes to know if the statistical characterization of the signal $x(t)$ changes with time. The most rigorous method for determining this important property is derived directly from the joint distribution.

If the joint distribution of the noise is shift-invariant, that is, if

$$\begin{aligned} \Pr[x(t_1) \leq x_1; x(t_2) \leq x_2, \dots, x(t_n) \leq x_n] \\ = \Pr[x(t_1 + \tau) \leq x_1; x(t_2 + \tau) \\ \leq x_2, \dots, x(t_n + \tau) \leq x_n] \end{aligned} \quad (2)$$

for all collections of times and vectors \mathbf{x} and for all choices of n , then $x(t)$ is said to be *strictly stationary*. In this case, the entire statistical description of the process is a function of only the relative locations of the samples with regard to one another rather than the absolute locations of the time samples.

Unfortunately, in general, determining $F_x(\mathbf{x}; \mathbf{t})$ for large values of n is almost always impractical. However it may often be the case that one has sufficient information so as

Figure 1. Plots of a common sinusoid embedded in low-level noise and high-level noise.

to be able to compute this important function for values of $n = 1$ or 2 . In this case we may introduce a weaker form of stationarity that has many important applications and uses in practice. This type of characterization is often referred to as the so-called *second-order* description of $x(t)$.

Under this characterization we seek to describe the mean and correlation of the noise signal rather than the instantaneous probabilities. Prior to presenting this definition, it is advantageous for us to supply the following definitions which will be used throughout the remainder of this article:

Definition 2. The amplitude probability density function of the signal $x(t)$ is given by

$$f_x(x; t) = \frac{\partial F_x(x; t)}{\partial x} \tag{3}$$

for all choices of x and
for all values of t

while the joint amplitude density function of $x(t)$ is given by

$$f_x(x_1, x_2; t_1, t_2) = \frac{\partial^2 F_x(x_1, x_2; t_1, t_2)}{\partial x_1 \partial x_2} \tag{4}$$

for all choices of x_1
and x_2 and for all t_1 and t_2

These two definitions completely characterize all the first- and second-order properties of $x(t)$ (e.g., mean values, signal energy and power, correlations and frequency content). In particular, the amplitude density function describes the statistical range of amplitude values of signal x at time t . Further, one should recall from basic probability theory [2] that the density functions $f_x(x; t)$ and $f_x(x_1, x_2; t_1, t_2)$ can be readily obtained from the n th joint distribution of the signal $x(t)$ given in Eq. (1) through simple limiting evaluations. Given these two density functions, we may define the second-order description of the noise or interference signal as follows:

Definition 3. The mean or average value of the noise as a function of time is defined as

$$\mu_x(t) = E[x(t)] \tag{5}$$

where the expectation is taken with respect to $f_x(x; t)$. The correlation function of the noise signal is defined as

$$R_x(t_1, t_2) = E[x(t_1)x^*(t_2)] \tag{6}$$

and where the expectation presented above is taken with respect to $f_x(x_1, x_2; t_1, t_2)$, and where x^* denotes the complex conjugate of $x(t)$.

If the mean function is a constant with respect to time (the average value of the noise does not change with time)

and the correlation function of the noise is a function of only the difference of times and not their absolute locations, that is, $R_x(t_1, t_2) = R_x(0, t_2 - t_1)$, then the noise is said to be *wide-sense stationary*. In this case we simplify the notation by letting the mean be μ and the correlation function be given by $R_x(\tau)$ where $\tau = t_2 - t_1$.

A signal $x(t)$ being wide-sense stationary implies that the average statistical properties as measured by the mean and the correlation function do not depend on when one observes the noise and interference. This is a very beneficial property since designers attempting to combat this noise are not required to include an absolute clock in their design, rather a fixed design will always be optimal.

As an important observation, one should note that if the noise happens to be strictly stationary, then the noise will also be wide-sense stationary. This is a direct consequence of the fact that the mean and correlation functions are expected values taken with respect to the first- and second-order joint density functions which, by supposition, are shift invariant. In general, the converse is not true. However, we will see later that among the most popular models for the noise, this will, in fact, be the case.

1.1. Power Spectral Density

Engineers are often more comfortable in describing or analyzing signals in the frequency domain as opposed to the statistical (or time) domain. This is equally true when dealing with random signals. However, random signals pose a few complications when one attempts to apply spectral techniques to them. This is a consequence of the fact that each time one makes an observation of this signal, the so-called noise *realization* (observation) is different and will therefore likely have a different spectrum. Moreover, many of these potential noise realizations might have infinite energy, and will therefore not have well-defined Fourier transforms.

Because of these complicating factors, we must consider the power spectrum (rather than the standard energy spectrum) averaged over all possible realizations to obtain a meaningful definition of the spectrum of a random signal. This approach leads to the well-known and often used *power spectral density* of the noise or interference as the basic frequency-domain description of $x(t)$.

To begin, assume that we only observe the noise signal $x(t)$ from $t = -T$ to $t = +T$ (we will later let T approach infinity to allow for the observation of the entire signal). The Fourier transform of this observed signal is

$$X_T(\omega) = \int_{-T}^T x(t)e^{-j\omega t} dt \quad (7)$$

We may then write the squared magnitude of $X_T(\omega)$ as follows:

$$|X_T(\omega)|^2 = \int_{-T}^T \int_{-T}^T x(t_1)x^*(t_2)e^{-j\omega(t_1-t_2)} dt_1 dt_2 \quad (8)$$

As described above, for the definition to have any utility, we need to compute the average magnitude squared power

spectrum, which requires that we must evaluate the expected value of $|X_T(\omega)|^2$ and then normalize this expectation by the length of the observation of $x(t)$ (this prevents the spectrum from blowing up with power signals). This leads to the following expression

$$\frac{1}{2T} E[|X_T(\omega)|^2] = \frac{1}{2T} \int_{-T}^T \int_{-T}^T R_x(t_1 - t_2) dt_1 dt_2 \quad (9)$$

$$= \int_{-T}^T \left[1 - \frac{|\tau|}{2T}\right] R_x(\tau) d\tau \quad (10)$$

where the second equation arises from a transformation of variables. The final step in the definition is to allow the observation window to grow to $(-\infty, +\infty)$, that is, to take the limit of Eq. (10) as T tends to infinity. From this we arrive at the following definition which holds for all wide sense stationary random signals.

Definition 4. The power spectral density of a wide sense stationary random signal $x(t)$ is given by

$$S_X(\omega) = \int_{-\infty}^{\infty} R_x(\tau)e^{-j\omega\tau} d\tau \quad (11)$$

Note that as a consequence of the preceding analysis, the power spectral density turns out to simply be the Fourier transform of the correlation function. Thus the correlation function of a random signal contains all the information necessary to compute the average spectrum of the signal and, furthermore, there is a one-to-one relationship between the average time dependency between samples (as measured by the correlation function) and the average frequency content in the signal.

The term “power spectral density” arises from the fact that $S_X(\omega)$ behaves like a probability density function. First, just like a standard density function, it is always nonnegative, and second, when integrated over a certain frequency range one obtains the average power of the signal over that frequency range. That is, computing the integral

$$\int_{-\omega_2}^{-\omega_1} S_X(\omega) d\omega + \int_{\omega_1}^{\omega_2} S_X(\omega) d\omega \quad (12)$$

results in the total power in the signal $x(t)$ between the frequencies ω_1 and ω_2 . (*Note:* We must consider both positive and negative frequencies.) This is just like the situation when one integrates a probability density function over a particular range to obtain the probability that the random variable will fall within that range.

Now given these few basic definitions, we may proceed to characterize various forms of noise or interference. From the statistical perspective, what differentiates various types of noise are, first and foremost, the specific joint distribution of the process. Since these joint density functions are exceedingly difficult to obtain, we are often relegated to comparing and classifying noise signals through $f_X(x; t)$ and $f_X(x_1, x_2; t_1, t_2)$, as well as the mean and correlation function or power spectral density.

2. NOISE MODELS

2.1. White Noise

White noise is a model used to describe any noise or interfering signal that has essentially equal power at all frequencies. More precisely, signals with a power spectral density given by

$$S_X(\omega) = \frac{N_0}{2} \text{ for all frequencies} \quad (13)$$

are said to be white because, similar to white light, these signals have equal power at all (visible) frequencies. Through simple integration it is easily shown that the amount of power contained in white noise over an angular frequency range of B radians per second is N_0B . (Note that the factor of 2 in the definition of the power spectral density accounts for the two-sided nature of the Fourier transform.)

It is important to note that this definition of white noise is not an explicit function of either the amplitude density function or the joint density function given in Eqs. (3) and (4), but rather a function of only the power spectral density of the signal. Thus, any noise source, irrespective of the specific forms of $f_X(x; t)$ and $f_X(x_1, x_2; t_1, t_2)$, can be white noise, so long as the power spectral density is a constant.

The corresponding correlation function of white noise is obtained through the inverse Fourier transform as

$$R_x(\tau) = \frac{N_0}{2} \delta(\tau) \quad (14)$$

where $\delta(\tau)$ is the familiar Dirac delta function [3]. Here one should observe from the above equation that white noise has zero correlation between all time samples of the signal, no matter how close the time samples are to one another. This does not imply that all samples of white noise are independent from one another, rather that they simply have zero correlation between them.

Unfortunately, by integrating the power spectral density over all frequencies we observe that the total power in white noise is infinite, which, of course, requires more energy than exists in the entire universe. Therefore, it is physically impossible for white noise to exist in nature. Yet, there are many noise processes which have essentially a constant power spectral density over a fixed and finite frequency range of interest, which suggests that white noise may be an appropriate and simplifying model. Yet, the real utility of the white noise model is in describing other “nonwhite” noise signals.

To demonstrate this, consider the output of a linear time-invariant system with frequency response $H(\omega)$ to a white-noise input. Under very general conditions, it can be shown [2] that this output, given by $y(t)$, is a noise signal with power spectral density given by

$$S_Y(\omega) = \frac{N_0}{2} |H(\omega)|^2 \quad (15)$$

Now, conversely, let us assume that we observe some nonwhite-noise signal with power spectral density $S_Y(\omega)$. If $\int \ln S_Y(\omega) / (1 + \omega^2) d\omega > -\infty$, then $y(t)$ can be modeled as the output of *some* linear time-invariant system with a white-noise input. That is, there will exist some well-defined system with frequency response given by $H(\omega)$ such that $N_0/2 |H(\omega)|^2 = S_Y(\omega)$. These processes are, in fact, physically realizable and constitute all random signals seen in practice. Thus, from a spectral perspective we may replace essentially all random signals seen in nature by a linear system driven by a white-noise signal.

2.2. Gaussian Noise

Gaussian noise is the most widely used model for noise or interference both in practice and in the scientific literature. There are two primary reasons for this: (1) many observations in nature follow the Gaussian law, and (2) the Gaussian density function is mathematically easy to analyze and manipulate.

The reason that so many natural observations are Gaussian arises from the so-called *central-limit theorem*. This theorem is stated as follows.

Theorem 1. Assume that Z_i are independent, and identically distributed random variables, each with mean μ_Z and finite variance σ_Z^2 . Then the so-called normalized sum given by

$$Y_n = \frac{1}{\sqrt{n}} \sum_{i=1}^{n-1} \frac{Z_i - \mu_Z}{\sigma_Z} \quad (16)$$

approaches a standard Gaussian random variable with mean equal to zero and unit variance, irrespective of the original distribution of the random variables Z_i .

What this very powerful theorem establishes is that if a particular observation of interest is a combination of infinitely many small and independent random components, then the combination, when properly normalized, is Gaussian Random variable with density function given by

$$f_x(x; t) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2} \quad (17)$$

This might suggest that all natural observations are Gaussian since most physical phenomena are impacted by many random events; however, extensive experimental results establish otherwise [4]. Therefore, in addition to various forms of Gaussian noise, later in this article we will present a number of other “non-Gaussian” noise models.

Definition 5. A random noise signal is said to a Gaussian signal if all n th-order joint density functions are jointly Gaussian, that is, if all joint density functions are of the form

$$f_x(\mathbf{x}) = \frac{1}{(2\pi)^{n/2} \sqrt{\det(\mathbf{K})}} \times \exp \left[-\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{K}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right] \quad (18)$$

where the vector $\boldsymbol{\mu}$ and the matrix \mathbf{K} represent the mean vector and covariance matrix [2], respectively, of the vector $\mathbf{x}(t_1), \mathbf{x}(t_2), \dots, \mathbf{x}(t_n)$.

The important feature here is we see that for any value n , the joint statistics of a Gaussian signal are completely determined from the mean and correlation functions of $x(t)$. Furthermore, when the signal is in addition wide-sense stationary, then the joint statistics are shift invariant, and as such, the signal is also strictly stationary.

Gaussian noise is further differentiated by the nature of the mean functions and the correlation functions. When the correlation function is given by $R_X(\tau) = N_0/2\delta(\tau)$, then the signal is said to be *Gaussian White Noise*, which is the single most common model in noise analysis. In this case, each time sample will be independent from all others and have infinite variance. Other well-known Gaussian models that we describe below are Wiener noise, thermal noise, and shot noise.

2.3. Wiener Noise

The Wiener Process is the limiting case of a random-walk signal. A random walk is a popular abstraction for describing the distance an individual is from home when this individual randomly steps forward or backward according to some probability rule. The model is as follows. Every T seconds an individual will take a length s step forward with probability $\frac{1}{2}$ or a length s step backward with probability $\frac{1}{2}$. Therefore, at time nT , the position of the random walk will be $x(nT) = ks - (n-k)s$, where n is the total number of steps taken, and k is the number of forward steps taken. For large values of time, it can be shown using the DeMoivre–Laplace theorem [2] that

$$\Pr(x(nT) = ks - (n-k)s) \approx \frac{1}{\sqrt{n\pi/2}} e^{-(2k-n)^2/2n} \quad (19)$$

or that the location of the walker is governed approximately by a Gaussian law.

Now, let us extend this by considering the limiting case where the length of time between steps tends to zero ($T \rightarrow 0$). It is easy to show that $E[x^2(nT)] = ns^2 = ts^2/T$ for $t = nT$. To ensure that we do not have a variance going to zero (the walker stops) or blowing up (not physically realizable), let us also add the condition that the size of the steps be proportional to the square root of the time between steps, that is, $s^2 = \alpha T$. Then the well-known Wiener process is the signal $x(t)$, which is the limit of the random walk under these conditions. Examples of this are given in Fig. 2, where we have depicted realizations from three succeeding approximations to the Wiener process. In all figures, we have let the proportionality constant $\alpha = 1$. In Fig. 2a T and s equal 1, in Fig. 2b $T = 0.1$ and $s = \sqrt{0.1}$, and in Fig. 2c $T = 0.01$ and $s = 0.1$. One can see that as the approximation gets closer to the limiting value it becomes smoother (more continuous) and begins to exhibit long-term trends. This, of course, makes sense because the steps are getting much smaller and, as a consequence, it

takes longer periods of time of the walker (signal) to change positions (values).

It should be pointed out that as $T \rightarrow 0$, the position of the random walk at any point in time is the sum of infinitely many random steps, and therefore by the central-limit theorem, the location at any point in time is a Gaussian random variable with zero mean and variance given by αt .

To compute the correlation function of the Wiener process, we note that $x(t_2) - x(t_1)$ is independent of $x(t_1)$ because, by supposition, the random movements between times t_1 and t_2 are independent of the random movements up to time t_1 . From this it must be that

$$E[(x(t_2) - x(t_1))x(t_1)] = E[x(t_2) - x(t_1)]E[x(t_1)] = 0 \quad (20)$$

from which it is easy to show that $R_X(t_1, t_2) = \alpha t_1$ whenever $t_2 > t_1$. Determining the correlation of the case that $t_1 > t_2$ results in the final value for the correlation function of the Wiener process as

$$R_X(t_1, t_2) = \alpha \min(t_1, t_2) \quad (21)$$

One can readily see that the Wiener process is not wide-sense stationary and therefore does not have a computable power spectral density. Nevertheless, it is a highly useful, physically motivated model for Gaussian data with relatively smooth realizations and which exhibits long-term dependencies.

2.4. Thermal Noise

Thermal noise is one of the most important and ubiquitous sources of noise in electrical circuitry. It arises primarily from the random motion of electrons in a resistance and occurs in all electronic circuits not maintained at absolute zero degrees Kelvin. This resulting low-level noise is then scaled to significant levels by typical amplifiers used to amplify other low-level signals of interest.

To derive a model for thermal noise, let us assume that we have a conducting rod of length L and cross-sectional area A for which we expect to measure low-level random voltages. Let $V_{x,k}(t)$ denote the component of velocity in the x direction of the k th electron at time t . The total current denoted by $I(t)$ is the sum of all electron currents in the x direction

$$I(t) = \sum_{k=1}^{nAL} i_k(t) = \sum_{k=1}^{nAL} \frac{q}{L} V_{x,k}(t) \quad (22)$$

where n is the number of electrons per cubic centimeter and q is the charge of an electron. Let us assume that the average velocity of each electron is zero and that all electrons behave independently of one another and have an identical distribution. From this, it is easy to show that the correlation function of the current is given by

$$R_I(\tau) = \frac{nAq^2}{L} E[V_x(t)V_x(t+\tau)] \quad (23)$$

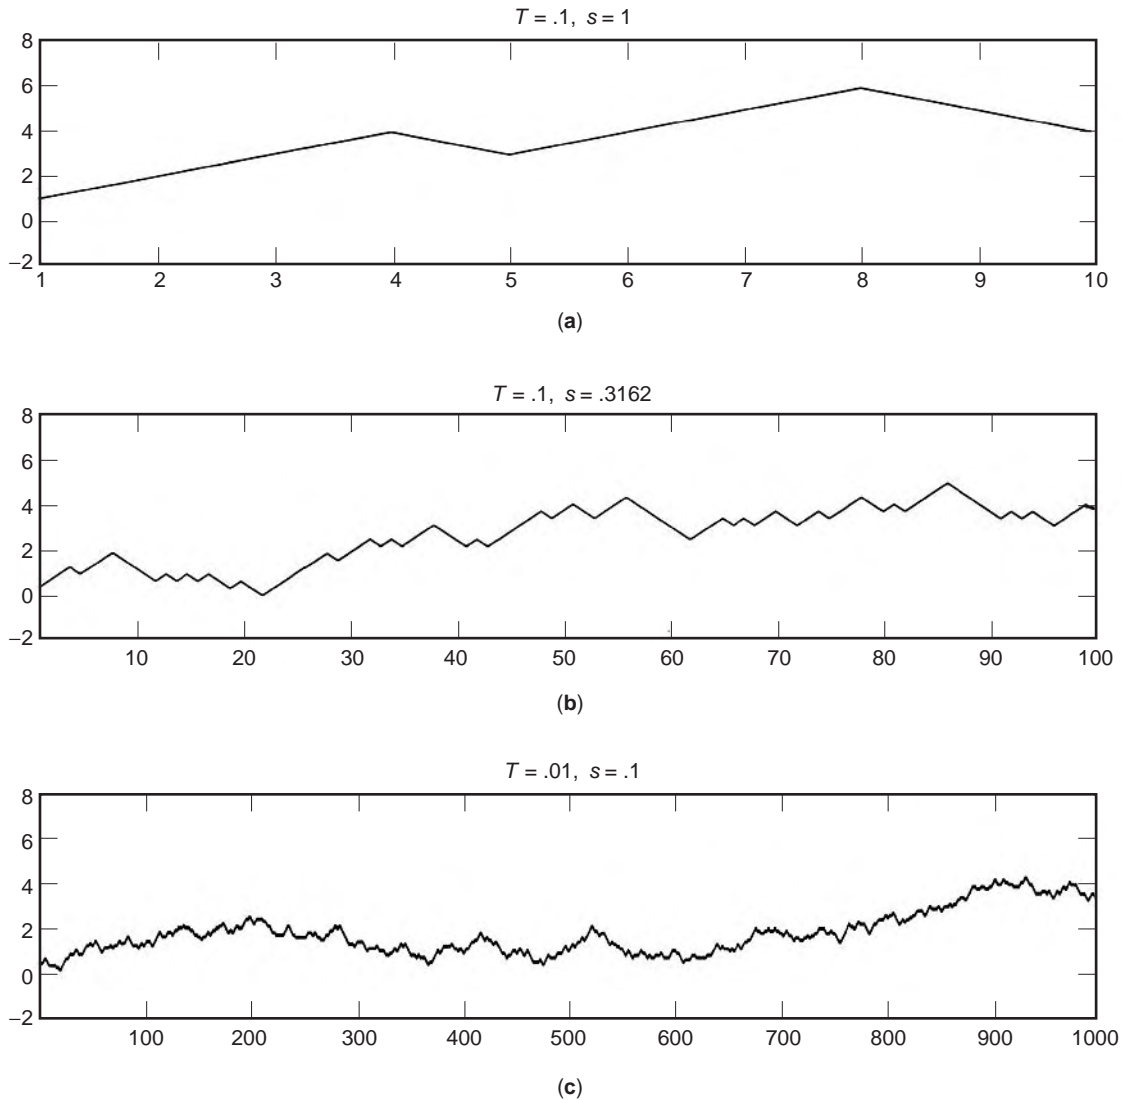

Figure 2. Plots of realizations from numerical approximations to the Wiener process for various values of s and T . In all cases, $\alpha = 1$. In (a), $T = 1$ and $s = 1$, in (b) $T = 0.1$ and $s = 0.3162$ and in (c) $T = 0.01$ and $s = 0.1$.

where we have dropped the subscript k for convenience. Assuming that electron collisions occur according to a Poisson law with intensity given by α [2] and that the average variance of the velocity of an electron is given by $k_B T/m$, where k_B is Boltzmann’s constant and m is the mass of an electron (from the equipartition theorem for electrons), it can be shown that

$$R_I(\tau) = \frac{kT}{R} \alpha e^{-\alpha|\tau|} \tag{24}$$

where R is the resistance of the rod. Recognizing that $E(t) = RI(t)$, we can easily obtain the correlation function of the voltage as

$$R_E(\tau) = kTR \alpha e^{-\alpha|\tau|} \tag{25}$$

Note that as the intensity of the electron collisions α increases, the correlation function begins to approach

a Dirac delta function, implying that the spectrum of thermal noise begins to better approximate white noise. Furthermore, we also observe that as we lower the temperature of the circuitry T , the power $R_E(0)$ in the thermal noise decreases proportionally. This, of course, suggests that if one wants to process very weak signals, for example, deep-space signals, then the circuitry must be cooled using some form of coolant. The central-limit theorem can be used to show that the voltage is very well approximated by a Gaussian process.

2.5. Shot Noise

Shot noise is used to model random and spontaneous emissions from dynamical systems. These spontaneous emissions are modeled as a collection of randomly located impulses (Dirac delta functions) given by $z(t) = \sum_i \delta(t - t_i)$, where the locations of the impulses in time

(t_i) are governed by a Poisson law with intensity λ which is then driven through some system.

The output of a system with impulse response $h(t)$ to the input $z(t)$ is said to be “shot noise.” From the convolution theorem, it is easily shown that this output is

$$x(t) = \sum_i h(t - t_i) \quad (26)$$

Using the properties of the Poisson law, it is easy to show that the mean value of shot noise is $\mu_x = \lambda H(0)$, where $H(\omega)$ is the frequency response (Fourier transform) of the system. The power spectral density function of $x(t)$ is given by

$$S_X(\omega) = \lambda^2 H^2(0) \delta(\omega) + \lambda |H(\omega)|^2 \quad (27)$$

Thus the frequency content of the shot noise is determined entirely by the system $h(t)$ and the intensity of the Poisson process, that is, average rate of emissions. As before, because $x(t)$ at large values of time is composed of the superposition of many random elements [see Eq. (26)] $x(t)$ is often modeled as a wide-sense stationary Gaussian random process with power spectral density given by Eq. (27).

3. NONGAUSSIAN MODELS

While the scope of the central-limit theorem might suggest otherwise, there are many datasets derived from the environment which do not conform well to the Gaussian model. Most of these data contain interfering signals emitted from a modest number of interferers or from interferers overlapping the signal of interest in the frequency domain in such a way that one could not easily remove these unwelcome elements by filtering.

Approaches to remedy this modeling problem fall into two categories: (1) generalize the Gaussian model to allow for statistical variation around the Gaussian process or (2) attempt to derive new statistical models directly from the physics of the problem. In both cases, most non-Gaussian specifications typically do not go beyond the amplitude probability density function given in Eq. (3) and power spectral density. This is due, in large part, to the severe complexity of merely specifying valid and useful joint probability functions with the desired amplitude density.

These non-Gaussian models for noise and interference generally differ statistically from Gaussian noise in the rate at which the so-called “tail” of the amplitude density tends to zero. More specifically, for Gaussian noise the amplitude probability density function is approximated by $e^{-x^2/2\sigma^2}$ for large values of $|x|$; that is, the tails (the probability density function from some large value to \pm infinity) of the amplitude density decay at an exponential rate with exponent equal to x^2 . From a physical point of view, this rate translates into the relative frequency of observing large amplitude values from the noise signal. That is, amplitude density functions with tails that decay to zero faster than the Gaussian tail give rise to datasets with fewer large values in the noise than one might see with Gaussian data. On the other hand, when the tail of the amplitude density decays slower than that of the Gaussian, one

is more likely to see large random values of the noise signal $x(t)$ than one would with Gaussian data. So, unlike differentiating noise models based on the spectrum of the noise, as seen in the preceding section, with non-Gaussian noise we typically differentiate various forms by the nature of the tail of the amplitude density function.

3.1. Generalized Gaussian Noise

The generalized Gaussian model is the most straightforward extension of the standard Gaussian model. In this case, the amplitude probability density function is given by

$$f_X(x; t) = a(p) \exp\left(-\left[\frac{|x|}{A(p)}\right]^p\right) \quad (28)$$

where the constant p parameterizes the density function and where $A(p) = \sqrt{[\Gamma(1/p)/\Gamma(3/p)]}$, $a(p) = p/[2 * \Gamma(1/p) * A(p)]$ and where $\Gamma(z)$ is the gamma function (generalized factorial). It should be noted that, irrespective of the value of p , the variance of the amplitude density function is held constant (in this case the variance is arbitrarily set to one). Plots of the amplitude density function for $p = 1, 2, 5, 50$ are depicted in Fig. 3. One can see that for small values of ($p < 2$), the tails of the density functions maintain relatively large values for large arguments. Conversely, for large values of ($p > 2$), the tails decay to zero quite rapidly.

From Eq. (28), it is easily recognized that for $p = 2$, the generalized Gaussian model results in a standard Gaussian model. Alternatively, when $p = 1$, we obtain the well-known *Laplacian* model for noise. In this case, the tail of the amplitude density function decays at a rate of $e^{-|x|}$, thus implying that one will likely observe many more large values of noise than one would see with Gaussian noise. In general, for $p < 2$ we obtain tails with more mass (more probability), resulting in “impulsive” data, while for $p > 2$ we obtain tails with less mass, resulting in datasets with very few outliers and more uniformly distributed over its range.

Figure 3. Plots of various specific amplitude density functions from the generalized Gaussian model.

To demonstrate the variation in the data under this model, Fig. 4 shows sample realizations from Laplacian noise ($p=1$), Gaussian noise ($p=2$), and generalized Gaussian noise ($p=50$). One can see that these datasets, all with a common variance (power), exhibit quite different behavior. The Laplacian noise better models interference which might contain spikes such as those produced by man-made devices, while $p=50$ might better model interference arising from signals with well-contained powers (Fig. 5).

3.2. Sub-Gaussian Noise

While in general one specifies a random signal through the joint distribution function, sub-Gaussian noise is specified through the joint characteristic function [2]. As a reminder, this function is simply the Fourier transformation of the joint density function and, as such, there exists a straightforward one-to-one relationship between characteristic functions and joint density functions. As opposed to the generalized Gaussian noise model, sub-Gaussian noise is parameterized in the exponent of the characteristic

function rather than the exponent of the amplitude density function [5].

Definition 6. A noise or interference signal is said to be an α -sub-Gaussian signal if for any positive integer n and time vector $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$, the characteristic function of the joint density function of $[x(t_1), x(t_2), \dots, x(t_n)]$ is given by

$$\varphi(\mathbf{u}) = \exp\left(-\left[\frac{1}{2} \sum_{m,l=1}^n u_m u_l R(t_m, t_l)\right]^{\alpha/2}\right) \quad (29)$$

where $\alpha \in (1, 2]$ and where $R(t,s)$ is a positive definite function and where $\mathbf{u} = \{u_1, u_2, \dots, u_n\}$.

Importantly, if the parameter $\alpha = 2$ then the sub-Gaussian process is simply a Gaussian process. Otherwise, the noise signal corresponds to some signal which has been parameterized away from the Gaussian signal. In all cases other than $\alpha = 2$, the corresponding tail of the amplitude

Figure 4. Plots of realizations from various density functions from the generalized Gaussian family of density functions.

Figure 5. Plots of realizations from the sub-Gaussian noise family: (a) corresponds to $\alpha = 1.99$; (b) corresponds to $\alpha = 1.5$.

density function decays at a polynomial rate (rather than an exponential rate) which translates into many more very large amplitude values than one would typically see with pure Gaussian noise. Therefore this model might be appropriate for characterizing data that contain many impulses.

There are a number of important properties of sub-Gaussian process [6,7]. From a modeling point of view, the most significant is that any sub-Gaussian process can be expressed as the product of a Gaussian process scaled by a so-called $\alpha/2$ stable random variable. That is, if $x(t)$ is an α -sub-Gaussian signal, then

$$x(t) = S^{1/2}y(t) \quad (30)$$

where $y(t)$ is a Gaussian random process with zero mean and correlation function given by $R(t,s)$ and S is an independent, positive $\alpha/2$ -stable random variable. (A $\alpha/2$ -stable random variable is a random variable with characteristic function given by $\varphi(u) = \exp[-\gamma|u|^{\alpha/2}]$.) One interesting property of sub-Gaussian signals is that all samples from this signal are always dependent on one another. In addition, for $\alpha \neq 2$, it can be shown that samples from

$x(t)$ will have infinite variance, thus making this model somewhat problematic in terms of accurately representing the average power of an interference signal. Nevertheless, the sub-Gaussian noise model has been used extensively to model noise or interference with a significant number of outliers or impulses and, in some applications, it serves well as a replacement for shot noise as an efficient model.

3.3. Middleton Noise and Interference

Unlike either the generalized Gaussian model or the sub-Gaussian model, Middleton models have been derived directly from physical arguments. These models attempt statistically to characterize the amplitude density of the envelope [8] of a signal in the presence of various types of man-made interference after it has passed through the front end of the receiver. Importantly, these models are canonical, in the sense that they do not depend on the specific source of the interference—only the relative bandwidth of the interferers with respect to the receiver. Therefore, interferers such as powerlines, atmospheric noise, and various mechanical machines are all accommodated well by these very powerful models.

There are two basic forms of Middleton noise [9–11]. Class A noise represents the statistical interference when the bandwidth of the interfering signals are on the order of or smaller than the bandwidth of the front end of the receiver. In this case, transient effects from the receiver can be ignored.

Alternatively, class B noise considers the case where the receiver bandwidth is substantially smaller than the interference bandwidth and thus transient effects must be accounted for. In addition to class A and B noise, Middleton has introduced the notion of class C noise, which is simply a linear combination of both A and B noise [12].

3.3.1. Physical Model. For both class A and class B noise, it is assumed that there are an infinite number of potential sources of interference within reception distance of the receiver. The individual interfering signals are assumed to be of a common form, except for such parameters as scale, duration, and frequency, among others.

The locations and parameters of the interferers in the source field are assumed to be randomly distributed according to the Poisson law. The emission times for each source are also assumed to be random and Poisson distributed in time. Physically speaking, this implies that the sources are statistically independent both in location and emission time.

3.3.2. Class A Noise. As described above, the physical model for class A noise assumes that the bandwidth of the individual interfering signals is smaller than the bandwidth of the receiver (data collection system.) This allows for the simplification of ignoring all transient effects (ringing) in the output of the receiver front end.

Avoiding the tedious analysis and simply stating the result, the (approximate) amplitude probability density function under these assumptions was shown by Middleton [9] to be

$$f_x(x; t) = e^{-A} \sum_{m=0}^{\infty} \frac{A^m}{m!} \frac{1}{\sqrt{2\pi\sigma_m^2}} e^{-(x^2/2\sigma_m^2)} \quad (31)$$

where

$$\sigma_m^2 = \frac{m/A + \Gamma}{1 + \Gamma} \quad \text{and} \quad \Gamma = \sigma_G^2/\Omega \quad (32)$$

One can see from these equations that the class A model is parameterized in three parameters (A, Γ, Ω), each with physical significance. The parameter A is a measure of the impulsiveness of the interference and is given by the product of the average number of impulses emitted per unit time with the average duration of an impulse. Small values of A indicate a highly impulsive signal, since this would imply a small number of interferers each with very short pulses. For large values of A we have many interferers each with long duration and, thus, by the central-limit theorem, the interference is nearly a Gaussian process. The constant Γ quantifies the ratio of the intensity of the independent Gaussian component arising from

thermal or ambient noise (given by σ_G^2) to the mean intensity of the interference (given by Ω).

3.3.3. Class B Noise. Class B noise assumes that the bandwidth of the interfering signals is larger than the front-end bandwidth of the receiver. This assumption significantly complicates the analysis. In particular, one is required to use two separate models for small and large signal levels instead of a single model as in the class A model. Because of the level of detail required to describe this model, it is recommended that the interested reader seeking a precise definition be directed to the original work found in Ref. 9.

3.4. ε -Mixture Noise

One might observe from the preceding Middleton models that the amplitude density functions are infinite linear combinations of zero-mean Gaussian models. Interestingly, it has been well known in the statistics literature that appropriately scaled Gaussian density functions can be combined together to obtain nearly all valid amplitude density functions, so it is not surprising that this combination appears as a canonical representation of signal interference.

However, working with infinite sums of density functions requires much careful analysis. It is because of this that researchers have introduced a simplifying approximation to the Middleton class A Model, which is referred to as the ε -mixture model.

In this simplification, the amplitude probability density function of interference plus background or thermal noise is approximated by a combination of just two Gaussian density functions

$$f_x(x; t) = (1 - \varepsilon) \frac{1}{\sqrt{2\pi\sigma_\varepsilon^2}} e^{-(x^2/2\sigma_\varepsilon^2)} + \varepsilon \frac{1}{\sqrt{2\pi\gamma\sigma_\varepsilon^2}} e^{-(x^2/2\gamma\sigma_\varepsilon^2)} \quad (33)$$

where the constant ε determines the fraction of impulsivity found in the data and where γ represents the ratio of intensities of the impulsive component to nominal ambient noise. In order to maintain a fixed power level of σ^2 in the noise and interference model for all choices of ε and γ , the parameters must satisfy the following power constraint:

$$\sigma_\varepsilon^2 = \frac{\sigma^2}{1 - \varepsilon + \varepsilon\gamma} \quad (34)$$

Sample realizations from the ε -mixture model are depicted in Fig. 6. The top figure corresponds to purely Gaussian noise ($\varepsilon = 0$), while the middle and bottom figures correspond to $\varepsilon = 0.01$ and 0.1 , respectively. As one can see, as ε increases the average number of “impulses” (spikes in the data) increases, while the average power of background thermal noise decreases in accordance with Eq. (34). Therefore, this model offers some of the flexibility

Figure 6. Plots of realizations from the ε -mixture noise family: (a) corresponds to $\varepsilon=0$ (pure Gaussian noise); (b) corresponds to $\varepsilon=0.01$ (a 1% chance of observing interference at any point in time); (c) corresponds to $\varepsilon=0.1$ (a 10% chance of observing interference at any point in time). One should observe that as ε increases, the empirical frequency of “impulses” arising from interference increases proportionally.

required by the Middleton models without the requisite computational complexity.

4. CONCLUSIONS

This article has described the basic techniques for characterizing noise and interference from both statistical and signal processing perspectives. These approaches have varied from the most analytic and fundamental (n th-order joint density or distribution functions) to more practical and data-oriented (means, correlation functions, and power spectral density).

The primary differentiation between various noise models has been based on the statistical characteristics of the signal. Of particular importance was the “Gaussianity” or non-Gaussianity of the signal. In many important applications, the central-limit theorem implies that the corruptive effects of noise will be well approximated by a Gaussian process. However, basic physical arguments, such as those found in Middleton’s work, also suggest that much of what we consider to be Gaussian noise is, in fact, substantially non-Gaussian. Moreover, it has been shown in much research that imposing the Gaussian model on data that are decidedly or marginally

non-Gaussian can have detrimental effects on the final designs. It is therefore critical that when one is dealing with data, particularly data arising from interfering sources, that the appropriate model be used and used accurately.

For readers interested in pursuing these topics further, one should begin with the important original work found in Ref. 13. Explicit models governing a wide variety of random phenomena can be found in Refs. 14–16. For an advanced treatment of random process in general, books by Doob [17] and Wong and Hajek [18] are excellent if not somewhat advanced treatments of the theory of random signals.

NOISE GENERATORS

SHAMBHU J. UPADHYAYA
State University of New York
at Buffalo

Noise is a broadbanded signal generated by environmental effects, such as lightning, or by man-made electrical devices. Two common categories of noise are thermal noise and shot noise. Looney [1] describes thermal noise as an electromotive force generated at the open terminals of a conductor due to the charges bound to thermally vibrating molecules. This type of noise is often referred to as Johnson noise in recognition of the first observations of the phenomenon [2]. On the other hand, shot noise is associated with the passage of current across a barrier. For instance, a circuit or an appliance that produces electric arcing produces noise. Shot noise was first described by Schottky using the analogy of a small shot patterning into a container [3]. Noise can be felt in audio systems as a crackle. Noise appears as white or black spots on a television screen.

Noise is generally characterized as a source of corruption of information and therefore is treated as an undesired signal. Noise contaminates informational signals to a certain extent by superimposing extraneous fluctuations that assume unpredictable values at each instant. Noise has been studied extensively in the literature because noise reduction is one of the major goals. A more compelling reason for the study of noise is its potential application in real life. These applications encompass biomedical engineering, electronic circuits, communication systems, cryptography, computers, electro-acoustics, geosciences, instrumentation, and reliability engineering. This article addresses the various noise generation techniques and implementing them in analog and digital circuit technology and concludes with a discussion of typical applications.

1. MODELING OF NOISE

A mathematical model of a phenomenon, such as noise, allows us to understand its generation, characteristics, and application well. We start with the observation that the structures of thermal and shot noise are similar, although their sources are different. Both types of noise can be represented as a random waveform consisting of a sequence of peaks randomly distributed in time. A noise signal can be modeled by a random process $X(t)$ with a probability distribution for the values of x it assumes. Any particular set of outcomes $\{(t, x_t)\}$ of the random variable X_t is called a realization of the noise process. An adequate characterization of such a random process can be often made with first- and second-order statistics. The first-order statistic of $X(t)$ is the expected value $E[X(t)]$ and the second-order statistic is the autocorrelation function $R_X(\tau) = E[X(t)X(t + \tau)]$, where E is the expectation operator. When the first- and second-order statistics do not change over time, the process is called wide-sense stationary [4].

Power spectral density, a standard measure used to describe a wide-sense stationary process, is defined as the Fourier transform of the autocorrelation function $R_X(\tau)$ [4]:

$$S_X(f) = \int_{-\infty}^{\infty} R_X(\tau) e^{-j2\pi f\tau} d\tau \quad (1)$$

With this modeling, we can analyze the spectra of noise. White noise is a wide-sense stationary process with zero mean. It has constant power spectral density over all frequencies. Stated another way, white noise is a process that is uncorrelated over time. The most mathematically tractable noise is the Gaussian wide-sense stationary process, where at each time t the probability distribution for the random variable $X_t = X(t)$ is Gaussian.

Colored noise is a variation of white noise that arises from the fact that actual circuits attenuate signals above certain frequencies. Therefore it makes sense to truncate the white noise spectral density at both extremes. Noise with this spectral characteristic is termed pink noise.

Apart from thermal noise and shot noise, a third category of noise observed in electronic systems is the $1/f$ noise. It is so called because the power spectral density of this noise varies with frequency as $|f|^{-\alpha}$, where α takes values between 0.8 and 1.2. This type of noise is exhibited by biological and musical systems in addition to electronics [3]. $1/f$ noise is variously called current noise, excess noise, flicker noise, semiconductor noise, and contact noise. It is applied in medical treatment and also in engineering, justifying the need for inclusion in our study.

2. NOISE GENERATION TECHNIQUES

Noise can be generated in many different ways. A diode tube operating at its saturation point produces broadband noise. A semiconductor diode is an inexpensive source of noise generation. When operated in the fully conducting region, the diode produces broadband noise. A current-carrying resistor produces thermal noise. It is necessary to condition noise signals by proper amplification, modulation, and filtering to suit one's application at a desired bandwidth. In our discussion of noise generation, we concentrate only on semiconductor techniques because approaches based on vacuum tubes are antiquated now.

The noise generation schemes range from simple mechanical techniques to electronic methods employing both analog and digital circuits. Inexpensive noise generators can be realized with discrete components and basic building blocks available in the IC market. We classify the noise generators into two categories, namely, analog and digital, based on their implementation.

2.1. Analog Techniques

Under this category, we discuss three different approaches: (1) a mechanical scheme, (2) amplifying inherent noise in op-amps, (3) oscillator method, and (4) using the chaotic behavior of deterministic systems.

2.1.1. Mechanical Approach. For audiofrequency noise, a very simple scheme can be devised at home or in the laboratory without any sophisticated circuits or components. Dunn [5] uses just a linen-covered phonograph and a foam-covered microphone. A piece of linen cloth is tied to the turntable and a foam-covered microphone is used to pick up the signal. As the turntable rotates, the microphone's foam cover rubs along the surface of the linen, producing sound with a nearly flat spectral density in the audiofrequency range of from 20 Hz to 20 kHz. Dunn shows that by using a good hi-fi microphone and a broadband amplifier, the output signal closely approximates white noise over the audiofrequency range. Other mechanical approaches include the use of gears and radioactive decay [6].

2.1.2. Amplification of Inherent Noise. The schematic of a relatively simple op-amp noise generator is shown in Fig. 1, which uses a single bipolar input amplifier and some discrete components. The principle used here to generate wideband noise is to amplify its own input noise in a decompensated op-amp [7]. Many op-amps have large $1/f$ input noise components. A bipolar input op-amp is chosen because bipolar devices exhibit much less $1/f$ noise than MOSFET devices.

In the figure, the op-amp is used as a fixed-gain stage amplifier with a closed-loop gain factor:

$$G = 1 + R_1/R_2 \quad (2)$$

If the input resistors R_2 and R_3 are chosen small, the thermal noise of the amplifier is forced to a small value. This choice of low values for the resistors also helps keep the amplifier's current noise component negligibly small when it is converted to voltage noise. Thus, the dominant noise of the circuit is the input voltage noise of the amplifier.

The choice of a single gain stage amplifier of the type shown in Fig. 1 results in a frequency-independent noise. This contrasts with multistage amplifiers, which may have peaks in the output noise response caused by frequency compensation effects. The values for resistors R_1 and R_2 can be designed by knowing the typical noise of the op-amp from datasheets and the required level of noise across the load R_L . The output is coupled through a blocking capacitor C_1 , which removes any amplified DC value at the output of the amplifier. However, the value of this

Figure 1. A simple analog noise generator based on amplification of op-amp input noise.

capacitor should be large enough to pass the lowest noise frequencies of interest. Interested readers may refer to Ref. 7 for a detailed circuit diagram and typical component values used to generate a noise of $50 \text{ nV}/\sqrt{\text{Hz}}$. Op-amp AD829 is used in the circuit that features flat voltage noise in the range from 100 Hz to 10 MHz.

2.1.3. Oscillator Method. A popular analog class of noise generators is the oscillator method [8], which samples the frequency noise or instability of free-running oscillators. In this scheme, the output of a fast oscillator is sampled on the rising edge of a slower clock using a D flip-flop. Oscillator jitter causes uncertainty in the exact sample values, ideally producing a random bit for each sample. For further details, readers may refer to Ref. 9.

2.1.4. Using Chaos in Deterministic Systems. Another elegant way of generating white noise is based on the observation that certain simple deterministic systems exhibit chaotic behavior [10]. The chaos or noise is generated by iterating a map either electronically or in a software program. A simple and most widely studied system for generating chaos is the logistic map [10] given by

$$x_{i+1} = 4\lambda x_i(1 - x_i), \quad i = 0, 1, 2, \dots, 0 \leq x_0 \leq 1 \quad (3)$$

The asymptotic behavior of the system described by the parabolic transfer function of Eq. (3) depends on the value of λ . McGonigal and Elmasry [11] show that values of λ between 0.89 and 1.0 result in oscillations without any detectable period. In fact, this is the region of chaotic behavior leading to power spectral density corresponding to white noise.

A noise generator can be implemented in hardware to test actual instruments or in software for simulation. McGonigal and Elmasry [11] use a multiplier and a difference amplifier to realize the term $x_i - x_i^2$ of the parabolic transfer function of Eq. (3). A variable-gain amplifier connected to the output of the differential amplifier, as shown

in Fig. 2, allows variation of λ . The iteration of the transfer function is realized by the feedback of the x_{i+1} signal as the next x_i input. The clock-driven multiplexer and the storage capacitors shown in the figure separate the impulses at the output of the circuit. During clock signal ck , the voltage on capacitor C_1 provides the input x_i whereas the resulting output x_{i+1} is stored on C_2 . During \bar{ck} , the roles of the capacitors are reversed leading to two iterations of the parabolic function in every clock cycle. The IC numbers and typical values of the discrete components are shown in the figure to generate a power spectrum from DC to 1 kHz. Experimental study in Ref. 11 confirms that the signal is uncorrelated in the chaotic region and that the power spectral density remains flat in this region. Interested readers may refer to Ref. 11 for further details of the circuit and a trace of the power spectrum.

The software implementation of the deterministic-chaotic, variably colored, noise generator is shown in Fig. 3. Colored noise is generated by organizing chaotic elements into a hierarchy and coupling them [12]. Each element of the hierarchy is modeled as a recursive loop whose output is a sequence of impulses. The unit delay element shown in the figure separates the instances of impulses of varying amplitude at the output. The gain unit and the nonlinear amplifier implement the map $x_{i+1} = g_{\lambda}f(x_i)$. The output at any instant becomes the input at the next instant. The initiator block is used only to set the amplitude of the first impulse and is then disconnected. This software setup yields sequences of impulses which are essentially aperiodic and hence noiselike from a practical point of view [12].

Researchers have used discrete, nonlinear, one-dimensional maps [13] that yield a transition between regions of chaotic motion to produce $1/f$ noise. The circuits used to implement such discrete maps are usually switched-capacitor type because discrete maps are described by nonlinear, finite-difference equations and they can be easily and accurately implemented by switched-capacitor circuits. Delgado-Restituto et al. [14] build a programmable

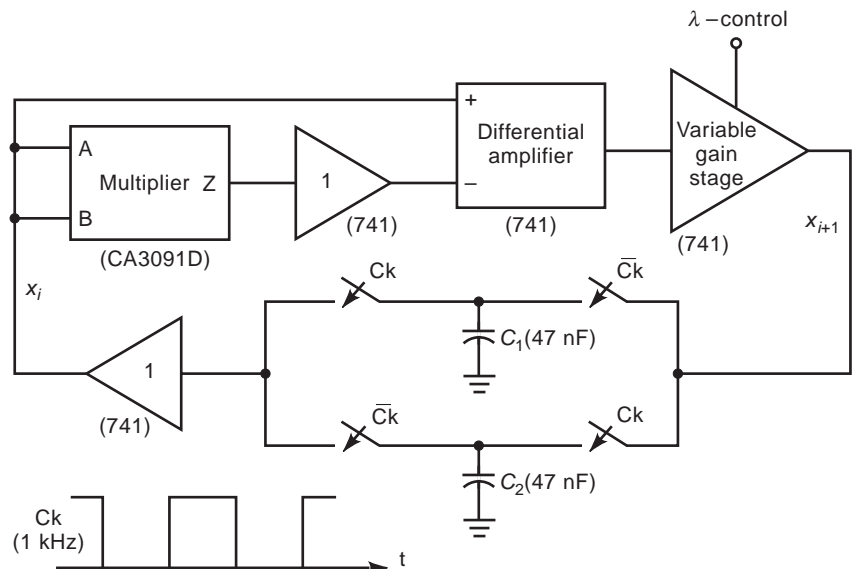

Figure 2. A low-frequency noise generator based on logistic map. (From Ref. 11, courtesy of IEEE, © 1987 IEEE.)

Figure 3. Block schematic of a software-based, deterministic-chaotic, variably colored noise generator.

prototype to generate colored noise to test systems with spectral density proportional to $1/f$. They use op-amps and switched capacitors to realize a chaotic, one-dimensional, piecewise-linear discrete map that yields a hopping transition between regions of chaotic motion. Murao et al. [15] propose a simple switched-capacitor circuit that realizes a one-dimensional, nonlinear, discrete map as opposed to a piecewise-linear approximation. With an IC and a couple of logarithmic and antilogarithmic amplifiers, they can synthesize a simple $1/f$ noise generator over a wide range of frequencies compared with the previous method of Delgado–Restituto et al. [14].

Of the four techniques of noise generation based on chaotic behavior of deterministic systems discussed here, the first is used for white-noise generation, whereas the next three implementations generate colored noise. Although colored noise is derived by properly filtering the output of white-noise sources [16], the direct methods described here are simpler and lend themselves to easy VLSI implementation. Some other simple IC-compatible chaos generators are found in Refs. 17 and 18.

2.1.5. Programmable Noise Generators. It is often desirable to have a programmable noise generator. The variability is achieved by multiplying the noise signal by a factor K and then passing the signal through a noise filter, as shown in Fig. 4. A linear phase filter passes frequencies between F_1 and F_2 , thus bandlimiting the filter output noise. In the simulated noise generator of Ref. 19, the output is sampled at a particular rate and stored in a data array. The statistics of the output data, such as mean, variance, min, and max are stored in another data array. This kind of programmable noise generator produces uniform Gaussian noise whose output noise power is set by adjusting the K factor shown in the figure.

Figure 4. Structure of a programmable noise generator.

Figure 5. Block schematic of a basic digital noise generator.

2.2. Digital Techniques

The first-generation digital noise generators utilized random waveforms based on telegraph signals to obtain random noise [20]. For application in modern digital circuits, however, pseudo-random-number sequence generators provide a better basis. Pseudorandom numbers are generated with linear congruent algorithms [21]. If noise is needed in analog form, the numbers generated in binary form are converted to analog quantity. The analog output at the converter is essentially Gaussian white noise. This signal can be filtered appropriately to obtain colored noise. Figure 5 shows the block schematic of a digital noise generator.

2.2.1. Linear Feedback Shift Register as Random-Number Generator. The digital circuitry implementing the pseudo-random-number generator can be realized using a linear feedback shift register (LFSR). An LFSR consists of two basic digital building blocks, D-type flip-flops and exclusive-OR gates. The LFSR draws theory from cyclic error detecting codes [22] where all algebraic manipulations on polynomials are done in $GF(2)$, that is, Galois field-modulo-2 addition, subtraction, multiplication, and division of binary vectors. A k -stage LFSR generates at most $(2^k - 1)$ distinct binary patterns, which then repeat on themselves. In general, the length of the sequences generated depends on the size of the LFSR and the polynomial representing it. If the polynomial representing the LFSR is primitive [22], the LFSR generates a maximal length sequence $[(2^k - 1)$ vectors]. If the polynomial is irreducible but nonprimitive, then the length of the sequence is not maximal and depends on the initial contents of the LFSR, called the seed. The presence of internal memory in the LFSR makes the choice of the seed critical for nonprimitive case. In the primitive case, the seed does not affect the statistical properties of the output. However, if all of the flip-flops are set to zero, the LFSR remains dormant and is useless.

The upper block of Fig. 6 shows an LFSR implementation of a primitive polynomial of degree 6.

$$x^6 \oplus x \oplus 1 \quad (4)$$

where \oplus is the exclusive-OR operator. In this implementation of LFSRs, the output and selected internal stages of the LFSR corresponding to the nonzero terms of the polynomial are exclusive-ored and fed back to the input. The pseudorandom digital output sequence is plotted in Fig. 7. A clock frequency of 1 MHz is used to run the LFSR. Because a six-stage LFSR is used, the period of the pseudorandom output waveform is $63 \mu\text{s}$. For clarity the figure shows a couple of periods of the waveform.

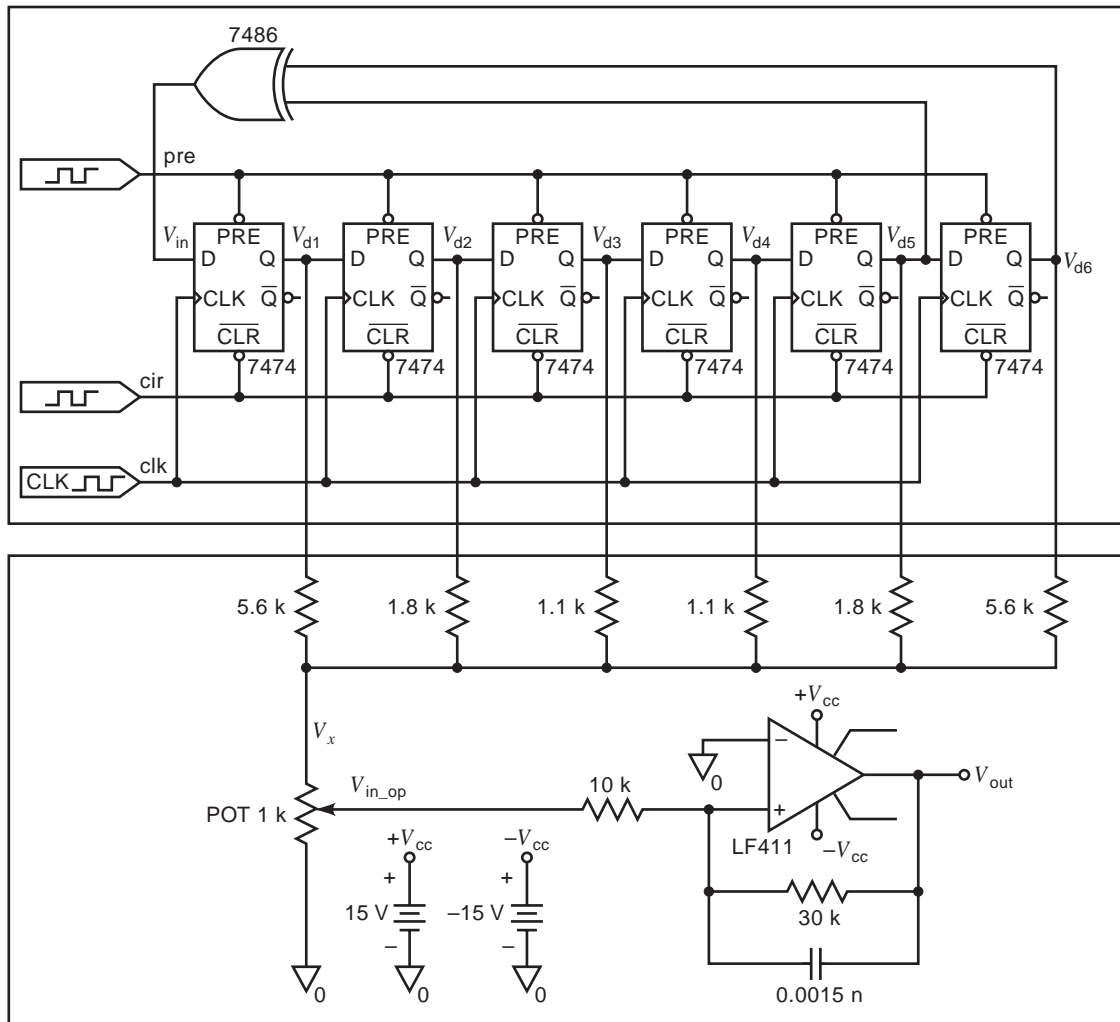

Figure 6. A six-stage linear feedback shift register with a resistive network for digital-to-analog conversion.

In the following, we describe several implementations of digital noise generators. They all have LFSRs as the basis for random number generation and use lowpass filtering to obtain the analog noise signal.

2.2.2. Analog Conversion by Time Integration. Alspector et al. [23] use a lowpass filter to convert the digital waveform at the outputs of the LFSR to a voltage signal. The cutoff frequency of the filter is kept at just a few percent of the clock frequency used to drive the LFSR. This arrangement has the effect of performing a time integration over many bits. If each bit is equally likely (i.e., a 0 or 1 with equal probability), as is the case in LFSRs, the value of this integration follows a binomial distribution that approaches Gaussian for a large number of bits. This creates a Gaussian pseudorandom noise source whose statistical properties are analogous to thermal or shot noise. A variable amplifier with gains low enough to avoid any coupling is used at the output.

2.2.3. Analog Conversion by a Resistive Network. D'Alvano and Badra [24] use a resistive network to convert the digital signal to an analog signal, as shown in the lower block of Fig. 6. The shift register outputs are linearly combined through the resistive network, which also plays the role of the coefficient set of a discrete-time FIR filter. These weights provide a lowpass transfer function with a raised-cosine impulse response. The output level at the filter is adjusted through a 1-k Ω trimmer.

The probability density function of the noise signal at the output can be predicted because of the random nature of the binary sequence generated at each of the shift register outputs. The random binary variables added to form the noise signal are statistically independent from one another. From the central-limit theorem [4], it follows that the probability density function of the signal at the output is asymptotically Gaussian.

To illustrate noise generation, we have performed a simulation using commercial software produced by MicroSim Corporation, USA. Figure 8 shows a trace of

Figure 7. The waveform of the digital sequence at the output of LFSR.

Figure 8. A simulation trace of an analog noise signal.

analog noise observed at the output of the op-amp (see Fig. 6). What is shown in Fig. 8 is repetitive noise. The periodicity in the noise is an undesirable feature, yet inevitable when small-size LFSRs are used for pseudo-random-number sequence generation. The periodicity can be broken by randomly changing the seed of the LFSR. The periodicity can also be improved by lengthening the shift register. Interested readers may refer to Ref. 24 for details of the circuit which produces truly random noise.

2.2.4. High-Frequency Noise Generation. A shift-register-based noise generator can be realized for RF noise power metrology [25]. Superconducting rapid, single-flux, quantum (RSFQ) logic [26] is used to meet the requirements of low noise and fast switching necessary to generate noise in the gigahertz range. In the RSFQ logic, the binary information is coded by flux quanta with the value $\phi_0 = h/2e$ in superconducting interferometers and is transmitted and processed as very short voltage pulses $V(t)$ of quantized area. The active circuit components are overdamped Josephson junctions (JJ), which need only dc bias currents set to values slightly below their critical currents. With these elements, SFQ pulses can be created, transmitted, reproduced, amplified, processed, and detected (25). The basic RSFQ logic elements for constructing complex digital circuits are available in current technology. Superconducting microstrip lines together with JJ technology allow transmitting picosecond waveforms with very low attenuation and dispersion. In a pseudorandom noise generator of this type, the logic enables the generation of pseudostatistical SFQ pulse sequences, operating as quasi-shot-noise sources.

2.2.5. Arrays of Noise Generators. It is often necessary to have an array of noise generators, especially in neural networks [25]. Although such noise generators can be designed with LFSRs, one should be careful to avoid any correlation among the outputs of these noise generators. Alspector et al. [23] accomplish this by tapping the outputs from various stages of the LFSR and processing them using exclusive-OR gates and lowpass filters. A cellular automata is used by Dupret et al. [27] to generate arrays of Gaussian white-noise sources. Cellular automata feature regular structure leading to compact VLSI layouts.

3. APPLICATION OF NOISE GENERATORS

Noise generators are used in a variety of testing, calibration, and alignment applications, especially with radio receivers. Some of the other applications are in digital communication, analog integrated circuit diagnosis, and learning processes of stochastic neural networks. In digital communication, noise is added as an “uncertainty” to a cryptographic exchange to confuse the information and to prevent unauthorized use or forgery. This is increasingly important in today’s electronic-commerce society. Random signals are also used for dithering in analog electronic circuits, forcing a signal to use the entire dynamic range of an analog system, one that reduces distortion. These

applications can be classified into four categories: noise used as a broadband random signal, measurements in which noise is used as a test signal, measurements in which noise is used as a probe into microscopic phenomena, and noise as a conceptual tool. This categorization of applications was first made by Gupta [28] and is used here. We include some examples and illustrations.

3.1. Noise as a Broadband Random Signal

This kind of signal is widely used in electronic countermeasures, microwave heating, simulation of random quantities, stochastic computing, and generation of random numbers. Noise generators are used to simulate random vibrations in mechanical systems. The combination of a random noise generator and a shake table is widely used to test the response of mechanical structures to random vibrations.

A well-known application of a high-power broadband noise generator is active jamming of radar and communication equipment. Radar jamming is called “active” if the jammer radiates a signal at the operating frequency of the radar system, as distinguished from “passive” jamming, which employs nonradiating devices like chaff. The broadband jamming signal can be generated either by a noise generator centered at the carrier frequency or by noise modulating a continuous-wave signal.

An interesting medical application is inducing sleep or anesthesia and suppressing dental pain in a technique called “audio-analgesia”. A dental patient listens to relaxing music via earphones, and switches to filtered random noise on feeling pain, increasing the intensity of noise as necessary to suppress pain. It is reported that audio-analgesia has about the same level of effectiveness as morphine [29].

In modern musical instruments, white-or color-noise generators are successfully used to generate the sound effect of desert wind, ocean surf, thunderstorm, lightning, and even the virtual cosmic background sound.

3.2. Noise as a Test Signal in Measurements

There are several cases of measurements where one needs a broadband signal with known properties like amplitude probability density and an autocorrelation function. Random noise is one such source and is ideal for measuring impulse response, insertion loss, linearity, and intermodulation of communication equipment, and in noise-modulated distance-measuring radar.

It is well known [4] that if a random signal $X(t)$ with auto-correlation function $R_X(\tau)$ is applied at the input of a linear system with an impulse response $H(t)$, the cross-correlation between the input and the resulting output $Y(t)$ is given by the convolution integral

$$R_{XY}(\tau) = \int_{-\infty}^{\infty} H(t)R_X(\tau - t) dt \quad (5)$$

This relationship can be used to calculate the impulse response $H(t)$ if R_X and R_{XY} are known. For causal, lumped, linear, time-invariant systems, this calculation

can be carried out algebraically. However, solving the integral equation for $H(t)$ is greatly simplified by using white noise as the input signal. If the bandwidth of the input signal is much larger than that of the system under test, $R_X(\tau)$ is effectively the impulse function $\delta(\tau)$, and the equation simplifies to

$$R_{XY}(\tau) = H(\tau) \quad (6)$$

Thus the impulse response is directly measured without involved calculation.

Spina and Upadhyaya [30] use the previous observation on impulse response measurement in testing and diagnosing analog VLSI. Here, a white-noise generator is used as input stimuli to the analog chip. At the output of the circuit under test, a pattern classifier which is usually an artificial neural network does the signature analysis and hence fault diagnosis. Alspector et al. [23] study application of noise as input to facilitate learning in parallel stochastic neural networks.

Noise is used in measuring linearity and intermodulation in a communication channel as follows. When a large number of telephone channels are to be carried by a coaxial cable or a broadband radiolink, any existing nonlinear distortions in the system introduce unwanted intermodulation products of the various components of the multiplexed signal. Calculation of the intermodulation noise so introduced is very difficult because of the large number of channels. Because statistical properties of white noise are similar to those of a complex multichannel signal with a large number of intermittently active channels, white noise is used to simulate such a signal. A bandlimited Gaussian white noise is introduced at the input into the system under test. The noise power in a test channel is measured first with all channels loaded with white noise and then with all but the test channel loaded with white noise. The ratio of the first to the second measurement is called the noise power ratio from which the channel noise due to intermodulation can be calculated. The spectral density of input noise can be shaped to match the signal under actual operating conditions.

The use of noise generators for checking system performance in manufacturing or in the laboratory is commonly known. The procedure can be extended to in-service monitoring of radar and communication equipment in the field because of the development of solid-state noise generators, which have smaller power consumption, weight, volume, radio frequency interference, turnon time, and turnoff time, but higher noise power output and reliability than gas discharge noise generators. As a result, the need for retuning or servicing the equipment is recognized before its performance becomes unacceptable. As the noise signal is very small and unrelated to all other signals, the monitoring can be carried out while the equipment is in operation, thus reducing the downtime due to checkups.

Noise is specifically used in the noise immunity test of several digital systems and TV pictures [31]. High-frequency noise generators are needed in RF noise power calibration.

The shift-register-based noise generator using RSFQ logic can function at frequencies up to 45 GHz (25) and can

be used for this purpose. Digital, pseudorandom numbers are also used to test a random collection of input possibilities with test circuits built on-chip.

3.3. Noise as a Probe into Microscopic Phenomena

Noise measurements can be used for estimating physical parameters related to microscopic phenomena, such as emission, recombination, or ionizing collision. Noise can also be used in testing semiconductors for uniformity and for estimating the reliability of semiconductor devices. Using noise in device reliability prediction has several advantages over conventional lifetime tests. Noise testing is nondestructive and does not take up a considerable fraction of the life of the device being tested. It also allows testing a specific individual device rather than measuring an average lifetime for a lot.

There are many ways in which measuring the noise in a device can be used to make reliability predictions. For instance, transistors with low $1/f$ noise exhibit longer lifespans, and reverse-biased p - n -junction diodes having a noise power spectral density with multiple peaks undergo rapid degradation. It has been found experimentally that the low-frequency $1/f$ noise output of a transistor increases by two or three orders of magnitude shortly before failure [28].

3.4. Noise as a Conceptual Tool

Noise is the motivating cause for developing new disciplines such as information theory, the statistical theory of communication, and circuit theory. It is also useful as a vehicle for theoretical investigations and for modeling other physical systems. For example, the concepts and principles developed with electrical noise have been used as guides in working with thermodynamics. Noise has been used as a tool for interpreting impedance in circuit theory. It has also led to the development of some analogies between quantum mechanics and the analyses of noisy circuits and systems and has helped simplify the concept of the quantum mechanical uncertainty principle. For further details, readers may refer to Ref. 28.

4. COMMERCIAL NOISE GENERATORS

A number of companies sell noise generators either as separate instruments or as part of an apparatus, such as a function generator. Table 1 lists the model numbers and the names of the manufacturers along with various features of the instruments, including noise range, the technique used in the design, and application areas where known. Some of the instruments are portable and battery-powered, whereas others are somewhat bulky. This list is not exhaustive and is provided only as a quick reference. The address of each company is provided in Table 2 as a ready reference. Although the internal circuitry of these noise generators is not available, the reader may refer to other guidebooks on electronics circuits, such as Ref. 32, which contains the circuit diagram of digital white-noise generators, thermal noise generators using incandescent lamp, and a simple diode noise generator.

Table 1. Commercial Noise Generators and Their Characteristics

Designation	Function	Name of Manufacturer	Noise Type and Range	Technique Used
AM700	Mixed signal audio measurement set	Tektronix	Shaped noise white and pink	Analog
3024	Very random noise generator	ACO Pacific, Inc.	White and pink (1.6 Hz–39 kHz)	Digital (pseudorandom)
SMT02	Signal generator	Rohde & Schwarz	500 kHz bandwidth	Not available
SMT03, 06				
IE-20B	Pink and white	Ivie Technologies, Inc.	Pink and white	Digital
PNG-2000	Portable noise generator	Research Electronics, Intl.	Audio frequency (300 Hz–3 kHz)	Not available
DS345	Waveform generator	Stanford Research Systems	White noise wideband (10 MHz)	Digital
DS360	Low-distortion function generator	Stanford Research Systems	White and pink	Digital
NG-1	Audible noise generator	Audio Technologies, Inc.	White and pink	Not available
PNG-7000	Precision noise generator	Noise/Com	Gaussian white noise	Not available
UFX7000	Broadband noise generator	Noise/Com	Broadband noise (10 Hz–40 GHz)	Not available

1. INTRODUCTION

The high-frequency behavior of electronic devices is of major interest in the field of research and development. Beside the typical RF device parameters, such as the cutoff frequencies f_T and f_{max} , high-frequency noise behavior has to be considered for circuit design, especially if noise has a significant influence on the system performance, for instance, the sensitivity of receivers. By this means, there is a demand for simple but exact RF noise models that must consider the physically relevant noise phenomena with a significant contribution to the total noise behavior of the device.

After an introduction to various physical noise sources, a general description of noisy two-ports will be presented, followed by a brief presentation of a special measurement setup for RF noise in the range of 2–18 GHz with dependence on temperature (15–400 K). In Section 4 the RF noise phenomena in certain devices are examined and high-frequency noise models for heterostructure field-effect transistors (HFETs) and heterojunction bipolar transistors (HBTs) based on the material system InP are presented. For both devices the capabilities of the model presented will be proved by comparing measured and modeled RF noise parameters. In Section 5 modifications of the HFET noise model and applications of this RF noise model are presented.

2. NOISE THEORY

2.1. Physical Noise Sources

2.1.1. Thermal Noise. The most important and best-known noise mechanism is the thermal noise or *Johnson Noise* [1,2]. This process can be observed in all electrically conductive materials. Assuming a finite temperature $T(T > 0 \text{ K})$, the free electrons statistically move in these materials forced by their thermal energy. Because of scattering processes at lattice atoms, this movement leads to a statistical fluctuation of the voltage at the terminals of the conductor (e.g., a resistor R). The corresponding noise spectrum of the thermal noise is given as [1]

$$S_{th}(f) = 4kTR \quad (1)$$

where k is Boltzmann's constant ($k = 1.38 \times 10^{-23} \text{ W} \cdot \text{s/K}$). The measurable mean-square values of the thermal noise current $i_{th}^2(t)$ or the thermal noise voltage $v_{th}^2(t)$ per unit bandwidth Δf are given respectively as [3,4]

$$\overline{i_{th}^2(t)} = 4kT \frac{\Delta f}{R} \quad (2)$$

$$\overline{v_{th}^2(t)} = 4kTR \Delta f \quad (3)$$

2.1.2. Shot Noise. The phenomenon of statistical current fluctuations is called *shot noise*. Because of the quantization of electron charge e , the electron flow, which corresponds to the number of electrons per unit time, is not continuous. Using these assumptions it is possible to divide a current $i(t)$ into a DC component I_0 and an AC component $i_s(t)$. Assuming that Z as the average number of electrons per unit time, $i(t)$ can be written as

$$i(t) = I_0 + i_s(t) \quad (4)$$

where $I_0 = Ze$. The noise contribution caused by the AC current $i_s(t)$ is interpreted as an *ergodic* fluctuation phenomenon. A typical device dominated by shot noise is the vacuum diode with a pure metal cathode. However, the relations derived for this device can be applied to most semiconductor devices, as well. For those frequencies that are small compared to the reciprocal time period $1/\tau$ of the discrete current pulses, the single spectral contributions of each current pulse to the total noise spectrum are neglectable. In this case the *Schottky relation* is valid for the spectrum of shot noise:

$$S_S(f) = 2eI_0 \quad (5)$$

This spectrum is directly proportional to the mean DC current I_0 through the device. Generally, the *Schottky relation* is valid even for fast semiconductor devices and at very high frequencies. Equation (5) is also suitable to describe the related noise contribution due to gate leakage current I_{leak} in case of field-effect transistors, if I_0 is replaced by I_{leak} .

2.1.3. Avalanche Noise. Charge carrier multiplication in semiconductor devices can occur in regions of high

2. NOISE THEORY

2.1. Physical Noise Sources

2.1.1. Thermal Noise. The most important and best-known noise mechanism is the thermal noise or *Johnson Noise* [1,2]. This process can be observed in all electrically conductive materials. Assuming a finite temperature $T(T > 0 \text{ K})$, the free electrons statistically move in these materials forced by their thermal energy. Because of scattering processes at lattice atoms, this movement leads to a statistical fluctuation of the voltage at the terminals of the conductor (e.g., a resistor R). The corresponding noise spectrum of the thermal noise is given as [1]

$$S_{th}(f) = 4kTR \quad (1)$$

where k is Boltzmann's constant ($k = 1.38 \times 10^{-23} \text{ W} \cdot \text{s/K}$). The measurable mean-square values of the thermal noise current $i_{th}^2(t)$ or the thermal noise voltage $v_{th}^2(t)$ per unit bandwidth Δf are given respectively as [3,4]

$$\overline{i_{th}^2(t)} = 4kT \frac{\Delta f}{R} \quad (2)$$

$$\overline{v_{th}^2(t)} = 4kTR \Delta f \quad (3)$$

2.1.2. Shot Noise. The phenomenon of statistical current fluctuations is called *shot noise*. Because of the quantization of electron charge e , the electron flow, which corresponds to the number of electrons per unit time, is not continuous. Using these assumptions it is possible to divide a current $i(t)$ into a DC component I_0 and an AC component $i_s(t)$. Assuming that Z as the average number of electrons per unit time, $i(t)$ can be written as

$$i(t) = I_0 + i_s(t) \quad (4)$$

where $I_0 = Ze$. The noise contribution caused by the AC current $i_s(t)$ is interpreted as an *ergodic* fluctuation phenomenon. A typical device dominated by shot noise is the vacuum diode with a pure metal cathode. However, the relations derived for this device can be applied to most semiconductor devices, as well. For those frequencies that are small compared to the reciprocal time period $1/\tau$ of the discrete current pulses, the single spectral contributions of each current pulse to the total noise spectrum are neglectable. In this case the *Schottky relation* is valid for the spectrum of shot noise:

$$S_S(f) = 2eI_0 \quad (5)$$

This spectrum is directly proportional to the mean DC current I_0 through the device. Generally, the *Schottky relation* is valid even for fast semiconductor devices and at very high frequencies. Equation (5) is also suitable to describe the related noise contribution due to gate leakage current I_{leak} in case of field-effect transistors, if I_0 is replaced by I_{leak} .

2.1.3. Avalanche Noise. Charge carrier multiplication in semiconductor devices can occur in regions of high

Figure 1. Model for the avalanche region at different locations and related timesteps $x_i(t_i)$ with input current I_{IN} and output current I_{OUT} .

electric field strengths. If the mean free path of carriers is long enough to achieve sufficient energy, additional electron–hole pairs are generated when colliding with lattice atoms (Fig. 1). This avalanchelike increase in the number of carriers often leads to a nonreversible degeneration of the device, known as *thermal breakdown*. If this process is limited, it becomes reversible and is often utilized to obtain special devices such as *avalanche photodiodes* (APD). In these devices the multiplication of optically generated electron–hole pairs enables a significant increase in the optical responsivity, hence receiver sensitivity. The corresponding noise contribution is called *avalanche noise*. The avalanche noise is characterized by two ionization factors, for electrons α and holes β , which describe the number of carriers generated per unit length. They are dependent on the location and electric field strength, respectively. Assuming that the input current I_{IN} shows shot noise and that the ionization coefficients for electrons and holes are equal, the following expression for the noise spectrum of the output current I_{OUT} can be derived [5]:

$$S_{I_{OUT}} = 2e I_{IN} M^3 \quad (6)$$

where M is the avalanche multiplication factor.

If the ionization coefficients are different but linearly dependent as in

$$\beta = c \cdot \alpha \quad (7)$$

where $c = \text{const}$ and the input current I_{IN} is caused by electrons only, the spectrum of the output current is derived by [6,7] as follows:

$$S_{I_{OUT}} = 2e I_{IN} M^3 \left[1 - (1 - c) \left(\frac{M - 1}{M} \right)^2 \right] \quad (8)$$

In the case of a pure hole current, c has to be replaced by $1/c$ in Eq. (8). As mentioned above, two restrictions have to be considered for the validity of both relations:

1. The spectrum of the injected current I_{IN} corresponds to that of shot noise only.
2. The length of the ionization region l_z is sufficient to achieve a high probability of collisions of the injected electrons with lattice atoms.

A modified relation is applicable to the phenomenon of impact ionization, which is of interest in conjunction with heterostructure FETs (see Section 4.1.3).

2.2. Noise in Linear Two-Ports

2.2.1. Equivalent Circuits for Noisy Impedances and Admittances. For physically related noise modeling of devices, a more generalized description of the single physical noise sources is necessary. The usual tool for noise calculations is the equivalent circuit, well known from RF modeling of devices. In the particular case of noise modeling all elements have to be treated as complex values.

The latter statement results in the fact that only devices assimilating real power are able to emit thermal noise power [8]. Replacing the real value R by the complex impedance $\mathbf{Z} = R + jX$ leads to the following equations for measurable frequency-dependent mean-square values of the thermal noise currents $i_{th}^2(t)$ and noise voltages $v_{th}^2(t)$ per unit bandwidth Δf .

$$\overline{i_{th}^2(t)} = 4kT \frac{\Delta f}{\Re\{\mathbf{Z}\}} \quad (9)$$

$$\overline{v_{th}^2(t)} = 4kT \Delta f \Re\{\mathbf{Z}\} \quad (10)$$

where the operator $\Re\{\}$ accesses the real part of the particular value.

In a similar way, more generalized relations for the thermal spectral noise densities can be derived using Eqs. (9) and (10) as follows:

$$S_{th,i} = \overline{i_{th}^2(t)} \frac{1}{\Delta f} = 4kT \frac{1}{\Re\{\mathbf{Z}\}} = 4kT \Re\{\mathbf{Y}\} \quad (11)$$

$$S_{th,v} = \overline{v_{th}^2(t)} \frac{1}{\Delta f} = 4kT \frac{1}{\Re\{\mathbf{Y}\}} = 4kT \Re\{\mathbf{Z}\} \quad \text{with} \quad (12)$$

$$\mathbf{Y} = \mathbf{Z}^{-1}$$

Finally, this leads to a description of physical noise processes based on a small-signal equivalent circuit. The individual noisy impedances or admittances can be described by either of two compatible equivalent circuits (Fig. 2):

1. A noise current source $i_{th}(f)$ and a noise-free ($T = 0$ K) admittance in parallel
2. A noise voltage source $v_{th}(f)$ and a noise-free ($T = 0$ K) impedance in series

Figure 2. Equivalent circuits of noisy impedances or admittances: (a) noise current source; (b) noise voltage source.

If the derived temperature of the impedance or admittance is different from the ambient temperature of the device, it is called the *equivalent noise temperature* T_n .

Using this definition of the equivalent noise temperature, which in the first instance is valid for one-ports, together with the derived equivalent RF circuits, we can calculate the noise behavior of complex circuits and systems. Typically, however, possible correlations between the individual noise sources of the total system also have to be considered.

2.2.2. The Noise Figure. Unfortunately, the term *noise figure*, which was originally defined for the description of noisy networks [9] and is valid only under certain assumptions [10], sometimes leads to an overestimation of its real significance, especially in the case of discrete devices. Nevertheless, for systems the noise figure F is a more suitable parameter for noise characterization. The term *noise figure* suggests the formally defined *standard noise figure* F , which assumes an input noise signal that is not arbitrarily given, but related to the reference noise temperature of $T_0 = 290$ K, and hence an absolute value [11].

In this way, F is a value for two-port inherent noise and thus is independent of external conditions or terminations of the ports. A noise-free two-port is characterized by a noise figure of $F = 1$ or $F' = 0$ dB. Figure 3 shows the principal equivalent circuit for the definition of the (standard) noise figure. It consists of the noisy two-port connected to a load impedance Z_L , assumed to be noise-free ($T = 0$ K). The input is connected to a noisy source impedance Z_S ($T > 0$ K). Again, this impedance is represented by a voltage noise source and a noise-free impedance Z_S ($T = 0$ K).

With S_{n2v} as the noise spectrum at the output of the noisy two-port and S_{n20v} as the spectrum of the noise-free

two-port, F is defined by [8]

$$F = \frac{S_{n2v}}{S_{n20v}} \quad (13)$$

An equivalent equation can be derived using the noise current spectra instead.

2.2.3. Calculation of the Noise Figure F Using Noise Equivalent Circuits. The noise figure F of noisy linear two-ports can be calculated using equivalent circuits [12,13]. A very simple and appropriate description for a noisy two-port is the chain matrix or *ABCD* parameter description, respectively, with one current noise source and one voltage noise source at the input terminal (Fig. 4). In this way, the noise behavior of the total two-port can be modeled by only two noise sources that are chained to the input.

Using this equivalent circuit for the noisy two-port, the noise figure is given as:

$$F = 1 + \frac{S_{nv} + |Z_S|^2 S_{ni} + 2\Re\{Z_S S_{vi}\}}{4kT_0 R_S} \quad (14)$$

where

S_{nv} = voltage noise spectrum

S_{ni} = current noise spectrum

S_{vi} = cross-correlation spectrum between v_n and i_n .

The noise figure is independent of the input impedance of the two-port Z_{in} and the load impedance Z_L . However, the values of the spectra of the equivalent noise sources of the two-port as well as the cross-correlation spectrum, which describes the correlation between both noise sources, are required. Additionally, the noise figure depends on the

Figure 3. Equivalent circuit for definition of (standard) noise figure F .

Figure 4. Noise equivalent circuit with noise current and noise voltage source “chained” at the input of the noise-free two-port.

source impedance Z_S . The value of the noise figure reaches a minimum at $F = F_{\min}$ for an optimal source impedance of $Z_S = Z_{S,\text{opt}}$. This is called *noise matching*. Unfortunately, the necessary impedances for noise matching differ from those for power matching. By this means, maximum available gain G_a of the two-port is actually not available, and a reduced power gain, the so-called *associated gain* G_{ass} , characterizes the two-port. Designing electronic circuits, which is always a compromise between *noise* and *power matching*, has to be realized.

2.2.4. Discussion of Noise Matching. As mentioned above, the noise figure is a function of the source impedance Z_S . Common measurement techniques for the determination of noise parameters are based on the relation given in Eq. (14). The dependence of F on deviations from the ideal matching condition can be described corresponding to [10] by

$$F = F_{\min} + \frac{R_n}{G_S} |Y_S - Y_{S,\text{opt}}|^2, \quad Y_S = G_S + jB_S \quad (15a)$$

or

$$F = F_{\min} + \frac{g_n}{R_S} |Z_S - Z_{S,\text{opt}}|^2, \quad Z_S = \frac{1}{Y_S} = R_S + jX_S \quad (15b)$$

using the equivalent noise conductance g_n with

$$g_n = R_n \cdot |Y_{S,\text{opt}}|^2 \quad (16)$$

Only four parameters—the minimum noise figure F_{\min} , the equivalent noise resistance R_n , and the real part $G_{S,\text{opt}}$ and the imaginary part $B_{S,\text{opt}}$ of the optimal generator (source) impedance—are necessary to completely describe the noise behavior of a linear two-port.

The term R_n is a measure for the sensitivity of the noise figure to deviations from the optimum source admittance $Y_{S,\text{opt}}$ or impedance $Z_{S,\text{opt}}$, respectively. By this means, R_n is a figure of merit regarding the noise behavior of the two-port. The equivalent noise resistance should be as small as possible to avoid a significant increase of noise if—depending on the actual application—the optimum noise matching ($Y_S = Y_{S,\text{opt}}$) has to be sacrificed for a potentially more important power matching at the input.

Usually, the admittance or impedance, respectively, are normalized and related to the characteristic impedance of the measurement setup Z_0 (typically $Z_0 = 50 \Omega$), which results in the following equation after transformation to the

Smith chart plane:

$$F = F_{\min} + 4r_n \frac{|\Gamma_S - \Gamma_{S,\text{opt}}|^2}{(1 - |\Gamma_S|^2)(1 + |\Gamma_{S,\text{opt}}|^2)} \quad (17)$$

where

- r_n = normalized equivalent noise resistance [$r_n = (R_n/Z_0)$]
- Γ_S = generator reflection coefficient
- $\Gamma_{S,\text{opt}}$ = optimum generator reflection coefficient for noise matching

Figure 5 shows a graphical interpretation of this equation, characterizing a paraboloidal surface, in the *Smith chart* plane. The minimum of the paraboloid represents the minimum noise figure F_{\min} at the optimum generator reflection coefficient $\Gamma_{S,\text{opt}}$. The latter can be derived by a perpendicular projection of the corresponding point onto the *Smith chart* plane. If Γ_S differs from $\Gamma_{S,\text{opt}}$, the noise figure F also rises. As discussed earlier, this increase is directly proportional to the value of the equivalent noise resistance R_n , which corresponds to the slope of the paraboloid at a specific point. In practice, this circumstance could imply an even higher priority to achieve a low R_n than an absolutely low F_{\min} , depending on several boundary conditions to be additionally considered.

3. RF NOISE MEASUREMENTS

Figure 6 shows a typical measurement setup that allows temperature-dependent noise figure measurements of two-ports in the temperature range of 15–400 K and frequency range of 2–18 GHz [14,15]. It comprises the *noise figure meter* (HP8970B) as the central unit and the calibrated *noise source* (HP346A) [16]. The *noise figure test set* (HP8971) and the *synthesizer* (HP8672A) are necessary to downconvert the measurement frequency to a frequency range of 10–1600 MHz, which the *noise figure meter* is able to directly process. To determine the four interesting noise parameters (F_{\min} , R_n , $G_{S,\text{opt}}$, and $B_{S,\text{opt}}$) of a linear two-port, the noise figures at various generator reflection coefficients Γ_S have to be measured [17,18].

These particular reflection coefficients can be achieved using a commercial *electronic tuner system* (see Fig. 6). The tuner subsystem consist of the *control unit* (NP5); the *mismatch noise source* (MNS), including the actual *tuner*; and the *remote receiver module* (RRM) with an integrated

Figure 5. Noise figure F with dependence of generator reflection coefficient (here: $F_{\min} = 1.5$, $R_n = 50 \Omega$, $|\Gamma_{S,\text{opt}}| = 2/3$, $\text{Arg}\{\Gamma_{S,\text{opt}}\} = 60^\circ$).

low-noise preamplifier. Additionally, both elements (MNS and RRM) contain *RF switches* necessary for system calibration. These switches also enable the simultaneous measurement of the noise and the corresponding scattering parameters.

The complete system is controlled by a computer system that allows the evaluation of the data and the extraction of the specific noise parameters from the measured noise figures [16,19–22].

4. RF NOISE IN ELECTRONIC DEVICES

4.1. Noise in Heterostructure Field-Effect Transistors

4.1.1. Thermal Noise in HFET. The channel of a field-effect transistor (FET) can be interpreted as a controlled resistance. The thermal noise generated in this channel is the dominating noise contribution.

For an n-doped semiconductor, the well-known equation of the thermal noise current for a resistance R [cf. Eq. (2)] can be transformed to [23]

$$\overline{i_{\text{th}}^2(t)} = 4kT_{\text{eff}} \frac{1}{R_{\text{ch}}} \Delta f \quad (18)$$

where T_{eff} is the effective temperature in the semiconductor channel and R_{ch} is the resistance of the channel.

The geometric aspects of the channel resistance can be expressed as

$$R_{\text{ch}} = \frac{1}{\kappa} \frac{l}{A} \Rightarrow \frac{1}{R_{\text{ch}}} = \kappa \frac{A}{l} \quad (19)$$

where A is the cross-sectional area of the channel and l is the length of the current path through the semiconductor.

The conductivity κ can be calculated for purely n-type (p-type) conductivity as

$$\kappa = en_0\mu_0 \quad (20)$$

where n_0 is the electron (hole) concentration and μ_0 is the low-field mobility of electrons (holes).

In addition, the diffusion coefficient D_0 can be derived from *Einstein's relation* as

$$D_0 = \frac{kT\mu_0}{e} \quad (21)$$

Finally, this leads to a description of the thermal noise in the channel as

$$\overline{i_{\text{th}}^2(t)} = 4e^2 \frac{A}{l} n_0 D_0 \Delta f \quad (22)$$

In the case of high electric fields, as occur in the region between gate and drain, the conventional *Einstein's relation* [Eq. (22)] is no longer valid. The diffusion coefficient, the low-field mobility, as well as the effective noise temperature $T_{n,\text{eff}}$ of the channel become dependent on the electrical field strength E and the frequency f [24,25], leading to

$$\frac{kT_{n,\text{eff}}(E,f)}{e} = \frac{D_0(E,f)}{\Re\{\mu(E,f)\}} \quad (23)$$

As a result of the relation between the thermal noise attributed to a resistor and the equivalent description for a semiconductor channel, this is often called *diffusion noise*.

4.1.2. The Shot Noise in HFET. In principle, the shot noise of the drain current can be described using Eq. (5) (see Section 2.1.2) [26,27]. Especially in heterostructure field-effect transistors, the recombination of carriers underneath the space charge region leads to a significantly reduced shot noise [28,29].

Without further proof, it can be assumed that the channel shot noise contribution is negligible. Nevertheless, shot noise again becomes of major interest if the device suffers from gate leakage that generates an additional noise contribution to the channel noise (see Section 2.1.2).

4.1.3. Impact Ionization Noise in HFET. The assumptions for avalanche noise as presented in Section 2.1.3 are not valid in the case of HFET. Nevertheless, in the gate–drain region a kind of avalanche noise occurs caused by impact ionization processes due to the high electric field strengths. Especially in HFET based on layers

Figure 6. Measurement setup for RF noise parameters in the range 2–18 GHz with dependence of temperature (15–400 K).

with an advanced carrier mobility (e.g., InGaAs), this additional noise contribution can be observed as a result of the low bandgap of these channel materials. Typically, the area between gate and drain, where impact ionization can occur, is extremely small ($l \leq 100$ nm). Therefore, impact ionization leads to a moderate increase of the drain current I_D at high bias voltages

V_{DS} only. The corresponding noise, called *impact ionization noise*, differs from the basic avalanche noise because of the significantly smaller multiplication factor M [see Eq. (6)].

Using the same assumptions as in the case of avalanche noise, but regarding to the special geometric design of the HFET, the spectral density of the impact ionization

noise can be derived from [30,31]

$$S_{I_{OUT}} = M^2 S_{I_{IN}} + 2eI_{IN}\sigma^2 \quad (24)$$

where $S_{I_{IN}}$ is the density of the induced current I_{IN} and σ^2 the variance of the noise process.

4.2. RF Noise Model of InAlAs/InGaAs/InP HFET

Figure 7 shows a typical equivalent RF noise model for InAlAs/InGaAs/InP HFET [32]. It is based on an extended temperature noise model (TNM) [33], which takes into account the influence of gate leakage current on both, the RF and noise performance. Gate leakage is modeled by the additionally included resistances R_{pgd} and R_{pgs} . Moreover, this model considers the effects due to impact ionization [34,35]. This is enabled by an additional voltage-controlled current source $g_{m,im}$ and a RC combination in parallel to the output resistance. The current source is controlled by the voltage drop across the high-field region at the drain end of the gate, which is equal to the drain–gate voltage v_{dg} . The characteristic frequency dependence of the impact ionization effects on RF and noise behavior, respectively, are described by the combination of R_{im} and C_{im} . For noise modeling purposes an additional white-noise source i_{im} is included in parallel to the current source $g_{m,im}$. This arrangement of noise source and RC combination characterizes the frequency dependence of the externally available noise current $i_{im,ext}$. This impact ionization

source can be described by

$$\sqrt{i_{im,ext}^2} = \sqrt{i_{im}^2} \cdot \frac{1}{\sqrt{1 + \left(\frac{\omega}{\omega_0}\right)^2}}, \quad \omega_0 = \frac{1}{R_{im} \cdot C_{im}} \quad (25)$$

This formula describes the Lorentzian shape of the external noise current, which typically is attributed to carrier generation processes, thus substantiating the occurrence of impact ionization noted in Section 4.1.3.

4.3. Noise in Heterojunction Bipolar Transistors

For modeling of the high-frequency noise behavior of both *bipolar junction transistors* (BJTs) and *heterojunction bipolar transistors* (HBTs), the physical noise sources have to be defined in more detail. The most important noise phenomenon in all bipolar transistors is shot noise. In addition to this predominant effect, thermal noise due to parasitic resistances must also be considered.

Basically, a bipolar transistor consists of two combined p-n junctions. Figure 8 schematically represents the various current paths and components within a n-p-n bipolar transistor at active bias conditions. In this way, the base–emitter junction is forward-biased and the base–collector junction is reverse-biased. The electron current from the emitter towards the collector [line (a) in Fig. 8] is the dominating current component. Electrons induced by line (b). Holes are injected from the base into the emitter [line (c)]. Electrons are thermally generated in the base and holes within the emitter, respectively [lines (d), (e)].

In the case of the reverse-biased base–collector diode, the current components due to the thermal generation of electron–hole pairs have to be taken into account [Fig. 8 lines (f), (g)] only. All these current components can be combined, corresponding to Fig. 8, leading to four independent currents $I_1, I_2, I_3,$ and I_4 . The measurable currents at the

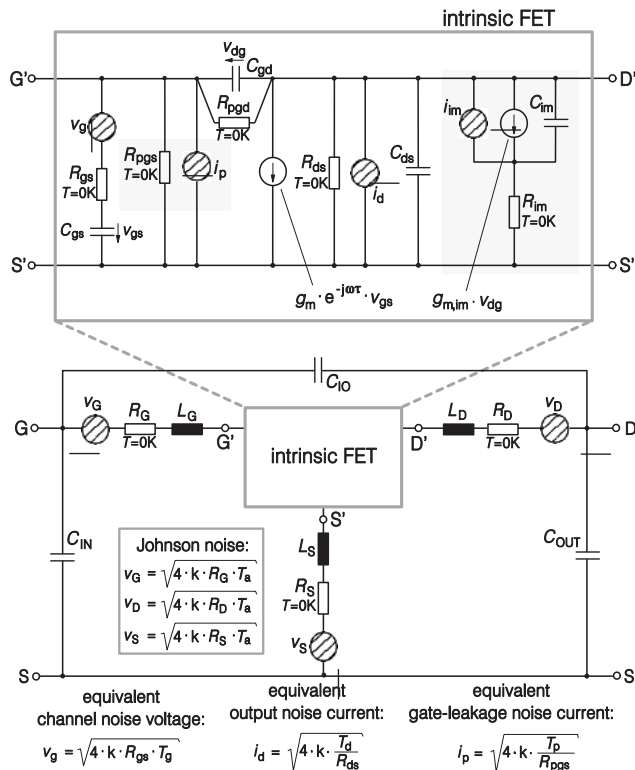

Figure 7. Intrinsic and extrinsic small-signal and noise equivalent circuit of HFET including modeling of gate leakage current and impact ionization on RF and noise behavior.

Figure 8. Current components and current flow in a n-p-n bipolar junction transistor.

terminals are then expressed as

$$I_E = I_1 + I_2 - I_3 \quad (26a)$$

$$I_C = I_1 + I_4 \quad (26b)$$

$$I_B = I_2 - I_3 - I_4 \quad (26c)$$

4.4. RF Noise Model of InGaAs/InP HBT

Figure 9 shows the typical three-mesa design of HBT based on III-V semiconductors [36]. The included T-like equivalent circuit can easily be found, associating all small-signal equivalent elements to a specific device region.

This extended small-signal equivalent circuit of HBT builds up the basis of the consistent small-signal and RF noise parameter model (Fig. 10). In the case of narrow-band noise, equivalent noise temperatures are associated with all resistances. In Fig. 10 all equivalent noise temperatures are included. As usual, the small-signal model is divided into two parts, an intrinsic one and an extrinsic one. The extrinsic resistances add only thermal noise; consequently their equivalent noise temperature is set to the ambient temperature T_A . The noise from the included RC combination R_{BP} and C_{BP} at the base contact (Fig. 10), taking into account a frequency dependence of the non-loyed ohmic base contact, is assumed to be thermal noise, too. As a consequence, only the four intrinsic equivalent noise temperatures have to be found for a complete RF noise parameter modeling of HBT. Additionally, with the help of these noise temperatures, a localization of various

noise sources and phenomena in specific HBT regions is possible.

4.5. Experimental Results and Verification of the Model for InAlAs/InGaAs/InP HFET

As an example of the applicability of the noise models discussed above, the RF noise behavior of a typical InAlAs/InGaAs/InP HFET with a gate length of $L_G = 0.7 \mu\text{m}$ and a gate width $W_G = 80 \mu\text{m}$ suitable for millimeter-wave and optoelectronic applications is presented. The material system has been selected to demonstrate the significance of both, the impact ionization in the InGaAs channel, and the gate leakage current. In contrast, typical GaAs-based HFET do not significantly suffer from those phenomena, mainly due to the larger bandgap of the corresponding materials [37,38].

All model parameters—the small-signal equivalent elements, equivalent noise temperatures (T_p, T_g, T_d), and equivalent impact ionization noise current (i_{im})—have been extracted using an optimization algorithm based on *simulated evolution* (evolution theory and genetic algorithms) [39–43]. These optimization strategies have to be applied because an analytical extraction of the model parameters from measured data (s parameters and noise parameters) is impossible because of the large number of model parameters and the complexity of the model.

4.5.1. RF-Performance. Figures 11 and 12 show both the measured and the modeled RF data in the frequency range from 45 MHz to 40 GHz, respectively. The good agreement demonstrate the applicability of the presented small-signal equivalent circuit including the significant effects of gate leakage and the impact ionization phenomena. The modeled parameters are calculated from the small-signal equivalent circuit, extracted from RF measurements using the *simulated evolution* described above. The corresponding bias conditions, geometry, performance data, and extracted small-signal equivalent elements are listed in Table 1.

Figure 13 shows the typical bias-dependent behavior of the extracted transconductance $g_{m,im}$ at room temperature ($T = 300 \text{ K}$). The low transconductance $g_{m,im}$ for small drain–source voltages V_{DS} demonstrates the negligible influence of impact ionization on RF performance at low V_{DS} corresponding to low fields in the HFET channel. With increasing V_{DS} , impact ionization and the inductive behavior of s_{22} occur, correlated with a drastically increased transconductance $g_{m,im}$.

4.5.2. Noise Behavior. The measured and modeled noise parameters ($F_{min}, R_n, g_n, G_{ass}, \Gamma_{opt}$) of the HFET are shown in Fig. 14. As a result of the Lorentzian shape of the external short-circuit noise current $i_{im,ext}$ [see Eq. (25)], corresponding to an upper frequency band limitation especially at low frequencies, a strong impact on the noise performance can be observed. The phenomenon of impact ionization now leads to an increase of the

Figure 9. Typical three-mesa design of InP/InGaAs HBT.

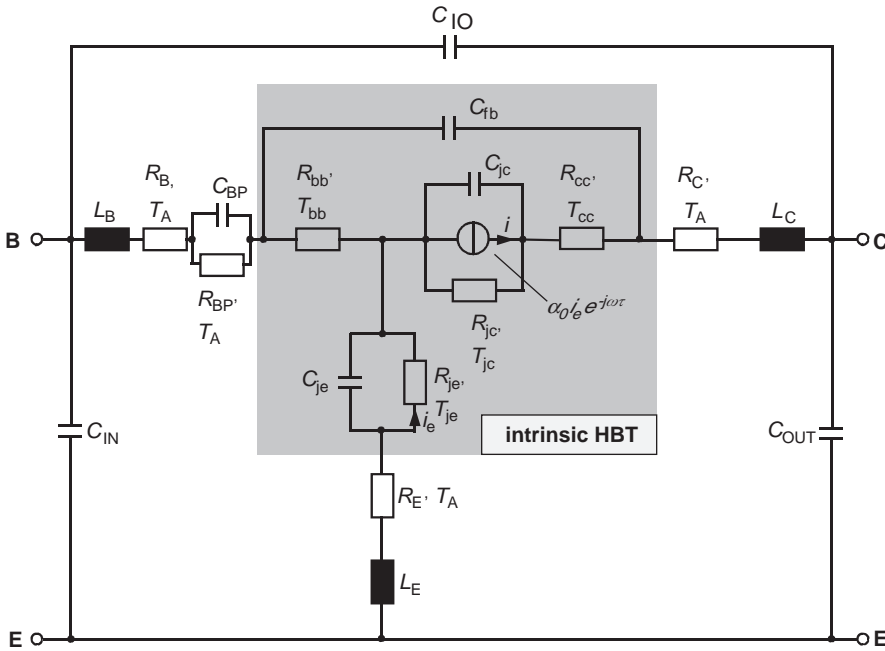

Figure 10. Consistent small-signal and RF noise parameter equivalent circuit of InP/InGaAs HBT.

minimum noise figure F_{min} . In particular, the increase of the minimum noise figure at low frequencies reflects the influence of the impact ionization process. In contrast to the influence of a gate leakage current [33], impact

ionization leads to higher optimum generator impedances and causes a sharp increase of the equivalent noise resistance R_n at low frequencies as well. The inductive behavior of the output path of the HFET also affects the associated gain G_{ass} and leads to a decrease at low frequencies. The three equivalent noise temperatures (T_g, T_p, T_d) and the equivalent impact ionization noise current i_{im} of the modeled extrinsic noise parameters are listed in Table 2.

Figure 11. Measured (x) and modeled (■) scattering parameters versus frequency of an InAlAs/InGaAs/InP HFET at a bias condition where impact ionization occurs ($T = 300$ K, $V_{DS} = 1.5$ V, $V_{GS} = 0$ V, $L_g = 0.7$ μ m, $W_g = 80$ μ m). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

4.5.3. Intrinsic Equivalent Noise Sources. The intrinsic equivalent noise sources [44] of the HFET are strongly bias-dependent [32]. Figure 15 shows the drastic increase in the extracted impact ionization noise current i_{im} with higher drain-source voltages V_{DS} , while at low drain-source voltages ($V_{DS} < 0.7$ V) this component is negligible. In the latter case electron energies are smaller than those of the bandgap and are insufficient to generate electron-hole pairs. With increasing drain-source voltage ($> V_{DS} \approx 0.8$ V), impact ionization occurs and leads to additional noise currents that dominate the noise behavior of the transistor. This behavior reflects the strong correlation between impact ionization, bias condition, and generated total noise current. Because the level of the extracted impact ionization noise current i_{im} exceeds the equivalent shot noise drain current ($i_D = \sqrt{2eI_D}$) in a wide range of bias conditions, carrier multiplication [6,30,31] supposedly occurs in the high-field domain, leading to the following relation

$$i_{im} \propto f(M(E)) \cdot \sqrt{2eI_D} \quad (27)$$

where $f(M(E))$ reflects the dependence of the multiplication factor $M(E)$ on the electric field strength [30]. The relation between the multiplication factor $M(E)$ and the majority-carrier impact ionization rate per unit length

Figure 12. Measured (×) and modeled (■) current gain $|h_{21}|^2$ and unilateral gain GU versus frequency of an InAlAs/InGaAs/InP HFET at a bias condition where impact ionization occurs ($T=300$ K, $V_{DS}=1.5$ V, $V_{GS}=0$ V, $L_g=0.7$ μm , $W_g=80$ μm). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$\alpha(x, E)$ can be described according to [30]

$$M(E) = \exp \left[\int_0^{L_{\text{eff}}} \alpha(\zeta, E) d\zeta \right] \quad (28)$$

where L_{eff} is the effective length of the impact ionization region.

Because of the position-dependent electric field strength and impact ionization rate, no simple analytical expression can be derived for the relation between bias conditions and the generated impact ionization noise current i_{im} .

The other equivalent intrinsic noise sources show the expected bias dependence [44] and reflect the strong correlation between equivalent intrinsic noise sources (i_d, i_p, v_g) and physical noise sources, such as shot noise drain current i_{sd} [see Eq. (29)] and shot noise gate current

i_{sg} [see Eq. (30)].

$$i_{\text{sd}} = \sqrt{2eI_D} \quad (29)$$

$$i_{\text{sg}} = \sqrt{2eI_G} \quad (30)$$

The equivalent output noise current i_d with dependence on the gate–source voltage V_{GS} versus the shot noise drain current is shown in Fig. 16. The equivalent noise current i_d is dominated by a reduced shot noise drain current [28]. The corresponding correlation is given by:

$$i_d = \sqrt{4k \frac{T_d}{R_{\text{ds}}}} \cong k_d \sqrt{2eI_D} + i_{d0} \quad (31)$$

with

$$k_d, i_{d0} = \text{const (value depending on the particular device)} \quad (32)$$

Table 1. Bias Conditions, Geometry, Performance Data, and Extracted Small-Signal Equivalent Elements of InAlAs/InGaAs/InP HFET

Bias conditions	
$V_{DS} = 1.5$ V, $V_{GS} = 0$ V,	
$I_D = 31.8$ mA, $I_G = -18$ μA	
Gate geometry	
$L_g = 0.7$ μm	
$W_g = 80$ μm	
Cutoff frequencies: $f_T = 45$ GHz, $f_{\text{max}} = 152$ GHz	
Small-signal equivalent elements

$R_G = 3$ Ω , $L_G = 63.1$ pH, $C_{\text{gs}} = 210.5$ fF	
$R_S = 8$ Ω , $L_S = 3.8$ pH, $L_D = 152$ pH	
$R_{\text{gs}} = 2.8$ Ω , $R_{\text{ds}} = 420$ Ω , $R_{\text{pgs}} = 12$ k Ω	
$R_D = 10$ Ω , $C_{\text{ds}} = 8.2$ fF, $R_{\text{pgd}} = 70.7$ k Ω	
$C_{\text{gd}} = 9.5$ fF, $g_m = 69$ mS, $\tau = 0.22$ ps	
$R_{\text{im}} = 38$ k Ω , $C_{\text{im}} = 1.42$ fF, $g_{m,\text{im}} = 4.26$ mS	

Figure 13. Impact ionization transconductance $g_{m,\text{im}}$ with dependence on the gate–source voltage V_{GS} , with the drain–source voltage V_{DS} as parameter; ($L_g=0.15$ μm , $W_g=100$ μm , $T=300$ K). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

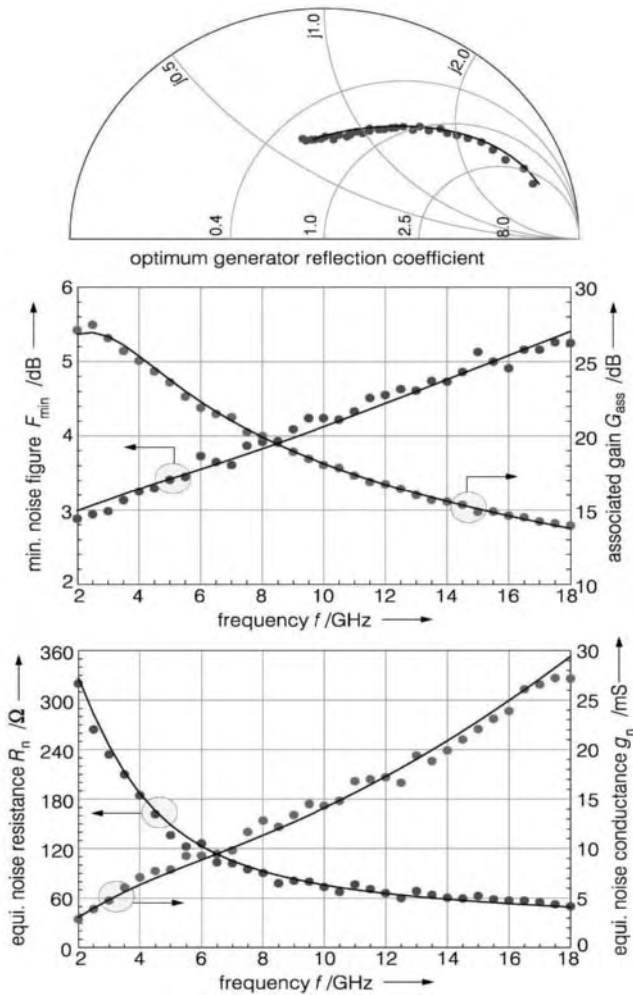

Figure 14. Measured (●) and modeled (■) noise parameters versus frequency of an InAlAs/InGaAs/InP HFET at a bias condition where impact ionization occurs ($V_{DS} = 1.5$ V, $V_{GS} = 0$ V, $I_D = 31.8$ mA, $L_g = 0.7$ μ m, $W_g = 80$ μ m, $T = T_a = 300$ K). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The behavior of the equivalent channel noise voltage v_g (Fig. 17) with dependence on the gate–source voltage V_{GS} exhibits a behavior inversely proportional to that of the intrinsic current gain cutoff frequency f_T ($f_T = g_m / (2\pi(C_{gs} + C_{gd}))$). This is caused by a strong correlation of v_g with the intrinsic delay-time behavior of the HFET. A transformation of the equivalent channel noise voltage v_g , which is a characteristic value for the input circuit of the transistor, to a noise measure of the output circuit can be derived by multiplying v_g by the ratio of the square of the transcon-

Table 2. Extracted Equivalent Noise Temperatures and Noise Current of Modeled HFET^a

Equivalent-channel noise temperature: $T_g = 4014.9$ K
Equivalent output noise temperature: $T_d = 18007.84$ K
Equivalent gate leakage noise temperature: $T_p = 918.65$ K
Equivalent impact ionization noise current: $i_{im} = 146$ pA

^aParameters: $V_{DS} = 1.5$ V, $V_{GS} = 0$ V, $I_D = 31.8$ mA, $L_g = 0.7$ μ m, $W_g = 80$ μ m, $T = T_a = 300$ K.

Figure 15. Extracted equivalent intrinsic impact ionization noise current i_{im} with dependence on gate–source voltage V_{GS} with drain–source voltage V_{DS} as parameter. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ductance g_m to the intrinsic current gain cutoff frequency f_T . The transformed channel noise voltage demonstrates a behavior nearly proportional to that of the shot noise drain current (see Fig. 18). Using this transformation, the equivalent-channel noise voltage v_g can be expressed

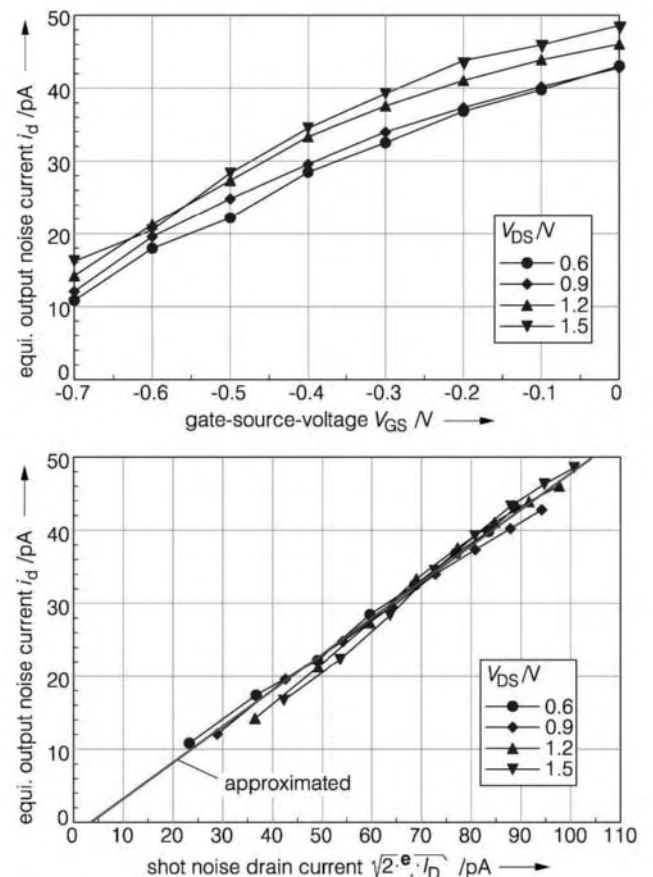

Figure 16. Extracted equivalent output noise current i_d with dependence on gate–source voltage V_{GS} (above) and on the shot noise drain current (below) with drain–source voltage V_{DS} as parameter. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

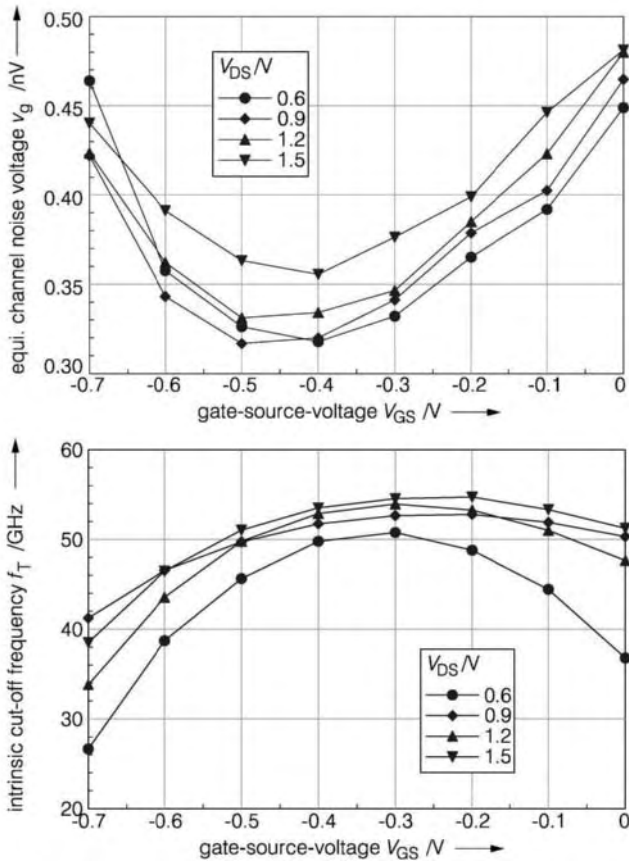

Figure 17. Equivalent channel noise voltage v_g (above) and intrinsic current gain cutoff frequency f_T (below) in dependence on gate–source voltage V_{GS} with drain–source voltage V_{DS} as parameter. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

by the following linear approximation

$$v_g \frac{g_m^2}{f_T} = \sqrt{4kT_g R_{gs}} \frac{g_m^2}{f_T} \cong k_g \sqrt{2eI_D} + i_{d1} \quad (33)$$

Figure 18. Extracted transformed equivalent channel noise voltage with dependence on the shot noise drain current with the drain–source voltage V_{DS} as parameter, respectively. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

with

$$k_g, i_{d1} = \text{const (value depends on the particular device)} \quad (34)$$

Figure 19 shows the equivalent gate leakage noise current i_p with dependence on the gate–source voltage V_{GS} versus the shot noise gate current. The equivalent gate leakage noise current i_p is nearly proportional to the shot noise gate current. This clearly demonstrates that a gate tunneling current causes pure shot noise [see Eq. (30)] [44]. The behavior described above leads to

$$i_p = \sqrt{4k \frac{T_p}{R_{pgs}}} \cong \sqrt{2eI_G} \quad (35)$$

These dependencies demonstrate the ability of the noise model presented above to separate the intrinsic noise sources, and the correlation to physical noise processes. Furthermore, only two independent noise parameter measurements are sufficient for extraction of the unknown parameters (k_g, k_d, i_{d0}, i_{d1}) in Eqs. (31)–(34).

Figure 19. Extracted equivalent gate–leakage noise current i_p with dependence on gate–source voltage V_{GS} (above) and on shot noise gate current (below) with the drain–source voltage V_{DS} as parameter. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

With the extracted bias dependence of the small-signal equivalent elements and using Eqs. (31)–(35), the behavior of the channel noise voltage v_g , output noise current i_d as well as the equivalent gate leakage noise current i_p of the HFET can be derived for each bias condition at any frequency where $1/f$ noise is negligible.

4.5.4. Analytical and Scalable Noise Model for HFET.

When the influence of impact ionization and gate leakage current on the small-signal and noise performance can be neglected, the RF noise of HFET is dominated mainly by channel and output noise sources [see Eqs. (31) and (33)].

The parameters k_g and k_d are bias-independent but gate-geometry-dependent. To investigate the geometry dependence (gate length L_g and gate width W_g) of these parameters, the equivalent intrinsic noise sources of transistors with varying gate width and gate length have been extracted and analyzed in dependence on the shot noise drain current (Fig. 20). On the basis of these investigations, the following final analytical expressions can be derived for the intrinsic equivalent noise sources [45]:

$$\begin{aligned} i_{d,n} &= \sqrt{4k \frac{T_d}{R_{ds}}} \\ &\cong K_d \left(\sqrt{2e|I_D|} - \sqrt{2eI_{D,d}} \right) \end{aligned} \quad (36)$$

$$\begin{aligned} v_{g,n} &= \sqrt{4kT_g R_{gs}} \\ &\cong \frac{K_g W_g L_g f_T}{g_m^2} \left[\sqrt{2e|I_D|} - \sqrt{2eI_{D,g}} \right] \end{aligned} \quad (37)$$

In practice, the small influence of the parameters $I_{D,d}$ and $I_{D,g}$ can be neglected; thus, the following equations are sufficient for the prediction of the noise behavior:

$$i_{d,n} = \sqrt{4k \frac{T_d}{R_{ds}}} \cong K_d \cdot \sqrt{2e|I_D|} \quad (38)$$

$$\begin{aligned} v_{g,n} &= \sqrt{4kT_g R_{gs}} \\ &\cong K_g W_g L_g \sqrt{2e|I_D|} \frac{f_T}{g_m^2} \end{aligned} \quad (39)$$

A simplified intrinsic temperature noise model [46] is used to derive analytical expressions for all four noise

parameters:

$$F_{\min} = 1 + \frac{2}{T_0} \times \frac{f}{f_T} \sqrt{R_{gs} T_g \frac{T_d}{R_{ds}}} \quad (40)$$

$$R_{S,\text{opt}} = \frac{f_T}{f} \times \sqrt{R_{gs} T_g \frac{R_{ds}}{T_d}} \quad (41)$$

$$X_{S,\text{opt}} = \frac{1}{f} \frac{1}{2\pi C_{gs}} \quad (42)$$

$$R_n = \frac{1}{T_0} \left(R_{gs} T_g + \frac{T_d}{R_{ds}} \times \frac{1}{g_m^2} \right) \quad (43)$$

These estimations are sufficient for the geometry scaling of the intrinsic noise parameters of HFETs. Using these formulas and Eqs. (38) and (39), a correspondence between the intrinsic noise parameters and additional transistor parameters can be derived:

$$F_{\min} - 1 = \frac{f}{T_0} \times \frac{K_g K_d}{2k} W_g L_g \frac{2e|I_D|}{g_m^2} \quad (44)$$

$$R_{S,\text{opt}} = \frac{f_T}{f} \times \frac{K_g}{K_d} W_g L_g \frac{f_T}{g_m^2} \quad (45)$$

$$X_{S,\text{opt}} = \frac{1}{f} \times \frac{1}{2\pi C_{gs}} \quad (46)$$

$$R_n = \frac{1}{T_0} \times \frac{2e|I_D|}{4kg_m^2} \left[\left(K_g W_g L_g \frac{f_T}{g_m^2} \right)^2 + K_d^2 \right] \quad (47)$$

With these estimations for the gate length and gate width dependences, the behavior of the drain current I_D , the transconductance g_m , and the gate–source capacitance C_{gs} (Table 3), as well as the geometry dependence of the intrinsic noise parameters, can be obtained (Table 4).

4.6. Experimental Results and Verification of the Model for InP/InGaAs HBT

4.6.1. RF Performance of Devices Investigated. Devices under test are carbon doped InP/InGaAs self-aligned HBT with typical emitter areas $A_E = 20 \mu\text{m}^2$, $A_E = 40 \mu\text{m}^2$, and $A_E = 60 \mu\text{m}^2$ [47]. The carbon-doped p-(InGa)As:C base ($p > 10^{19} \text{cm}^{-3}$) is compositionally graded to increase current gain (Fig. 21) and transit frequency (Fig. 22), and a high-temperature in situ annealing sequence is carried out in TMAs/N₂ ambient at $T > 600^\circ\text{C}$ to activate the carbon doping in the base [48].

Figure 23 shows the capability of the model used to describe s parameters of the HBTs in the entire frequency range measured up to 40 GHz. To compare the three devices with respect to various emitter area A_E values, bias conditions are chosen in the active device region at constant collector-emitter voltage $V_{CE} = 1.2 \text{V}$ and constant current densities $S_E = I_C/A_E$. The range of current density increases from $S_E = 0.3 \times 10^4 \text{A/cm}^2$ up to $S_E = 6.7 \times 10^4 \text{A/cm}^2$. The results given in Fig. 23 show the measured and modeled s parameters for the three devices at high current

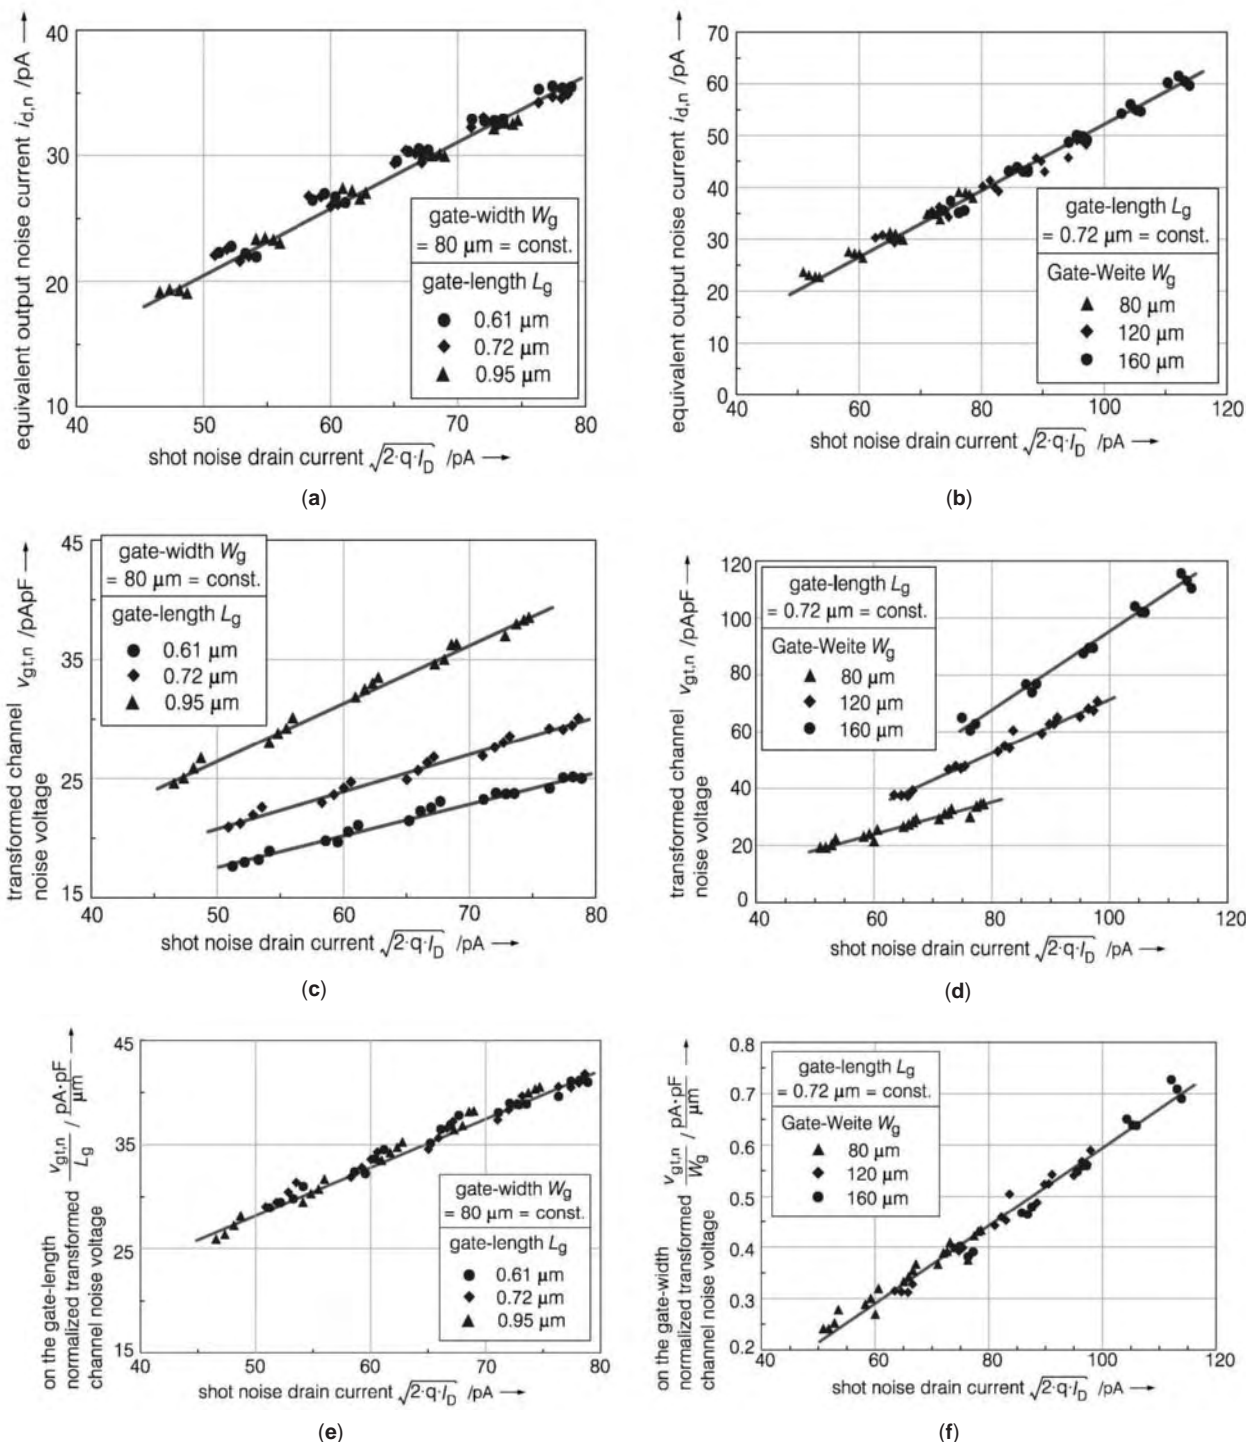

Figure 20. (a,b) Equivalent output noise current $i_{D,n}$ versus the shot noise drain current with (a) gate length L_G as a parameter and (b) gate width W_G as a parameter; (c,d) transformed equivalent channel noise voltage $v_{Gt,n}$ versus the shot noise drain current with (c) gate length L_G as a parameter and (d) gate width W_G as a parameter; (e,f) normalized transformed equivalent channel noise voltage $v_{Gt,n}$ versus the shot noise drain current (e) normalized on the gate length L_G and (f) normalized on the gate width W_G ($T = 300$ K, $V_{DS} = 0.9$ V up to 1.8 V, $V_{GS} = -0.3$ V up to 0.1 V). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

density $S_E = 5 \cdot 10^4$ A/cm². All small-signal equivalent elements are extracted by optimization strategies using multibias optimization [49]. These strategies take into account the bias independence of the extrinsic small-signal

equivalent elements. All measured bias conditions are optimized simultaneously with the same extrinsic elements. The symbols in Fig. 23 represent the measured data; the solid lines, the modeled values.

Table 3. Scaling Properties of Some Small-Signal Equivalent Elements and Device Parameters

Gate Length Dependence	Gate Width Dependence
$g_m \neq f(L_g) = \text{const}$	$g_m \propto W_g$
$C_{gs} \propto L_g$	$C_{gs} \propto W_g$
$f_T \propto 1/L_g$	$f_T \neq f(W_g) = \text{const}$
$I_D \neq f(L_g) = \text{const}$	$I_D \propto W_g$

Table 4. Derived Scaling Behavior of the Intrinsic Noise Parameters

Gate Length Dependence	Gate Width Dependence
$F_{\min} - 1 \propto L_g$	$F_{\min} - 1 \neq f(W_g) = \text{const}$
$R_{Q,\text{opt}} \propto 1/L_g$	$R_{Q,\text{opt}} \propto 1/W_g$
$X_{Q,\text{opt}} \propto 1/L_g$	$X_{Q,\text{opt}} \propto 1/W_g$
$R_n \neq f(L_g) = \text{const}$	$R_n \propto 1/W_g$

Figure 21. DC current gain $\beta = I_C/I_B$ with dependence on current density S_E at $V_{CE} = 1.2$ V for the three different device geometries.

Figure 23. Measured (symbols) and modeled (lines) s parameters in frequency range from 45 MHz to 40 GHz at $V_{CE} = 1.2$ V and $S_E = 5 \times 10^4$ A/cm²: (a) s_{11} in Smith chart, s_{12} in polar diagram; (b) s_{22} in Smith chart, s_{21} in polar diagram.

4.6.2. Noise Behavior. To prove the consistency with RF noise parameter modeling, bias-dependent RF noise parameter measurements were performed for the same bias conditions.

First, the bias-dependent behavior of all noise parameters are given for the HBT with the smallest emitter area of $A_E = 20 \mu\text{m}^2$. Figures 24–26 show the measured and modeled RF noise parameters for three different current

Figure 24. Measured (symbols) and modeled (lines) minimum noise figure F_{min} at constant $V_{CE} = 1.2$ V with dependence on current density S_E ($A_E = 20 \mu\text{m}^2$).

densities in the range from $S_E = 3.0 \cdot 10^3$ A/cm² up to $S_E = 6.7 \cdot 10^4$ A/cm² at constant collector-emitter voltage $V_{CE} = 1.2$ V in the active-device region. The model parameters factoring in RF noise behavior are optimized with the evolutionary algorithm as well. The small-signal equivalent elements, which were found during the abovementioned multibias optimization, were used and kept constant within the RF noise parameter optimization algorithm. As a consequence, only the four intrinsic equivalent noise temperatures of the intrinsic resistances have to be determined. The minimum noise figure F_{min} increases with rising collector current (Fig. 24). At low current density the value of the minimum noise figure is about $F_{min} = 1.3$ dB at $f = 2$ GHz for the devices investigated. The equivalent noise resistance is about $R_n = 175 \Omega$ at $f = 1$ GHz and decreases with higher frequencies. The noise resistance shows only minor dependence on collector current (Fig. 25). The last measured RF noise parameter is the optimum generator reflection coefficient Γ_{opt} . The magnitude of this reflection coefficient decreases with rising current density S_E (Fig. 26). This result shows the

Figure 25. Measured (symbols) and modeled (lines) equivalent noise resistance R_n at constant $V_{CE} = 1.2$ V with dependence on current density S_E ($A_E = 20 \mu\text{m}^2$).

Figure 26. Measured (symbols) and modeled (lines) optimum generator reflection coefficient Γ_{opt} at constant $V_{CE} = 1.2$ V with dependence on current density S_E ($A_E = 20 \mu\text{m}^2$).

measurement difficulty in case of low currents because of the limited number of tuner states during noise parameter measurements, which show source reflection coefficients near the optimum generator reflection coefficient [18]. In addition to the three RF noise parameters given above, the associated gain g_{ass} is given with dependence on current density (Fig. 27). With rising current, RF gains of all the devices increase, which can be seen looking on the current density-dependent transit frequency (Fig. 22) and the associated gain.

Looking on the geometry dependence of HBT RF noise parameters, Figs. 28–30 show the measured and modeled RF noise parameters for the three devices with different emitter area A_E at the same bias condition in the active-device region with constant collector-emitter voltage $V_{CE} = 1.2$ V and constant high current density $S_E = 5 \cdot 10^4$ A/cm².

The HBTs show better RF noise performance for smaller emitter area. With increasing emitter area A_E , the minimum noise figure increases (Fig. 28), as does the equivalent noise resistance R_n (Fig. 29). Only the optimum generator reflection coefficient shows minimal influence on the emitter area of the device (Fig. 30). The devices with the smallest emitter area show the highest values of associated gain g_{ass} as well (Fig. 31).

Figure 27. Measured (symbols) and modeled (lines) associated gain g_{ass} at constant $V_{CE} = 1.2$ V with dependence on current density S_E ($A_E = 20 \mu\text{m}^2$).

Figure 28. Measured (symbols) and modeled (lines) minimum noise figure F_{\min} with dependence on emitter area A_E at constant bias condition $V_{CE} = 1.2\text{ V}$ and $S_E = 5 \cdot 10^4\text{ A/cm}^2$.

4.6.3. Equivalent Intrinsic Noise Sources. With the extended bias and geometry-dependent modeling of RF parameters of HBT, the intrinsic noise sources of the model used can be investigated in detail. As a result of the small-signal and RF noise parameter model, a localization of various noise sources in the specific device regions is possible. With the optimization results of the bias and geometry-dependent modeling, the spectral densities of the four intrinsic noise current sources can be calculated (cf. Fig. 10). The intrinsic noise currents are calculated, knowing the values of the intrinsic resistances and the associated equivalent noise temperatures. Equations (48)–(51) are used for calculation of the following intrinsic noise currents: (1) the base noise current $i_{bb,n}$, based on the intrinsic base resistance R_{bb} in combination with T_{bb} ; (2) the base–emitter junction noise current $i_{je,n}$, using the values of the base–emitter junction resistance R_{je} and T_{je} ; (3) the base–collector junction noise current $i_{jc,n}$, which is calculated with base–collector junction resistance R_{jc} and T_{jc} ; and (4) the intrinsic collector noise current $i_{cc,n}$, known from combination of collector resistance R_{cc} and associated

Figure 29. Measured (symbols) and modeled (lines) equivalent noise resistance R_n with dependence on emitter area A_E at constant bias condition $V_{CE} = 1.2\text{ V}$ and $S_E = 5 \cdot 10^4\text{ A/cm}^2$.

Figure 30. Measured (symbols) and modeled (lines) optimum generator reflection coefficient Γ_{opt} with dependence on emitter area A_E at constant bias condition $V_{CE} = 1.2\text{ V}$ and $S_E = 5 \cdot 10^4\text{ A/cm}^2$.

temperature T_{cc} :

$$i_{bb,n} = \sqrt{4k \frac{T_{bb}}{R_{bb}}} \quad (48)$$

$$i_{je,n} = \sqrt{4k \frac{T_{je}}{R_{je}}} \quad (49)$$

$$i_{jc,n} = \sqrt{4k \frac{T_{jc}}{R_{jc}}} \quad (50)$$

$$i_{cc,n} = \sqrt{4k \frac{T_{cc}}{R_{cc}}} \quad (51)$$

These calculated values are now plotted with dependence on bias condition; here we calculate the base $i_{B,S}$ and collector $i_{C,S}$ shot noise currents due to DC values with

$$i_{B,S} = \sqrt{2eI_B} \quad (52)$$

$$i_{C,S} = \sqrt{2eI_C} \quad (53)$$

Figure 31. Measured (symbols) and modeled (lines) associated gain g_{ass} with dependence on emitter area A_E at constant bias condition $V_{CE} = 1.2\text{ V}$ and $S_E = 5 \cdot 10^4\text{ A/cm}^2$.

Figure 32. Extracted (symbols) intrinsic base noise currents with dependence on base current shot noise at constant $V_{CE} = 1.2$ V. Solid line represents linear fit.

Figure 32 shows the intrinsic base noise current $i_{bb,n}$ with dependence on base shot noise current $i_{B,S}$ of all HBT devices. The intrinsic base noise current shows a linear dependence on the shot noise due to extrinsic DC base current with a gradient of about 0.5. But a very high offset is obvious, which is correlated to the intrinsic noise source.

The other intrinsic noise currents show a strong influence on the shot noise of the DC currents. Figure 33 shows the intrinsic base–collector junction noise current $i_{jc,n}$, which is equal to the base current shot noise due to DC base current. The base–emitter junction noise $i_{je,n}$ (Fig. 34) and the intrinsic collector noise current $i_{cc,n}$ (Fig. 35) both are fully correlated to the DC collector current shot noise.

Interpreting the results achieved, all RF noise parameters of InP/InGaAs HBT can be modeled to fit only one equivalent noise temperature T_{bb} of the intrinsic base resistance R_{bb} . The other intrinsic equivalent noise temperatures can be calculated directly from the shot noise of the DC currents and the small-signal equivalent elements, which are known from s -parameter measurements. The number of unknown model parameters decreases. Addi-

Figure 33. Extracted (symbols) intrinsic base–collector junction noise currents in dependence on base current shot noise at constant $V_{CE} = 1.2$ V. Solid line represents linear fit.

Figure 34. Extracted (symbols) intrinsic base–emitter junction noise currents with dependence on collector current shot noise at constant $V_{CE} = 1.2$ V. Solid line represents linear fit.

tionally, in case of noise modeling no emitter area scaling has to be taken into account. This scaling is included using the area-dependent small-signal equivalent elements only.

5. EXTENSION AND APPLICATION OF THE NOISE MODELS PRESENTED

5.1. Dual-Gate HFET in Cascode Configuration

Figure 36 shows a dual-gate HFET (DGHFET) and the corresponding equivalent circuit with the definition of extrinsic and intrinsic voltages and currents [50]. The DGHFET can be represented by two single-gate HFETs (SGHFETs), connected at the virtual node D_1 [51]. Consequently, the DGHFET can be separated into three parts (Fig. 37), all connected by a coupling network consisting of an additional resistance R_{coup} and a capacitance C_{coup} :

- The parasitic environment
- One single-gate HFET in common-source configuration
- One single-gate HFET in common-gate configuration

Figure 35. Extracted (symbols) intrinsic collector noise currents with dependence on collector current shot noise at constant $V_{CE} = 1.2$ V. Solid line represents linear fit.

Figure 36. Dual-gate HFET and its equivalent circuit using two HFETs and defining extrinsic and intrinsic voltages and currents.

Correspondingly, the DGHFET can be modeled on the basis of the particular equivalent circuits of SGHFET described in Section 4.2. The small-signal equivalent elements as well as the noise temperatures and currents can also be extracted using the evolutionary algorithm [39].

Measured and modeled noise properties of a typical InP-based DGHFET are shown in Fig. 38 at two bias conditions, indicated in Table 5, with a comparable drain current. The modeled equivalent noise temperatures, the corresponding resistances and the extracted data of the noise sources (Table 5) demonstrate the influence of impact ionization with dependence on the bias condition.

Compared to single-gate HFET, the dual-gate HFET shows a reduced impact ionization noise component at comparable bias conditions [52]. Additionally, the RF performance of DGHFET corresponds to that of SGHFET. Moreover, even an increase of the unilateral gain and a reduced feedback can be obtained. Thus, dual-gate HFET are commonly used for mixers, oscillators, variable-gain amplifiers, and high-frequency applications such as OEICs or MMIC amplifiers [53].

5.2. Application of Noise Models for Circuit Design

The importance of reliable noise modeling of single devices is demonstrated below for an optoelectronic receiver circuit.

The necessary minimum optical input power $P_{opt,min}$ applied to an optoelectronic receiver in order to detect the original signal tolerating a certain error can be derived

Figure 38. Measured and modeled noise parameter for bias conditions 1 ($V_{DS}=3\text{ V}$, $V_{G1S}=0.1\text{ V}$, $V_{G2S}=0.6\text{ V}$) (above) and bias conditions 2 ($V_{DS}=3\text{ V}$, $V_{G1S}=0\text{ V}$, $V_{G2S}=2.2\text{ V}$) (below). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Q = the noise factor, which is $Q \approx 6$ for $\text{BER} = 10^{-9}$

$\sqrt{i_{na}^2}$ = the root mean square of the equivalent input noise current density

The noise factor Q is derived from probability calculations that consider the statistical nature of the noise signal as well as the pseudorandom characteristic of a real information signal. Q can be derived from the *Gaussian* probability integral where BER is the bit error rate of the detected digital signal behind the decision circuit:

$$\text{BER} = \frac{1}{2\pi} \int_Q^\infty e^{-x^2/2} dx \quad (55)$$

Typically, a bit error rate of $\text{BER} = 10^{-9}$ is assumed to be the maximum tolerable number of incorrectly detected bits per second. Hence, the corresponding noise factor equals

$$Q \approx 6|_{\text{BER} = 10^{-9}}.$$

The mean input noise current $\sqrt{i_{na}^2}$ is a function of numerous device- and circuit-related parameters. In particular, the noise sources of active devices—as discussed in earlier sections—have a dominant contribution at higher frequencies. The second important contribution comes from thermal noise currents generated in ohmic resistors that can be found at different locations of the receiver circuit itself. A closed formulation taking into account some of the small-signal related device parameters was derived

by [54] and can be written as

$$\overline{i_{na}^2} = \frac{4kT}{R_f} X_1 B + 2eI_L X_2 B + \frac{4kT\Gamma}{g_m} (2\pi C_T)^2 (f_c X_f B^2 + X_3 B^3) \quad (56)$$

where

X_1, X_2, X_3, X_f = special weight-functions (Personick integrals)

B = bit rate of the datastream

I_L = total leakage current (combination of dark current of photodetector (PD) and gate leakage current of input transistor)

g_m = transconductance of first transistor

C_T = total capacitance (usually $C_T = C_{gs} + C_{pd}$)

R_f = feedback resistance

f_c = corner frequency of $1/f$ noise contribution

Γ = channel noise factor (a function of transistor-related parameters)

In general, the primary aim of noise modeling in conjunction with circuit design and development is to enable a reliable estimation of the noise behavior of the total circuit.

As an example of the applicability of the abovementioned temperature noise model (TNM) for circuit noise simulation, the optoelectronic circuit shown in Fig. 39 is discussed. It consists of a four-stage traveling-wave amplifier (TWA) combined with a pin photodiode (PD) to form up a high-speed receiver module for transfer rates up to 35 Gbps (gigabits per second) [55,56]. The TWA comprises four HFET devices with varying gate widths, hence utilizing the scalability of the applied noise model. The single stages within the TWA are fed from an input transmission line that is connected to the PD (left side) and terminated by a resistor at the end (right side). The single line segments are built up as coplanar waveguides (CPWs) and are fed toward the transistor gate contact with airbridge interconnections treated as microstrip lines (MSLs) with $\epsilon_r = 1$. At the drain ends, again feeding MSL lines are connected to a CPW output transmission line, which is again terminated by a complex impedance (RC combination) at the opposite end of the RF output. Figure 40 shows a photograph of the realized receiver.

Figure 39. Circuit layout of a four-stage traveling-wave amplifier (TWA) combined with a pin photodiode (PD).

Figure 40. Photograph of realized optoelectronic receiver based on a TWA and waveguide fed pin photodetector (PD) in coplanar technique (C—RF-blocking capacitors, R—metal-film resistors).

The most interesting noise contributions are generated mainly by single HFET devices and the termination resistors. During circuit simulation that has been carried out using *microwave design systems* (Hewlett-Packard), noise behavior of the HFETs was considered using the TNM model. The inset in Fig. 41 depicts the transfer characteristic of the TWA derived from RF measurements up to 45GHz. In the particular case of optoelectronic receivers, the transimpedance is of major interest and is defined as follows with i_{ph} = photocurrent of detector generated by optical signal:

$$Z_T(f) = \frac{v_{out}}{i_{in}} = \frac{v_{out}}{i_{ph}} \quad (57)$$

The transfer characteristic is necessary for calculation of the equivalent input noise current $\sqrt{i_{na}^2} = \sqrt{\int i_{na}^2(f)df}$, which is not directly measurable. It has to be derived from measurements of the frequency-dependent noise factor F (or the absolute output noise power, respectively) by using the reverse transfer function $Z_T^{-1}(f)$ [57].

Both the validity and the reliability of the noise simulation are demonstrated in Fig. 41, where the simulated as well as the measured and recalculated frequency-dependent input noise current density $i_{na}(f)$ are depicted. The

Figure 41. Measured (◆) and modeled (—) transfer characteristic of the TWA (transimpedance Z_T vs. frequency f). The inset shows the measured (●) and calculated (—) noise data (equivalent input noise current density i_{na} vs. frequency f). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

almost negligible differences between both curves clearly demonstrate the applicability and validity of the noise models employed, even for circuit noise simulations. Finally, these results enable the circuit designer to achieve reliable estimations of the total receiver sensitivity P_{min} using Eq. (54).

NOISE, HOT CARRIER EFFECTS

ARVYDAS MATULIONIS
Semiconductor Physics Institute

Electric noise, or fluctuation in electric circuits, results from the discrete nature of charge carriers and their chaotic motion. Electric noise manifests itself as an acoustic noise in a telephone or a radio receiver, also as an irregular flickering on a television screen, known as a “snow-fall” flicker, and otherwise. In general, fluctuations are temporary deviations of variables (current, voltage, resistance, frequency, etc.) either from their long-term averages or from some regular time-dependent values of information-bearing signals. This article deals with electronic noise caused by electrons and holes in semiconductors. For simplicity, the term electrons will be used, unless mentioning holes is necessary for specific reasons.

Fluctuations are best understood for electron gas that is in thermodynamic equilibrium with lattice vibrations. The universal relations of Nyquist and Einstein, together with Ohm’s law, interrelate noise, current, and other electronic transport, including electron diffusion. These relations are sufficient to estimate the ultimate accuracy for electrical measurements and signal processing under near-equilibrium conditions. However, advances in instrumentation and communication technology increasingly depend on progress in microelectronics, where deviations

from equilibrium are essential, and the universal relations fail. High electric field enhances chaotic motion of electrons in devices and circuits. The customary name for this situation is *hot electrons*. Correspondingly, noise acquires features absent at equilibrium. Indeed, hot-electron noise differs from equilibrium, like a stormy sea differs from a mill pond. Measuring noise out of equilibrium provides new information about kinetic processes in electron gas—new as compared with that available from the average values of observables. As a result, investigation of hot electron noise proves to be a powerful tool for diagnosing nonequilibrium states in semiconductors subjected to high electric fields. Moreover, the knowledge obtained of the microscopic origin of hot-electron noise helps to control it and suggests how to eliminate some sources of excess noise through improvement of material technology and circuit design, thus contributing to development of highly sensitive low-noise devices.

1. HOT-ELECTRON VELOCITY FLUCTUATIONS

1.1. Electric Noise at Equilibrium and in Nonequilibrium State

1.1.1. Fluctuations at Equilibrium. Fluctuations have been under investigation since 1827, when R. Brown published the results of his observations on the endless irregular motion of microscopic particles suspended in a liquid. Numerous sophisticated investigations of this phenomenon, called Brownian motion, led to the conclusion that the mean kinetic energies of a Brownian particle and a molecule of the liquid were equal, provided enough care was taken not to disturb their thermal equilibrium. Moreover, fluctuations of position of a Brownian particle were found closely related to the viscosity of the surrounding liquid and the force of friction acting on the particle. Experiments on Brownian motion and its theory, developed by A. Einstein and M. Smoluchowski, were important arguments in favor of the molecular kinetic theory. The theory provided methodology to treat spreading of a cloud of particles (diffusion), friction, viscosity, and so on, in terms of velocity fluctuations. In particular, the Einstein relation associates the electron diffusion coefficient with electron mobility—the main electron transport parameter for a semiconductor in Ohm’s law for current flow. Nyquist [1], in 1928, related the spectral density of current fluctuations in a resistor to the dissipative part of its conductance, or resistance. The Nyquist theorem and Einstein’s relation together led to the fluctuation–diffusion relation, between electronic noise and electron diffusion.

In Nyquist’s derivation one can also trace ideas of Rayleigh (1900), who applied the equipartition theorem to the standing-wave modes of blackbody radiation. In some sense, the available noise power is a special low-frequency case of blackbody radiation. Under proper matching, a resistor emits noise power into the matched transmission line connected to a radiometer—a sensitive device to measure radiation power. At thermal equilibrium, noise is white over a wide range of frequencies, that is, the spectral density of noise power does not depend on frequency and is the universal function of the absolute temperature. Thus,

the noise radiometer serves as the absolute thermometer. (Visible and infrared radiation of a blackbody is used to measure the absolute temperature as well.) Provided noise power differs from thermal power, the equivalent noise temperature (or, simply, noise temperature) is introduced, in order to estimate the deviation from equilibrium. The logarithmic ratio, in decibels, of the noise temperature over the absolute temperature is widely used for the same purpose.

In 1951, Callen and Welton [2] completed the theory of fluctuations at equilibrium by formulating the general fluctuation-dissipation theorem, which expresses the spectral density of fluctuations in a physical system at a given frequency, in terms of the dissipative part of the response of the system to some external perturbation. Accordingly, calculation, or measurement, of the system of linear response at a given frequency provides data on the spectral density of fluctuations of the corresponding variable at the same frequency. Consequently, measurement of electric noise at equilibrium gives no complementary information, as compared with that available from impedance measurements. On the other hand, measuring electron mobility and electron density in a semiconductor is sufficient to determine its noise properties at equilibrium.

The thermodynamic arguments collapse for an open system, subjected to a continuous energy flow, when some energy is supplied from the external world and then dissipated back to the external world. No universal relation is valid between noise and impedance in this case. This statement has fundamental and practical consequences. First of all, investigation of fluctuations from the nonequilibrium state is a valuable tool for diagnosis of different mechanisms of dissipation: relaxation of momentum, energy, intervalley transfer, as well as free-carrier number relaxation, which are reflected in the noise spectrum pattern of a biased semiconductor. On the other hand, the failure of the fluctuation-dissipation theorem allows, to a certain extent, independent control of the response and the noise through variation of the applied field, frequency, semiconductor doping, ambient temperature, sample length, and so on. Such a study, aimed at finding the favorable conditions for coexistence of high drift velocity and low excess noise, is important for the development of high-speed, low-noise devices.

1.1.2. Excess Noise at Low Electric Fields. Hot-electron effects are negligible in low electric fields, where the electrons easily dissipate energy gained from the applied electric field, and the electron temperature remains approximately equal to that of the semiconductor lattice. Nevertheless, electric current disturbs equilibrium and changes fluctuation spectra. For example, fluctuations of resistance (already present at equilibrium) cause no noise at zero bias, but they modulate current and manifest themselves in a biased semiconductor.

Many sources of excess electric noise, such as flicker noise, generation-recombination noise, and shot noise need current to appear [3-5]. Flicker noise dominates at low frequencies, whereas generation-recombination noise is usually observed at intermediate frequencies. Shot noise is white over a wide range of frequencies. These

sources of excess noise are not observed in directions transverse to the current. On the contrary, the noise resulting from electron velocity fluctuations is observed in all directions. It exceeds the flicker and generation-recombination noise at high frequencies.

Shot noise is important when the current is controlled by a barrier: a p-n junction, a Schottky barrier, a heterojunction, a tunneling structure, nonuniformities of doping, nonohmic contacts, and so on. The universal Schottky formula [6] says that, for shot noise, the spectral density of current fluctuations is proportional to the current. Measurement of noise characteristics as a function of current. Measurement of noise characteristics as a function of current, frequency, and lattice temperature helps to distinguish different sources of excess noise, and suggests how to eliminate those of no interest. In particular, perfect ohmic contacts, uniform doping, and relatively high density of majority carriers, are prerequisites for avoiding interference of shot noise during experiments on hot-electron velocity fluctuations.

1.1.3. Electron Heating by Electric Field. A high electric field accelerates mobile electrons, and they accumulate excess energy. The steady state is reached when energy loss (usually at the lattice vibrations) compensates energy gain at a certain elevated mean energy of the electrons. The electron mean energy rising above its thermal equilibrium value—termed *hot electrons*—is specific to the electron behavior at high electric fields in semiconductors. The lattice temperature tends to increase as well, due to the Joule effect. However, the heat capacity of a semiconductor sample is much higher than that of the electron gas. Moreover, the lattice dissipates excess heat to the ambient, and the lattice temperature remains the same as (or only insignificantly higher than) the ambient temperature, provided a short voltage pulse is applied and the heat dissipation is efficient. The associated noise resulting from hot electrons is called hot-electron noise.

1.1.4. Hot-Electron Noise. Electronic processes inside the conduction band are fast, so the associated spectral features of excess noise appear at microwave frequencies. Therefore, it is quite natural that investigation of hot-electron noise at microwave and higher frequencies serves for diagnostics of fast and ultrafast processes in a semiconductor subjected to high electric fields. Microwave noise measurements usually deal with the noise power expressed in terms of the equivalent noise temperature. Another fluctuation characteristic is the spectral density of current fluctuations available from experimental data on noise temperature and small-signal microwave conductivity.

Experiments on hot-electron noise provide information on the anisotropy of kinetic energies in the longitudinal and transverse directions, the transverse and longitudinal diffusion coefficients of majority carriers, the energy relaxation time constant and its dependence on the applied electric field and lattice temperature, the intervalley transfer-time constants for equivalent and nonequivalent valleys, and other important kinetic parameters of electronic processes inside the conduction and valence bands.

1.2. Kinetic Theory of Fluctuations from Nonequilibrium State

1.2.1. Toward the Price Relation. Kinetic theory of hot-electron fluctuations in semiconductors is an important part of physical kinetics [7]. The crystal lattice presents an unperturbed thermal bath for the nonequilibrium electron gas in a semiconductor, allowing detailed treatment of hot-electron interaction with equilibrium phonons. This situation, and an understanding of the importance of fluctuations for the kinetic theory, immediately led to interesting results on hot electron fluctuations in semiconductors, reported by Lax [8], Price [9], Gurevich [10], Price [11], Gurevich and Katilius [12], and Kogan and Shul'man [13].

In particular, Price [11] extended to hot electrons the fluctuation–diffusion relation between the spectral density of current fluctuations caused by electron velocity fluctuations and the diffusion coefficient associated with fluctuations of position of the same electrons. The Price relation was proven to hold, despite the failure of the Einstein relation, Ohm's law, and the Nyquist theorem for hot electrons.

1.2.2. General Theory. Later results, obtained for the case of frequent electron–electron collisions, contradicted the earlier results, and Gantsevich et al. [14,15] and Kogan and Shulman [16] developed a self-consistent kinetic theory of fluctuations in a nonequilibrium case, based on the first principles of quantum mechanics and statistical physics. The theoretic apparatus of kinetic theory was generalized to obtain spectral properties of noise from statistical properties of collisions. The criteria of applicability of the theory were the same as for Boltzmann's equations used for response calculations. An important result obtained was [15] that the Price fluctuation–diffusion relation for hot electrons [11] had a narrower range of applicability than originally expected, with a high-density hot-electron gas being outside this range because of electron–electron collisions. The theory and its numerous applications to analytically tractable models are described in monographs [4,7] and review papers [17,18].

1.3. Hot-Electron Noise in Lightly Doped Semiconductors

1.3.1. Longitudinal and Transverse Noise. Developed theory and practical needs stimulated experimental investigation of hot-electron noise in semiconductors. Erlbach and Gunn [19] measured hot-electron noise temperature for n-type germanium in the transverse direction to the current. The resultant increase of the transverse noise temperature with the applied electric field indicated that the electrons were hot. Bryant reported on longitudinal noise temperature for n-type GaAs [20]. Avoiding possible contribution of generation–recombination noise, Bareikis et al. [21] measured the longitudinal noise temperature of hot carriers in n-type and p-type germanium [22] at microwave frequencies. Their study of longitudinal and transverse noise gave the first experimental evidence that noise temperature and spectral density of velocity fluctuations of hot carriers were anisotropic quantities. The experiment was performed on samples containing a

relatively low density of hot carriers, and the results were interpreted in terms of the Price fluctuation–diffusion relation with the correct conclusion [21] that the diffusion coefficient of hot carriers was anisotropic as well. (Some time later, Wagner, Davis, and Hurst observed the anisotropy of electron diffusion in ordinary gases at high electric fields [23].) So, microwave noise experiments demonstrated the possibility to obtain results on field-dependent longitudinal and transverse diffusion coefficients for majority carriers in uniform samples without introducing carrier density gradients, and this technique [21,22] was applied to investigate hot-electron diffusion in the principal semiconductors used in electronics [24,25]. The diffusion coefficient results obtained from microwave noise measurements were confirmed by experiments using other techniques [25].

1.3.2. Fluctuations in One-Valley Semiconductors. The physics of noise relates the observed fluctuations in macroscopic variables to the microscopic processes inside a semiconductor. For hot-electron scattering by acoustic phonons in a one-valley semiconductor, theory predicted a negative convective contribution to longitudinal current fluctuations resulting from energy fluctuations [11,12]. This phenomenon was experimentally confirmed in p-type germanium [22].

An essentially different contribution to longitudinal noise comes from inelastic scattering of hot electrons by optical phonons—the main energy loss mechanism at elevated electron energies. This scattering mechanism leads to resonant-type spectrum of velocity fluctuations in a narrow range of moderate electric fields at low lattice temperatures, as illustrated by experiments performed for p-type Ge and n-type InSb at 10 K lattice temperature [18,26]. Optical phonon scattering, dominating over a wide range of electric fields in n-type GaAs and InP, leads to a broad and relatively weak noise source resolved at liquid nitrogen and room temperatures [24].

1.3.3. Intervalley Fluctuations In Elementary Semiconductors. The conduction band of Ge and Si has several equivalent valleys, containing equal parts of the electron gas in equilibrium. An applied electric field introduces differences in the drift velocities and mean energies in the ellipsoidal valleys, oriented at different angles to the field, and the excess noise—hot-electron intervalley noise—appears [9]. It is anisotropic, with respect to the electric field direction and to the crystallographic orientation [27]. Intervalley noise and generation-recombination noise are examples of so-called partition noise [25].

1.3.4. Intervalley Fluctuations in Compound Semiconductors. The conduction band of direct-bandgap compound semiconductors differs essentially from that of silicon and germanium. Equilibrium electrons occupy the lowest single valley, where their mobility is high. The upper low-mobility valleys are usually empty at equilibrium (except for high lattice temperatures), and a high electric field is needed for their occupation. Intervalley transitions of hot electrons cause longitudinal fluctuations of drift velocity. Intervalley noise of this type dominates in GaAs [28] and

InP [29] at the subthreshold field for the Gunn effect. Sources of noise due to hot-electron transfer into satellite valleys located along the (111) and (100) directions (L and X valleys) were resolved in short submicrometer samples of n-type GaAs [30].

1.4. Monte Carlo Simulation of Fluctuations

Experimental studies demonstrate that hot-electron noise characteristics are sensitive to subtle details of the semiconductor band structure and scattering mechanisms. This stimulates the interpretation of experimental data, in terms of realistic semiconductor models. While analytical models perfectly illustrate the kinetic theory with deep insight into the physics of hot-electron noise, numerical techniques are useful in extracting quantitative information on the dominant kinetic processes inside the conduction band.

1.4.1. Simulation of Hot-Electron Fluctuations. The Monte Carlo method—a versatile numerical technique—introduces hot-electron velocity fluctuations into the simulation procedure in a natural way. The first calculation of hot-electron noise spectra by the Monte Carlo technique [31] was immediately followed by a paper [32] in which a better estimate of the scattering parameters of holes in the valence band of germanium was obtained by fitting the Monte Carlo simulation data to the experimental results. Simulation techniques and calculation of the spectral properties of hot-electron noise are described in a monograph [33] on Monte Carlo methods and their application to semiconductor devices. More recent developments and results with emphasis on hot-electron noise in semiconductor structures are discussed in review papers [34–36]. This Monte Carlo approach applies at low electron densities, and modified procedures are needed to treat fluctuations when electron–electron collisions are essential [37–39].

1.4.2. Simulation of Hot-Electron Diffusion. The Price fluctuation–diffusion relation, valid at low electron densities, provides another possibility to compare experimental data on hot-electron velocity fluctuations and numerical results for realistic models. Motion of individual electrons in real space, resulting in diffusive spreading of an electron cloud, was simulated by the Monte Carlo technique, and the diffusion coefficient available from this simulation was compared with data on spectral density of current fluctuations available from microwave noise measurements [24,25].

1.5. Effect of Electron–Electron Collisions

Electron–electron collisions are energy and momentum conserving; they have no direct effect on energy and drift velocity, but do influence these averages through other scattering mechanisms. For example, an electron–electron collision can assist emission of an optical phonon by one of the electrons supposing that each electron lacks energy for the emission before the collision. The associated loss of energy is essential. It causes a slow increase of hot-electron noise temperature at moderate electric fields and

cryogenic temperatures, as illustrated by comparing the results of Monte Carlo simulation with the experimental data for n-type GaAs [39]. Moreover, theory predicts that two-carrier collisions in hot-electron gas create additional correlation, and the additional term enters the fluctuation–diffusion relation [15,37].

1.6. Semiconductor Structures

1.6.1. Short Channel Effects. Modern microelectronics is shaped by small-size and low-dimension semiconductor structures. Investigation of hot-electron noise in such structures is important when one tries to minimize the associated excess noise at high speed of operation. Hot electrons fail to reach the steady state, corresponding to an infinitely long sample, provided the sample is short and the hot electrons leave the sample for the electrode early enough. As a result, a higher electric field is needed for the intervalley noise to appear in short samples [37]. In other words, at a fixed electric field, the intervalley noise is suppressed in short channels. The essential suppression of hot-electron noise in short channels has been demonstrated for lightly doped n-type GaAs [40] and InP [41], and for standard-doped n-type GaAs [42]. For a comparison with the results of Monte Carlo simulation, see Ref. 24.

1.6.2. Two-Dimensional Electron Gas Channels. In two-dimensional electron gas (2-DEG), the electrons are free to undergo planar motion, but their transverse freedom is limited by the heterojunction and electrostatic barriers. The degree of transverse freedom depends on the barrier height and the electron kinetic energy, the latter being easily controlled by the electric field applied in the plane of electron localization. This introduces sources of excess noise specific to low-dimensional channels [43,44]. Dependence of hot-electron noise on channel length is also important for low-noise operation of 2-DEG channels at microwave frequencies [44].

2. THEORETIC BACKGROUND

Hot-electron fluctuations depend on the details of kinetic processes taking place in a biased semiconductor. This requires consideration of the values in the nonequilibrium spectra that reflect these details. Definitions and relations appropriate for the nonequilibrium state and converging to the equilibrium states at zero bias are introduced in this section.

2.1. Correlation Function and Spectral Density of Fluctuations

Electric current in a semiconductor sample results from motion of the mobile electrons present in the sample. Random motion of individual electrons produces fluctuations of the current $\delta\mathbf{I}(t)$ around the time-independent mean value $\bar{\mathbf{I}}$. Let us consider N electrons in a uniform sample under steady-state, reached in a uniform static electric field \mathbf{E} . The time-dependent velocity of the all-electron mass center, averaged over the mobile electrons, or drift

velocity, is

$$\mathbf{v}_d(t) = \frac{1}{N} \sum_n^N \mathbf{v}_n(t) \quad (1)$$

where $\mathbf{v}_n(t)$ is the instantaneous velocity of the n th electron and t is time. Fluctuations of the drift velocity $\delta\mathbf{v}_d(t)$ around the time-independent mean value $\overline{\mathbf{v}_d(t)}$ are present in all directions:

$$\delta\mathbf{v}_d(t) = \mathbf{v}_d(t) - \overline{\mathbf{v}_d(t)} \quad (2)$$

The bar here and in the following designates the average over time. The fluctuating time-dependent drift velocity for a chosen model can be obtained from Monte Carlo simulation [33].

The quantity that yields important physical information on the size of the fluctuations and how they decay in time is the drift velocity autocorrelation function (see Ref. 4). In the direction of interest, the autocorrelation function is

$$\Phi(\tau) = \overline{\delta v_d(t) \delta v_d(t + \tau)} \quad (3)$$

where τ is the time difference between two observations and $v_d(t)$ is the drift velocity component in the chosen direction. The autocorrelation function value $\overline{\delta v_d^2(t)}$ at $\tau = 0$ is called variance. Correlation functions are available from the equations of fluctuation kinetics or from Monte Carlo simulation [17,18,33,34].

Fourier transformation of the drift velocity autocorrelation function [Eq. (3)] gives the spectral density of drift velocity fluctuations in the direction of interest (Wiener-Khinchine theorem) [3]:

$$S_v(\omega) = 4 \int_0^\infty \Phi(\tau) \cos(\omega\tau) d\tau \quad (4)$$

Electron velocity fluctuations induce voltage fluctuations on the sample terminals and current fluctuations in the circuit. It is a convention to deal with the open-circuit voltage fluctuations and the short-circuit current fluctuations unless otherwise mentioned. The current, which is usually measured outside the sample, can be related to the electron drift velocity inside the sample. In a similar way, the current fluctuations can be expressed in terms of the drift velocity and other fluctuations. In general, the relation is complicated, but it acquires a simple form in the case of a uniform electric field in a uniformly doped sample of constant cross section at high frequencies where electron number fluctuations can be ignored. Hence, the spectral density of current fluctuations S_I is proportional to that of drift velocity fluctuations

$$S_I(\omega) = e^2 n S_v(\omega) Q / L \quad (5)$$

where e is the elementary charge, n is the electron density, Q is the cross-sectional area, L is the sample length (interelectrode distance), ω is the circular frequency, and S_I

is determined in A^2s . Discussion of more complicated cases can be found elsewhere [34,36,45].

In general, the spectral density of current fluctuations is a tensor quantity, consisting of three diagonal and six off-diagonal components. A diagonal component results from the autocorrelation function of the time-dependent drift velocity component along the corresponding Cartesian axis [see Eq. (3)]. An off-diagonal component comes from the velocity covariation function [of a similar form as Eq. (3)], but containing the product of the time-dependent drift velocity components along two Cartesian axes. In an isotropic medium, for example, in an amorphous solid, the tensor of spectral density can be reduced to three diagonal nonzero components, the parallel to the applied electric field component and two transverse components; the latter two are equal to each other. In crystals, for example Si or Ge subjected to electric field, the off-diagonal components are also important.

2.2. Available Noise Power and Noise Temperature

Hot-electron velocity fluctuations and associated fluctuations of current dominate over other sources of fluctuations at microwave frequencies. The fluctuating, that is, time-dependent current, causes emission of electromagnetic waves into an open space or into the load (a coaxial cable, a waveguide, a coplanar line, etc.). Therefore, the semiconductor sample feeds the power into the load. The emitted noise power is of special importance in this frequency range, since the current fluctuation spectra (directly available from the velocity fluctuation spectra, in theory) are not measured at microwave frequencies directly. It is a convention to consider the emitted/absorbed noise power for matched impedances of the sample and the load, unless stated otherwise. Under this condition, the noise power is called the power available at the noise source or the available noise power.

The available noise power $P_n(f)$ emitted by a source of noise in a fixed frequency band Δf around a frequency $f = \omega/2\pi$ can be estimated by comparing it with the power radiated into the same frequency band by an absolutely blackbody kept at a known temperature. In case of equal powers at a given frequency, one can say that the equivalent noise temperature of the noise source at this frequency equals the absolute temperature of the reference blackbody. The equivalent noise temperature, or noise temperature, $T_n(f)$, multiplied by the Boltzmann constant k_B is, by definition, the power, per unit frequency band around the frequency f , dissipated by the sample into the matched load [4]:

$$T_n(f) = \frac{P_n(f)}{k_B \Delta f} \quad (6)$$

Hot-electron noise power depends on frequency, direction, electric field, and so on. This forces one to introduce frequency-, direction- and field-dependent equivalent noise temperature. In an isotropic medium, the nonequilibrium noise temperature differs in the directions parallel and transverse to the current. The hot-electron noise temperature $T_n(f)$ represents a property of an electron gas

differing from its energy temperature T_e , which is defined on the basis of the electron average energy, $T_e = (2/3)\langle \epsilon \rangle / k_B$.

In equilibrium, the noise temperature of the sample in question is independent of frequency over the wide range of frequencies, and equals the absolute temperature: $T_n = T_0$. The equilibrium noise spectrum is white (until $\omega \ll k_B T_0$; see Ref. 41), and the available noise power in this range of frequencies can serve for establishment of the absolute scale of temperature.

2.3. Spectral Density of Current Fluctuations and Noise Temperature

Noise power can be expressed in terms of spectral density of current fluctuations and impedances of the sample and the load. For the matched impedances one has

$$P_n(f) = \frac{1}{4} S_I(f) \operatorname{Re}\{Z(f)\} \Delta f \tag{7}$$

where S_I is the spectral density of current fluctuations determined under the short-circuit condition, and $Z(f)$ is the AC impedance of the sample around the DC bias point. (The matching of the sample and the load means that their impedances are equal.)

From Eqs. (6) and (7), the spectral density of short-circuit current fluctuations for hot electrons in a sample subjected to electric field E can be related to the noise temperature and the sample impedance

$$S_I(f, E) = \frac{4k_B T_n(f, E)}{\operatorname{Re}\{Z(f, E)\}} \tag{8}$$

where S_I , T_n , and Z are determined in a chosen direction (e.g., longitudinal or transverse to the electric field E for isotropic semiconductors). Thus, measurement of the impedance and the noise temperature are sufficient to obtain the experimental short-circuit value of current fluctuation spectral density for hot electrons. Since the same quantity is available from theory [see Eq. (5)], a comparison of the experimental data with the results of calculation is possible.

Voltage fluctuations are seldom considered at microwave frequencies. For completeness, note that the spectral density of voltage fluctuations on the sample terminals for the open circuit and the spectral density of current fluctuations under the short-circuit condition are inter-related, according to $S_V(f) = |Z(f)|^2 S_I(f)$.

2.4. Fluctuation–Dissipation Theorem and Its Extension

2.4.1. The Nyquist Theorem. As discussed above, the noise temperature at equilibrium equals the absolute temperature. Hence, for equilibrium it follows, from Eq. (8):

$$S_I(f) = 4k_B T_0 / \operatorname{Re}\{Z(f)\} \tag{9}$$

This relation is called the *Nyquist theorem* in the classical limit ($\hbar\omega \ll k_B T_0$). A sophisticated derivation of the Nyquist theorem can be found elsewhere [4].

2.4.2. The Einstein Relation. At equilibrium, the electron mobility and the diffusion coefficient are closely related according to the Einstein relation. For low-density nondegenerate electron gas, the relation is simplified to

$$D_0 = \mu_0 \frac{k_B T_0}{e} \tag{10}$$

where μ_0 is the low-field low-frequency electron mobility and D_0 is the zero-field diffusion coefficient in the expression for the diffusion current density, $j_d = -eD_0 \nabla n$, resulting from the electron density gradient ∇n .

2.4.3. Lorentz-Type Spectrum. The principle of energy equipartition means that the equilibrium mean energy contained in every degree of freedom equals $k_B T_0 / 2$. Applied to the mean energy of the all-electron mass center at equilibrium, the principle relates the drift velocity fluctuation variance in the direction of interest to the temperature

$$Nm \overline{v_d^2(t)} = k_B T_0 \tag{11}$$

where m is the electron effective mass.

For a rectangular sample, the variance of current at equilibrium can be presented as

$$\overline{I^2(t)} = e^2 N^2 \overline{v_d^2(t)} / L^2 = \frac{e^2 N}{m L^2} k_B T_0 \tag{12}$$

This equation relates equilibrium fluctuations of the current component in a given direction to the absolute temperature.

The electron momentum relaxation time τ_p in the simple expression for the low-field electron mobility,

$$\mu_0 = (e/m)\tau_p \tag{13}$$

determines the decay of corresponding fluctuations

$$\overline{\delta I(t) \delta I(t + \tau)} = \overline{\delta I^2} e^{-\tau/\tau_p} \tag{14}$$

Integration [see Eq. (4)] yields the frequency dependence of the spectral density of current fluctuations at equilibrium

$$S_I(\omega) = 4 \int_0^\infty \overline{\delta I^2} e^{-\tau/\tau_p} \cos(\omega\tau) d\tau = \overline{\delta I^2} \frac{4\tau_p}{1 + \omega^2\tau_p^2} \tag{15}$$

A spectral dependence like this is called a Lorentz spectrum.

Equations (12) and (15) lead to the Nyquist relation

$$S_I(\omega) = 4k_B T_0 e N \operatorname{Re}\{\mu(\omega)\} / L^2 \tag{16}$$

where the real part of AC mobility $\mu(\omega)$ is introduced:

$$\operatorname{Re}\{\mu(\omega)\} = \frac{(e/m)\tau_p}{1 + \omega^2\tau_p^2} \tag{17}$$

The electron mobility μ (determined by the momentum relaxation time constant τ_p) and the electron density n are the most important parameters of electron transport in semiconductors. According to the Nyquist relation, in the form of Eq. (16), the same parameters decide noise at equilibrium.

2.4.4. Fluctuation–Diffusion Relation. Velocity fluctuations of individual electrons cause fluctuations of their positions, resulting in diffusive spreading of a cloud of electrons, diffusion current, and other diffusion phenomena. As a result, an important relation exists between the diffusion coefficient and the spectrum of current fluctuations. Using the Einstein relation [Eq. (10)] and the Nyquist theorem [Eq. (16)] for $\omega\tau_p \ll 1$, one obtains [see Eq. (5)]:

$$S_v(0) = 4D_0 \quad (18)$$

So, the basic kinetic coefficients (mobility, diffusion coefficient) and spectral density of velocity fluctuations are interrelated through Nyquist [Eq. (16)], Einstein [Eq. (10)], and fluctuation–diffusion [Eq. (18)] relations at thermal equilibrium. Measurements or calculation of velocity fluctuation characteristics at equilibrium give no additional information not already available from the mobility.

2.5. Beyond the Fluctuation–Dissipation Theorem

Calculation of hot-electron noise is an independent problem of kinetic theory, which cannot be reduced to the calculation of the response of an electron system to external deterministic perturbation. So, in general, knowledge of the sample impedance is not sufficient for determination of excess noise. Nevertheless, under well-defined conditions, some useful relations can be applied to hot electrons in a biased semiconductor.

2.5.1. The Price Relation. Price [10] generalized the fluctuation–diffusion relation for a semiconductor subjected to a high electric field under the following conditions: (1) the system is electrically stable, that is, $\text{Re}\{\mu(E, f)\} > 0$; (2) two-carrier interaction is neglected; (3) the thermal bath is not perturbed; and (4) the electronic processes in the conduction band are essentially faster than those including energy levels in the gap (electron trapping) and the valence band (electron-hole recombination). It turns out that, as for the thermal equilibrium, the fluctuation–diffusion relations are valid for hot electrons

$$(S_v)_{xx} = 4D_{xx} \quad (19)$$

$$(S_v)_{xy} = 2(D_{xy} + D_{yx}) \quad (20)$$

where S_v stands for the tensor components of drift velocity fluctuation spectral density in the frequency range, where the maximum contribution comes from all intraband electronic processes.

Equations (19) and (8) lead to the equivalent form of the Price relation:

$$D_{xx}(E) = \frac{1}{e} k_B T_{nx}(E) \cdot \text{Re}\{\mu_{xx}(E)\} \quad (21)$$

where the hot-electron noise temperature T_{nx} is determined in the direction x , the electric field E being applied in any direction. The corresponding diagonal component of the real part AC mobility tensor, μ_{xx} , is determined at frequencies low, compared with the inverse time constants of the momentum relaxation and other relaxation processes inside the conduction band.

The Price relation is valid for hot electrons even when the Ohm, Einstein, and Nyquist relations do not hold. It is a useful relation for low-density, hot-electron gas, in contact with an unperturbed thermal bath of a semiconductor. The relation has suggested a convenient way to measure the components of the diffusion coefficient tensor for hot electrons, without introducing electron density gradient [21].

Further on, the diagonal components of the longitudinal and transverse directions to the applied electric field will be discussed (let the field be directed along the x axis): $(S_v)_{\parallel} = (S_v)_{xx}$ and $(S_v)_{\perp} = (S_v)_{yy}$.

2.5.2. Additional Correlation Due to Electron–Electron Collisions. The Price relation has been generalized [15] into

$$S_v = 4(D + \Delta) \quad (22)$$

where Δ is the tensor resulting from the additional correlation caused by the interelectron collisions [15,17,18,37]. The additional correlation arises only at nonequilibrium conditions, disappearing at equilibrium.

2.5.3. Excess Noise in Electron Temperature Approximation. Frequent electron–electron collisions establish hot-electron distributions governed by the electron temperature. In the electron temperature approximation for quasielastic scattering, the kinetic theory of fluctuations allows one to express the noise temperature in terms of conductivities, and lattice T_0 and electron T_e temperatures (13):

$$(T_n)_{\perp} = T_e \quad (23)$$

$$(T_n)_{\parallel} = T_e \left[1 + \frac{T_e}{4(T_e - T_0)} \left(\frac{\mu_{\parallel}}{\mu_{\perp}} + \frac{\mu_{\perp}}{\mu_{\parallel}} - 2 \right) \right] \quad (24)$$

where $(T_n)_{\parallel}$ and $(T_n)_{\perp}$ are the longitudinal and transverse noise temperatures, and μ_{\parallel} and μ_{\perp} are the longitudinal and transverse AC mobilities. Equations (23) and (24) hold at low microwave frequencies $\omega \ll \tau_e^{-1}$, provided the electron–electron collisions control the electron distribution in energy: $\tau_p \ll \tau_{ee} \ll \tau_e$ (here τ_{ee}^{-1} is the frequency of the interelectron collisions). It is noteworthy that the longitudinal excess noise depends on the small-signal mobilities in the longitudinal and transverse directions, this dependence disappearing in absence of hot-electron effects: when

either $T_e = T_0$ or Ohm's law holds and $\mu_{\perp} = \mu_{\parallel}$. One can notice a possible simplification at high electric fields, where $T_e \gg T_0$, the resultant expression demonstrating the same complex dependence on the deviations from Ohm's law.

2.6. Examples of Hot-Electron Fluctuation Spectra

In the previous section the main concepts, definitions, and important theoretic results on fluctuations near a non-equilibrium state were presented in the limit of low microwave frequencies. This section presents some examples of possible spectra of spatially homogeneous current fluctuations (for more details, see Ref. 18).

2.6.1. Convective Noise. Energy fluctuations contribute to fluctuations of current in the direction of a steady current. The contribution is easy to resolve in one-valley semiconductors in case of quasielastic scattering. Quasielastic scattering means that a collision changes the direction of the electron motion remarkably, with little effect on the absolute value of the electron velocity. The well-known example is electron scattering by acoustic phonons at not too low lattice temperatures; many collisions are needed for energy relaxation, so two time constants decide relaxation of fluctuations. They are the momentum relaxation time τ_p and the energy relaxation time τ_e ; the latter is larger than the first.

The spectral density of longitudinal current fluctuations in the presence of an external electric field contains the term due to energy fluctuation, resulting in the so-called convective contribution to noise [11,12]

$$S_I(\omega, E) = \frac{4\overline{\delta I^2}\tau_p}{1 + \omega^2\tau_p^2} + \frac{C}{1 + \omega^2\tau_e^2} \quad (25)$$

where C is the low-frequency ($\omega\tau_e \ll 1$) limit of the convective term. The latter is important, provided Ohm's law does not hold. The sign of deviation from Ohm's law decides the sign of C [12,16]: $C < 0$ in case of a sublinear current-voltage characteristic, and $C > 0$ for a superlinear one. The mobility decreases with increasing electron energy in lightly doped semiconductors. In this case, the convective contribution causes the partial suppression of current fluctuations in the longitudinal direction at frequencies $\omega\tau_e \sim 1$.

2.6.2. Intervalley and Real-Space Transfer Noise. In many-valley semiconductors the total number of electrons consists of the partial numbers corresponding to different valleys. Fluctuations of occupancies modulate the current and cause current fluctuations. Price [8] introduced the term *intervalley noise* to account for the extra contribution arising from the occupancy fluctuations.

Assuming that the intravalley processes are fast, as compared with the intervalley processes, the spectral density of velocity fluctuations in a chosen direction for a

simple two-valley model can be written as

$$S_v(\omega, E) = \frac{\bar{n}_1}{n} S_1 + \frac{\bar{n}_2}{n} S_2 + 4 \frac{\bar{n}_1\bar{n}_2}{n^2} \times (\bar{v}_1 - \bar{v}_2)^2 \frac{\tau_i}{1 + (\omega\tau_i)^2} \quad (26)$$

where τ_i is the intervalley relaxation time constant (inversely proportional to the squared intervalley coupling constant), n is the electron density, while $\bar{n}_1, \bar{v}_1, S_1$ and $\bar{n}_2, \bar{v}_2, S_2$ are the average electron densities, drift velocities, and spectral densities of velocity fluctuations in valleys of types 1 and 2, respectively. Consequently, hot-electron noise in a many-valley semiconductor is not equal to the sum of the corresponding intravalley contributions weighted by the partial numbers of electrons. The last term in Eq. (26) is always positive; it vanishes in two cases: for equivalent valleys, when $\bar{v}_1 = \bar{v}_2$, and at thermal equilibrium, when $\bar{v}_1 = 0$ and $\bar{v}_2 = 0$. Thus, current is necessary for the contribution from intervalley fluctuations, but electron heating is not necessary, in general. For example, at a relatively high lattice temperature, the transitions between nonequivalent valleys can lead to intervalley noise at low electric fields, without electron heating.

From Eqs. (19) and (26) one obtains a simplified expression for the intervalley diffusion

$$\Delta D = \frac{\bar{n}_1\bar{n}_2}{n^2} (\bar{v}_1 - \bar{v}_2)^2 \tau_i \quad (27)$$

Expressions given by Eqs. (26) and (27) are also suitable to describe excess noise and diffusion caused by transverse electron transitions from one layer to another in semiconductor structures containing layers with different electron mobilities. The related noise, appearing in the longitudinal direction, is called real-space-transfer noise.

3. EXPERIMENTAL TECHNIQUES

Noise spectroscopy, unlike the usual optical one, deals with relaxation, that is, aperiodic processes. Different electronic processes, characterized by relaxation times τ_m , cause steps at frequencies around $\omega\tau_m = 1$. Each step has a simple Lorentzian form, provided the decay of fluctuations is exponential. As mentioned, hot-electron noise results from the kinetic processes taking place inside the conduction band. Their relaxation times are in the picosecond and subpicosecond range. Therefore, microwave and higher frequencies serve best for experimental investigation of hot-electron fluctuation spectra. In this range of frequencies, other sources of noise, such as $1/f$ fluctuations, generation-recombination noise, and the like, do not mask hot-electron effects.

3.1. General Requirements

3.1.1. Samples. A semiconductor sample for hot-electron noise measurements at microwave frequencies is a nonlinear resistor. A typical shape is a rectangular

parallelepiped, with two Ohmic electrodes at its bases. For investigation of epitaxial conductive channels, coplanar ohmic electrodes are more convenient. The epitaxial sample is cut from a transmission-line-model structure. A standard coplanar configuration with different inter-electrode distances (often exploited to estimate contact resistance) is quite acceptable. Longitudinal and transverse noise temperatures can be measured by placing the sample oriented either normal or parallel to the wide walls of the waveguide. Fluctuations of current excite the H_{10} mode in the waveguide, and the AC electric field of the emitted noise, depending on the sample orientation, is either parallel or transverse to the bias field.

On-wafer microwave noise measurements can be performed using microprobes. Each microprobe consists of a central wire and two side wires attached for screening. Microprobes are connected to hard coaxial lines or waveguides, and are put in contact with the sample electrodes on the wafer.

3.1.2. Pulsed Measurements of Hot-Electron Noise. Spectral analyzers are now commercially available for a wide range of frequencies up to and including the V band of millimeter waves. They operate in a cw mode and support standard cw measurements of noise in semiconductor devices in many laboratories. However, investigation of hot-electron effects and other effects at high electric fields require pulsed rather than CW modes of operation. Pulsed measurements help to avoid thermal walkout, due to the Joule effect prevailing in a CW mode. The increase in the lattice temperature masks hot-electron effects. Unfortunately, spectral analyzers for pulsed measurements are not commercially available yet, and radiometric techniques operating at fixed frequencies are used to obtain the data specific to hot electrons. The noise power in the chosen frequency band Δf at frequency f is selected by a filter, then amplified and fed into a radiometer for noise power measurement.

3.1.3. Waveguide and Coaxial Techniques. Pulsed measurements of noise power impose several special requirements. The noise must be measured when the electric field is on, that is, when the radiometer is opened for a short time. One has to deal with a low and extremely short noise signal in the presence of high pulsed voltage, the latter penetrating into the noise-measuring circuit and disturbing the sensitive amplifier, unless the radiometric circuit is safely decoupled from the one which is used to heat the electrons. The decoupling is easily achieved at microwave frequencies. This frequency range is also useful for another reason—flicker and generation-recombination noise sources are cut off at microwaves and do not interfere with hot-electron noise measurements.

Measurement at high electric fields introduces a problem. The electric field changes the sample impedance and causes a mismatch of the sample to the load—the transmission line connecting the sample to the radiometer. The mismatch must be eliminated by changing the load impedance.

These problems have been solved by developing a waveguide-type short-time-domain gated modulation radiometer [47]. Low transmission losses in waveguides narrowband low-noise, high-gain parametric microwave amplifier available at microwave frequencies, efficient filtering out of parasitic signals, make a waveguide-type radiometer a valuable instrument for research of hot-electron fluctuations [18,24].

Coaxial techniques have also been widely used [19,20,27,29] (see also Ref. 24). The coaxial technique, using a wideband amplifier, appropriate filters, and pulsed bias, assures measurement of hot-electron noise over a wide range of frequencies, without changing the sample-holder hardware.

3.2. Waveguide-Type Short-Time-Domain Gated Radiometer

3.2.1. Radiometric Setup. Figure 1 presents a schematic view of the radiometric setup for hot-electron noise

Figure 1. A schematic setup for hot-electron microwave noise power measurements: 1—the investigated sample in the waveguide; 2—the pulsed voltage generator; 3—the master generator; 4—the microwave generator; 5—the microwave line; 6—the SWR indicator; 7,11—the microwave switches; 8—the impedance transformer; 9—the resistance bridge; 10,13—the reference noise generators at $T_0 = 293$ K; 12—the reference noise generator at $T = (T_0 + 200)$ K; 14—the modulator; 15—the gated modulation radiometer; 16—the indicator.

measurements at microwave frequencies. The experimental procedure for determining the noise temperature T_n consists of two steps.

The first step is the measurement of the current–voltage characteristic and matching the waveguide impedance to that of the sample at each bias. The bias voltage pulses are typically from 1 to 5 μ s duration, fed at a 125 Hz repetition rate. The master generator 3 drives the pulse voltage generator 2 and the microwave generator 4. When microwave switch 7 (Fig. 3) is connected to port 7a, the microwave generator 4, the microwave line 5, and the transformer 8 are used to match the sample, that is, to reach the minimum standing microwave ratio. The resistance bridge 9 controls the sample resistance at each bias level.

The second step is the noise temperature measurement of the sample at a chosen bias. The switches 7 and 11 are connected to ports 7b and 11a, respectively. The noise signals from the sample 1 and the reference noise generator 13 are periodically fed into the input of the gated modulation radiometer, which is opened twice during the period of modulation: first, to connect the biased sample 1 to the radiometer, and for the second time to connect the reference noise generator 13. The difference between the signal levels is used to determine the noise temperature of hot electrons. The delay of the gating pulse ensures the noise power measurements before, during, and after the voltage pulse, if necessary. This is sufficient to control the channel overheat. The best matching data (transformer data) obtained for each bias are used. The standard noise reference sources 10 and 12 are connected to check the zero level (switch at port 11c) and the gain of the radiometer amplifiers (port 11b). The limit parameters of the X-band radiometer with 10^{-7} s gating time are as follows. The power sensitivity 10^{-15} W, the systematic error 0.25 dB, the noise temperature range up to $100 k_B T_0$.

3.2.2. Measured and Available Noise Power. The measured noise power data are sufficient to determine the available noise power, provided the sample is matched to the waveguide and the waveguide losses (and the associated waveguide related noise) are negligible. Since the sample impedance is field-dependent, the optimal conditions are not achieved over the wide range of electric field values. Losses and mismatch are corrected by additional microwave measurements.

3.2.3. Small-Signal Response and Current Fluctuations. The spectral density of current fluctuations $S_I(E)$ is determined from the data on noise temperature $T_n(E)$ and small-signal AC conductance $\text{Re}\{Y(E)\}$ of the sample, according to Eq. (8). Let us give a brief description of the technique to measure $\text{Re}\{Y(E)\}$, operating at the pulsed bias and using the same sample mounting, which is compatible with the gated radiometer. First, the standing-wave ratio $K(E, B=0)$ is measured at a strong electric field E at zero magnetic field at the ambient temperature. Then, the electric field is switched off, and the previous value of the standing-wave ratio is reached at zero electric field $K(E=0, B)=K(E, B=0)$, by changing the sample conductance with external magnetic field B or by changing

the lattice temperature. Now, the DC low-field conductance is measured in the standard way, at a very low DC electric field. Since a strong inequality holds at microwave frequencies, $(\omega\tau_p)^2 \ll 1$, one has $Y(\omega=0, E=0, B)=\text{Re}\{Y(\omega, E=0, B)\}$, where $Y(\omega, E=0, B)$ is the zero-field AC admittance at the microwave frequency in the magnetic field. The equality of the standing-wave ratios means that the small-signal microwave AC impedances are also equal, and $\text{Re}\{Y(\omega, E, B=0)\} = Y(\omega=0, E=0, B)$. Therefore, the required small-signal conductance at the microwave frequency under strong pulsed electric field E is available from the zero-field DC conductance, measured at a low electric field. This technique allows one to determine the small-signal conductance at the microwave frequency in the direction parallel and transverse to the bias field E .

3.2.4. Extremely High Electric Fields in Conductive Channels. Experimental study of hot-electron noise in conductive channels at extremely high electric fields is hindered by host crystal heating and thermal breakdown. A technique was developed to perform the measurements at fields up to the impact ionization threshold [30]. A nanosecond/microwave sample holder was designed to perform short-time-domain pulsed measurements of hot-electron noise power at microwave frequencies. The sample was placed into the coaxial part of the holder, enabling the application of 100 ns pulses of electric field along the channel. For coupling the investigated channel to the waveguide, a T-shaped antenna was used. Matching of the channel circuit to the waveguide was controlled by the standing-wave-ratio meter. The noise power emitted by the channel into the waveguide was compared with that of the “blackbody” radiation source kept at known temperature. This technique was applied to measure the equivalent noise temperature of hot electrons in the channel in the direction of the applied electric field. The average fields up to 300 kV/cm were reached in standard doped ungated GaAs channels for field-effect transistors.

4. EXPERIMENTAL RESULTS ON HOT-ELECTRON NOISE

Failure of the fluctuation–dissipation relation at nonequilibrium conditions means that spectra of noise are rich, containing many features, and knowledge of electron density and mobility is not sufficient to predict noise characteristics of a particular semiconductor subjected to a high electric field. Detailed information on excess noise is available, either from noise measurements or from realistic model calculations. This article contains the experimental results selected to illustrate the most specific effects of hot electrons on excess noise.

4.1. Anisotropy of Hot-Carrier Noise

4.1.1. Longitudinal and Transverse Noise Temperature. Hot-electron noise temperature T_n is an anisotropic quantity. The directions parallel and transverse to the steady current are not equivalent, even in the simplest case of a spherically symmetric band structure and isotropic scattering mechanisms. This is illustrated in Fig. 2, which presents the noise temperatures measured for p-type

Figure 2. Equivalent noise temperature of hot holes increases with applied electric field in different ways when measured in the longitudinal and transverse directions to the steady current. Experimental data for p-type germanium [22] ($p = 1.5 \times 10^{14} \text{ cm}^{-3}$, $T_0 = 80 \text{ K}$). Solid curves are guides to the eye.

germanium at 9.6 GHz frequency and 80 K lattice temperature [21]. The origin of the transverse noise temperature is similar to that at equilibrium—it is closely related to the hole kinetic energy. Therefore, the measured transverse noise temperature gives experimental evidence that the holes become hot when subjected to a high electric field. This effect is not masked by contributions from the fluctuations that modulate the steady current flow and appear in the longitudinal direction.

4.1.2. Transverse Noise Temperature and Energy Relaxation. For a simple band structure in the carrier temperature approximation, the transverse noise temperature equals the carrier temperature; the latter is determined by the mean energy of carriers [see Eq. (23)]. Monte Carlo simulation shows this to be approximately true for holes in p-type germanium [31], where measurements of the transverse noise temperature can serve for estimation of the mean energy of hot holes, $\langle \varepsilon \rangle \approx (3/2)k_B(T_n)_\perp$, and of the energy relaxation time constant τ_e :

$$\tau_e = \frac{\langle \varepsilon \rangle - \langle \varepsilon_0 \rangle}{e(\bar{v}_d \mathbf{E})} \approx \frac{3}{2} \frac{k_B((T_n)_\perp - T_0)}{e(\bar{v}_d \mathbf{E})} \quad (28)$$

Figure 3 presents the dependence on the applied electric field of the energy relaxation time constant obtained for p-type Ge, according to Eq. (28) from the experimental data on the transverse noise temperature and the steady drift velocity \bar{v}_d [48]. Values exceeding 20 ps are obtained at low electric fields. As is often the case, the energy relaxation time constant decreases on carrier heating.

4.1.3. Tensor of Diffusion Coefficients. The first experimental results on diffusion coefficient tensor components for hot majority carriers were obtained using the noise technique [20]. The longitudinal and transverse hot-electron noise temperatures were measured at 9.6 GHz for n-type Ge, and the Price relation [Eq. (21)] was used to obtain the electric field dependence of the diffusion coefficient tensor components (see Fig. 4). The transverse

Figure 3. Hot-hole energy relaxation time constant τ_e in p-type germanium, deduced from the transverse noise temperature measured in the $\langle 110 \rangle$ direction for electric field applied in $\langle 1\bar{1}0 \rangle$ direction [48]. The time constant decreases as the electric field increases. Solid curve is a guide to the eye. $p = 1.5 \times 10^{14} \text{ cm}^{-3}$, $T_0 = 80 \text{ K}$.

component at nonequilibrium was found to exceed its value at equilibrium. The longitudinal component decreases as the electric field increases. As mentioned earlier (see Section 2.6.1), the energy fluctuations contribute to the longitudinal rather than the transverse fluctuations [see Eq. (25)]. Consequently, Fig. 4 gives experimental evidence of the negative contribution of the convective noise to the spectral density of longitudinal current fluctuations [11,12].

4.1.4. Comparison to Time-of-Flight Experiment. It would be interesting to compare the results on hot-carrier diffusion obtained by the noise technique with those available from other experiments. Time-of-flight technique (see Ref. 33) provides direct observation of longitudinal diffusion. In this technique, a sheet of electrons (or holes) drifts in an electric field in a semi-insulating plate placed into a charged condenser. The shape of the pulse of the condenser discharge current contains information on the average time of flight and its dispersion, where the latter

Figure 4. Hot-electron diffusion coefficients differ in the longitudinal and transverse directions to the steady current. Experimental data for n-type germanium [21] ($n = 2 \times 10^{14} \text{ cm}^{-3}$, $T_0 = 300 \text{ K}$).

is dependent on the sheet spreading, with hot-electron diffusion among other possible causes. Noise and time-of-flight experiments are difficult to perform on exactly the same material, because of almost incompatible requirements inherent in these techniques. Insulating or semi-insulating samples with rectifying contacts are preferable in the time-of-flight experiment, while the noise experiment must be performed on doped (better on lightly doped) samples with ohmic electrodes. As already mentioned, the latter requirements are important for matching the sample to the input circuit of the microwave radiometer, and in order to avoid contribution from shot noise. In spite of these difficulties, a few successful experiments have provided some valuable comparisons. Figure 5 compares the longitudinal tensor components of hot-hole diffusion coefficient available from noise (closed circles) and spreading (open circles) experiments, performed on silicon at 300 K [25]. The agreement is good throughout the range of electric fields, where the results are available from both experiments.

4.2. Excess Noise Spectra

As a rule, several kinetic processes contribute to longitudinal fluctuations. This leads to rich noise spectra, Lorentz-type contributions appearing as steps at $\omega \ll 1/\tau_m$. So, spectral investigation of excess noise in the current direction deserves more attention than that in the transverse direction. Herein-after the focus will be on the longitudinal fluctuations, longitudinal noise, and other longitudinal quantities. For simplicity, the subscript indicating the direction of measurements is omitted.

4.2.1. Generation-Recombination and Intervalley Noise in Silicon. Measurements of noise spectra at low frequencies necessitate application of long pulses of voltage, and the Joule effect limits the range of electric fields where hot-electron effects can be investigated experimentally. Figure 6 shows the spectral density of longitudinal current fluctuations measured in $\langle 100 \rangle$ direction for n-type silicon at 200 V/cm at 78 K temperature (Fig. 6, symbols, see Ref. 24). In addition to $1/f$ noise at low frequencies, two

Figure 5. Longitudinal diffusion coefficient of hot holes in silicon at $T_0 = 300$ K: the results obtained from noise experiments (closed circles) match those available from spreading experiments (open circles) [25].

Figure 6. Experimental results on spectral density of longitudinal current fluctuations in n-type Si (squares [24]) in the frequency range from 1 MHz to 10 GHz can be described by two Lorentz-type contributions (curves) with the time constants $\tau_R = 20$ ns and $\tau_v = 50$ ps. $S_I \parallel \mathbf{E} \parallel \langle 100 \rangle$, $T_0 = 78$ K, $n = 3 \times 10^{13}$ cm $^{-3}$, $E = 200$ V/cm.

plateaus of the excess noise are resolved in the frequency range below 10 GHz. The fluctuations of electron number in the conduction band dominate at frequencies below 50 MHz, while the hot-electron fluctuations prevail at microwave frequencies. The solid curve is the fitted approximation, assuming 20 ns and 50 ps time constants for two Lorentz-type contributions [see Eq. (15)]. The hot-electron contribution (dashed curve) dominates in the frequency range $\omega\tau_R \gg 1$, where $\tau_R = 20$ ns is the time constant of the generation-recombination process.

4.2.2. Intervalley Noise, Comparison to Monte Carlo Data. Important information on the origin of hot-electron fluctuations in n-type Si at $\omega\tau_R \gg 1$ (Fig. 6) follows from comparison [44] of the longitudinal fluctuations measured in two directions of applied electric fields, $\mathbf{E} \parallel \langle 100 \rangle$ and $\mathbf{E} \parallel \langle 111 \rangle$ (see the open and closed circles in Fig. 7). Due to the conduction band structure of silicon, all valleys are oriented at the same angle to the electric field when the latter is applied along the $\langle 111 \rangle$ axis. Consequently, there is no intervalley noise in this configuration, but the intervalley noise is activated when the valleys are made nonequivalent, for example, for $\mathbf{E} \parallel \langle 100 \rangle$ [see Eq. (26)].

The results of Monte Carlo simulation of longitudinal velocity fluctuations [49] (Fig. 7, solid lines) give a satisfactory description of the experimental data (Fig. 7, symbols). In the configuration $\mathbf{E} \parallel \langle 111 \rangle$ (curve 3 of Fig. 7), corresponding to no intervalley noise, the convective noise leads to a negative contribution due to energy fluctuations at frequencies below $\omega \sim 1/\tau_e$ (11,12) [see Eq. (25)]. The results of Monte Carlo simulation allow one to estimate the energy relaxation time constant for this configuration: $\tau_e \approx 15$ ps at $E = 200$ V/cm, $T_0 = 78$ K (curve 3 in Fig. 7).

There is a competition of the convective and intervalley noise in the configuration $\mathbf{E} \parallel \langle 100 \rangle$. For the energy relaxation time constant in this configuration at $E = 200$ V/cm, $T_0 = 78$ K, one obtains $\tau_e \approx 5$ ps. The energy relaxation time constant appears to be shorter than the intervalley time constant $\tau_i \approx 50$ ps, and the local minimum is resolved at

Figure 7. Experimental and simulated spectra of longitudinal velocity fluctuations of hot electrons in n-type Si at $T_0 = 78$ K, $E = 200$ V/cm [44] to illustrate the intervalley noise observed at frequencies below 10 GHz for the field \mathbf{E} applied along (100) axis, and the negative-convective-type contribution prevailing at frequencies below 20 GHz for $\mathbf{E} \parallel (111)$. Experimental results: $\mathbf{E} \parallel (100)$ (open circles), $\mathbf{E} \parallel (111)$ (closed circles). Results of Monte Carlo simulation 1— $\mathbf{E} \parallel (100)$, intervalley transitions neglected; 2— $\mathbf{E} \parallel (100)$, intervalley transitions included; 3— $\mathbf{E} \parallel (111)$ the intervalley transitions are included, but they do not contribute because $\bar{v}_1 = \bar{v}_2$; see Eq. (26).

frequencies $\tau_i^{-1} < \omega = 2\pi f < \tau_v^{-1}$, as evidenced by the Monte Carlo simulation data (curve 2 in Fig. 7).

As discussed in relation to Fig. 3, the energy relaxation time constant decreases as the electric field increases. The experimental data and the results of Monte Carlo simulation show [18] that the intervalley time constant τ_i in n-type Si becomes shorter at a higher electric field as well.

4.2.3. Hot-Carrier Effect on Generation-Recombination Noise. The Lorentz-type step at $\omega \sim \tau_R^{-1}$ due to generation–recombination fluctuations shifts toward higher frequencies at higher electric fields, as shown experimentally for p-type silicon at 77 K (see Ref. 25). This behavior is caused by the hot-hole effect on generation–recombination

Figure 8. Lorentz-type contributions due to generation–recombination noise (curves) are important at $f < 1$ GHz and are not important at 10 GHz frequency, where the longitudinal excess noise temperature $(T_n)_{\parallel} - T_0$ results from hot electrons noise. Experimental data on lightly doped n-type InP ($n = 2.7 \times 10^{15} \text{ cm}^{-3}$) at $T_0 = 300$ K (29) (symbols): 1—10 kV/cm, 2—9 kV/cm, 3—8 kV/cm, 4—7 kV/cm, 5—6 kV/cm, 6—5 kV/cm, 7—4 kV/cm, 8—3 kV/cm, 9—2 kV/cm.

noise. Indeed, hole trapping and release probabilities (entering the time constant of the generation–recombination process) depend on the electric field and the hot-hole energy, in particular. For spectral analysis of the noise in p-type silicon, including hot-hole velocity fluctuations and the hot-hole effect on generation–recombination fluctuations, see review papers [25,34].

4.2.4. High Electric Fields. The hot-electron noise spectra at moderate fields in the frequency range down to 50 kHz (see Fig. 6) were obtained using long pulses of voltage. However, at high electric fields, the short-time-domain pulsed technique must be used in order to avoid lattice heating. This technique puts the limit on the frequency range $f \gg 1/\Delta t$, where Δt is the voltage pulse duration. As a result, the experimental noise spectra over the wide range of electric fields are available at high frequencies, usually exceeding 100 MHz [25,29,50].

The experimental results on frequency-dependent longitudinal noise temperature in n-type InP (29) (Fig. 8, symbols) can be interpreted in terms of sources of noise caused by generation–recombination and velocity fluctuations (Fig. 8, solid lines). At X-band microwave frequencies, where the contribution of generation–recombination noise is negligible, the kinetic processes inside the conduction band of InP contribute to the longitudinal noise. Again, 10 GHz frequency proves to be convenient to investigate details of hot-electron noise, its dependence on electric field, sample length, lattice temperature, and semiconductor parameters.

4.3. Intervalley Noise in n-Type GaAs and InP

4.3.1. Dependence on Intervalley Separation Energy. As is well known, the intervalley separation energy in InP is wider as compared with that of GaAs. Therefore, higher electric fields are required for hot-electron intervalley transfer, and the resultant noise to appear in InP [24,25]. The intervalley noise dominates at electric fields over 2 kV/cm in GaAs and over 6 kV/cm in InP (Fig. 9), which are below the threshold field for negative

Figure 9. A higher intervalley separation energy causes the intervalley noise to appear at higher fields [24], as illustrated by experimental results on longitudinal noise temperature for n-type GaAs [squares, $\mu_0 = 7500 \text{ cm}^2/(\text{V} \cdot \text{s})$, $n = 0.9 \times 10^{15} \text{ cm}^{-3}$] and n-type InP [crosses, $\mu_0 = 4600 \text{ cm}^2/(\text{V} \cdot \text{s})$, $n = 3.2 \times 10^{15} \text{ cm}^{-3}$].

differential mobility due to the intervalley transfer, respectively, around 3.5 kV/cm and 12 kV/cm at 300 K. This is a good illustration that even a small number of high-energy electrons (available, e.g., at $E \sim 6$ kV/cm in InP) is essential for hot-electron noise.

4.3.2. Intervalley Coupling Constants. The intervalley contribution to the spectral density of velocity fluctuations is inversely proportional to the squared intervalley coupling constant [see Eq. (26) and the text following it]. This important parameter of hot-electron intervalley transfer can be estimated by comparing the experimental results with those obtained by model calculations. Monte Carlo simulation [31,51] predicted the intervalley-related maximum of the spectral density of longitudinal velocity fluctuations in n-type InP, to appear at around 8 kV/cm fields. Figure 10 compares the results of simulation with the experimental ones. The experimental results obtained on long samples (crosses 1 in Fig. 10; see Ref. 24) are in a reasonable agreement with those of simulation when the coupling constant 1.10^9 eV/cm is assumed (Fig. 10, solid line, [51]). A lower value of the coupling constant would be responsible for a longer intervalley time constant and the higher values of the intervalley contribution to $S_v(E)$ [see Eq. (26)], as illustrated by dashed curve 6 in Fig. 10.

The spectral density of intervalley fluctuations in lightly doped n-type GaAs [28] is essentially higher as compared with InP. This comparison suggests a low value of the intervalley coupling constant. The problem was considered in the framework of a three-valley (Γ -L-X) model, and a rather low Γ -L coupling constant, 1.8×10^8 eV/cm [52], was proposed. The model predicted a strong frequency dependence of S_v at around 10 GHz, which was not confirmed by the experimental data [50], and an intermediate value of

Figure 10. Normalized longitudinal spectral density of current fluctuations depends on sample length in the field range where the intervalley noise dominates in n-type InP. The experimental data on long samples (symbols 1) compared with the results of Monte Carlo simulation (curves 5 and 6) provide an estimate of the intervalley coupling constant. Experimental results for samples of different length L (symbols): 1— $L=10 \mu\text{m}$, $n=3.2 \times 10^{15} \text{ cm}^{-3}$, $\mu_0=4600 \text{ cm}^2/(\text{V}\cdot\text{s})$ [24], 2— $L=5 \mu\text{m}$, $n=2.7 \times 10^{15} \text{ cm}^{-3}$, $\mu_0=4500 \text{ cm}^2/(\text{V}\cdot\text{s})$ [28] 3— $L=5 \mu\text{m}$, $n=2.3 \times 10^{15} \text{ cm}^{-3}$, $\mu_0=4600 \text{ cm}^2/(\text{V}\cdot\text{s})$ [24], 4— $L=1.7 \mu\text{m}$, $n=5.4 \times 10^{15} \text{ cm}^{-3}$, $\mu_0=4500 \text{ cm}^2/(\text{V}\cdot\text{s})$ [23]. Results of Monte Carlo simulation for long samples [46] assuming different intervalley coupling constant (curves): 5— 1×10^9 eV/cm; 6— 3×10^8 eV/cm.

the Γ -L coupling constant, 3×10^8 eV/cm, was assumed to avoid contradictions of the three-valley model with the experimental data (see Ref. 24 and references cited therein).

4.3.3. Intervalley Noise Due to L and X Valleys in GaAs. Sources of hot-electron noise with threshold energies corresponding to the L and X valleys in n-type GaAs are resolved using nanosecond pulses of voltage applied to short channels. Figure 11 shows the excess noise temperature $\Delta T_n = T_n - T_0$, plotted as a function of voltage V at $T_0 = 293$ K ambient temperature [30]. As the channel length is $0.2 \mu\text{m}$, the average fields up to 300 kV/cm are reached in standard-doped GaAs channels ($3 \times 10^{17} \text{ cm}^{-3}$). The steep increase in current accompanies the increase in noise temperature at the highest fields—an experimental evidence for the impact ionization noise of hot electrons resolved in a conduction channel.

The $\Delta T_n(V)$ dependence can be decomposed into four sources of hot-electron noise; thin lines in Fig. 11 indicate possible contributions of each source. The lowest threshold appears at around 0.2 V; it results from the resonant scattering of hot electrons by the impurity levels located inside the conduction band [53] (see also Ref. 54). The thresholds at 0.3 and 0.5 V result from scattering of almost ballistically accelerated electrons into the L and X valleys of the conduction band (the L and X valley energies are close to 0.3 eV and 0.5 eV, respectively). The extrapolation of the experimental data on $\Delta T_n(V)$ obtained at the highest average fields yields the threshold energy for the impact ionization noise; the threshold energy, as expected, exceeds the forbidden gap.

The quasisaturation of hot-electron noise temperature takes place at the average electric fields, ranging from 50 to 200 kV/cm. This very specific noise behavior has been used to estimate the time constant for the Γ -X transfer experienced by the high-energy electrons present in the Γ valley at the energy $\varepsilon > \varepsilon_X \approx 0.5$ eV: $30 \text{ fs} < \tau_{\Gamma X} < 60 \text{ fs}$ [30]. This estimate, based on the hot-electron noise data, provides an independent confirmation of the results available from femto-second and cw luminescence data.

Figure 11. Four sources of hot-electron noise (activated at different threshold energies) are resolved in n-type GaAs channel of submicrometer length ($n=3 \times 10^{17} \text{ cm}^{-3}$, $L=0.2 \mu\text{m}$) at $T_0=293$ K [30]. Voltage pulse duration; $2 \mu\text{s}$ (dots), 100 ns (squares). Solid curve stands for the sum of the contributions given by the thin curves.

4.4. Suppression of Hot-Electron Noise In Short Samples

Time and space are needed for the complete development of fluctuations, and hot-electron noise depends on sample dimensions. Indeed, a hot electron spends limited time in a short sample and cannot acquire the energy accessible in a longer sample. Since the tail of the autocorrelation function [see Eq. (3)] is cut off, Eq. (4) leads to lower values of the spectral density. Hence, sources of noise caused by relatively slow kinetic processes and/or appearing at high threshold energies are suppressed in short samples. In other words, threshold-type sources of noise appear at higher electric fields in short samples.

4.4.1. Suppression of Intervalley Noise. Figure 12 illustrates the length-dependent behavior of hot-electron noise in lightly doped n-type GaAs [40]. There is no dependence of the noise temperature T_n on sample length L in long samples (symbols 1 and 2 of Fig. 12). However, the same noise temperature requires essentially higher electric fields in short samples (see symbols 2 and 3, 4 in Fig. 12). For a fixed average electric field, say, $V/L = 3$ kV/cm, the noise suppression exceeds 10 dB as the sample length L is reduced from 7.5 μm (symbols 2) to 1.5 μm (symbols 3).

A detailed interpretation of suppression is reached by comparing the experimental results with those obtained by Monte Carlo simulation. Figure 13 presents the spectral density of current fluctuations $S_I(E)$ normalized to its value at zero bias $S_I(0)$. The experimental data for n-type GaAs are presented by open symbols from 1 to 4. As noted earlier, the main source of current fluctuations in long samples at fields over 2 kV/cm results from hot-electron intervalley transfer. This source of fluctuations is heavily suppressed in a 1 μm sample (Fig. 13, points 4): the monotonously increasing dependence on electric field changes into a monotonously decreasing one, typical for one-valley semiconductors. Closed symbols in Fig. 13

Figure 12. Suppression of the intervalley noise in short samples as illustrated by experimental results on longitudinal noise temperature of hot electrons in n-type GaAs at room temperature [28,40]. Samples length and other data: 1— $L = 1000 \mu\text{m}$, $\mu_0 = 6000 \text{ cm}^2/(\text{V}\cdot\text{s})$, 2— $L = 7.5 \mu\text{m}$, $n = 10^{15} \text{ cm}^{-3}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V}\cdot\text{s})$, 3— $L = 1.5 \mu\text{m}$, $n = 10^{15} \text{ cm}^{-3}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V}\cdot\text{s})$, 4— $L = 1 \mu\text{m}$, $n = 10^{15} \text{ cm}^{-3}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V}\cdot\text{s})$.

Figure 13. Transition from the monotonously increasing (diamonds 1) to the monotonously decreasing (open triangles 4) dependence on electric field of the normalized longitudinal spectral density of current fluctuations, illustrating suppression of the intervalley fluctuations in short (micrometer) samples. Experimental results correspond to lightly doped n-type GaAs (open symbols, curves are to guide the eye): 1— $L = 1000 \mu\text{m}$, $\mu_0 = 6000 \text{ cm}^2/(\text{V}\cdot\text{s})$, (28); 2— $L = 11 \mu\text{m}$, $\mu_0 = 5200 \text{ cm}^2/(\text{V}\cdot\text{s})$ [45]; 3— $L = 7.5 \mu\text{m}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V}\cdot\text{s})$ [37], 4— $L = 1 \mu\text{m}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V}\cdot\text{s})$ [37]. Monte Carlo simulation data (closed symbols) correspond to different values of sample length and Γ - L intervalley coupling constant [50]: 5— $L = 7.5 \mu\text{m}$, $1.8 \times 10^8 \text{ eV/cm}$, 6— $L = 1 \mu\text{m}$, $1.8 \times 10^8 \text{ eV/cm}$, 7— $L = 1 \mu\text{m}$, $1 \times 10^9 \text{ eV/cm}$.

correspond to Monte Carlo simulation of hot-electron fluctuations [55] (nonuniformity of the electric field and space charge fluctuations are taken into account). There is a reasonable agreement between the results of experiment and simulation.

In a similar way, the hot-electron intervalley fluctuations observed in long samples of n-type InP at fields over 6 kV/cm are suppressed in short samples (Fig. 10). Indeed, the maximum of spectral density in 10 μm samples (Fig. 10, crosses 1) diminishes and disappears as the sample length L is reduced down to 1.7 μm (symbols 4).

4.4.2. Critical Length for Noise Suppression. Under steady flow of current, hot electrons are constantly leaving the sample, and equilibrium electrons are entering at the cathode. This “exchange” opens an additional (external) energy loss mechanism by the hot electrons present in the sample. The external loss is negligible, as compared with the internal loss in long samples, but its relative weight increases when the sample length L is reduced. At a certain critical length the external loss assumes primary importance. It is evident that the critical length is shorter, provided the internal loss is greater.

Figure 14 compares the hot-electron noise temperature at a fixed average electric field, $V/L = 4$ kV/cm, for GaAs samples of different length and doping [53]. The results can be interpreted in terms of the critical lengths required for the electrons to gain the threshold energy of the dominant source of noise. The curves in Fig. 14 assume two critical lengths used as fitting parameters: L_1 stands for the lucky

Figure 14. Suppression of hot-electron noise in short channels; essentially shorter lengths are needed for the suppression in the standard-doped n-type GaAs, as compared with the lightly doped samples, provided the same average electric field $V/L = 4 \text{ kV/cm}$ is applied [53]. Open squares— $n = 3 \times 10^{17} \text{ cm}^{-3}$, $\mu_0 = 4000 \text{ cm}^2/(\text{V} \cdot \text{s})$, closed squares— $n = 3 \times 10^{15} \text{ cm}^{-3}$, $\mu_0 = 7500 \text{ cm}^2/(\text{V} \cdot \text{s})$; solid curves are fitted approximations based on concepts of ballistic and dissipative critical lengths.

electrons, which do not undergo scattering events before they reach the threshold energy, and L_2 takes into account energy loss during electron acceleration to the same threshold energy. The curves correspond to $L_1 = 1.3 \mu\text{m}$, $L_2 = 3 \mu\text{m}$ for lightly doped (curve 1, Fig. 14) and to $L_1 = 0.3 \mu\text{m}$, $L_2 = 0.2 \mu\text{m}$ for standard-doped GaAs (curve 2). The critical lengths are shorter and the threshold energies are lower in the standard-doped GaAs channels.

4.5. Transition from Shot Noise to Hot-Electron Noise

So far uniformly doped samples with ohmic electrodes have been considered. These conditions favoring hot-electron noise rather than shot noise. However, most electronic devices contain barriers formed by nonuniform doping, surface charges, and heterojunctions. According to the Schottky formula [5] the spectral density of longitudinal current fluctuations due to shot noise increases proportionally to the constant current, while the corresponding dependence is steeper for hot electrons. In a diode, the shot noise prevails at low currents, but a transition to hot-electron noise can occur at high currents, unless the thermal breakdown takes place before the critical current is reached. The thermal breakdown has been avoided and the transition in question is observed in GaAs Schottky and planar-doped barrier diodes at high forward currents, by using short-time-domain radiometry of the noise power [56].

Figure 15 presents the spectral density of current fluctuations, S_I , measured [56] at 10 GHz frequency for the forward-biased GaAs Schottky diode and planar-doped barrier diode (PDBD). The measured spectral density is almost proportional to the current at very low current levels (Fig. 15), when the barrier controls the current and the shot noise dominates. The experimental points are close to the solid line (Fig. 15) standing for the Schottky formula $S_I = 2eI$. The sublinear dependence of $S_I(I)$ indicates onset of the screening effect of space charge of drift electrons. Eventually, at high currents, the sublinear

Figure 15. Spectral density of longitudinal current fluctuations of GaAs diodes demonstrates transition from shot noise to hot-electron noise at high forward currents [56]. Schottky diode (dashed line) and planar-doped barrier diode (PDBD, closed circles). Solid line is the Schottky formula for shot noise, $S_I = 2eI$.

dependence becomes superlinear. This change of the dominant source of fluctuations is accompanied by an onset of a different electron transport mechanism: the barrier diminishes and fails to control the current flow. These results give experimental evidence for transition to hot-electron-dominated noise in GaAs Schottky and planar-doped barrier diodes.

4.6. Noise in 2DEG Channels

Modern heterostructure growth technology provides a great variety of AlGaAs/GaAs, InAlAs/InGaAs, and InP/InGaAs channels for lattice-matched and pseudomorphic high-electron-mobility transistors (HEMT and PHEMT), containing two-dimensional electron gas (2DEG) confined in the quantum well (QW). High mobility of confined electrons is advantageous for fast operation of 2DEG channels. However, electron heating by an electric field applied along the channel is accompanied by enhanced chaotic motion of hot electrons in the plane of electron confinement, occupation of upper subbands, hot-electron deconfinement (real-space transfer) and other kinetic processes specific to a hot two-dimensional electron gas. The associated longitudinal fluctuations appear in QW channels [see Ref. 44]. Hot-electron velocity fluctuations due to real-space transfer have been resolved first in selectively doped AlGaAs/GaAs channels [40]. The experimental results are in reasonable agreement with the results of Monte Carlo simulation [57]. Moreover, the threshold field for this noise source increases as the heterobarrier height increases [58,59]. This supports the idea of transverse real-space transfer being responsible, among other factors, for the longitudinal fluctuations of current. A special case of real-space transfer is transverse tunneling of hot electrons across a thin barrier of AlAs, separating the 2DEG channel and the ionized donors in AlGaAs/GaAs/AlAs/GaAs structure. The associated longitudinal fluctuations are heavily suppressed in short channels [60]. The intersubband noise appears in δ -doped GaAs channels, where the upper subbands support higher electron mobilities as compared with more confined electronic states of the lower subbands. Dependence of hot-electron noise on the

quantum-well shape [61] is important in quasitriangular and quasirectangular quantum wells in InAlAs/InGaAs/InAlAs channels. These heterostructures can be heavily doped, in order to obtain high-density 2DEG useful for high-power applications. Heavy doping of the structures is accompanied by the excess fluctuations [62] absent in the low-density 2DEG.

4.6.1. Real-Space Transfer Noise. Figure 16 compares [59] the spectral density of longitudinal current fluctuations in GaAs samples and AlGaAs/GaAs single-heterojunction 2DEG channels. The local maximum of the spectral density appears (Fig. 16, squares and circles) at the intermediate fields $100 \text{ V/cm} < E < 2 \text{ kV/cm}$, which are low, as compared with the intervalley transfer field in GaAs. The height and position of the maximum depend on the Al mole ratio in the selectively doped AlGaAs layer: the source of fluctuations in question appears at a higher field (circles 2 in Fig. 16), when the hetero-barrier is higher. This is strong experimental evidence for hot-electron jumps from the QW into the AlGaAs layer and backward. The experimental data also show that this real-space transfer suppresses the intervalley fluctuations of hot electrons dominating in GaAs at fields over 2 kV/cm (see symbols and solid line in Fig. 16). The shape of the maximum is similar to that obtained by Monte Carlo simulation of the real-space transfer fluctuations [57], as illustrated by Fig. 17.

Interpret the maximum observed at 1 kV/cm field (Fig. 17, circles) in terms of Eq. (26). Since electron mobility is high in the quantum well channel and low in the adjacent doped layer of AlGaAs, the electron drift velocities \bar{v}_1 and \bar{v}_2 differ. The increase in electric field causes the monotonous decrease of electron density in the QW (the ratio \bar{n}_1/\bar{n}_2 decreases), and the maximum of spectral density forms at around $\bar{n}_1 \approx \bar{n}_2$ [see Eq. (26)]. Under assumption that $\bar{v}_1 - \bar{v}_2 \sim 10^7 \text{ cm/s}$ and $\bar{n}_1 \approx \bar{n}_2$, the real-space trans-

Figure 16. Spectral density of longitudinal velocity fluctuations in AlGaAs/GaAs quantum-well channels gives an experimental evidence for sources of fluctuations specific to two-dimensional electron gas (symbols) absent in GaAs samples (dashed curve) [58]. Al mole ratio in the spacer: 1–25% Al, $n = 6 \times 10^{11} \text{ cm}^{-2}$, $\mu_0 = 75,000 \text{ cm}^2/(\text{V}\cdot\text{s})$, 2–33% Al, $n = 2 \times 10^{11} \text{ cm}^{-2}$, $\mu_0 = 103,000 \text{ cm}^2/(\text{V}\cdot\text{s})$. Dashed line is for n-type GaAs [$n = 9 \times 10^{14} \text{ cm}^{-3}$, $\mu_0 = 77,000 \text{ cm}^2/(\text{V}\cdot\text{s})$]. Solid curves are guides to the eye.

Figure 17. Real-space transfer in AlGaAs/GaAs channel causes the maximum of spectral density of longitudinal velocity fluctuations appearing at electric fields well below those for the intervalley transfer. Open circles stand for the experimental results [59]: AlGaAs/GaAs, 33% Al, $n = 2 \times 10^{11} \text{ cm}^{-2}$, $\mu_0 = 103,000 \text{ cm}^2/(\text{V}\cdot\text{s})$, $T_0 = 80 \text{ K}$. Stars stand for the results of Monte Carlo simulation for a simplified model of a quantum well channel [52]. Solid lines are guides to the eye.

fer time constant is estimated from the maximum value of the spectral density: $\tau \sim 5 \text{ ps}$ [59]. The time constant obtained is short; this enables observation of the real-space transfer at 10 GHz frequency and supports the idea of reversible real-space transfer.

4.6.2. Longitudinal Fluctuations Due to Transverse Tunneling. A triple-heterojunction AlGaAs/ δ -GaAs/AlAs/GaAs structure has been designed [60] to separate the 2DEG channel from the doped layer by the thin layer of AlAs. Strong excess noise appears [60] at electric fields well below those for the intervalley transfer (Fig. 18, symbols). The barrier of AlAs is high and thin; therefore, electron jumps over the barrier are excluded, but the high-energy electrons can penetrate it by tunneling. It has been concluded [60] that transverse tunneling is responsible for the steep increase in the longitudinal hot-electron noise

Figure 18. Contribution of transverse tunneling through a thin barrier of AlAs to the spectral density of hot-electron longitudinal velocity fluctuations, appearing in AlGaAs/ δ -GaAs/AlAs/GaAs quantum-well (QW) channel at electric fields well below those for the intervalley transfer [60]. Experimental data for the QW channel [closed circles, $n = 1.3 \times 10^{12} \text{ cm}^{-2}$, $\mu_0 = 35,000 \text{ cm}^2/(\text{V}\cdot\text{s})$, $T_0 = 80 \text{ K}$] are compared with those for bulk n-type GaAs (see Fig. 16).

Figure 19. Experimental evidence for suppression (up to 15 dB at 1.1 kV/cm) of the longitudinal noise due to transverse tunneling of hot electrons in short AlGaAs/ δ -GaAs/AlAs/GaAs QW channels at 80 K [60]. Channel length: 1–18 μm , 2–3 μm . For the Hall effect data, see Fig. 18.

temperature (Fig. 19, open circles) and the maximum of spectral density of longitudinal velocity fluctuations (Fig. 18, closed circles) resolved at a field around 1 kV/cm at 80 K lattice temperature. In the framework of Eq. (26) under assumption $\bar{v}_1 - \bar{v}_2 \sim 2 \cdot 10^7$ cm/s, the time constant for the transverse tunneling is estimated to be $\tau \sim 10$ ps [60].

The transverse-tunneling-related noise source observed in a 18 μm channel at a 1 kV/cm field (open circles 1 in Fig. 19) is very weak in the 3- μm channel (closed circles 2). This strong dependence on channel length, being an illustration of suppression of hot-electron noise in short channels, suggests a way for an independent estimate of the transverse tunneling time constant using the electron transit time. The values for tunneling time constant estimated from these two independent experiments are in reasonably good agreement [60]. Similar results on the tunneling-time constant are available from luminescence data for resonant tunneling, while the nonresonant tunneling time constants are essentially longer.

5. SUMMARY

Hot-carrier noise in semiconductors, which is a special case of nonequilibrium noise, does not obey the fluctuation-dissipation theorem and other relations valid for electron gas at thermal equilibrium. Characteristics of hot-electron noise cannot be predicted from data on electron density and mobility measured at low electric fields; the noise spectra at high electric fields display features resulting from subtle details of semiconductor band structure and scattering mechanisms. Experimental investigation of these features at microwave frequencies, together with Monte Carlo simulation, provide the possibility to determine parameters (time constants, coupling constants, etc.) of fast kinetic processes in the conduction (or valence) band of a semiconductor subjected to a high electric field. Suppression of hot-electron noise, favoring low-noise operation of short channels at microwave frequencies, is shown experimentally and through Monte Carlo

simulation. A great variety of diverse sources of noise being resolved in low-dimensional channels demonstrates diagnostic possibilities of short-time-domain radiometry of hot-electron noise and high potentials of nanometric technology for development of high-speed, low-noise devices for electronics.

NOISE, LOW-FREQUENCY

PETER H. HANDEL
University of Missouri St. Louis

Low-frequency noise, containing fluctuations of current or voltage with frequency components below 10 kHz, is mainly fundamental $1/f$ noise and sometimes nonfundamental $1/f$ noise. In addition, shot noise, generation–recombination (GR) noise, and thermal noise, which are important at higher frequencies, also extend to the low-frequency domain. All these forms of electronic noise, each defined below, are characterized by the mean squared current fluctuation $\langle(\delta I)^2\rangle$ [or $\langle(\delta V)^2\rangle \equiv \text{RMS } \delta V^2$ for voltage], measured in series with (or across) the device or sample under test, when a constant voltage (or current) is applied, except for thermal noise, which is present even in thermal equilibrium, with no bias applied. All the other forms of noise present in addition to thermal noise are also known as current noise and are absent in thermal equilibrium. Nevertheless, $1/f$ noise and GR noise also modulate the RMS level of the thermal noise currents (or voltages) in thermal equilibrium, while the available power remains constant at $k_B T$ per hertz, where $k_B = 1.38 \times 10^{-23}$ J/K is Boltzmann’s constant and T the absolute temperature. These two forms of current noise are also called modulation noise, because they modulate the resistance. If a bandpass filter is inserted between the measuring device (usually a quadratic meter) and the noise source, then the spectral density of the fluctuations, $\langle(\delta I)^2\rangle_f \equiv S_I(f)$ [or $S_V(f)$] is obtained by dividing the measured mean square by the bandwidth Δf of the filter.

1. SHOT NOISE

With the notable exception of $1/f$ noise, also known as excess noise, the various type of noise mentioned above were well known and understood in the third decade of the twentieth century through the works of J. B. Johnson, H. Nyquist, and W. Schottky. For instance, shot noise is caused, in vacuum tubes, electron beams, Schottky diodes, p-n junctions, and any other device carrying a current, by the discrete, atomistic nature of electricity. It is easily described as a Poisson process, and is given at low

frequencies by

$$S_I(f) = 2eI_0 \quad (1)$$

where e is the electric charge of the charge carriers and I_0 the average electrical current in the direction of their motion. For electrons both e and I_0 are negative. The mean squared current in a frequency interval Δf is thus $2eI_0 \Delta f$. The general formula is given by Carson’s theorem, which gives the spectral density of a random uncorrelated repetition of identical processes with spectrum $\phi(f)$ and repetition rate λ as

$$2\lambda|\phi(f)|^2 \quad (2)$$

The case with arbitrary correlations present between the moments t_0 of passage was treated by C. Heiden [1] and is usually not called shot noise. The elementary process in shot noise is the current $i(t - t_0)$ caused by the passage of a single carrier. Therefore

$$\phi(0) = \int_{-\infty}^{\infty} i(t - t_0) dt = e \quad (3)$$

is the total charge e transported by a single carrier. With $e\lambda = I_0$, Carson’s theorem then gives Eq. (1). The term “shot noise” recalls the noise caused by small shot (or raindrops) falling on a drum.

$1/f$ noise, however, remained shrouded in mystery, and fundamental $1/f$ noise was understood only after the advent of the quantum $1/f$ theory [2] in 1975. It turns out there is always fundamental $1/f$ noise [3,4] caused by the quantum $1/f$ effect (Q $1/f$ E), a new aspect of quantum mechanics as fundamental as space and time or existence itself. But there is also nonfundamental $1/f$ noise, characterized by accidental $1/f$ -like spectra arising from a fortuitous superposition of GR noise spectra. Both fundamental and nonfundamental $1/f$ noise types are important in practice, as we show below.

We briefly consider first GR and thermal noise here before tackling $1/f$ noise at an elementary level. Armed with an understanding of the basic low-frequency noise processes, we then proceed to practical device applications. Next, we delve into the quantum $1/f$ theory and finally consider briefly the epistemological and ontological origin of the $1/f$ spectra in general, trying to understand their much wider presence in nature, their ubiquitous character.

2. GENERATION–RECOMBINATION NOISE

GR noise is caused by the random generation and recombination or trapping and detrapping of current carriers in semi-conductors, being described by the (always one-sided) spectral density

$$S_I(f) = \frac{8\langle(\delta I)^2\rangle\pi\tau}{1 + \omega^2\tau^2} \quad (4)$$

NOISE, LOW-FREQUENCY

PETER H. HANDEL
University of Missouri St. Louis

Low-frequency noise, containing fluctuations of current or voltage with frequency components below 10 kHz, is mainly fundamental $1/f$ noise and sometimes nonfundamental $1/f$ noise. In addition, shot noise, generation–recombination (GR) noise, and thermal noise, which are important at higher frequencies, also extend to the low-frequency domain. All these forms of electronic noise, each defined below, are characterized by the mean squared current fluctuation $\langle(\delta I)^2\rangle$ [or $\langle(\delta V)^2\rangle \equiv \text{RMS } \delta V^2$ for voltage], measured in series with (or across) the device or sample under test, when a constant voltage (or current) is applied, except for thermal noise, which is present even in thermal equilibrium, with no bias applied. All the other forms of noise present in addition to thermal noise are also known as current noise and are absent in thermal equilibrium. Nevertheless, $1/f$ noise and GR noise also modulate the RMS level of the thermal noise currents (or voltages) in thermal equilibrium, while the available power remains constant at $k_B T$ per hertz, where $k_B = 1.38 \times 10^{-23}$ J/K is Boltzmann’s constant and T the absolute temperature. These two forms of current noise are also called modulation noise, because they modulate the resistance. If a bandpass filter is inserted between the measuring device (usually a quadratic meter) and the noise source, then the spectral density of the fluctuations, $\langle(\delta I)^2\rangle_f \equiv S_I(f)$ [or $S_V(f)$] is obtained by dividing the measured mean square by the bandwidth Δf of the filter.

1. SHOT NOISE

With the notable exception of $1/f$ noise, also known as excess noise, the various type of noise mentioned above were well known and understood in the third decade of the twentieth century through the works of J. B. Johnson, H. Nyquist, and W. Schottky. For instance, shot noise is caused, in vacuum tubes, electron beams, Schottky diodes, p-n junctions, and any other device carrying a current, by the discrete, atomistic nature of electricity. It is easily described as a Poisson process, and is given at low

frequencies by

$$S_I(f) = 2eI_0 \quad (1)$$

where e is the electric charge of the charge carriers and I_0 the average electrical current in the direction of their motion. For electrons both e and I_0 are negative. The mean squared current in a frequency interval Δf is thus $2eI_0 \Delta f$. The general formula is given by Carson’s theorem, which gives the spectral density of a random uncorrelated repetition of identical processes with spectrum $\phi(f)$ and repetition rate λ as

$$2\lambda|\phi(f)|^2 \quad (2)$$

The case with arbitrary correlations present between the moments t_0 of passage was treated by C. Heiden [1] and is usually not called shot noise. The elementary process in shot noise is the current $i(t - t_0)$ caused by the passage of a single carrier. Therefore

$$\phi(0) = \int_{-\infty}^{\infty} i(t - t_0) dt = e \quad (3)$$

is the total charge e transported by a single carrier. With $e\lambda = I_0$, Carson’s theorem then gives Eq. (1). The term “shot noise” recalls the noise caused by small shot (or raindrops) falling on a drum.

$1/f$ noise, however, remained shrouded in mystery, and fundamental $1/f$ noise was understood only after the advent of the quantum $1/f$ theory [2] in 1975. It turns out there is always fundamental $1/f$ noise [3,4] caused by the quantum $1/f$ effect (Q $1/f$ E), a new aspect of quantum mechanics as fundamental as space and time or existence itself. But there is also nonfundamental $1/f$ noise, characterized by accidental $1/f$ -like spectra arising from a fortuitous superposition of GR noise spectra. Both fundamental and nonfundamental $1/f$ noise types are important in practice, as we show below.

We briefly consider first GR and thermal noise here before tackling $1/f$ noise at an elementary level. Armed with an understanding of the basic low-frequency noise processes, we then proceed to practical device applications. Next, we delve into the quantum $1/f$ theory and finally consider briefly the epistemological and ontological origin of the $1/f$ spectra in general, trying to understand their much wider presence in nature, their ubiquitous character.

2. GENERATION–RECOMBINATION NOISE

GR noise is caused by the random generation and recombination or trapping and detrapping of current carriers in semi-conductors, being described by the (always one-sided) spectral density

$$S_I(f) = \frac{8\langle(\delta I)^2\rangle\pi\tau}{1 + \omega^2\tau^2} \quad (4)$$

Here τ is the lifetime of the carriers and $\omega = 2\pi f$. According to the Wiener–Kinchine theorem, the spectral density is the Fourier transform of the autocorrelation function

$$A(\tau) \equiv (I(t)I(t + \tau)) \quad (5)$$

and is given by

$$S(f) = 4 \int_0^\infty A(\tau) \cos(2\pi f \tau) d\tau \quad (6)$$

Equation (3) is obtained by Fourier transformation from the exponential autocorrelation function $A(\tau) = ((\delta I)^2) e^{-t/\tau}$, which describes, for instance, the exponential decay of the number of carriers that have not yet recombined at the time t . There is a term similar to Eq. (4) present in the spectral density of current noise in semiconductors, for each type of carrier.

Let N be the number of carriers of a certain type in a semiconductor sample in stationary conditions. In terms of the generation rate $g(N)$ and of the recombination rate $r(N)$, the general formulas for both the lifetime τ and the mean square entering in Eq. (4) are

$$\tau = \frac{1}{r'(N_0) - g'(N_0)}, \quad (7)$$

$$((\delta I)^2) \equiv \frac{I_0^2}{N_0^2} ((\delta N)^2) = \frac{I_0^2}{N_0^2} \tau g(N_0)$$

Here the prime denotes a derivative w.r.t. (with respect to) N . The derivatives are taken for $N = N_0 \equiv (N)$, and we have denoted (I) by I_0 . The following special cases are highlighted:

1. For a n-type semiconductor with N_d deep donors, the generation rate $g(N) = \gamma(N_d - N)$ is proportional to the number of neutral donors, $N_d - N$, while $r(N) = \rho N^2$, with constant γ and ρ , because there are N free electrons and N ionized donors. Therefore, one obtains

$$\tau = \frac{1}{\gamma + 2\rho N_0} = \frac{N_d - N_0}{\rho N_0(2N_d - N_0)} \quad (8)$$

$$((\delta N^2)) = \frac{N_0(N_d - N_0)}{2N_d - N_0}$$

2. For a near-intrinsic n-type semiconductor with N electrons, N_d donors (all ionized), and $P = N - N_d$ holes, we write $g = \text{const}$ because the fluctuations are due to the thermal generation of electron–hole pairs. In this case the recombination rate is $r = \rho NP = \rho N(N - N_d)$. Therefore

$$\tau = \frac{1}{\rho(N_0 + P_0)}, \quad ((\delta N)^2) = ((\delta P)^2) = \frac{N_0 P_0}{N_0 + P_0} \quad (9)$$

3. For a semiconductor with N_t traps and N trapped electrons, the trapping rate is proportional to the

number $N_t - N$ of empty traps, while the release rate is proportional to N . Therefore, $g(N) = a(N_t - N)$ and $r(N) = bN$. The constants a and b are determined by the equilibrium condition $a(N_t - N_0) = bN_0$, which yields $N_0 = [a/(a + b)]N_t$. Therefore

$$\tau = \frac{1}{a + b}, \quad ((\delta N)^2) = \frac{bN_0}{a + b} = \frac{abN_t}{(a + b)^2} \quad (10)$$

In this special case the rate g and r are not nonlinear functions of N and Eqs. (10) are therefore independent of N_0 . In this case, the fluctuation of N obeys the binomial distribution law.

3. THERMAL NOISE

Also known as Johnson (or Nyquist) noise, thermal equilibrium noise has a white (frequency-independent) spectrum at not too high frequencies. It is given in general, for a circuit component of impedance $Z = 1/Y$ of conductance $G = \text{Re } Y$ and resistance $R = \text{Re } Z$, by the Planck–Nyquist formula

$$S_I(f) = 4G \frac{hf}{e^{hf/kT} - 1} \approx 4kTG \quad (11)$$

$$S_V(f) = 4R \frac{hf}{e^{hf/kT} - 1} \approx 4kTR$$

Here $h = 6.62 \times 10^{-34} \text{ J} \cdot \text{s}$ is Planck's constant, and $k = 1.38 \times 10^{-23} \text{ J/K}$ is Boltzmann's constant. The thermal noise power available (for a matched load) is

$$S_a(f) = \frac{hf}{e^{hf/kT} - 1} \approx kT \quad (12)$$

With the exception of ultrahigh frequencies at very low temperatures, only the approximate forms are used in practice and are known as equivalent forms of the Nyquist formula. The amplitude distribution of thermal noise is Gaussian, with small deviations of fundamental origin caused by the $Q1/fE$ noise even in thermal equilibrium [4].

4. GENERAL INTRODUCTION TO $1/f$ NOISE

At low frequencies, the observed noise spectrum, in general, is roughly proportional to the reciprocal frequency, as Johnson first observed in 1925 in vacuum tubes. This $1/f$ noise accounts for most of the low-frequency noise. Low-frequency noise is therefore often considered synonymous with $1/f$ noise in practice. Schottky first called the $1/f$ noise “flicker noise” in 1926 and blamed it on a random flickering process on the surface of the cathode. In 1937 Schottky observed that flicker noise is suppressed by space charge in vacuum tubes to a larger extent than shot noise.

4.1. Nonfundamental $1/f$ Noise

A. L. McWhorter suggested in 1954 that $1/f$ noise in semiconductor samples and devices might arise from

transitions of electrons to and from traps in the oxide at the surface. The superposition of many Lorentzian spectra [Eq. (4)] resulting from traps with different exponential relaxation times τ in the interval $\tau_1 < \tau < \tau_2$ can yield a $1/f$ -like spectrum in a limited frequency domain if two conditions are satisfied, causing a nonfundamental, or accidental, $1/f$ noise, as mentioned above. The two conditions are (1) an electron is not allowed to interact with many traps at the same time and (2) the distribution of the characteristic times has a probability density c/τ . Indeed, one expects then an addition of power spectra

$$\begin{aligned} S_I(f) &= 8((\delta I)^2)\pi c \int_{\tau_1}^{\tau_2} \frac{\tau}{1 + \omega^2\tau^2} \frac{d\tau}{\tau} \\ &= 8((\delta I)^2) \frac{\pi c}{\omega} (\arctan \omega\tau_2 - \arctan \omega\tau_1) \quad (13) \\ &\approx 8((\delta I)^2) \frac{\pi^2 c}{\omega} \end{aligned}$$

The last approximation is valid only for $1/\tau_2 \ll \omega \ll 1/\tau_1$. There is strong evidence favoring a major contribution of this mechanism in MOSFETs from studies of the relaxation of slow surface states, particularly since the observed spectrum often differs slightly from $1/f$. The slow states are distributed uniformly in the oxide volume, which serves as gate insulation, at the surface of the semiconductor. This nonfundamental contribution is usually larger in MOSFETs than the fundamental $1/f$ noise. The constant c is proportional to the superficial density of slow surface states, which can in principle be determined from the slow relaxation of the surface charges, but is hard to determine in practice without measuring the $1/f$ noise. Therefore, Eq. (13) is difficult to apply in practice.

4.2. General Aspect of Fundamental $1/f$ Noise

In fact, $1/f$ noise was found in carbon resistors and microphones, in all semiconductors and semiconductor devices, in contacts (contact noise), in infrared detectors, in bolometers, in photodetectors, in piezoelectric transducers and sensors, in mixers, in thin metallic sheets, in Josephson junctions and SQUIDS, in electron beams in vacuum, in the rate of electron tunneling and cold emission, in the recombination and generation rates for current carriers in the bulk and on the surface of semiconductors, in the frequency fluctuations of quartz resonators and SAW devices and arrays, and so on. It is always observed when a bottleneck is present, causing an electrical current to be carried by only a few current carriers. This ubiquity of $1/f$ noise indicates that $1/f$ noise is “the way of life” for electric currents.

The ubiquitous character of $1/f$ noise inspired the development of a turbulence theory of it [5,6], which generalized Heisenberg’s hydrodynamic turbulence theory to the hydromagnetic plasma turbulence case. This theory yielded for the first time a universal $1/f$ spectrum from postulated instabilities of the laminar flow in the plasma of current carriers (electrons and holes in semi-

conductors). This physical theory was limited to homogeneous isotropic turbulence in an infinite, randomly stirred-up plasma of current carriers, and could therefore not be applied in practice. Nevertheless it demonstrated the fundamental nature of the $1/f$ spectrum caused by the universal feedback reaction of the electric current on itself via the electromagnetic field.

F. N. Hooge recognized that the turbulence theory [5,6] was the only physical theory of fundamental $1/f$ noise available at the time. This sparked experiments trying to verify $1/f$ -noise universality in the laboratory. In 1969 Hooge claimed, on the basis of his measurements, that the known inverse proportionality of $1/f$ noise with the volume of the sample under test becomes universal (i.e., with the same coefficient α_0 for any semiconductor, metal, or electrolyte) if the number of carriers N , rather than the volume of the sample (assumed to be homogeneous), is used in the denominator:

$$S_I(f) = \alpha_0^2 / Nf \quad (14)$$

This relation was known long before Hooge’s work, but the coefficient α_0 was considered dependent on the material, and the volume of the sample was used with preference in the denominator, instead of N . This was thought to be equivalent, because the volume is proportional to N . Early experiments seemed to support Hooge’s hypothesis, with a universal α_0 of 2–3 times 10^{-3} , but later experiments with smaller samples showed that Hooge was wrong, because any α_0 value from 10^3 down to 10^{-10} was shown to be possible. Although Hooge was proved wrong in his suggestion of a universal constant, his initial optimism helped accredit the notion of the fundamental nature of $1/f$ noise. The experimental “constant” α_0 was called the “Hooge parameter” [7] by A. van der Ziel, although it was in fact material-dependent, as had been assumed before Hooge. In 1974 the quantum $1/f$ theory derived Eq. (10) for the first time from first principles, allowing the exact calculation of α_0 , and explaining why small devices have α_0 values ranging from 10^{-5} to 10^{-10} . In 1982 it also explained why large devices have α_0 values close to 4×10^{-3} and why ferroelectric substances have α_0 values as large as 10^3 . This quantum-electrodynamics (QED) theory is presented here, first at an over simplified elementary level and with practical applications to devices, in order to clarify the physical basis and the new notions it introduces.

4.3. Elementary Introduction to Fundamental $1/f$ Noise

The main form of fundamental $1/f$ noise known at the present time is quantum $1/f$ noise, which is a manifestation of the coherent and conventional $Q1/fE$, representing a little-known new aspect of quantum mechanics. It can be obtained from a straightforward QED calculation of fundamental quantum fluctuations in cross sections, process rates, and electric currents, resulting from the author’s attempts to quantize the earlier turbulence theory. These attempts were necessitated by the absence of instabilities with zero threshold, which could otherwise trigger the

turbulence. They resulted in the discovery first of the conventional (1–4) and then of the coherent [3,8–10] quantum $1/f$ effect. The $Q1/fE$ was proven to be responsible for most of the $1/f$ noise observed in electronic devices, thereby allowing for a unified presentation of noise in electronic devices [7,11–22].

Other forms of fundamental $1/f$ noise are found in nature beyond the realm of electrophysics. Like the $Q1/fE$, these other forms of fundamental $1/f$ noise have been proved [23] to arise from a coincidence of nonlinearity and homogeneity in physical system. Just as in the case of the ontologically more fundamental $Q1/fE$, these other forms occur in systems that satisfy a universal sufficient criterion.

4.4. Simplified Derivation of the Conventional Quantum $1/f$ Effect

4.4.1. Definition. The $Q1/fE$ is a fundamental quantum fluctuation of all physical cross sections σ , process rates Γ , and currents j given by the universal formula $S(f) = 2\alpha A/fN$ (conventional quantum $1/f$ equation (16)) for small devices, and $S(f) = 2\alpha/\pi fN$ (coherent quantum $1/f$ equation [16,23,24]) for large devices. These two forms can be combined into a single large devices. These two forms can be combined into a single general formula, as we show below. Here $S(f)$ is the spectral density of fractional fluctuations in current, $\delta j/j$, in the scattering or recombination cross section $\delta\sigma/\sigma$, or in any other process rate $\delta\Gamma/\Gamma$. The number $\alpha \equiv e^2/\hbar c \approx \frac{1}{137}$ is Sommerfeld's fine structure constant, a basic number of our world depending only on Planck's constant \hbar , the charge of the electron, e , and the speed of light in vacuum c . The quantity $A \equiv 2(\Delta v/c)^2/3\pi$ is essentially the square of the vector velocity change Δv of the scattered particles in the scattering process whose fluctuations we are considering, in units of c . Finally, N is the number of particles used to define the notion of current j , of cross section σ or of process rate Γ .

4.4.2. Plan. We will present here first a back-of-the-envelope derivation of the conventional $Q1/fE$. After presenting some practical applications to devices, we present below first an elementary derivation and later a more rigorous derivation of both the conventional and coherent $Q1/fE$.

4.4.3. Origin. The physical origin of electrodynamic conventional quantum $1/f$ noise is easy to understand. Consider, for example, Coulomb scattering of current carriers (e.g., electrons) on a center of force, keeping in mind that electrons are described as probability amplitude waves ψ according to quantum mechanics. The scattered electrons reaching a detector at a given angle away from the direction of the incident beam are described by de Broglie waves ψ of a frequency corresponding to their energy. However, the electrons have energy loss amplitudes in the scattering process, due to the emission of bremsstrahlung into low-frequency photon modes. Therefore, part of the outgoing de Broglie waves are shifted to slightly lower frequencies. When we calculate the probability density $|\psi|^2$ in the scattered beam, we obtain also cross terms, linear in both the parts of ψ scattered with and without bremsstrahlung. These cross terms oscillate

with the same frequency as the frequency of the emitted bremsstrahlung photons. The emission of photons at all frequencies results therefore in probability density fluctuations at all frequencies. The corresponding quantum fluctuations of the current density $v|\psi|^2$ are obtained by multiplying the probability density fluctuations by the velocity v of the scattered current carriers. Finally, these current fluctuations, present in the scattered beam, will be noticed at the detector as low-frequency current fluctuations, and will be interpreted as fundamental fluctuations in the physical scattering cross section of the scatterer.

4.4.4. Derivation. For a simple semiclassical calculation of the conventional $Q1/fE$ along these lines, we start from the classical (Larmor) formula

$$P = 2q^2 a^2 / 3c^3 \quad (15)$$

for the power P radiated by a particle of charge q in the scattering process. The acceleration \mathbf{a} can be approximated by a delta function $\mathbf{a}(t) = \Delta v \delta(t)$ whose Fourier transform Δv is constant and is the change in the velocity vector of the particle during the almost instantaneous scattering process. The one-sided spectral density P_f of the emitted bremsstrahlung power

$$P_f = 4q^2 (\Delta v)^2 / 3c^3 \quad (16)$$

is therefore also constant, independent of frequency, but goes to zero for frequencies larger than the reciprocal duration of the scattering process. The number $4q^2 (\Delta v)^2 / 3\hbar f c^3$ of emitted photons per unit frequency interval is obtained by dividing by the energy $\hbar f$ one photon. The probability amplitude of photon emission

$$A_f = \left(\frac{4q^2 (\Delta v)^2}{3\hbar f c^3} \right)^{1/2} e^{i\gamma} \quad (17)$$

is given by the square root of this photon number spectrum, including also a phase factor $e^{i\gamma}$. The Schrödinger wavefunction Ψ of the scattered outgoing charged particles can be constructed from products of single-particle wavefunctions ψ . The beat term in the probability density $|\psi|^2$ is linear both in this bremsstrahlung amplitude A_f and in the nonbremsstrahlung amplitude, which does not depend on f . The spectral density of this beat term will therefore be given by the product of the squared probability amplitude $|A_f|^2 \ll 1$ of photon emission (proportional to $1/f$) with the squared nonbremsstrahlung amplitude $1 - |A_f|^2 \approx 1$, which is practically independent of f . The resulting spectral density of fractional probability density fluctuations is obtained by dividing $|\psi|^4$ and is therefore

$$\begin{aligned} |\psi|^{-4} S_{\delta|\psi|}^2(f) &= \frac{8q^2 (\Delta v)^2}{3\hbar f N c^3} \equiv \frac{2\alpha A}{fN} \\ &= j^{-2} S_j(f) = S_{\delta j/j}(f) = S_{\delta\sigma/\sigma}(f) \end{aligned} \quad (18)$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant is $q = e$ is the elementary charge, $\hbar = h/2\pi$, and $\alpha A = 2e^2(\Delta v)^2/3\pi\hbar c^3$ is the bremsstrahlung coefficient, also known as the infrared exponent in quantum field theory. It is derived here as the quantum $1/f$ -noise coefficient in electrophysics.

The spectral density S_j of current density fluctuation $\delta j = v\delta|\psi|^2$ is obtained by multiplying the probability density fluctuation spectrum with the velocity $v = p/m$ of the outgoing particles. When we calculate the spectral density of fractional fluctuations in the scattered current j , the outgoing velocity simplifies or drops out, and therefore Eq. (18) also gives the spectrum of current fluctuation $S_j(f)$, as indicated above. Finally, the scattered particle current j per unit incoming flux is what we shall call the *physical scattering cross section* σ . This allows for the first equality in Eq. (18) after the identity sign.

The quantum $1/f$ noise contribution of each carrier is independent, and therefore the quantum $1/f$ noise from N carriers is N times larger; however, the current j will also be N times larger, and therefore in Eq. (1) a factor N was included in the denominator for the case in which the cross section fluctuation is observed on N carriers simultaneously. Finally, note that the simplified back-of-the-envelope derivation which led to Eq. (18) is similar to considering diffraction of a single photon in Young's diffraction experiment and then estimating the autocorrelation function and the spectral density in the probability fringes obtained on the screen, claiming it should apply to the diffraction pattern generated by a large number of photons. The correct way is based on the two-particle wavefunction, which is a product of two single-particle functions in the noninteracting case considered here. This yields the same result, replacing $|\psi|^4$ in the calculation with the physically reasonable squared absolute value of the two-particle wavefunction (see below).

4.4.5. Discussion. We have defined the physical cross section as the quantum-mechanical cross section plus the corresponding quantum fluctuations, which were eliminated in the calculation of the quantum-mechanical expectation value, which is usually defined as the cross section. Our new notion of *physical process rate* is defined in the same way. The physical quantities are the directly observed ones, because in the Q1/fE the quantum fluctuations become macroscopic—observable at low frequencies—due to the $1/f$ dependence.

Although the wavefunction φ of each carrier is split into a bremsstrahlung part and a nonbremsstrahlung part, no quantum $1/f$ noise can be observed from a single carrier. A single carrier will only provide a pulse in the detector. Many carriers are needed to produce the quantum $1/f$ noise effect, just as in the case of electron diffraction patterns, where each individual particle is diffracted, but unless we repeat the experiment many times, or use many particles, no diffraction pattern can be seen. A single particle only yields a point of impact on the photographic plate in diffraction, or a pulse in the detector in $1/f$ noise. While incoming carriers may have been Poisson distributed, the scattered beam will exhibit super-Poissonian statistics, or *bunching*, due to this new effect, the Q1/fE. The Q1/fE is thus a many-body or collective effect, at least a two-particle

effect, best described through the two-particle wavefunction and two-particle correlation function.

In conclusion, the conventional Q1/fE [1–4,6,8–15] is a fundamental fluctuation of physical cross sections and process rates, caused by the infrared-divergent coupling of current carriers to low-frequency photons (electrodynamic Q1/fE) and to other infraquanta, such as transverse phonons with piezoelectric coupling (lattice-dynamic Q1/fE), or electron–hole pairs on the Fermi surface of metals (electronic Q1/fE).

4.4.6. Application. The fundamental quantum $1/f$ fluctuations of physical cross section σ and process rates Γ are reflected in the collision frequency $\nu = 1/\tau$ and collision time τ of the carriers, and in various kinetic coefficients in condensed matter, such as the mobility μ and the diffusion constant D , the surface and bulk recombination speeds s , and recombination times τ_r , the rate of tunneling j_t , and the thermal diffusivity in semiconductors. Specifically, neglecting the energy distribution of the carriers or using appropriate averages, $\delta\sigma/\sigma = \delta\Gamma/\Gamma = \delta\nu/\nu = -\delta\tau/\tau = -\delta\mu/\mu = -\delta D/D$. Therefore, the spectral density of fractional fluctuations in all these coefficients is given also by Eq. (18) in a first approximation that neglects the statistical effects of the momentum distribution of the current carriers. This is true in spite of the fact that each carrier will undergo many consecutive scattering transitions in the diffusion process. The resulting quantum $1/f$ noise in the mobility and in the diffusion coefficient is most often practically the same as (and can never be smaller than) the quantum $1/f$ noise in a single representative scattering event that limits the mobility or the diffusion coefficient.

4.4.7. Coherent Effect. For large devices the concept of coherent-state Q1/fE was introduced by the author [23,24]. In this case the $1/f$ noise parameter α_0 as derived in the theory section below is given by

$$\alpha_0 = (\alpha_0)_{\text{coh}} = 2\alpha/\pi = 4.6 \times 10^{-3} \quad (19)$$

where $\alpha \approx \frac{1}{137}$ is the fine-structure constant as mentioned above. This is of the same order of magnitude as the empirical value $\alpha_0 = 2\text{--}3$ times 10^{-3} that Hooge and others found for large devices. It is obvious that Hooge's empirical value for α_0 is due to the coherent Q1/fE and has a fundamental origin.

4.4.8. Conventional Effect. For small samples or devices we consider conventional quantum $1/f$ noise [1–6,8–15], which is just the cross-section fluctuation introduced above in Eq. (18). In that case α_0 may be written

$$\alpha_0 = (\alpha_0)_{\text{conv}} = \frac{4\alpha(\Delta v)^2}{3\pi c^2} \quad (20)$$

This general principle is now illustrated on practical examples of materials and devices. The exact meaning of large and small is explained below and also in the theory section in terms of the parameters [24–26].

4.4.9. Simplified Application to Homogeneous Semiconductor Samples. In a homogeneous sample of length L , cross section A , volume $V=AL$, carrier mobility μ , carrier concentration n , and total number of carriers $N=nAL$, the conductance $C=n\mu eA/L$ and the resistance $R=1/C$ will exhibit quantum $1/f$ fluctuations with a spectral density $S_{\delta C/C}$ of fractional fluctuations $\delta C/C = -\delta R/R$ given by

$$S_{\delta C/C}(f) = S_{\delta R/R}(f) = S_{\delta\mu/\mu}(f) = \alpha_0/fN \quad (21)$$

4.4.9.1. Size Dependence. To calculate α_0 we first evaluate the parameter $s = nA \times 5.5 \times 10^{-13}$ cm introduced in the theory section below. If $s \geq 1$, coherent quantum $1/f$ noise is observed with $\alpha_0 = 2\alpha/\pi$.

If $s < 1$, Eq. (21) requires knowledge of $(\alpha_0)_{\text{conv}}$. The latter is calculated from Eq. (18) or (20) for each type of scattering that limits the mobility $\mu = e\tau/m^*$ of the carriers. Here τ is the mean collision time or scattering time of the carriers and m^* is their effective mass. In terms of the mean frequency of collisions $\nu = 1/\tau = \sigma\nu n_i$, one obtains $\mu = e/\nu m^* = e/\sigma\nu n_i m^*$. Here ν is the mean speed of the carriers between collisions, σ a scattering cross section, and n_i the concentration of scatterers.

4.4.9.2. Conventional Quantum $1/f$ Effect in the Mobility.

In general, Matthiessen's rule allows us to write, in terms of mobility,

$$\frac{1}{\mu} = \sum_j \frac{1}{\mu_j} \quad (22)$$

where μ_j is the mobility that would be obtained if only the j th scattering mechanism were present and limited the mobility. Applying a quantum $1/f$ fluctuation to Eq. (22), squaring, and averaging quantum-mechanically and statistically, we obtain as a reasonable first approximation

$$\frac{\delta\mu}{\mu^2} = \sum_j \frac{\delta\mu_j}{\mu_j^2}, \quad S_{\delta\mu/\mu}(f) = \sum_j \left(\frac{\mu}{\mu_j}\right)^2 S_{\delta\mu/\mu_j}(f) \quad (23)$$

Equation (20) yields the strongest conventional quantum $1/f$ noise for umklapp scattering, followed by the f and g forms of intervalley scattering or intervalley with umklapp scattering (in indirect bandgap semiconductors such as Si and Ge only), followed by normal phonon scattering, by neutral-impurity scattering, and by ionized impurity scattering. The corresponding terms in Eq. (23) reflect this hierarchy only partially, because of the factors $(\mu/\mu_j)^2$, which gauge the importance of each of the scattering processes in limiting the resultant mobility. To gain physical insight, the conventional Q $1/f$ E present in the various scattering processes is only estimated below and is actually calculated in the theory section in the second half of this article, taking into account the corrections introduced by the momentum distribution of the carriers and by the phonon distribution function at the temperature T .

4.4.9.3. Impurity Scattering. For instance, in the case of impurity scattering, n_i is. One obtains $S_{\delta\mu/\mu}(f) = S_{\delta\sigma/\sigma}(f)$. The physical scattering cross section σ , in turn, exhibits the Q $1/f$ E with the spectral density given by Eqs. (18) and (20):

$$S_{\delta\sigma/\sigma}(f)_i = \frac{4\alpha}{3\pi f N} \left\langle \left(\frac{\Delta v}{c}\right)^2 \right\rangle \approx \frac{3 \times 10^{-3}}{fN} \left(\frac{\hbar\Delta k}{m^*c}\right)^2 \quad (24)$$

The average quadratic velocity change of the electrons in a scattering process is smaller in impurity scattering than in lattice scattering, which includes normal phonon scattering, intervalley scattering in indirect-bandgap semiconductors with several valleys, and umklapp scattering, as well as optical phonon scattering. The Coulomb–Rutherford or Conwell–Weisskopf scattering cross section is proportional to $1/|\Delta k|^4$, which favors small-angle scattering. Nevertheless, there are a few larger-angle scattering events, which are most effective in limiting the mobility and which therefore are decisive in the exact evaluation of the Q $1/f$ E coefficient as a slow function of n_i , the concentration of impurities, given in the theory section below. This corresponds approximately to assuming randomizing collisions

$$\langle (\Delta v)^2 \rangle_i = 2(v^2) = 6k_B T/m^* \quad (25)$$

although impurity scattering is not randomizing. With m_0 representing the free-electron mass, we obtain this way

$$S_{\delta\mu/\mu}(f)_i = S_{\delta\sigma/\sigma}(f)_i = \frac{4\alpha}{3\pi f N} \left\langle \frac{6k_B T}{m^*c^2} \right\rangle \approx \frac{10^{-9}}{fN} \frac{Tm_0}{4m^*(100\text{ K})} \quad (26)$$

The quantum $1/f$ noise power present in impurity scattering is therefore proportional to T .

4.4.9.4. Normal Acoustic Phonon Scattering. For normal-phonon scattering, the product $\sigma\nu n_i$, has to be replaced by the lattice scattering rate Γ , given by an effective number of phonons times the squared phonon scattering matrix element, $|M|^2$. The latter exhibits quantum $1/f$ fluctuations, because the carriers emit bremsstrahlung photons in the scattering process. Therefore, if the mobility μ of electrons (of random velocity $v = \hbar k/m^*$) is limited by phonon scattering, we get

$$S_{\delta\mu/\mu}(f)_{\text{ap}} = S_{\delta\Gamma/\Gamma}(f)_{\text{ap}} = \frac{4\alpha}{3\pi f N} \left\langle \left(\frac{\hbar\Delta k}{m^*c}\right)^2 \right\rangle = \frac{3 \times 10^{-3}}{fN} \left\langle \left(\frac{\hbar\Delta q}{m^*c}\right)^2 \right\rangle \quad (27)$$

Here Δq is the acoustic-phonon momentum transfer in the scattering process, and the brackets indicate the average value. Using the linear approximation of the acoustic phonon dispersion relation $E_q = v_s q \hbar$, with v_s denoting the speed of sound, we obtain for a thermal phonon with

$$E_q = k_B T / 2$$

$$\langle (\hbar \Delta \mathbf{q} / m^* c)^2 \rangle = \left(\frac{k_B T}{2 v_s m^* c} \right)^2 = 1.25 \times 10^{-5} \left(\frac{m_0}{m^*} \right)^2 \quad (28)$$

we finally obtain

$$S_{\delta\mu/\mu}(f)_{\text{ap}} = \frac{3.75 \times 10^{-8}}{fN} \left(\frac{m_0}{m^*} \right)^2 \quad (29)$$

The mean squared momentum change and the $1/f$ noise are much larger (e.g., 50 times; see Fig. 1) for acoustic-phonon scattering, because impurity scattering is mainly small-angle scattering. A more rigorous treatment for the many types of scattering present in semiconductors, taking into account the corrections introduced by the momentum distribution of the carriers and the phonon distribution function at the temperature T , is given in the theory section in the second half of this article for the case of silicon.

4.4.9.5. Umklapp Scattering. In this case the momentum change is close to the smallest reciprocal lattice vector approximated by $\hbar G = 2\pi\hbar/a$, where a is the lattice constant. Therefore, Eq. (20) yields

$$(\alpha_{0u})_{\text{conv}} = \frac{4\alpha}{3\pi} \left(\frac{2\pi\hbar}{am^*c} \right)^2 = \frac{6 \times 10^{-8}}{fN} \left(\frac{m_0}{m^*} \right)^2 \quad (30)$$

for umklapp scattering.

4.4.9.6. Intervalley Scattering. In indirect-bandgap semiconductors the location of the energy minima of the conduction band in \mathbf{k} space is different from the location of the valence-band energy maxima. In thermal equilibrium electrons and holes are present close to the minima of the conduction and valence bands. Scattering processes

Figure 1. Acoustic Hooke parameter in units of 10^{-8} (open diamonds), and impurity Hooke parameter in units of 10^{-9} for three doping concentrations: 10^{21} (open squares), 10^{23} (solid diamonds), and 10^{24} (solid squares).

carrying electrons from one minimum (or valley) to the other are known as intervalley scattering. This is large-angle scattering, compared with normal (intervalley) scattering, and it is therefore affected by larger conventional quantum $1/f$ noise, almost as large as umklapp scattering. Indeed, for example, in Si the eight minima are located at $0.85G$ from the origin, where G is the smallest reciprocal lattice vector magnitude. For g processes, which scatter an electron to the valley symmetrically located on the other side of the origin, Eq. (30) remains valid with a correction factor of $(0.85)^2$. On the other hand, for f processes in Si, scattering electrons between neighboring valleys, the factor is 2 times smaller. There is also the possibility of intervalley scattering with umklapp, which requires a correction factor of $(1 - 0.85)^2$. Equation (20) thus yields for intervalley scattering with umklapp

$$(\alpha_{0iu})_{\text{conv}} = 0.0225 \frac{4\alpha}{3\pi} \left(\frac{2\pi\hbar}{am^*c} \right)^2 = \frac{1.35 \times 10^{-9}}{fN} \left(\frac{m_0}{m^*} \right)^2 \quad (31)$$

While this appears to indicate a lower contribution from these intervalley umklapp processes, the corresponding factor $(\mu/\mu_0)^2$ in Eq. (23) ensures a larger contribution to the resulting spectral density of quantum $1/f$ noise, $S_{\delta\mu/\mu}(f)$. Physically, this is caused by the scarcity of high-energy phonons able to bridge the momentum gap of $0.85G$.

5. CALCULATION OF THE CONVENTIONAL QUANTUM $1/f$ EFFECT IN HOMOGENEOUS SEMICONDUCTOR MATERIALS

A first-principles calculation of quantum $1/f$ cross-correlations, performed for the first time in 1987 by Handel [27], has yielded a slightly different result from earlier expectations. This same new form of the quantum $1/f$ cross-correlations was rederived with a different method by Van Vliet [15] in 1989. It differs from the old form used in the 1985 calculation of Kousik et al. [28] by a correction that is zero when the momentum changes of the two current carriers involved in the cross correlation are identical, but increases when the momentum differences caused by the scattering process are different. The correction is proportional to the squared difference of the two momentum changes. Handel and Chung [29] have repeated all calculations in the original paper by Kousik et al. [28], obtaining both for impurity scattering and for the various types of phonon scattering new analytical expressions that show a considerable increase of the final quantum $1/f$ noise. The results obtained are in general applicable both to direct- and to indirect-bandgap semiconductors.

5.1. Introduction

Handel and Chung [29] have performed an analytical calculation of mobility fluctuations in silicon and gallium arsenide, using the new quantum $1/f$ cross-correlations formula. This calculation is of major importance for the $1/f$ -noise-related optimization of the two types of materials, and of the many devices constructed with them for

military and civilian applications in the electronic and optoelectronic industries.

The new cross-correlation formula gives the cross-spectral density, which describes the way in which simultaneous quantum $1/f$ scattering rate fluctuation ΔW observed in the direction of the outgoing scattered wave vector \mathbf{K} are correlated with those in the \mathbf{K}' direction when the two corresponding incoming current carriers have the wavevectors \mathbf{K}_1 and \mathbf{K}_2 :

$$\begin{aligned} S_{\Delta W}(\mathbf{K}_1, \mathbf{K}'; \mathbf{K}_2, \mathbf{K}'; f) \\ = \frac{2\alpha}{3\pi f} \left(\frac{\hbar}{m^*c} \right)^2 W_{\mathbf{K}_1, \mathbf{K}'} W_{\mathbf{K}_2, \mathbf{K}'} \\ \times [(\mathbf{K}' - \mathbf{K}_1)^2 + (\mathbf{K}'' - \mathbf{K}_2)^2] \delta_{\mathbf{K}_1, \mathbf{K}_2} \end{aligned} \quad (32)$$

The form conjectured by us earlier had $2(\mathbf{K}' - \mathbf{K}_1)(\mathbf{K}'' - \mathbf{K}_2)$ in place of the rectangular bracket. The difference between the rectangular bracket and $2(\mathbf{K}' - \mathbf{K}_1)(\mathbf{K}'' - \mathbf{K}_2)$ is the perfect square $[(\mathbf{K}' - \mathbf{K}_1) - (\mathbf{K}'' - \mathbf{K}_2)]^2$. Therefore we expect the new results to be always larger than the results obtained on the basis of the previously conjectured form.

5.2. Impurity Scattering

For impurity scattering of electrons in solids, fluctuations $\Delta\tau$ of the collision times τ will cause mobility fluctuations

$$\Delta\mu_{\text{band}}(t) = \frac{e}{m^* \langle \langle v^2 \rangle \rangle} \sum_{\mathbf{K}} v_{\mathbf{K}}^2 \Delta\tau(t) n_{\mathbf{K}} \quad (33)$$

Where $\langle \langle v^2 \rangle \rangle$ is both average over all states of wave vectors \mathbf{K} , with occupation number $n_{\mathbf{K}}$, in the conduction band, and the thermal equilibrium average, of the squared carrier velocities. With the help of the relation

$$\frac{1}{\tau(\mathbf{K})} = \frac{V}{8\pi^3} \int \left(1 - \frac{\cos\theta'}{\cos\theta} \right) W_{\mathbf{K}, \mathbf{K}'} d^3K' \quad (34)$$

the mobility fluctuations are reduced to fluctuations of the elementary scattering rates $W_{\mathbf{K}, \mathbf{K}'}$, governed by Eq. (32). Here V is the volume of the normalization box, which disappears in the final result, and θ and θ' respectively the angles \mathbf{K} and \mathbf{K}' form with the direction of the applied field. One finally obtains, after tedious multiple integrations

$$\begin{aligned} \mu^{-2} S_{\Delta\mu}(f) &= \frac{256\pi\alpha\kappa^2\varepsilon^4\hbar^{12}}{3m^{*8}Z^4e^8N_i^2f} \\ &\times \sum_{\mathbf{K}} K^{10} \left(\ln(1+a^2) - \frac{a^2}{1+a^2} \right)^{-3} \\ &\left(\frac{2a^2+a^4}{1+a^2} - 2\ln(1+a^2) \right) F(E_{\mathbf{K}}) \\ &\times \left(\sum_{\mathbf{K}} v_{\mathbf{K}}^2 \tau(\mathbf{K}) F(E_{\mathbf{K}}) \right)^{-2} \end{aligned} \quad (35)$$

where $a = 2K/\kappa$, $\kappa^2 = e^2 n(T)/\varepsilon k_B T$, $n(T)$, is the electron concentration, $F(E_{\mathbf{K}}) = \exp(E_{\mathbf{F}} - E_{\mathbf{K}})$ for nondegenerate semiconductors, N_i is the concentration of impurities of charge Ze and ε is the dielectric constant. The corresponding partial Hooke parameter for impurity scattering is thus

$$\begin{aligned} \alpha_i &= \frac{4\sqrt{2\pi}\alpha\kappa\hbar^5 N_c}{3m^{*7/2}(k_B T)^{3/2}c^2} \\ &\int_0^\infty dx x^{11/2} e^{-x} \left(\ln(bx+1) - \frac{bx}{bx+1} \right)^{-3} \\ &\left(\frac{2bx+b^2x^2}{bx+1} - 2\ln(bx+1) \right) \\ &\times \left[\int_0^\infty dx x^3 e^{-x} \left(\ln(bx+1) - \frac{bx}{bx+1} \right)^{-1} \right]^{-2} \end{aligned} \quad (36)$$

This result is graphed in Fig. 1 for three different values of the donor concentration N_d and is compared with old results obtained by simply recalculating the old analytical expression [28]. As expected, the new cross-correlation formula leads to slightly higher α_i values than the previously conjectured expression. This was mentioned in connection with Eq. (32) above.

5.3. Electron Acoustic Phonon Scattering

In this case the calculation is similar, and leads to the result

$$\begin{aligned} \alpha_{ac} &= \frac{32\pi\alpha N_c m^* C_1^3 \hbar^3}{(3c^2 k_B T)^4} \left[\frac{1}{R^2} \int_1^\infty dx x^{-4} \right. \\ &\times \left(\frac{(x-1)^7}{7} + (R+1) \frac{(x-1)^6}{6} + R \frac{(x-1)^5}{5} \right) \\ &\times \left(\frac{(x-1)^5}{5} + (R+1) \frac{(x-1)^4}{4} + R \frac{(x-1)^3}{3} \right) \exp\left(-\frac{x^2}{4R}\right) \\ &+ \int_0^1 dx x^{-4} \left(\frac{(x+1)^5}{5} - \frac{(x+1)^6}{6} + \frac{(x-1)^5}{5} + \frac{(x-1)^6}{6} \right) \\ &\times \left(\frac{(x+1)^3}{3} + \frac{(x-1)^4}{4} + \frac{(x-1)^3}{3} - \frac{(x+1)^4}{4} \right) \\ &\exp\left(-\frac{x^2}{4R}\right) + \int_1^\infty dx x^{-4} \left(\frac{(x+1)^5}{5} - \frac{(x+1)^6}{6} \right) \\ &\left. \left(\frac{(x+1)^3}{3} - \frac{(x+1)^4}{4} \right) \exp\left(-\frac{x^2}{4R}\right) \right] \end{aligned} \quad (37)$$

where $R = k_B T/2m^* C_1^2$, C_1 is the deformation potential, and N_c is the effective density of states for the conduction band.

5.4. Nonpolar Optical Phonon Scattering

This time one obtains

$$\begin{aligned} \alpha_{\text{nonph}} = & \frac{8\pi\sqrt{2\hbar\omega_0}\alpha N_c\hbar^2}{3m^{*5/2}c^2\omega_0} \left[\int_0^\infty dx x^{5/2} \right. \\ & \times [(F+1)(x-1)^{1/2}\theta(x-1) + F(x+1)^{1/2}]^{-4} \\ & \times [(F+1)^2(x-1)(2x-1)\theta(x-1) \\ & \left. + F^2(x+1)(2x+1)\exp\left(-\frac{\hbar\omega_0x}{k_B T}\right)] \right] \\ & \times \left[\int_0^\infty dx x^{3/2} [(F+1)(x-1)^{1/2}\theta(x-1) \right. \\ & \left. + F(x+1)^{1/2}]^{-1} \exp\left(-\frac{\hbar\omega_0x}{k_B T}\right) \right]^{-2} \end{aligned} \quad (38)$$

where $F = [\exp(\hbar\omega_0/k_B T) - 1]^{-1}$, and ω_0 is the optical phonon frequency.

5.5. Polar Optical Phonon Scattering

Proceeding as in the cases of impurity and nonpolar optical-phonon scattering, we obtain

$$\begin{aligned} \alpha_{\text{poph}} = & \frac{8\pi\sqrt{2\hbar\omega_1}\alpha N_c\hbar^2}{3m^{*5/2}c^2\omega_1} \left(\int_0^\infty dx x^4 \right. \\ & \times \{F^2(x+1)^{1/2} \ln[2x^{1/2} + 2(x+1)^{1/2}] \\ & + (F+1)^2(x-1)^{1/2} \ln[2x^{1/2} \\ & \left. + (x-1)^{1/2}\theta(x-1)] \exp(-\hbar\omega_1x/k_B T) \right. \\ & \times \{(F+1)\text{arcsinh}[(x-1)^{1/2}\theta(x-1)] \\ & \left. + F \text{arcsinh}(x^{1/2})\}^{-4} \right) \end{aligned} \quad (39)$$

Here ω_1 is the longitudinal phonon frequency.

5.6. Intervalley Scattering

This type of scattering, present in indirect-bandgap semiconductors, transfers electrons from one of the six minima (or valleys) of the conduction band energy in \mathbf{k} space to one of the other five minima. Transitions between a valley and the nearest valley, which is along the same \mathbf{k} -space direction in the next copy of the first Brillouin zone in the periodic zone scheme, are of the umklapp type, and are called g processes. Transitions to the four valleys present in the same zone along the other two \mathbf{k} -space directions are called f processes. Repeating a previous calculation [31] on the basis of the new cross-correlation formula

Eq. (32), we obtain for g processes

$$\begin{aligned} \alpha_g = & \frac{8\pi\sqrt{2\hbar\omega_{ij}}\alpha N_c\hbar^2}{3m^{*5/2}c^2\omega_{ij}} \left[\int_0^\infty dx x^{5/2} \right. \\ & \times [(F+1)(x-1)^{1/2}\theta(x-1) + F(x+1)^{1/2}]^{-4} \\ & \times [(F+1)^2(x-1)(2x-1)\theta(x-1) \\ & \left. + F^2(x+1)(2x+1)\exp\left(-\frac{\hbar\omega_{ij}x}{k_B T}\right)] \right] \\ & \times \left[\int_0^\infty dx x^{3/2} [(F+1)(x-1)^{1/2}\theta(x-1) \right. \\ & \left. + F(x+1)^{1/2}]^{-1} \exp\left(-\frac{\hbar\omega_{ij}x}{k_B T}\right) \right]^{-2} \end{aligned} \quad (40)$$

where $\hbar\omega_{ij}$ is the phonon energy corresponding to the momentum difference required by the intervalley transition. For the corresponding f process we obtain (30)

$$\alpha_f = \left(\frac{k_0}{q_0}\right)^2 \alpha_g \frac{\hbar\omega_{ijf}}{k_B T} \quad (41)$$

where k_0/q_0 is the ratio between length of the position vector of a conduction band energy minimum in \mathbf{k} space, and twice the distance of the same minimum from the Brillouin zone boundary, 0.85/0.3 for silicon. $\alpha_g(\hbar\omega_{ijf}/k_B T)$ is calculated with the f momentum difference. There are three g -type alphas, α_{g1} , α_{g2} , and α_{g3} (from LA, TA, and LO phonons, respectively), and three f -type ones, α_{f1} (`<chemNamesilicon </chemName>`, α_{f2} , and α_{f3} (from TA, LA, and TO phonons). Their values are given in Fig. 2 and are a few times larger than the old values.

The various quantum $1/f$ contributions derived here can be approximately superposed to yield the resultant

Figure 2. Hooke parameters for intervalley scattering in units of 10^{-8} for g processes (solid) and f processes (shaded).

quantum $1/f$ coefficient according to the rule

$$\alpha_H = \sum_j \left(\frac{\mu}{\mu_i} \right)^2 \alpha_i \quad (42)$$

In the next section we illustrate the application of these results to inhomogeneous semiconductor devices on the simplest case of p-n junctions. The case of transistors and other junction devices, as well as the cases of field-effect transistors, HEMTs, PBTs, and other devices, is presented in the literature (see, e.g., Ref. 16)

6. DERIVATION OF MOBILITY QUANTUM $1/f$ NOISE IN N^+P DIODES AND METAL-INSULATOR-SEMICONDUCTOR DEVICES

6.1. Mobility Quantum $1/f$ Noise in n^+p Diodes

For a diffusion limited n^+p junction the current is controlled by diffusion of electrons into the p region over a distance of the order of the diffusion length $L = (D_n \tau_n)^{1/2}$, which is shorter than the length w_p of the p region in the case of a long diode; τ_n is the lifetime of the electrons. Quantum $1/f$ fluctuations of the scattering rates, discussed in the previous section, will cause fluctuations in the local carrier mobility μ and diffusion constant $D = \mu kT/e$. If $N(x)$ is the number of electrons per unit length and D_n their diffusion constant, the electron current at x is

$$I_{nd} = -eD_n \frac{dN}{dx} \quad (43)$$

where we have assumed a planar junction and taken the origin $x=0$ in the junction plane. Diffusion constant fluctuations, given by kT/e times the mobility fluctuations, will lead to local current fluctuations in the interval Δx :

$$\delta \Delta I_{nd}(x, t) = I_{nd} \Delta x \frac{\delta D_n(x, t)}{D_n} \quad (44)$$

The normalized weight with which these local fluctuations representative of the interval Δx contribute to the total current I_d through the diode at $x=0$ is determined by the appropriate Green function and can be shown to be $(1/L) \exp(-x/L)$ for $w_p/L \gg 1$. Therefore the contribution of the section Δx is

$$\delta \Delta I_d(x, t) = \frac{\Delta x}{L} \exp\left(-\frac{x}{L}\right) I_{nd} \frac{\delta D_n(x, t)}{D_n} \quad (45)$$

with the spectral density

$$S_{\Delta I_d}(x, f) = \left(\frac{\Delta x}{L} \right)^2 \exp\left(-\frac{2x}{L}\right) \frac{I_{nd}^2 S_{D_n}(x, f)}{D_n^2} \quad (46)$$

For mobility and diffusion fluctuations the fractional spectral density is given by $\alpha_{Hnd}/(fN\Delta x)$, where the quantum $1/f$ coefficient α_{Hnd} for electronic diffusion or mobility is determined from quantum $1/f$ theory according to

Eq. (42). With Eq. (43) we then obtain

$$S_{\Delta I_d}(x, f) = \frac{\Delta x}{L^2} \exp\left(-\frac{2x}{L}\right) \left(eD_n \frac{dN}{dx} \right)^2 \frac{\alpha_{Hnd}}{fN} \quad (47)$$

The electrons are distributed according to the solution of the diffusion equation:

$$N(x) = [N(0) - N_p] \exp\left(-\frac{x}{L}\right) \quad (48)$$

$$\frac{dN}{dx} = -\frac{N(0) - N_p}{L} \exp\left(-\frac{x}{L}\right)$$

Substituting into Eq. (47) and simply summing over the uncorrelated contributions of all intervals Δx , we obtain

$$S_{I_d}(f) = \alpha_{Hnd} \left(\frac{eD_n}{L^2} \right)^2 \int_0^{w_p} \frac{[N(0) - N_p]^2 e^{-4x/L} dx}{[N(0) - N_p] e^{-x/L} + N_p} \quad (49)$$

We note that $eD_n/L^2 = e/\tau_n$. With the expression for the saturation current $I_0 = e(D_n/\tau_n)^{1/2} N_p$ and of the current $I = I_0 [\exp(eV/kT) - 1]$, we can carry out the integration

$$S_{I_d}(f) = \alpha_{Hnd} \frac{eI}{f\tau_n} \int_0^1 \frac{a^2 u^3 du}{au + 1} = \alpha_{Hnd} \frac{eI}{f\tau_n} F(a) \quad (50)$$

Here we have introduced the notation

$$u = \exp(-x/L), \quad a = \exp(eV/kT) - 1 \quad (51)$$

$$F(a) = \frac{1}{3} - \frac{1}{2a} + \frac{1}{a^2} - \frac{1}{a^3} \ln(1+a)$$

Equation (50) gives the diffusion noise as a function of the quantum $1/f$ noise parameter α_{Hnd} . A similar result can be derived for the quantum $1/f$ fluctuations of the recombination rate in the bulk of the p region. The result is the same, with α_{Hnd} replaced by α_{Hnr} .

6.2. Mobility Quantum $1/f$ Noise in Metal-Insulator-Semiconductor Devices

As an example of results on quantum $1/f$ noise in high-tech devices, we provide here without proof the results obtained by Handel for the $1/f$ -limited performance of metal-insulator-semiconductor (MIS) HgCdTe infrared detectors. The current density I in the detector contains a diffusion term I_d , a term I_r caused by recombination in the space charge region, a surface recombination term I_s , a tunneling term I_t , and a photovoltaic term caused by the creation of electron-hole pairs by photons:

$$I = I_d + I_r + I_s + I_t + q\eta\Phi$$

$$= qn_i \left[\frac{n_i}{n_0} \left(\frac{D_n}{\tau_n} \right)^{1/2} (e^{qV/kT} - 1) + \frac{W}{\tau} (e^{qV/2kT} - 1) + s \right] \quad (52)$$

$$+ I_t + q\eta\Phi$$

Here n_i is the intrinsic concentration, n_0 the concentration of acceptors on the p side, D_n and τ_n the diffusion constant and lifetime of minority carriers on the p side, W the width of the depletion region, $\tau = \tau_{p^0+n^0}$ the Shockley–Hall–Read lifetime, V the applied voltage, s the surface recombination speed, η the quantum efficiency, and Φ the incident flux of photons. With the exception of the last term, the terms in Eq. (52) are known as dark-current components.

We write the total dark-current fluctuation in the form

$$\delta I_d = \delta I_d + \delta I_r + \delta I_s + \delta I_{tb} + \delta I_{tc} + \delta I_{tsc} \quad (53)$$

and the spectral density of current fluctuations will be

$$S_{I_d} = S_{I_d} + S_{I_r} + S_{I_s} + S_{I_{tb}} + S_{I_{tc}} + S_{I_{tsc}} \quad (54)$$

Here we have lumped the recombination current on the back surface I_b together with the surface recombination (generation) current I_s . If we denote all the corresponding spectral densities of fractional fluctuations by a prime ($S'_{I_i} = S_{I_i}/I_i^2$), we obtain

$$\begin{aligned} S'_{I_d} = & (I_{dif}/I_d)^2 S'_{I_{dif}} + (I_{dep}/I_d)^2 S'_{I_{dep}} + (I_s/I_d)^2 S'_{I_s} \\ & + (I_{tb}/I_d)^2 S'_{I_{tb}} + (I_{tc}/I_d)^2 S'_{I_{tc}} + (I_{tsc}/I_d)^2 S'_{I_{tsc}} \end{aligned} \quad (55)$$

This equation was obtained by dividing the previous equation through I_d^2 , and shows that the biggest contribution will not necessarily come from the process with the highest fractional quantum $1/f$ noise, that is, with the highest $1/f$ noise coefficient. The weight of each type of noise is determined by the corresponding squared current ratio.

The detectivity of infrared detectors is limited in general by three types of noise: (1) current noise in the detector, (2) noise due to background photons (photon noise), (3) noise in the electronic system following the detector. We shall neglect here the background photon noise and the noise in the electronic system. The detectivity is defined as

$$D^*(\lambda, f) = \frac{(A\Delta f)^{1/2}}{\text{NEP}} \quad (\text{cm} \cdot \text{Hz}^{1/2}/\text{W}) \quad (56)$$

where A is the area of the detector; NEP is the noise equivalent power, defined as the RMS optical signal of wavelength λ required to produce an RMS noise voltage (current) equal to the RMS noise voltage (current) in a bandwidth Δf , and f is the frequency of modulation. The noise equivalent power is given by

$$\text{NEP} = \frac{h\nu}{\eta q} [S_{I_d}(f)\Delta f]^{1/2} \quad (57)$$

Therefore we obtain for the detectivity

$$D^*(\lambda, f) = \frac{q\eta\lambda}{hc} \left(\frac{A}{S_{I_d}(f)} \right)^{1/2} = \frac{q\lambda}{hc} [S_{I_d}(f)]^{-1/2} \quad (58)$$

We notice that $D^*(\lambda, f)$ is proportional to λ up to the peak wavelength λ_c . For $\lambda > \lambda_c$ we have $\eta = 0$ and thus $D^*(\lambda, f) = 0$. By substituting our result for S_{I_d} , we obtain the general expression for the detectivity as a function of various parameters of the MIS device.

Let us now evaluate the spectral density $S'(f)$ of fractional fluctuations in the various dark-current noise contributions per square centimeter of transversal detector (or gate) area, including also a numerical example for a MIS infrared detector. For a given detector, this needs to be divided by the area A of the detector to yield the corresponding fractional spectral densities: $S(f) = S'(f)/A$. Fractional fluctuations are dimensionless, so $S'(f)$ will have the dimension of a reciprocal frequency times a squared length unit, which simplifies when we divide by the area of the detector at hand. Let S'_{I_d} be the spectral density of fractional fluctuations in the noise caused by quantum $1/f$ fluctuations in diffusion, S'_{I_r} in bulk recombination, S'_{I_s} in surface recombination, and S'_{I_t} in tunneling. With $m_p^* = 0.55m_0$, $m_n^* = 0.02m_0$, $\tau_n = 10^{-6}$ s, $E_g = 0.1$ eV, $3kT/2 = 0.01$ eV, we obtain for a p-type MIS device with $w_p \gg L_d$

$$\begin{aligned} S'_{I_d} = & (\alpha_{Hnd} + \alpha_{Hnr}) \frac{e}{f\tau_n I_d} F(a) = \alpha_{\text{coh}} \frac{e^{1/2}}{f(kT\mu\tau_n)^{1/2} N_p} \frac{F(a)}{a} \\ = & \frac{4.6 \times 10^{-3}}{4fN_p} \frac{4 \times 10^{-10} C^{1/2}}{[(10^{-6} \text{ s})(1.5 \times 10^5 \text{ cm}^2/\text{V} \cdot \text{s})(4 \times 10^{-21} \text{ J})]^{1/2}} \\ = & \frac{1.8 \times 10^{-6} \text{ cm}^2}{f} \end{aligned} \quad (59)$$

$$\begin{aligned} S'_{I_r} = & \frac{\alpha_{\text{He}} e}{f(\tau_{n0} + \tau_{p0}) I_r} \tanh x = \frac{\alpha_{\text{He}} e}{feAwn_i \tanh x} \tanh x \\ = & \frac{\alpha_{\text{He}}}{feAwn_i} = \frac{4.6 \times 10^{-9} \text{ cm}^2}{f} \quad (x = eV/2kT) \end{aligned} \quad (60)$$

$$\begin{aligned} S'_{I_s} = & \frac{4\alpha}{3\pi m^* c^2} \left(\frac{3kT}{2} + \frac{eU}{2} + 0.1Ve \right) \frac{e \tanh x}{f(\tau_{n0} + \tau_{p0}) I_s} \\ = & \frac{4\alpha}{3\pi \times 0.02500,000} (0.025 + 0.5 + 0.5) \frac{e \tanh x}{feAwn_i (e^x - 1)} \\ = & \frac{7 \times 10^{-8} \text{ cm}^2}{f} \approx S_{I_b} \end{aligned} \quad (61)$$

$$\begin{aligned} S'_{I_{tb}} = & \frac{4\alpha E_g + 3kT/2}{3\pi m^* c^2} = \frac{4}{9.5 \times 137 \times 0.02500,000} \frac{0.11}{1} \\ = & \frac{3.310^{-8} \text{ cm}^2}{f} \end{aligned} \quad (62)$$

$$\begin{aligned} S'_{I_{tc}} = & \frac{4\alpha E_g + 3kT}{3\pi 2m^* c^2} = \frac{4}{9.5 \times 137 \times 0.02 \cdot 10^6} \frac{0.12}{1} \\ = & \frac{1.8 \times 10^{-8} \text{ cm}^2}{f} = S'_{I_{tsc}} \end{aligned} \quad (63)$$

S'_{I_d} was calculated in the small-bias limit for $w_p \gg L$, but $w_p = 0.25L$ gives the same result; the incoherent case with a lattice constant of 0.65 nm and $\Theta = 320$ K was also listed

above (because a 10- μm -thick device is very small, so it may be applicable), and would give $(1.8 \times 10^{-10} \text{ cm}^2)/f$ for a n-type device. Equations (60)–(63) would be reduced $m_p^*/m_n^* = 27.5$ times for n-type devices. We mention that S'_{I_s} has been calculated with the inclusion of a term of 10% of the applied gate voltage V in the kinetic energy of the carriers at the surface, and that for the back-surface recombination current this term has to be dropped in the similar expression for S'_{I_b} . However, we have neglected this here, because the surface recombination terms will not turn out to be important, as we will see below. The applied gate voltage was taken to be $V = 5 \text{ V}$. Calculating the fraction of each current, we obtain

$$\begin{aligned}
 (1 \text{ cm}^{-2})fS'_I(f) &= (20/132)^2 \times 1.8 \times 10^{-6} + (10/132)^2 \\
 &\quad \times 4.6 \times 10^{-9} + (3.6/132)^2 \times 7 \times 10^{-8} \\
 &\quad + (0.01/132)^2 \times 3.3 \times 10^{-8} + (80/132)^2 \\
 &\quad \times 1.8 \times 10^{-8} + (17.5/132)^2 \times 1.8 \times 10^{-8} \\
 &= 3.67 \times 10^{-8} + 2.6 \times 10^{-11} + 5.2 \times 10^{-11} \\
 &\quad + 1.9 \times 10^{-16} + 6.61 \times 10^{-9} + 3.17 \times 10^{-10} \\
 &= 4.37 \times 10^{-8} \tag{64}
 \end{aligned}$$

or for incoherent $1/f$ noise, 7.1×10^{-9} (p) and 3×10^{-10} (n). This value can be used in order to estimate the detectivity of the device in our example. Substituting into Eq. (57), we obtain with a quantum efficiency $\eta = 0.7$ and wavelength of $\lambda = 10 \mu\text{m}$

$$\begin{aligned}
 D^*(\lambda, f) &= \frac{\eta q \lambda}{hc} [S_{I_d}(f)]^{-1/2} \\
 &= \frac{(0.7 \times 1.6 \times 10^{-19} \text{ C})(10^{-5} \text{ m})}{(6.6 \times 10^{-34} \text{ J} \cdot \text{s})(3 \times 10^8 \text{ m/s})} \\
 &\quad \left(\frac{f}{(4.37 \times 10^{-8} \text{ cm}^2)(1.74 \times 10^{-6} \text{ A}^2/\text{cm}^4)} \right)^{1/2} \tag{65} \\
 &= (2 \times 10^7 \text{ cm} \cdot \text{Hz}^{1/2}/\text{W}) \times f^{1/2}
 \end{aligned}$$

or for incoherent $1/f$ noise, 5×10^7 (p) and 2.5×10^8 (n).

In conclusion we note that for the relatively large devices which we have considered, most of the quantum $1/f$ noise comes from fluctuations in diffusion and in the rate of tunneling via impurity centers in the bandgap. The effective mass of the carriers is present in the denominator of all quantum $1/f$ noise contributions except the coherent quantum $1/f$ fluctuation present in the diffusion current of large devices. In smaller devices the diffusion current will also be given by the conventional quantum $1/f$ formula, which contains the effective mass of the carriers in the denominator. For umklapp scattering the mass of the carriers in the denominator is squared. Consequently we

expect lower quantum $1/f$ noise from n-type devices, in which the minority carriers are holes, particularly if the devices are very small, say, below $10 \mu\text{m}$. We are now in a position to explain how “smart” ultralow-noise materials can be designed for specific classes of device applications (see Section 11).

7. DERIVATION OF THE CONVENTIONAL QUANTUM $1/f$ EFFECT

The simplified description of quantum $1/f$ noise was presented above in the elementary terms of Schrödinger’s statistical catalog model, without using second quantization. This approach is natural in view of the close connection between this new effect and diffraction, which is usually treated without second quantization, in the statistical catalog model based on the single-particle solution of the Schrödinger equation, normalized to the number of particles, N . Just as the superposition of elementary phase-shifted waves allows for the simplest and most intuitive description of diffraction through a slit, the description of quantum $1/f$ noise in terms of interference beats between slightly frequency-shifted scattered partial waves with bremsstrahlung energy losses will always provide the simplest and most elementary quantitative derivation of the $Q1/fE$, easily accessible even at the undergraduate level.

Below we now present the derivation of the $Q1/fE$ in a general form that determines the scattered current j from the observation of a sample of N outgoing particles. The minimal outgoing sample for defining particle–particle correlations in the scattered wave consists of two particles, and therefore the effect can be calculated for the case of two outgoing particles. Since the general derivation also yields a factor $1/N$ for bosons and a factor $1/(N-1)$ for fermions, and since the simplifying restriction to $N=2$ has given rise to some misinterpretations, a presentation of the general case of N bosons or N fermions will be of interest. We consider the case of bosons.

We start with the expression of the Heisenberg representation state $|S\rangle$ of N identical bosons of mass M emerging at an angle θ from some scattering process with various undetermined bremsstrahlung energy losses reflected in their one-particle waves $\varphi_i(\xi_i)$:

$$|S\rangle = (N!)^{-1/2} \prod_i d^3 \xi_i \varphi_i(\xi_i) \psi^\dagger(\xi_i) |0\rangle = \prod_i d^3 \xi_i \varphi_i(\xi_i) |S^0\rangle \tag{66}$$

where $\psi^\dagger(\xi_i)$ is the field operator creating a boson with position vector ξ_i , $\psi(\xi_i)$ is the field operator annihilating a particle, and $|0\rangle$ is the vacuum state, while $|S^0\rangle$ is the state with N bosons of position vectors ξ_i with $i = 1, \dots, N$. All products and sums in this section run from 1 to N , unless otherwise stated.

To calculate the particle density autocorrelation function in the outgoing scattered wave, we need the

expectation value of the operator

$$O(\mathbf{x}_1, \mathbf{x}_2) = \psi^\dagger(\mathbf{x}_1)\psi^\dagger(\mathbf{x}_2)\psi(\mathbf{x}_2)\psi(\mathbf{x}_1) \tag{67}$$

known as the operator of the pair correlation. This operator corresponds to a density autocorrelation function. The presence of two-particle coordinates in the operator O does not mean that we are considering two-particle interactions; it only means that the expectation value that we are calculating depends on the relative position of the particles. Using the well-known commutation relations for boson field operators,

$$\psi(\mathbf{x})\psi^\dagger(\mathbf{y}) - \psi^\dagger(\mathbf{y})\psi(\mathbf{x}) = \delta(\mathbf{x} - \mathbf{y}) \tag{68}$$

$$\psi(\mathbf{x})\psi(\mathbf{y}) - \psi(\mathbf{y})\psi(\mathbf{x}) = 0 \tag{69}$$

$$\psi^\dagger(\mathbf{x})\psi^\dagger(\mathbf{y}) - \psi^\dagger(\mathbf{y})\psi^\dagger(\mathbf{x}) = 0 \tag{70}$$

we first calculate the matrix element:

$$\begin{aligned} N| \langle S^o | O | S^o \rangle &= \sum'_{\mu\nu} \sum'_{mn} \delta(\eta_\nu - \mathbf{x}_1)\delta(\eta_\mu - \mathbf{x}_2)\delta(\xi_n - \mathbf{x}_1)\delta(\xi_m - \mathbf{x}_2) \sum_{(i,j)} \tag{71} \\ &\times \prod'_{ij} \delta(\eta_j - \xi_i) \end{aligned}$$

where $|S^o\rangle$ is the state with well-defined particle coordinates. Here the prime excludes $\mu = \nu$ and $m = n$ in the summations and excludes $i = m, i = n, j = \mu,$ and $j = \nu$ in the product. The summation $\sum_{(i,j)}$ runs over all permutations of the remaining $N - 2$ values of i and j . On the basis of this result we now calculate the complete matrix element

$$\begin{aligned} \langle S | O | S \rangle &= \frac{1}{N(N-1)} \sum'_{\mu\nu} \sum'_{mn} d^3\eta_\mu d^3\eta_\nu d^3\xi_m d^3\xi_n \\ &\times \varphi_\mu^*(\eta_\mu)\varphi_\nu^*(\eta_\nu)\varphi_m(\xi_m)\varphi_n(\xi_n)\delta(\eta_\nu - \mathbf{x}_1) \\ &\delta(\eta_\mu - \mathbf{x}_2)\delta(\xi_n - \mathbf{x}_1)\delta(\xi_m - \mathbf{x}_2) \\ &= \frac{1}{N(N-1)} \sum'_{\mu\nu} \sum'_{mn} \varphi_\mu^*(\mathbf{x}_2)\varphi_\nu^*(\mathbf{x}_1)\varphi_m(\mathbf{x}_1)\varphi_n(\mathbf{x}_2) \tag{72} \end{aligned}$$

The one-particle states are spherical waves emerging from the scattering center located at $x = 0$:

$$\varphi(\mathbf{x}) = \frac{C}{x} e^{iKx} \left(1 + \sum_{\mathbf{k},l} b(\mathbf{k},l) e^{-iqx} a_{\mathbf{k}l}^\dagger \right) \tag{73}$$

Here C is an amplitude factor, K the boson wave vector magnitude, and $b(\mathbf{k}, l)$ the bremsstrahlung amplitude for photons of wave vector \mathbf{k} and polarization l , while $a_{\mathbf{k}l}^\dagger$ is the corresponding photon creation operator, allowing the

emitted photon state to be created from the vacuum if Eq. (73) is inserted into Eq. (72). The momentum magnitude loss $\hbar q = Mck/K \equiv 2\pi Mf/K$ is necessary for energy conservation in the bremsstrahlung process. Substituting Eq. (73) into Eq. (72), we obtain

$$\begin{aligned} \langle S | O | S \rangle &= \left| \frac{C}{x} \right|^4 (N(N-1) \\ &+ 2(N-1) \sum_{\mathbf{k},l} |b(\mathbf{k},l)|^2 [1 + \cos q(x_1 - x_2)]) \tag{74} \end{aligned}$$

where we have neglected a small term of higher order in $b(\mathbf{k}, l)$. To perform the angular part of the summation in Eq. (74), we calculate the current expectation value of the state in Eq. (73) and compare it with the well-known cross sections without and with bremsstrahlung:

$$\mathbf{j} = \frac{\hbar \mathbf{K}}{Mx^2} \left[1 + \sum_{\mathbf{k},l} |b(\mathbf{k},l)|^2 \right] = \mathbf{j}_0 \left(1 + \alpha A \frac{df}{f} \right) \tag{75}$$

where the quantum fluctuations have disappeared; $\alpha A = (2\alpha/3\pi)(\Delta v/c)^2$ is the fractional bremsstrahlung rate coefficient, also known in QED as the infrared exponent; and the $1/f$ dependence of the bremsstrahlung part displays the well-known infrared catastrophe, that is, the emission of a logarithmically divergent number of photons in the low-frequency limit. Here Δv is the velocity change $\hbar(\mathbf{K} - \mathbf{K}_0)/M$ of the scattered boson, and $f = ck/2\pi$ the photon frequency. Equation (74) thus gives

$$\begin{aligned} \langle S | O | S \rangle &= \left| \frac{C}{x} \right|^4 (N(N-1) + 2(N-1)\alpha A \\ &\times [1 + \cos q(x_1 - x_2)] \frac{df}{f}) \tag{76} \end{aligned}$$

which is the pair correlation function, or density autocorrelation function, along the scattered beam with $df/f = dq/q$. The spatial distribution fluctuations along the scattered beam will also be observed as fluctuations in time at the detector, at any frequency f . According to the Wiener-Khinchine theorem, we obtain the spectral density of fractional scattered particle density ρ , (or current j , or cross section σ) fluctuations in frequency f or wave number q by dividing the coefficient of the cosine by the constant term $N(N - 1)$:

$$\rho^{-2} S_\rho(f) = j^{-2} S_j(f) = \sigma^{-2} S_\sigma(f) = \frac{2\alpha A}{fN} \tag{77}$$

where N is the number of particles or current carriers used to define the current j whose fluctuations we are studying. Quantum $1/f$ noise is thus a fundamental $1/N$ effect. The exact value of the exponent of f in Eq. (77) can be determined by including the contributions from all real and virtual multiphoton processes of any order (infrared radiative corrections), and turns out to be

$\alpha A - 1$ rather than -1 , which is important only philosophically, since $\alpha A \ll 1$. The spectral integral is thus convergent at $f=0$.

For fermions we repeat the calculation, replacing in the derivation of Eq. (10) the commutators of field operators by anticommutators, which finally yields in the same way

$$\rho^{-2}S_\rho(f) = j^{-2}S_j(f) = \sigma^{-2}S_\sigma(f) = \frac{2\alpha A}{f(N-1)} \quad (78)$$

which causes no difficulties, since $N \geq 2$ for particle correlations to be defined, and which is practically the same as Eq. (77), since usually $N \gg 1$. Equations (77) and (78) suggest a new notion of physical cross sections and process rates that contain $1/f$ noise and express a fundamental law of physics, important in most high-technology applications [16].

We conclude that the conventional quantum $1/f$ effect can be explained in terms of interference beats between the part of the outgoing de Broglie waves scattered without bremsstrahlung energy losses above the detection limit (given in turn by the reciprocal duration T of the $1/f$ noise measurement) on one hand, and the various parts scattered with bremsstrahlung energy losses; but there is more to it than that—exchange between identical particles is also important. This, of course, is just one way to describe the reaction of the emitted bremsstrahlung back on the scattered current. This reaction thus reveals itself as the cause of the quantum $1/f$ effect, and implies that the effect cannot be obtained with the independent boson model. The effect, just like the classical turbulence-generated $1/f$ noise, is a result of the scale-invariant nonlinearity of the equations of motion describing the coupled system of matter and field. Ultimately, therefore, this nonlinearity is the source of the $1/f$ spectrum in both the classical and the quantum form of the author's theory. We can say that the quantum $1/f$ effect is an infrared divergence phenomenon, this divergence being the result of the same nonlinearity. The new effect is, in fact, the first time-dependent infrared radiative correction. Finally, it is also deterministic in the sense of a well-determined wave function, once the initial phases γ of all field oscillators are given. In quantum-mechanical correspondence with its classical turbulence analog, the new effect is therefore a quantum manifestation of classical chaos, which we can take as the definition of a certain type of quantum chaos.

8. PHYSICAL DERIVATION OF THE COHERENT QUANTUM $1/f$ EFFECT

This effect arises in a beam of electrons (or other charged particles propagating freely in vacuum) from the definition of the physical electron as a bare particle plus a coherent state of the electromagnetic field. It is caused by the energy spread characterizing any coherent state of the electromagnetic field oscillators, an energy spread that spells nonstationarity, that is, fluctuations. To find the spectral density of these inescapable fluctuations, which are known to characterize any quantum

state that is not an energy eigenstate, we use an elementary physical derivation based on Schrödinger's definition of coherent states, followed by a rigorous derivation from a well-known quantum-electrodynamical propagator. The chaotic character of these fluctuations is discussed later.

The coherent quantum $1/f$ effect will be derived in three steps: First we consider a hypothetical world with just a single mode of the electromagnetic field coupled to a beam of charged particles; considering the mode to be in a coherent state, we calculate the autocorrelation function of the quantum fluctuations in the particle density (or concentration) that arise from the nonstationarity of the coherent state. Then we calculate the amplitude with which this one mode is represented in the field of an electron, according to electrodynamics. Finally, we take the product of the autocorrelation functions calculated for all modes with the amplitudes found in the previous step.

Let a mode of the electromagnetic field be characterized by the wave vector q , the angular frequency $\omega = cq$ and the polarization λ . Denoting the variables q and λ simply by q in the labels of the states, we write the coherent state [25,31,32] of amplitude $|z_q|$ and phase $\arg z_q$ in the form

$$\begin{aligned} |z_q\rangle &= \exp\left(-\frac{1}{2}|z_q|^2\right) \exp(z_q a_q^\dagger) |0\rangle \\ &= \exp\left(-\frac{1}{2}|z_q|^2\right) \sum_{n=0}^{\infty} \frac{z_q^n}{n!} |n\rangle \end{aligned} \quad (79)$$

Here a_q^\dagger is the creation operator that adds one energy quantum to the energy of the mode. Let us use a representation of the energy eigenstates in terms of Hermite polynomials $H_n(x)$:

$$|n\rangle = (2^n n! \sqrt{\pi})^{-1/2} \exp(-x^2/2) H_n(x) e^{i\omega t} \quad (80)$$

This yields for the coherent state $|z_q\rangle$ the representation

$$\begin{aligned} \psi_q(x) &= \exp\left(-\frac{1}{2}|z_q|^2\right) \exp\left(-\frac{x^2}{2}\right) \sum_{n=0}^{\infty} \frac{(z_q e^{i\omega t})^n}{[n!(2^n \sqrt{\omega})]^{1/2}} H_n(x) \\ &= \exp\left(-\frac{1}{2}|z_q|^2\right) \exp\left(-\frac{x^2}{2}\right) \exp(-z_q^2 e^{-2i\omega t} + 2xz_q e^{i\omega t}) \end{aligned} \quad (81)$$

In the last form the generating function of the Hermite polynomials was used. The corresponding autocorrelation function of the probability density function, obtained by averaging over the time t or the phase of z_q , is, for $|z_q| \ll 1$

$$\begin{aligned} P_q(\tau, x) &= \langle |\psi_q|_t^2 |\psi_q|_{t+\tau}^2 \rangle \\ &= [1 + 8x^2 |z_q|^2 (1 + \cos \omega\tau) - 2|z_q|^2] \exp(-x^2/2) \end{aligned} \quad (82)$$

Integrating over x from $-\infty$ to ∞ , we find the autocorrelation function

$$A^1(\tau) = 2^{-1/2}(1 + 2|z_q|^2 \cos \omega\tau) \tag{83}$$

This result shows that the probability distribution contains a constant background with small superposed oscillations of frequency ω . Physically, the small oscillations in the total probability describe self-organization, or bunching, of the particles in the beam. They are thus more likely to be found in a measurement at some times and places than at others along the beam. Note that for $z_q = 0$ the coherent state becomes the ground state of the oscillator, which is also an energy eigenstate, and therefore stationary and free of oscillations.

We now determine the amplitude z_q with which the field mode q is represented in the physical electron. One way to do this is to let a bare particle dress itself through its interaction with the electromagnetic field, by performing first-order perturbation theory with the interaction Hamiltonian

$$H' = A_\mu j^\mu = -\frac{e}{c} \mathbf{v} \cdot \mathbf{A} + e\phi \tag{84}$$

where \mathbf{A} is the vector potential and ϕ the scalar electric potential. Another way is to Fourier-expand the electric potential e/r of a charged particle in a box of volume V . In both ways we obtain

$$|z_q|^2 = \pi(e/q)^2(\hbar c q V)^{-1} \tag{85}$$

Considering now all modes of the electromagnetic field, we obtain from the single-mode result of Eq. (83)

$$\begin{aligned} A(\tau) &= C \prod_q (1 + 2|z_q|^2 \cos \omega_q \tau) = C \left(1 + \sum_q 2|z_q|^2 \cos \omega_q \tau \right) \\ &= C \left(1 + \frac{4V}{2^3 \pi^3} d^3 q |z_q|^2 \cos \omega_q \tau \right) \end{aligned} \tag{86}$$

Here we have again used the smallness of z_q , and we have introduced a constant C . Using Eq. (85) we obtain

$$\begin{aligned} A(\tau) &= C \left(1 + 4\pi \frac{V}{2^3 \pi^3} \frac{4\pi e^2}{V \hbar c} \frac{dq}{q} \cos \omega_q \tau \right) \\ &= C \left(1 + 2 \frac{\alpha}{\pi} \cos \omega\tau \frac{d\omega}{\omega} \right) \end{aligned} \tag{87}$$

Here $\alpha = e^2/\hbar c$ is the fine-structure constant $\approx \frac{1}{137}$. The first term in the large parentheses is unity and represents the constant background, or the dc part of the current carried by the beam of particles through vacuum. The autocorrelation function for the relative (fractional) density fluctuations, or for the current density fluctuations in the beam of charged particles, is obtained therefore by dividing the second term by the first term. The constant C drops out when the fractional fluctuations are considered.

According to the Wiener-Khinchine theorem, the coefficient of $\cos \omega\tau$ is the spectral density of the fluctuations, $S_{|\psi|}^2$ for the particle concentration, or S_j for the current density $j = e(k/m)|\psi|^2$:

$$S_{|\psi|}^2 \langle |\psi|^{-2} \rangle = S_j(j)^{-2} = 2 \frac{\alpha}{\pi f N} = 4.6 \times 10^{-3} f^{-1} N^{-1} \tag{88}$$

Here we have included in the denominator the total number N of charged particles that are observed simultaneously, because the noise contributions from each particle are independent. This result is related to the conventional $Q1/fE$ considered in the next section. A similar calculation yields the gravodynamical quantum $1/f$ effect (QGD $1/f$ effect) by substituting gravitons for the photons considered so far as infra-quanta.

9. RIGOROUS DERIVATION OF THE COHERENT QUANTUM $1/f$ EFFECT

The present derivation is based on the well-known new propagator $G_s(x' - x)$ derived relativistically [33,34] in 1975 in a new picture required by the infinite range of the Coulomb potential. The corresponding nonrelativistic form [35] was provided by Zhang and Handel (see Section 10.2.6):

$$\begin{aligned} &-i \langle \Phi_0 | T \psi_s(x') \psi_s^\dagger(x) | \Phi_0 \rangle \\ &\equiv \delta_{ss'} G_s(x' - x) \\ &= \frac{i}{V} \sum_{\mathbf{p}} \left(\exp i \frac{\mathbf{p} \cdot (\mathbf{r} - \mathbf{r}') - \mathbf{p}^2(t - t')/2m}{\hbar} \right) n_{\mathbf{p},s} \\ &\quad \times \left(-i \frac{\mathbf{p} \cdot (\mathbf{r} - \mathbf{r}')}{\hbar} + i(m^2 c^2 + \mathbf{p}^2)^{1/2} (t - t') \frac{c}{\hbar} \right)^{\alpha/\pi} \end{aligned} \tag{89}$$

Here $\alpha = e^2/\hbar c \approx 1/137$ is Sommerfeld's fine structure constant, $n_{\mathbf{p},s}$ the number of electrons in the state of momentum \mathbf{p} and spin s , m the rest mass of the fermions, $\delta_{ss'}$ the Kronecker symbol, c the speed of light, $x = (\mathbf{r}, t)$ any spacetime point, and V the volume of a normalization box. T is the time-ordering operator, which orders the operators in the order of decreasing times from left to right and multiplies the result by $(-1)^P$, where P is the parity of the permutation required to achieve this order. For equal times, T normal orders the operators, that is, for $t = t'$ the left-hand side of Eq. (89) is $i \langle \Phi_0 | \psi_s^\dagger(x) \psi_s(x') | \Phi_0 \rangle$. The state Φ_0 of the N electrons is described by a Slater determinant of single-particle orbitals.

The resulting spectral density coincides with the result $2\alpha/\pi f N$, derived directly in the section above from the coherent state of the electromagnetic field of a physical charged particle. The connection with the conventional quantum $1/f$ effect is discussed in the section.

To calculate the current autocorrelation function we need the density correlation function, which is also known

as the two-particle correlation function, and is defined by

$$\begin{aligned} & \langle \Phi_0 | T \psi_s^\dagger(x) \psi_s(x) \psi_s^\dagger(x') \Phi^{s'}(x') | \Phi_0 \rangle \\ &= \langle \Phi_0 | \psi_s^\dagger(x) \psi_s(x) | \Phi_0 \rangle \langle \Phi_0 | \psi_s^\dagger(x') \psi_s(x') | \Phi_0 \rangle \\ & \quad - \langle \Phi_0 | T \psi_s(x') \psi_s^\dagger(x) | \Phi_0 \rangle \langle \Phi_0 | T \psi_s(x) \psi_s^\dagger(x') | \Phi_0 \rangle \end{aligned} \quad (90)$$

The first term can be expressed in terms of the particle density of spin s , $n/2 = N/2V = \langle \Phi_0 | \psi_s^\dagger(x) \psi_s(x) | \Phi_0 \rangle$, while the second term can be expressed in terms of the Green function Eq. (89) in the form

$$\begin{aligned} A_{ss'}(x-x') &\equiv \langle \Phi_0 | \psi_s^\dagger(x) \psi_s^\dagger(x') \psi_s(x') \psi_s(x) | \Phi_0 \rangle \\ &= (n/2)^2 + \delta_{ss'} G_s(x'-x) G_s(x-x') \end{aligned} \quad (91)$$

The *relative* autocorrelation function $A(x-x')$ describing the normalized pair correlation independent of spin is obtained by dividing by n^2 and summing over s and s' :

$$\begin{aligned} A(x-x') &= 1 - \frac{1}{n^2} \sum_s G_s(x-x') G_s(x'-x) \\ &= 1 - \frac{1}{N^2} \sum_s \sum_{\mathbf{p}\mathbf{p}'} \\ & \quad \left(\exp i \frac{(\mathbf{p}-\mathbf{p}') \cdot (\mathbf{r}-\mathbf{r}') - (E_{\mathbf{p}} - E_{\mathbf{p}'})(t-t')}{\hbar} \right) n_{\mathbf{p},s} n_{\mathbf{p}',s} \\ & \quad \times \left(\frac{\mathbf{p} \cdot (\mathbf{r}-\mathbf{r}')}{\hbar} - (m^2 c^2 + \mathbf{p}^2)^{1/2} (t-t') \frac{c}{\hbar} \right)^{\alpha/\pi} \\ & \quad \times \left(\frac{\mathbf{p}' \cdot (\mathbf{r}'-\mathbf{r})}{\hbar} - (m^2 c^2 + \mathbf{p}'^2)^{1/2} (t'-t) \frac{c}{\hbar} \right)^{\alpha/\pi} \end{aligned} \quad (92)$$

Here we have used Eq. (89).

We now consider a beam of charged fermions (e.g., electrons), represented in momentum space by a sphere of radius p_F centered on the momentum \mathbf{p}_0 , which is the average momentum of the fermions. The energy and momentum differences between terms of different \mathbf{p} are large, leading to rapid oscillations in space and time, which contain only high-frequency quantum fluctuations. The low-frequency and low-wavenumber part A_1 of this relative density autocorrelation function is given by the

terms with $\mathbf{p} = \mathbf{p}'$:

$$A_l(x-x') = 1 - \frac{1}{N^2} \sum_s \sum_{\mathbf{p}} n_{\mathbf{p},s} \quad (93)$$

$$\begin{aligned} & \times \left| \frac{\mathbf{p} \cdot (\mathbf{r}-\mathbf{r}')}{\hbar} - (m^2 c^2 + \mathbf{p}^2)^{1/2} (t-t') \frac{c}{\hbar} \right|^{2\alpha/\pi} \\ & \approx 1 - \frac{1}{N} \left| \frac{\mathbf{p}_0 \cdot (\mathbf{r}-\mathbf{r}')}{\hbar} - \frac{m c^2 \tau}{\hbar} \right|^{2\alpha/\pi} \\ & \quad \text{for } p_F \ll \left| p_{03} - \frac{m c^2 \tau}{z} \right| \end{aligned} \quad (94)$$

Here we have used the mean value theorem, considering the $2\alpha/\pi$ power as a slowly varying function of \mathbf{p} and neglecting \mathbf{p}_0 in the coefficient of $\tau \equiv t-t'$, with $z \equiv |\mathbf{r}-\mathbf{r}'|$. The correlations propagate along the beam with a group velocity given by the average velocity \mathbf{p}_0/m of the particles in the beam, and with the phase velocity c^2/v . Using an identity in Ref. 36, we obtain from Eq. (94) with $\theta \equiv |\tau - \mathbf{p}_0 \cdot (\mathbf{r}-\mathbf{r}')/m c^2|$ the form

$$\begin{aligned} A_1(x-x') &= 1 - \frac{1}{N} \left| \frac{m c^2 \theta}{\hbar} \right|^{2\alpha/\pi} = 1 - \frac{1.25}{N} |\Theta|^{2\alpha/\pi} \\ &= 1 - \frac{1.25}{N} e^{(2\alpha/\pi) \ln \Theta} \\ &\approx 1 - \frac{1.25}{N} \left(1 + \frac{2\alpha}{\pi} \ln \Theta \right) \\ &= 1 - \frac{2.5}{N} + \frac{1.25}{N} \left(1 - \frac{2\alpha}{\pi} \ln \Theta \right) \\ &\approx \frac{N-2.5}{N} + \frac{1.25}{N} e^{-(2\alpha/\pi) \ln \Theta} \\ &= \frac{1}{N} \left(N - 2.5 + \frac{2.5\alpha}{\pi \cos \alpha} \int_0^{\cos \omega \Theta d\omega} \frac{\cos \omega \Theta d\omega}{\omega^{1-2\alpha/\pi}} \right) \end{aligned} \quad (95)$$

This indicates a $\omega^{-1+2\alpha/\pi}$ spectrum and a $1/(N-2.5)$ dependence of the spectrum of fractional fluctuations in density n and current j . The total error corresponding to the two linear approximations of exponentials in Eq. (95) is less than 1%, provided $|\ln \Theta| < 20$, or $(250,000)^{-1} \text{ h} < |\theta| < 250,000 \text{ h}$. Here $\Theta = \theta/(1 \text{ s})$, and ω is the circular Fourier frequency in radians per second. We have used $[(1 \text{ s}) m c^2 / \hbar]^{2\alpha/\pi} \approx 1.25$; this accounts also for the presence of the number 2.5 instead of the more usual number 2 in the final form. The form we have chosen here is more convenient for applications. The equivalent normal form would have been

$$\begin{aligned} A_1(x-x') & \approx \frac{1}{N} \left(N - 2 + \frac{2\alpha}{\pi \cos \alpha} \int_0^{\left(\frac{m c^2}{\hbar \omega} \right)^{2\alpha/\pi} \cos \omega \theta \frac{d\omega}{\omega}} \right) \end{aligned} \quad (96)$$

in which the error caused by the two linear approximations of exponentials would have been of the order of 20%, and in which the fractional power would also have been neglected

in the integrand for all purposes except for the theoretical question of the integrability of the $1/\omega$ spectrum.

The fractional autocorrelation of current fluctuations δj is obtained by multiplying Eq. (92) on both sides by $(ep_0/m)^2$ and dividing by $(enp_0/m)^2$, which is the square of the average current density j , instead of just dividing by n^2 . So it is the same as the fractional autocorrelation for quantum density fluctuations. The last form of Eq. (95) for the coherent quantum-electrodynamical chaos process in electric currents becomes

$$S_{\delta j/\delta j}(k) \approx \frac{2.5\alpha}{\pi\omega(N-2.5)}\omega^{2\alpha} \approx \frac{2.5\alpha}{\pi\omega N} = \frac{0.0058}{\omega N} \quad (97)$$

Being observed in the presence of a constant applied field, these fundamental quantum current fluctuations are usually interpreted as mobility fluctuations. Most of the conventional quantum $1/f$ fluctuations in physical cross sections and process rates are also mobility fluctuations, but some are also in the recombination speed or tunneling rate.

10. MORE RECENT RESULTS

Six developments are reported. They include (1) a first-principles proof of the absence of the $Q1/fE$ in the process of photogeneration of carriers in photodetectors, (2) the verification of the quantum $1/f$ noise theory in quartz resonators, (3) the application of quantum $1/f$ noise to explain the anisotropy observed for conventional quantum $1/f$ noise in mono-crystal silicon, (4) the derivation of the nonrelativistic propagator of QED, which predicts the presence of the coherent quantum $1/f$ effect, and (5) a clear formulation of the problem of transition between the coherent and conventional quantum $1/f$ effects. In addition we have improved our universal sufficient criterion for $1/f$ spectra in chaotic nonlinear systems, and (6) we have applied it to QED, obtaining the quantum $1/f$ effect as a consequence of the nonlinearity of the system formed by the charged particles together with the electromagnetic field.

10.1. Method Used

The derivation of the coherent nonrelativistic propagator of QED was performed in the picture introduced by Dollard in 1964, and uses the branchpoint propagator introduced later by Zwanziger and Kibble [33,34]. The derivation of the anisotropy of $1/f$ noise in monocrystalline silicon is based on the conventional quantum $1/f$ noise theory and the known structure of the conduction band of silicon in the Brillouin zone.

10.2. Results

Below we report the main results of the four [33,34] achievements mentioned above.

10.2.1. First-Principles Proof of the Absence of the Quantum $1/f$ Effect in the Photogeneration of Carriers in Photodetectors. Quantum $1/f$ noise is a fundamental aspect of quantum mechanics, representing universal fluctuations

of physical process rates R and cross sections σ given by the fractional (or relative) spectral density $S(f) = 2\alpha A/fN$. Therefore it is present in the process rates generating the dark current observed in junction photodetectors, such as *diffusion* (scattering cross sections fluctuate) in diffusion-limited junctions, and *recombination* in the recombination-limited regime. One is therefore tempted to expect similar fluctuations in the *photogeneration* of electron-hole pairs. However, as we show below, the corresponding quantum $1/f$ coefficient is zero, precluding the existence of quantum $1/f$ fluctuations in the photogeneration rate. Here N is the number of carriers used to define or measure the process rate or cross section considered.

For an arbitrary process involving a total of n incoming and outgoing charged particles, the nonrelativistic quantum $1/f$ coefficient is given [37] by

$$2\alpha A = \frac{4\alpha}{3\pi c^2} \sum_{i,j=1}^n \eta_i \eta_j q_i q_j (\mathbf{v}_i - \mathbf{v}_j)^2 \quad (98)$$

where the summation runs over the charges q_i and velocities \mathbf{v}_i of all incoming ($\eta_i = -1$) and outgoing ($\eta_i = 1$) particles (altogether n of them) in the process whose $Q1/fN$ we want to find, and α is Sommerfeld's fine structure constant, $e^2/\hbar c \approx \frac{1}{137}$. In a photogeneration process a photon ($q = 0$) is absorbed, and a pair of oppositely charged particles is generated ($\eta = 1$) with velocities \mathbf{v}_1 and \mathbf{v}_2 , which either are zero or quickly decay to zero in a time negligible with respect to the reciprocal frequency at which we calculate the quantum $1/f$ noise. Thus in our case there are no incoming charged particles, and $n = 0 + 2 = 2$. The coefficient αA of a photogeneration process is therefore zero:

$$\begin{aligned} \alpha A_{\text{ph}} &= (1, 1) + (2, 2) + (1, 2) + (2, 1) \\ &= 0 + 0 + \frac{4\alpha}{3\pi c^2} (\mathbf{v}_1 - \mathbf{v}_2)^2 \approx 0 \end{aligned} \quad (99)$$

All photogenerated carriers of the right sign are collected in the well of the charge-coupled device, although they may generate quantum $1/f$ voltage fluctuations on their way. Since usually only the number of carriers collected at readout matters, no quantum $1/f$ noise will be observed in a photoelectric CCD as long as the dark current is negligible with respect to the photocurrent. This is in agreement with the experiments performed by Mooney [38]. The same considerations apply to MIS photodetectors.

10.2.2. Verification of the Quantum $1/f$ Noise Theory in Quartz Resonators. According to the general quantum $1/f$ formula (2), $\Gamma^{-2} S_{\Gamma}(f) = 2\alpha A/f$, where $\alpha = e^2/\hbar c \approx 1/137$ and $A = 2(\Delta\mathbf{J}/ec)^2/3\pi$ is the quantum $1/f$ effect in any physical process rate Γ . Setting

$$\mathbf{J} = \frac{d\mathbf{P}}{dt} = \dot{\mathbf{P}} \quad (100)$$

where \mathbf{P} is the vector of the dipole moment of the quartz crystal, we obtain for the fluctuations in the rate Γ of phonon removal from the main resonator oscillation mode

of the crystal (by scattering on a phonon from any other mode of average frequency (ω) , or via a two-phonon process at a crystal defect or impurity, involving a phonon of average frequency (ω')) the spectral density

$$S_{\Gamma}(f) = \Gamma^2 4\alpha(\Delta\dot{\mathbf{P}})^2 / 3\pi e^2 c^2 \quad (101)$$

where $(\Delta\dot{\mathbf{P}})^2$ is the square of the dipole moment rate change associated with the process causing the removal of a phonon from the main oscillator mode. To calculate it, we write the energy W of the interacting resonator mode (ω) in the form

$$W = n\hbar(\omega) = 2 \frac{Nm}{2} \left(\frac{dx}{dt} \right)^2 = \frac{Nm}{e^2} \left(e \frac{dx}{dt} \right)^2 = \frac{m}{Ne^2} \varepsilon^2 \dot{\mathbf{P}}^2 \quad (102)$$

The factor 2 includes the potential energy contribution. Here m is the reduced mass of the elementary oscillating dipoles, e their charge, ε a polarization constant, and N their number in the quartz crystal. Applying a variation $\Delta n = 1$, we get

$$\frac{\Delta n}{n} = 2 \frac{|\Delta\dot{\mathbf{P}}|}{|\dot{\mathbf{P}}|}, \quad \text{or} \quad \Delta\dot{\mathbf{P}} = \frac{\dot{\mathbf{P}}}{2n}$$

Solving Eq. (102) for $\dot{\mathbf{P}}$ and substituting, we obtain

$$|\Delta\dot{\mathbf{P}}| = \left(\frac{N\hbar(\omega)}{n} \right)^{1/2} \frac{e}{2\varepsilon}$$

Substituting $\Delta\dot{\mathbf{P}}$ into Eq. (3), we get

$$\Gamma^{-2} S_{\Gamma}(f) = N\alpha\hbar(\omega) / 3n\pi mc^2 f \varepsilon^2 \equiv \Lambda / f \quad (103)$$

This result is applicable to the fluctuations in the loss rate Γ of the quartz.

The corresponding resonance frequency fluctuations of the quartz resonator are given by [39]

$$\omega^{-2} S_{\omega}(f) = \frac{1}{4Q^4} \frac{\Lambda}{f} = \frac{N\alpha\hbar(\omega)}{12n\pi mc^2 f \varepsilon^2 Q^4} \quad (104)$$

where Q is the quality factor of the single-mode quartz resonator considered, and (ω) is not the circular frequency of the main resonator mode, ω_0 , but rather the practically constant frequency of the average interacting phonon, considering both three-phonon and two-phonon processes. The corresponding $\Delta\dot{\mathbf{P}}$ in the main resonator mode has to be also included in principle, but is negligible because of the very large number of phonons present in the main resonator mode.

Equation (6) can be written in the form

$$S(f) = \beta V / f Q^4 \quad (105)$$

where, with a moderate value $(\omega) = 10^8 \text{ s}^{-1}$ and with $n = kT / \hbar(\omega)$, $T = 300 \text{ K}$, and $kT = 4 \times 10^{14}$

$$\beta = \frac{N}{V} \frac{\alpha\hbar(\omega)}{12n\pi\varepsilon^2 mc^2} = 10^{22} \frac{(1/137)(10^{-27} \times 10^8)^2}{12kT \times \pi \times 10^{-27} \times 9 \times 10^{20}} = 1$$

This is in very good agreement with experiment [40].

10.2.3. Application of Quantum 1/f Noise to Explain the Anisotropy of Conventional Quantum 1/f Noise in Monocrystalline silicon. The conduction band of silicon has six equivalent energy minima along the six $\langle 100 \rangle$ directions in the reciprocal lattice, which is bcc. These directions correspond to [111] in the direct lattice, which is fcc. If an electric field is applied along the [111] direct lattice axis, along which the energy minima are located, a lot of easy umklapp intervalley scattering processes (g processes) will take place along the direction opposing the applied field, because in the reciprocal lattice the minima are at $0.85K$ from the center of the first Brillouin zone, so there is only $0.3K$ to the next minimum in the neighboring zone. Here K is the distance between the center and the edge of the Brillouin zone. But umklapp processes are associated with the largest conventional $Q1/fE$, because in the expression $(4\alpha/3\pi)(\hbar\Delta k/mc)^2$ we have $\Delta k = G = 2\pi/a$ for umklapp, while normal scattering processes have smaller Δk . Therefore, the [111] direction will yield the highest quantum 1/f noise for identical currents applied in different directions in a Si mono-crystal. Experimentally it is well known that devices built on (100) silicon surfaces have lower 1/f noise than those built on (111) surfaces [41].

10.2.4. Derivation of the Nonrelativistic Propagator of Quantum Electrodynamics. The derivation of the coherent $Q1/fE$ by us [42] in second quantization was done on the basis of a new picture of QED introduced by Dollard, Zwanziger, and Kibble [29,31,33,34,43,44]. This new picture includes the long-range part of the Coulomb potential in the unperturbed Hamiltonian H_0 . The result is a more complicated free particle and a new propagator with a branch point instead of a pole. We used a nonrelativistic form of this new propagator and obtained the universal spectral density of fractional current fluctuations $S_{\delta j/j}(f) = 2\alpha/3\pi fN$, which we called the coherent $Q1/fE$. The purpose here is to derive this nonrelativistic propagator from the well-known relativistic propagator based on Dollard's picture.

Our derivation is similar to the derivation of the nonrelativistic equation from Dirac's theory of the electron. It is based on the distinction between the large and small components of the Dirac spinor.

The relativistic propagator $S(x' - x)$ in the equation

$$\theta(t' - t)\psi^\dagger(x') = i \int S(x' - x)\gamma_0\psi^\dagger(x)d^3x \quad (106)$$

is

$$S(x) = i(2\pi)^{-3} \int \frac{d^3\mathbf{p}}{2E} e^{ipx} (-ipx)^{\alpha/\pi} (i\gamma p - m) \quad (107)$$

and valid for very large time t' . In the nonrelativistic limit, the Dirac spinor can be written in the form

$$\psi^\dagger(x) = e^{-imc^2t'/h} \begin{bmatrix} \varphi(\mathbf{x}) \\ \chi(\mathbf{x}) \end{bmatrix} \tag{108}$$

So we get

$$\begin{aligned} & \vartheta(t' - t)\psi^\dagger(x') \\ &= i(-i) \iint \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - E(t' - t) - mc^2t}{h}\right) \\ & \times (-ipx)^{\alpha/\pi} \frac{E\gamma_0 - ic\mathbf{p}\cdot\boldsymbol{\gamma} + mc^2}{2E} \beta \begin{bmatrix} \varphi(\mathbf{x}) \\ \chi(\mathbf{x}) \end{bmatrix} d^3\mathbf{x} \\ &= \iint \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - E(t' - t) - mc^2t}{h}\right) \\ & \times (-ipx)^{\alpha/\pi} \frac{E + c\mathbf{p}\cdot\boldsymbol{\alpha} + \beta mc^2}{2E} \beta \begin{bmatrix} \varphi(\mathbf{x}) \\ \chi(\mathbf{x}) \end{bmatrix} d^3\mathbf{x} \end{aligned} \tag{109}$$

and then we have

$$\begin{aligned} & \vartheta(t' - t) \begin{bmatrix} \varphi(\mathbf{x}) \\ \chi(\mathbf{x}) \end{bmatrix} \\ &= \vartheta(t' - t)\psi^\dagger(x') e^{imc^2t'/h} \\ & \iint \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - (E - mc^2)(t' - t)}{h}\right) \\ & \times (-ipx)^{\alpha/\pi} \frac{E + c\mathbf{p}\cdot\boldsymbol{\alpha} + \beta mc^2}{2E} \beta \begin{bmatrix} \varphi(\mathbf{x}) \\ \chi(\mathbf{x}) \end{bmatrix} d^3\mathbf{x} \\ &= \iint \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - (E - mc^2)(t' - t)}{h}\right) \\ & \times (-ipx)^{\alpha/\pi} \left(\frac{1}{2} \begin{bmatrix} \varphi \\ \chi \end{bmatrix} + \frac{c\mathbf{p}}{2E} \cdot \begin{bmatrix} \sigma\chi \\ \sigma\varphi \end{bmatrix} + \frac{mc^2}{2E} \begin{bmatrix} \varphi \\ -\chi \end{bmatrix} \right) d^3\mathbf{x} \end{aligned} \tag{110}$$

Furthermore, after using the nonrelativistic limit spinor component relation

$$\chi \approx \frac{\boldsymbol{\sigma}\cdot\mathbf{p}}{2mc} \varphi \tag{111}$$

we get

$$\begin{aligned} & \vartheta(t' - t)\varphi^\dagger(x') \\ &= \int d^3\mathbf{x} \left[\int \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - (\mathbf{p}^2/2m)(t' - t)}{h}\right) \right. \\ & \left. \times (-ipx)^{\alpha/\pi} \right] \varphi(\mathbf{x}) \end{aligned} \tag{112}$$

If we compare this with the equation

$$\vartheta(t' - t)\varphi(x') = i \int d^3\mathbf{x} G(x' - x)\varphi(x) \tag{113}$$

which defines the nonrelativistic propagator, we get for the latter

$$\begin{aligned} G(x' - x) &= -i \int \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - (\mathbf{p}^2/2m)(t' - t)}{h}\right) \\ & \times (-ipx)^{\alpha/\pi} \end{aligned} \tag{114}$$

The propagator with a phase factor is

$$\begin{aligned} G(x' - x) &= -i \int \frac{d^3\mathbf{p}}{(2\pi)^3} \exp\left(i\frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x}) - (\mathbf{p}^2/2m)(t' - t)}{h}\right) \\ & \times (-i)^{\alpha/\pi + i\gamma} \left(-\frac{(m^2c^2 + \mathbf{p}^2)(t' - t)c}{h} + \frac{\mathbf{p}\cdot(\mathbf{x}' - \mathbf{x})}{h} \right)^{\alpha/\pi + i\gamma} \end{aligned} \tag{115}$$

This is just the nonrelativistic propagator used by us in the preceding section. It has a branchpoint instead of a pole. For $\mathbf{x} = \mathbf{x}'$

$$G = -i \left(i\frac{mc^2}{h}(t' - t) \right)^{\alpha/\pi + i\gamma} \left(\frac{m}{2\pi i(t' - t)} \right)^{3/2} \tag{116}$$

This propagator expresses the essence of our coherent Q1/f E.

10.2.5. Formulation of the Problem of Transition between the Coherent and Conventional Quantum 1/f Effects. From the beginning of the theory of fundamental 1/f noise in semiconductors and metals two situations were distinguished [45]. The first, applicable to small semiconductor samples and very small (mesoscopic) metallic samples, has most of the energy excess $Nmv_d^2/2$ present in the stationary state carrying a finite current through the sample (excess over the energy of the equilibrium state) contained in the sum of the individual kinetic energies of the N current carriers, $\sum_i mv_i^2/2$. Here the velocities v_i of the carriers of mass m contain a small drift term v_d . The second, applicable in larger semiconductor or metal samples, has most of that energy excess contained in the

collective magnetic energy of the current-carrying state, $(B^2 8\pi) d^3x = LI^2/2$. The ratio s of this magnetic energy to the kinetic energy excess is roughly equal [45,46] to the number of carriers N' per unit length of the sample, multiplied by the classical radius of the electron, $r_0 = e^2/mc^2$: $s = N'r_0$. This situation was considered already in our classical magnetic turbulence theory [45,47].

In the first situation conventional quantum $1/f$ noise is applicable for fluctuations in physical scattering cross sections σ , in physical process rates Γ , and in the mobility μ or diffusion coefficient D (the latter two only if exclusively limited by σ or Γ):

$$\sigma^{-2} S_\sigma(f) = \Gamma^{-2} S_\Gamma(f) = \mu^{-2} S_\mu(f) = 2\alpha A/fN \quad (s \ll 1) \quad (117)$$

because in this case the coherent, collective term in the Hamiltonian is negligible. In the second case, however, the coherent $Q1/fE$ [26] is dominant:

$$j^{-2} S_j(f) = \mu^{-2} S_\mu(f) = 2\alpha/\pi f N \quad (s > 1) \quad (118)$$

because the incoherent kinetic term can be neglected.

For the intermediate case, an interpolation formula was proposed [46]

$$j^{-2} S_j(f) = \mu^{-2} S_\mu(f) = \frac{2\alpha}{fN} \left(\frac{A}{s+1} + \frac{s}{\pi(s+1)} \right) \quad (119)$$

which is heuristic. The main purpose of Ref. 48 was to discuss various avenues to derive the correct form for the intermediary situation, and to consider initially the problem of coherent quantum $1/f$ noise in the $s \leq 1$ case.

For a finite sample or device Eq. (115) should be replaced by a propagator that approaches the classical free-particle propagator of the Schrödinger equation when the transverse sample size, or the number of particles per unit length of the sample, approaches zero. This would cause the coherent $Q1/fE$ to become very small compared with the conventional quantum $1/f$ noise present in the beam, due to the particular way in which the beam was generated. A formula like the interpolation in Eq. (119) would then express the fact that conventional quantum $1/f$ is always present, but is masked in larger samples by the coherent $Q1/fE$. However, a formula with a size-dependent infrared parameter intermediate between the coherent and conventional limits of α/π and αA , present in both the coefficient and the exponent, would express the same transition in a slightly different, physically more meaningful form:

$$j^{-2} S_j(f) = \mu^{-2} S_\mu(f) = \frac{2\beta}{f^{1-\beta} N} \quad \text{with } \beta = \frac{\alpha A}{s+1} + \frac{\alpha s}{\pi(s+1)} \quad (120)$$

So far we have not derived an expression equivalent to Eq. (120) in any way. However, the physical unity of coherent and conventional $Q1/fE$ s speaks in favor of a more sophisticated relation than Eq. (119). This same physical content can be expressed in a slightly different way by noting that Eq. (115) is equivalent to a energy-

momentum relation that is not sharp, allowing for quantum fluctuations of the rest mass of the charged particle, or of any other particle with infrared divergent coupling to a group of massless infraquanta. Describing these quantum fluctuations of the rest mass μ with the help of a distribution function $\rho(\mu)$ peaked at the measured rest mass m , we could attempt to write Eq. (115) in the form

$$\begin{aligned} & -i \langle \Phi_0 | T \psi_{s'}(x') \psi_s^\dagger(x) | \Phi_0 \rangle \\ & \equiv \delta_{ss'} G_s(x' - x) \\ & = \frac{i}{V} \sum_{\mathbf{p}} \left(\exp \frac{\mathbf{p} \cdot (\mathbf{r} - \mathbf{r}') - \mathbf{p}^2(t - t')/2m}{\hbar} \right) n_{\mathbf{p},s} \\ & \quad \times \left(-i \frac{\mathbf{p} \cdot (\mathbf{r} - \mathbf{r}')}{\hbar} + i(m^2 c^2 + \mathbf{p}^2)^{1/2} (t - t') \frac{c}{\hbar} \right)^{\alpha/\pi} \\ & = \frac{i}{V} \int d\mu \rho(\mu) \sum_{\mathbf{p}} \left(\exp i \frac{\mathbf{p}(\mathbf{r} - \mathbf{r}') - \mathbf{p}^2(t - t')/2m}{\hbar} \right) n_{\mathbf{p},s} \end{aligned} \quad (121)$$

The distribution function $\rho(\mu)$ can be used to transform various classical results calculated simply with the Schrödinger propagator into the corresponding quantum $1/f$ results.

To determine $\rho(\mu)$, we represent the nonrelativistic form [38] of the new QED propagator as a superposition of classical propagators, defined by an unknown mass distribution $\rho(\mu)$ that describes the fuzzy mass shell:

$$\begin{aligned} & \exp \left\{ \frac{im}{\hbar} \left[\mathbf{v} \cdot (\mathbf{r} - \mathbf{r}') - \left(c^2 + \frac{v^2}{2} \right) (t - t') \right] \right\} \\ & \cdot \left\{ \frac{im}{\hbar} \left[\mathbf{v} \cdot (\mathbf{r} - \mathbf{r}') - \left(c^2 + \frac{v^2}{2} \right) (t - t') \right] \right\}^{\alpha/\pi} \\ & = \int_0^\infty d\mu \rho(\mu) \exp \left\{ \frac{i\mu}{\hbar} \left[\mathbf{v} \cdot (\mathbf{r} - \mathbf{r}') - \left(c^2 + \frac{v^2}{2} \right) (t - t') \right] \right\} \end{aligned} \quad (122)$$

Let $u = (1/\hbar)[\mathbf{v} \cdot (\mathbf{r} - \mathbf{r}') - (c^2 + v^2/2)(t - t')]$. This allows us to simplify the equation presented above

$$\int_0^\infty d\mu \rho(\mu) e^{i\mu u} = e^{imu} (imu)^{\alpha/\pi} \quad (123)$$

When we used $\mu' = \mu - m$, the equation becomes

$$\int_{-m}^\infty d\mu' \rho'(\mu') e^{i\mu' u} = (imu)^{\alpha/\pi} \quad (124)$$

Because $\rho'(\mu')$ is different from zero only around $\mu' = 0$ or $\mu = m$, we can extend the domain of integration:

$$\int_{-\infty}^\infty d\mu' \rho'(\mu') e^{i\mu' u} = (imu)^{\alpha/\pi} \quad (125)$$

Let us take the derivative with respect to u . This yields

$$\int_{-\infty}^{\infty} d\mu' \rho'(\mu') e^{i\mu' u} \cdot i\mu' = \frac{(\alpha/\pi)(im)^{\alpha/\pi}}{u^{1-\alpha/\pi}} \quad (126)$$

We can further simplify this equation with the notation $\mu' \rho'(\mu') = X(\mu')$ and get

$$\int_{-\infty}^{\infty} d\mu' X(\mu') e^{i\mu' u} = \frac{(\alpha/\pi)m^{\alpha/\pi}}{(iu)^{1-\alpha/\pi}} \quad (127)$$

We can determine $X(\mu')$ by taking the Fourier transformation of the right-hand side:

$$\begin{aligned} X(\mu') &= \int_{-\infty}^{\infty} du \frac{(\alpha/2\pi^2)m^{\alpha/\pi}}{(iu)^{1-\alpha/\pi}} e^{-iu\mu'} = \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \int_{-\infty}^{\infty} du \frac{e^{-iu\mu'}}{u^{1-\alpha/\pi}} \\ &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left(\int_{-\infty}^0 du \frac{\cos(\mu' u) + i \sin(\mu' u)}{u^{1-\alpha/\pi}} \right. \\ &\quad \left. + \int_0^{\infty} du \frac{\cos(\mu' u) + i \sin(\mu' u)}{u^{1-\alpha/\pi}} \right) \end{aligned} \quad (128)$$

$$\begin{aligned} &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left(\int_0^{\infty} d(-u') \frac{\cos(-\mu' u') + i \sin(\mu' u')}{(-u')^{1-\alpha/\pi}} \right. \\ &\quad \left. (u' = -u) + \int_0^{\infty} du \frac{\cos(\mu' u) + i \sin(\mu' u)}{u^{1-\alpha/\pi}} \right) \\ &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left(\int_0^{\infty} du' \frac{-\cos(-\mu' u') + i \sin(\mu' u')}{u'^{1-\alpha/\pi}} (-1)^{1-\alpha/\pi} \right. \\ &\quad \left. + \int_0^{\infty} du \frac{\cos(\mu' u) + i \sin(\mu' u)}{u^{1-\alpha/\pi}} \right) \\ &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left([1 - (-1)^{1-\alpha/\pi}] \int_0^{\infty} du \frac{\cos(\mu' u)}{u^{1-\alpha/\pi}} \right. \\ &\quad \left. + i[1 + (-1)^{1-\alpha/\pi}] \int_0^{\infty} du \frac{\sin(\mu' u)}{u^{1-\alpha/\pi}} \right) \end{aligned} \quad (129)$$

$$\begin{aligned} &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left([1 - (-1)^{1-\alpha/\pi}] \frac{\Gamma(\alpha/\pi)}{\mu'^{\alpha/\pi}} \cos \frac{\alpha}{2} \right. \\ &\quad \left. + i[1 + (-1)^{1-\alpha/\pi}] \frac{\Gamma(\alpha/\pi)}{\mu'^{\alpha/\pi}} \sin \frac{\alpha}{2} \right) \\ &\quad \text{(for } \mu' > 0) \\ &= \frac{\alpha m^{\alpha/\pi}}{2\pi^2 i^{1-\alpha/\pi}} \left([1 - (-1)^{1-\alpha/\pi}] \frac{\Gamma(\alpha/\pi)}{\mu'^{\alpha/\pi}} \cos \frac{\alpha}{2} \right. \\ &\quad \left. - i[1 + (-1)^{1-\alpha/\pi}] \frac{\Gamma(\alpha/\pi)}{\mu'^{\alpha/\pi}} \sin \frac{\alpha}{2} \right) \end{aligned} \quad (130)$$

(for $\mu' < 0$)

Because both $1 + (-1)^{1-\alpha/\pi}$ and $\sin(\alpha/2)$ are much smaller than $1 - (-1)^{1-\alpha/\pi}$ and $\cos(\alpha/2)$, we can just use

$$X(\mu') = [1 - (-1)^{1-\alpha/\pi}] \frac{\alpha \Gamma(\alpha/\pi) \cos(\alpha/2)}{2\pi^2 i^{1-\alpha/\pi}} \left(\frac{m}{\mu'} \right)^{\alpha/\pi} \quad (131)$$

for all practical purposes. We thus conclude that the mass distribution function has to be

$$\rho(\mu) = \frac{\alpha \Gamma(\alpha/\pi) \cos(\alpha/2)}{\pi^2 i^{1-\alpha/\pi}} \frac{m^{\alpha/\pi}}{(\mu - m)^{1+\alpha/\pi}} \quad (132)$$

This is a remarkable result. It allows us to approximate the effect of infrared radiative corrections on any electronic propagator by multiplying it by $\rho(\mu)$ and integrating over μ as was done with the free-particle propagator on the right-hand side of our first equation above. The result will represent an approximation of the physical electron's propagator corresponding to the problem at hand, that is, an approximation of the physical propagator including the infrared radiative corrections, which corresponds to the given potential in which the electron has to move, and which satisfies the given boundary conditions.

10.2.6. Application of the Universal Sufficient Criterion for $1/f$ Spectra in Chaotic Nonlinear Systems to Quantum Electrodynamics. The nonlinearity causing the $1/f$ spectrum of turbulence in both semiconductors and metals is caused by the reaction of the field generated by charged particles and their currents back on themselves. The same nonlinearity is present in QED, where it causes the infrared divergence, the infrared radiative corrections for cross sections and process rates, and the quantum $1/f$ effect. We shall prove this on the basis of our sufficient criterion for $1/f$ spectral density in chaotic systems.

Consider a beam of charged particles propagating in a well-defined direction, so that the Schrödinger equation describes the longitudinal fluctuations in the concentration of particles. Considering the nonrelativistic case, which is encountered in most quantum $1/f$ noise applications, we write in second quantization the equation of motion for the Heisenberg field operators ψ of the particles in the form

$$i\hbar \frac{\partial \psi}{\partial t} = \frac{1}{2m} \left(-i\hbar \nabla - \frac{e}{c} \mathbf{A} \right)^2 \psi \quad (133)$$

With the nonrelativistic form $\mathbf{J} = -i\hbar \psi^* \nabla \psi / m +$ (Hermitian conjugate), and with

$$\mathbf{A}(x, y, z, t) = \frac{\hbar}{2cmi} \cdot \frac{[\psi^* \nabla \psi - \psi \nabla \psi^*]}{|\mathbf{x} - \mathbf{x}'|} d^3 x' \quad (134)$$

where the small rectangular brackets are defined to include retardation, we obtain

$$i\hbar \frac{\partial \psi}{\partial t} = \frac{1}{2m} \left(-i\hbar \nabla - \frac{e\hbar}{2c^2 mi} \frac{[\psi^* \nabla \psi - \psi \nabla \psi^*]}{|\mathbf{x} - \mathbf{x}'|} d^3 x' \right)^2 \psi \quad (135)$$

At very low frequencies or wave numbers the second term in the large parentheses is dominant on the

right-hand side, being of order λ , while the first term is of order λ^{-1} when \mathbf{x} is replaced by $\lambda\mathbf{x}$, giving

$$i\hbar \frac{\partial\psi}{\partial t} = -\frac{1}{2m} \left(\frac{e\hbar}{2c^2m} \frac{[\psi^*\nabla\psi - \psi\nabla\psi^*]}{|\mathbf{x} - \mathbf{x}'|} d^3x' \right)^2 \psi \quad (136)$$

For \mathbf{x} replaced by $\lambda\mathbf{x}$, and \mathbf{x}' formally replaced by $\lambda\mathbf{x}'$, we obtain

$$\begin{aligned} i\hbar \frac{\partial\psi}{\partial t} &= -\frac{1}{2m} \left(\frac{e\hbar}{2c^2mi} \frac{[\psi^*(\nabla/\gamma)\psi - \psi(\nabla/\gamma)\psi^*]}{\lambda|\mathbf{x} - \mathbf{x}'|} \lambda^3 d^3x' \right)^2 \psi \\ &= \lambda^2 H\psi = \gamma^{-p} H\psi \end{aligned} \quad (137)$$

This satisfies our homogeneity criterion with $p = -2$, because if we also replace t with $\lambda^{-2}t$ on the left-hand side, λ drops out altogether, and the equation is invariant. Our sufficient criterion only requires homogeneity, with any value of the weight p , for the existence of a $1/f$ spectrum in chaos. Therefore, we expect partial self-ordering of the current carriers with long-range correlations leading to a universal $1/f$ spectrum of fundamental quantum current fluctuations (coherent quantum $1/f$ effect) and of fluctuations in physical cross sections and process rates, as derived in detail above. This is in agreement with the experimentally verified results of the quantum $1/f$ theory.

In conclusion, we realize that, both in classical and in quantum-mechanical nonlinear systems, the limiting behavior at low wave numbers is usually expressed by homogeneous functional dependences, leading to fundamental $1/f$ spectra on the basis of our criterion. This explains the ubiquity of the $1/f$ spectrum.

11. DEVELOPMENT OF SPECIAL MATERIALS FOR ULTRA-LOW-NOISE FET AND JUNCTION DEVICES

11.1. Fet Devices

Consider, for example, the class of devices that are homogeneous in the direction of the current flow, such as FETs, including JFETs, MODFETs, or HEMTs, and photoconductive detectors, as opposed to bipolar transistors, HJBTs, pn diodes, junction photodetectors, and other junction devices. The mobility quantum $1/f$ noise is determined in this class of devices by Eq. (57), with the various quantum $1/f$ coefficients α_i , given by the results presented earlier for impurity scattering, acoustic phonon scattering in indirect-bandgap semiconductors, various kinds of intervalley scattering with or without umklapp, and polar and nonpolar optical phonon scattering. Ionized impurity scattering consists of many small-angle scattering events, all with small velocity changes $\Delta\mathbf{v}$, and therefore also with a small value of the quantum $1/f$ coefficient α_i . On the other hand, intervalley scattering with or without umklapp causes large velocity changes, corresponding to wave vector changes of the order of the fundamental reciprocal lattice vector \mathbf{G} , and a large quantum $1/f$ coefficient of the order $(4\pi/3\pi)(\hbar G/mc)^2 = (4\pi/3\pi)(\hbar 2\pi/amc)^2$, where a is the lattice constant and m the effective mass of the

carriers. To reduce the $1/f$ noise of the resulting devices, one is interested in materials practically free of intervalley and umklapp scattering, even if this comes at the expense of a shorter lifetime of the carriers. One designs materials in which the mobility is limited mainly by ionized impurity scattering. If this is not practicable due to other constraints, one takes advantage of the inverse square dependence of the intervalley- and umklapp-scattering quantum $1/f$ coefficients and chooses the conduction type (n or p) and the host material in order to maximize m . Finally, the $1/N$ dependence also favors materials with a large concentration of ionized impurities.

11.2. Junction Devices

On the other hand, for materials designed for use in junction devices, the last form of Eq. (65) requires a large lifetime of the minority carriers in the low-doping part of the device. In this case, the material must have particularly low concentrations of recombination centers, of point defects, of dislocations, and of other lattice defects. For this class of devices the elimination of surface recombination currents through surface passivation is very important, because volume recombination is much less noisy according to our equations.

12. DEVICE OPTIMIZATION FOR ULTRALOW $1/f$ NOISE

After the design of optimal materials for each class of solids-state devices, the next objective is the use of these materials and of the quantum $1/f$ theory for practical device optimization. The following is the present list of our principles of optimal quantum $1/f$ noise design, which we currently use in creating new technological prototypes of devices:

1. Avoid coherent-state quantum $1/f$ noise by device size reduction below the coherent limit. This size limit is concentration-dependent, as seen from the expression for the coherence parameter $s = 2e^2 N' / mc^2 = 5 \times 10^{-13} \text{cm}^{-1} \times N'$ defined in Eq. (27). $N' = nA$ is the number of carriers per unit length of the device in the direction of current flow. A is the cross-sectional area of the current-carrying device, and n is the concentration of carriers. For $s \ll 1$ we expect conventional quantum $1/f$ noise, while for $s \gg 1$ the much larger coherent-state quantum $1/f$ noise is to be expected. In conclusion: think submicron, think transversely ultrasmall.
2. Avoid control of the device current or voltage by elementary cross sections or process rates tested by a small number of carriers only. Indeed, the number of carriers interrogating the cross section or process rate appears in the denominator of both the conventional and coherent quantum $1/f$ noise formulas. In particular, avoid current concentrations in bottle-necks, and current inhomogeneities. In junction devices higher lifetimes of the carriers lead to an increase in the number of carriers present in the sample that have tested the current-controlling

cross sections, and therefore lead to lower quantum $1/f$ noise.

3. Avoid control of a device exhibiting conventional quantum $1/f$ noise through elementary processes that involve large accelerations of the current carriers, or large velocity changes. The squared vector velocity change appears as a factor in the conventional quantum $1/f$ noise formula. For example, umklapp, intervalley, and lattice scattering are respectively worst, very bad, and bad, compared with ionized impurity scattering, in terms of the fractional mobility fluctuations they yield. For a given scattering mechanism, choosing current carriers with a large effective mass will in general reduce the conventional quantum $1/f$ noise, because for the same momentum transfers this results in smaller accelerations. Bulk recombination control of the current through a pn junction will lead to lower quantum $1/f$ noise than having the current controlled even in part by surface recombination, because the surface recombination centers are in a high-localized-field region at the interface between bulk and the passivation layer. Therefore, the best passivation is one that reduces the number and the cross section of the surface recombination centers, while also providing the smallest surface potential jump.

On this basis a detailed identification and analysis of the various noise sources can be performed. In a next step, a figure of merit can be defined on the basis of the mission specification for the devices in the focal plane array. Finally, material and design improvements are calculated and suggested, which optimize the figure of merit defined in the previous step. A similar sequence is applicable for quartz crystal resonators and SAW devices.

Use of these principles leads to lower $1/f$ device noise. The quantum $1/f$ theory can consequently be used for CAD optimization of $1/f$ device noise suppression.

13. DISCUSSION

We now have a clear understanding both of the general origin of fundamental $1/f$ spectra and of my practical engineering formulae $2\alpha A/fN$ and $2\alpha/\pi fN$ applicable to high-technology devices. No matter which device is concerned, if it is a high-technology device all trivial forms of instability and fluctuations have been eliminated, and the device will be limited in its performance by the fundamental quantum $1/f$ effect present in the elementary cross sections and process rates controlling the kinetics of the device. A Q1/E research institute is needed to translate these fundamental discoveries into valuable practical breakthroughs in modern high-technology applications.

Many contributions to this field are included in the Proceedings of the IV–VI International Symposia on Quantum $1/f$ Noise (1990, 1992, and 1994) and in the session on “ $1/f$ noise and quantum chaos” at the March 1992 meeting of the American Physical Society in Indianapolis. Continuing progress was reported in the

Proceedings of the International Conference on Noise in Physical Systems and $1/f$ Noise, which were published 1975–1996; see the reviews [26,49].

NONLINEAR CIRCUIT ANALYSIS

ALMUDENA SUÁREZ
University of Cantabria
Santander, Cantabria, Spain

1. INTRODUCTION

There is an increasing demand in modern communication systems for high-performance radiofrequency circuits. This fact, together with the common use of monolithic technologies, for which no modification is possible after manufacturing, requires the use of accurate and efficient simulation tools, in order to meet the circuit specifications. This simulation has added difficulties in the case of nonlinear circuits, such as those based on semiconductor devices, transistors, or diodes. The superposition principle does not hold in nonlinear circuits and so they exhibit characteristics, such as dependence on the input amplitude or the generation of harmonic frequencies, that are never observed in linear ones [1–3].

The self-sustained oscillation, exhibited by the oscillator circuits and also by unstable amplifiers, is possible only in nonlinear nonconservative systems. Other phenomena, exclusive to nonlinear systems, are the coexistence of solutions and the hysteresis, the oscillation synchronization with external sources, and the generation of subharmonic oscillations. Note that, although the special properties of the nonlinear circuits are sometimes undesired, they also make them the only choice for performing analog functions such as frequency mixing, frequency multiplication, oscillation, and frequency division.

In general, the nonlinear circuit will be described by a set of differential algebraic equations (DAEs) [4]. Two different kinds of circuits may be distinguished [1]: autonomous and nonautonomous. In an autonomous circuit, the DAEs do not explicitly depend on time, due to the absence of time-varying generators. This is the case of the free-running oscillators, which contain DC generators only. In a nonautonomous (forced) circuit, the DAEs explicitly depend on time, due to the existence of time-varying generators $g(t)$. Four main types of steady-state solutions are possible: the DC solution, the periodic solution, the quasiperiodic solution, and the chaotic solution. The periodic solution has one fundamental frequency only. The quasiperiodic solution has two or more incommensurable fundamentals, namely, two or more fundamental frequencies that cannot be rationally expressed in terms of a common period. It is the regime in which a frequency mixer

operates. Finally, the chaotic solution is neither periodic nor quasiperiodic, and, because of this nonperiodicity, it exhibits a continuous spectrum, at least for some frequency intervals [1].

Another essential characteristic of nonlinear circuits is the possible coexistence of two or more steady-state solutions for the same circuit values. Only the stable steady-state solutions are physically observed. A solution is stable when it is capable of recovering from small perturbations. For this reason, the stable solution is also called *robust* [1–3]. Since perturbations are always present in real life, nonrobust solutions cannot be obtained experimentally. As an example of coexistence of solutions with different stability properties, Fig. 1 shows the simulation of a free-running oscillator. As already mentioned, a free-running oscillator is an autonomous circuit and its equations can always be solved for a DC solution. In the case of Fig. 1, this DC solution is simply $v_{DC} = 0$, $i_{DC} = 0$, $\forall t$. If no initial value is provided to either of the two circuit nodes, the solution will remain at $v(t) = 0$, $i(t) = 0$ during the entire simulation interval. However, if the initial conditions differ from $v = 0$, $i = 0$, a transient will lead the circuit to the oscillating steady state. The DC solution is thus unstable. In contrast, the oscillating solution is stable. To show this, a perturbation is applied at $t = 5$ ns. This starts a transient that leads back to the oscillating solution.

Different methods exist for the simulation of nonlinear circuits. These methods can be classified into three main categories: time domain, frequency domain, and the more recent time–frequency methods. There are also analytical methods and numerical methods. The analytical methods, such as the describing function [2,5] or Volterra series [6,7], are very well suited for circuit design, since they give insight into the nonlinear behavior and enable an evaluation of its dependence on the circuit parameters. The describing function has been widely used for oscillator design, while the Volterra series is a good approach for identifying the linearity limiting factor of a given transistor technology. It is also very well suited for the analysis of

Figure 1. Coexistence of solutions in the cubic nonlinearity oscillator. The DC solution lies on the horizontal axis. Two perturbations are applied at $t = 0$ and $t = 5$ ns, respectively.

multitone signals and nonlinearities with memory. However, when the goal is to obtain an accurate solution, in terms of waveforms and spectral content, numerical iterative methods are generally preferred. These numerical simulation methods are the object of this contribution.

The nonlinear circuit can be simulated by applying integration algorithms to its corresponding DAE, from an initial condition [8–10]. This method, used in programs such as SPICE [10], provides the entire evolution of the circuit solution from the initial values to the steady state. Both the transient and steady state are simulated. However, the transient, which usually has little interest for the designer, may be too long in comparison with the solution period. To cope with this problem, the fast time-domain algorithms [11], such as the shooting [8,12,13] and finite-difference methods [11,13–15], perform the time-domain analysis of the steady state only, avoiding the transient. This is achieved using an additional constraint on the state of the solution. In the case of periodic regimes, the constraint imposes the equality of the circuit variables after one period. The fast time-domain methods are more difficult to apply to steady-state regimes of other kinds.

The distributed elements, with loss and frequency dispersion, are difficult to model and analyze in the time domain. The most general approaches use impulsive responses for the description of these elements, and the required convolution products may be long and inefficient, since the integration must be carried out from the initial time value. The linear elements are more easily described in the frequency domain, since it is generally simpler to obtain their response using phasor analysis. Taking this fact into account, the harmonic balance (HB) method [16–19] uses frequency-domain representations for the linear elements, lumped or distributed, maintaining the time-domain descriptions for the nonlinear devices. The circuit variables are represented by means of a Fourier series, with one or more fundamental frequency. Because of this representation, only the steady state is simulated. On the other hand, the use of a sinusoidal basis for the expression of the circuit signals restricts the applicability of the method to circuits with relatively mild nonlinearities. Regimes with fast time transitions are better analyzed in the time domain, with the shooting or finite-difference methods.

As already mentioned, only the stable steady-state solutions are physically observed. In the case of the time-domain integration, provided the integration step and the algorithm are properly selected, the steady-state solution obtained will be stable. This is due to the fact that the integration process follows the actual time evolution of the circuit solution (transient), up to the steady state (see Fig. 1). When using steady-state methods such as HB, the possible coexistence of steady-state solutions must be taken into account. It is possible to obtain a steady-state solution to which the circuit never evolves and, as a consequence, is never observed in practice. This situation is often faced in circuits such as power amplifiers. The designer simulates the desired periodic amplifier solution, which is actually unstable, and obtains a mixerlike spectrum in the measurement. This stable solution is due to the mixing of the signal delivered by the input generator with a self-oscillation. As can be gathered,

the verification of the solution stability will be essential for some analysis methods.

Because of the required Fourier series expression of the circuit variables, the HB technique cannot be applied to nonlinear circuits with modulated inputs. On the other hand, for a carrier frequency with a much higher value than the modulation bandwidth, the time-domain simulation may be inefficient or even impossible. However, in most of these circuits, two different timescales may be considered: one associated with the modulation signal (slower timescale) and the other associated with the high-frequency carrier (faster timescale). Because the circuit is periodic with respect to the time variable associated to the faster timescale, it will be possible to express the circuit variables in a harmonic series, with time-varying harmonic components, at the slower timescale. This is done in the envelope transient method [20,25]. The harmonic components become the unknowns of a system of differential algebraic equations. The advantage over the time-domain integration is its lower computational cost, since the equation system is integrated at the timestep of the slower timescale.

The objective of this contribution is to introduce and compare the different techniques for the numerical simulation of nonlinear circuits, showing the advantages and shortcomings of each of them, when applied to different kinds of circuits and regimes. In order to illustrate the different simulation techniques, a frequency divider will be used throughout this article. The frequency dividers are challenging circuits in terms of analysis, due to the variety of nonlinear operation modes [26] that they exhibit.

2. TIME-DOMAIN INTEGRATION

The most practical way to perform the time-domain analysis of a nonlinear circuit is to formulate the circuit as a system of differential algebraic equations (DAEs). But some facts must be taken into account. The distributed elements are originally described through partial differential equations, and are difficult to introduce in this formulation. To overcome this problem, the transmission lines may be segmented into lumped elements. Unfortunately, it has been shown that this segmentation often gives rise to numerical instabilities [27], that is, to artificial poles on the right-hand side of the complex plane. In addition, this technique cannot directly model the frequency-dependent parameters. A more general approach is the one based on the computation of the impulse responses of the linear elements from their frequency-domain descriptions [27,28]. Then, convolution products are calculated.

The transistors and diodes are usually described through lumped electrical models, containing linear and nonlinear elements. Examples of nonlinear elements are the voltage-controlled current $i(v)$ and junction capacitance $c_j(v)$ of a Schottky diode or the field-effect current $i_{ds}(v_{gs}, v_{ds})$ of a FET transistor, which is controlled by the gate-to-source voltage $v_{gs}(t)$, and the drain-to-source voltage $v_{ds}(t)$. The nonlinear elements are described through their instantaneous relationships with their control

variables, like the well-known diode–current model $i(t) = I_0(e^{\alpha v(t)} - 1)$, having I_0 and α as parameters. In the case of nonlinear capacitances, the model is written in terms of the associated nonlinear charge $q_j(v)$. In the case, for instance, of a junction capacitance, the nonlinear charge is given by $q_j(v) = -2C_{j0}\phi\sqrt{1 - v/\phi}$, with ϕ , the built-in potential and C_{j0} , the capacitance for $v = 0$. For the modeling of more complex nonlinearities, for example, some of those contained in FET or bipolar transistors, great research effort has been necessary. The most usual models can be found in Refs. 29 and 30. The nonlinear models must allow an efficient calculation of the circuit solution, with the existent simulation methods.

The modified nodal approach, obtained from the direct application to the circuit of Kirchhoff’s laws, allows a global formal expression of the DAE [8], which are written

$$\begin{aligned} \bar{i}(\bar{v}(t)) + \frac{d\bar{q}}{dt}(\bar{v}(t)) \\ + \int_{-\infty}^t \bar{h}(t - \tau)\bar{v}(\tau) d\tau + \bar{g}(t) = 0 \end{aligned} \tag{1}$$

where $\bar{v} \in R^P$ is the vector containing the node voltages and branch currents, $\bar{q} \in R^P$ is the vector of charges and fluxes, and $\bar{i} \in R^P$ is the vector of sums of currents (that enter each node) and branch voltages. The vector $\bar{h} \in R^P$ contains the impulsive responses, associated to the distributed elements, and $\bar{g}(t) \in R^P$ is the vector where the input generators are included. Whenever the relationship $\bar{q}(\bar{v})$ is invertible, it will be convenient to use \bar{q} as unknown, since this ensures the charge conservation [8].

As already mentioned, the impulsive responses in (1) are obtained from the inverse Laplace transforms of the distributed elements. In the general case of frequency-dependent distributed elements, the Laplace domain transfer functions are developed in Taylor series and approached using closed-loop Padé approximants [31,32]. The approximants can be expressed in partial fraction form. Then, the inverse Laplace transform provides a sum of exponentials in time domain that are used in the convolution calculation. To avoid the introduction of any artificial instability, all the poles of the computed approximation must have negative real parts [32].

For the practical solution of (1), the continuous-time variable t is discretized and replaced with the timepoints $[t_0, \dots, t_n, \dots, t_N]$. Then, the modified nodal equation is rewritten in terms of the discrete points t_n . At each point t_n , the convolution products are calculated through a discrete sum

$$\bar{i}(t_n) \cong \sum_{i=0}^{n-1} \bar{h}(t_n - t_i)\bar{v}(t_i)\Delta t_i \tag{2}$$

where $\Delta t_i = t_{i+1} - t_i$. For simplicity, a rectangular rule has been considered in (2), although other more efficient schemes of higher order are generally used in practice [33]. From (2), it is clear that the evaluation of the circuit response over the total simulation interval $[t_0, t_N]$ requires

$O(N^2)$ operations. Kapur et al. [33] proposed an algorithm to reduce the number of operations to $O(N \log(N))$.

Several algorithms exist for the numerical integration of (1). The difference between one and another is the way how the derivative $d\bar{q}/dt$ is approximated, in terms of the time samples t_n . A few of these algorithms will be shown here, for illustration. The forward and backward Euler approaches are, respectively, given by

$$\begin{aligned} \frac{d\bar{q}(\bar{v}(t_n))}{dt} &= \frac{\bar{q}(\bar{v}(t_{n+1})) - q(\bar{v}(t_n))}{h} \\ &\text{(forward Euler)} \\ \frac{d\bar{q}(\bar{v}(t_n))}{dt} &= \frac{\bar{q}(\bar{v}(t_n)) - q(\bar{v}(t_{n-1}))}{h} \\ &\text{(backward Euler)} \end{aligned} \tag{3}$$

where h is the timestep, initially assumed constant and such that $t_n = t_0 + nh$. In the forward Euler approach, the derivative at the time t_n involves the variable evaluated at the next timepoint t_{n+1} ; thus, the term “forward.” In the backward Euler approach, it involves the variable calculated at the previous timepoint t_{n-1} . The backward Euler algorithm is an implicit algorithm. An algorithm is called “implicit” when the point $\bar{q}(\bar{v}(n+1))$ is a function of itself:

$$\bar{q}(\bar{v}(t_{n+1})) = \bar{q}(\bar{v}(t_n)) + \frac{d\bar{q}(\bar{v}(t_{n+1}))}{dt} h \tag{4}$$

The implicit algorithms are generally more complicated in terms of computation. However, compared to the explicit algorithms, they offer better accuracy and improved stability properties [1]. This can be understood as the result of a feedback effect, due to the dependence of the point $\bar{q}(\bar{v}(t_{n+1}))$ on itself [see (4)].

The commonly used trapezoidal approximation estimates the derivative $d\bar{q}/dt$, using the average of its value at t_n and t_{n+1} . This provides the following relationship:

$$\begin{aligned} \frac{d\bar{q}(\bar{v}(t_{n+1}))}{dt} &= \frac{2}{h}(\bar{q}(\bar{v}(t_{n+1})) \\ &\quad - q(\bar{v}(t_n)) - \frac{d\bar{q}(\bar{v}(t_n))}{dt} \end{aligned} \tag{5}$$

The algorithms presented so far require one past point only, corresponding to the previous time t_n . There are also more complex multistep algorithms, which require two or more past points. A given algorithm has P order when the solution $\bar{q}(\bar{v}(t))$ and its P first time derivatives are continuous at the limits of the interval $[t_n, t_{n+1}]$. Thus, the integration is error-free for a system whose solution is a polynomial of the same order P or smaller order [1,34]. In particular, it is easily shown that the backward Euler algorithm has order 1, while the trapezoidal algorithm has order 2. The algorithms of higher order use more information about the system and are generally more exact. All the integration algorithms with similar formal structure are grouped in families, each member of a given family having

a different order P . A detailed classification of the different integration algorithms is given in Ref. 1.

The integration algorithm transforms the continuous-time system into a discrete-time system that is different for each particular algorithm. Particularizing the derivative in (1) to the trapezoidal approach (5), a discretized version of the modified nodal equation is obtained:

$$\begin{aligned} \bar{e}(t_{n+1}) \equiv & 2 \frac{(\bar{q}(\bar{v}(t_{n+1})) - \bar{q}(\bar{v}(t_n)))}{t_{n+1} - t_n} \\ & - \frac{d\bar{q}(\bar{v}(t_n))}{dt} + \bar{i}(\bar{v}(t_{n+1})) \\ & + \sum_{i=1}^n \bar{h}(t_{n+1} - t_i) \bar{v}(t_i) \Delta t_i + \bar{g}(t_{n+1}) = 0 \end{aligned} \quad (6)$$

This equation should provide the entire evolution of the circuit solution versus the time variable. The simulation starts with a DC analysis of the circuit, giving the initial value $\bar{v}(0)$. Then, the integration algorithm is applied from $t_0 = 0, \bar{v}(0)$, to obtain $\bar{v}(t_1)$ and recursively applied to obtain $t_{n+1}, \bar{v}(t_{n+1})$ from the knowledge of $t_n, \bar{v}(t_n)$ and all the past points, required for the calculation of the convolution products.

For the numerical determination of $\bar{v}(t_{n+1})$, an error function $\bar{e}(t_{n+1})$, equal to the term of the left-hand side, has been introduced in (6). Some tolerance limits in the circuit variables and a maximum error value, below which the solution $\bar{v}(t_{n+1})$ is considered to be a valid one, must be specified at the beginning of the process. This calculation can be carried out with the aid of the Newton–Raphson algorithm [1,8], which requires the computation of Jacobian matrix of the error function. Compared to other techniques, the advantage of the Newton–Raphson algorithm comes from the large value of the stepsize $\Delta t_{n+1} = t_{n+1} - t_n$ that it allows. As time evolves, the Newton–Raphson algorithm uses the result $\bar{v}(t_n)$ for the previous timepoint t_n as the initial guess for $\bar{v}(t_{n+1})$.

The truncation error of a given integration algorithm is due to the particular discretization method and can be defined as the error that would be present if the algorithm could be implemented with infinite precision [1]. For a multistep algorithm of order P , it can be expressed $\varepsilon_T = A_p h^{P+1}$ [1], where A_p is a real number that depends on the order P , the number of utilized past points, the particular time-domain equation, and the particular point $n + 1$ of the curve. In the trapezoidal rule ($P = 2$), the error is proportional to h^3 . In the backward Euler rule ($P = 1$), the error is proportional to h^2 . For sufficiently small h , the higher-order algorithms will be more accurate than the lower-order ones. The situation can, however, be reversed if the step h becomes too big. Provided the integration step is relatively small, it will be possible to use a larger stepsize with a higher-order algorithm.

For maximum efficiency of the algorithm, with the largest stepsize for a prefixed error tolerance, the stepsize must be adjusted during the integration process. The need for adjusting the stepsize comes from the fact that the truncation error ε_T changes at each timestep. Note, however, that, in multistep algorithms, the input past points

must be equally spaced in time. Thus, when the stepsize is changed, the evenly spaced points must be calculated, which will require additional computational effort.

These techniques have been applied to a frequency divider by 2, by harmonic injection. This circuit is basically an oscillator, whose second harmonic synchronizes with the input signal. Actually, the harmonic injection dividers exhibit a free-running oscillation, when no signal is delivered by the input generator. The divider that has been considered here, based on a MESFET transistor, is shown in Fig. 2. The generator frequency is about $f_{in} = 6$ GHz. The input network is a bandpass filter at this frequency. The output network is a bandpass filter about the divided frequency $f_{out} \cong 3$ GHz. The parallel LC network, at the source terminal, provides series feedback at the self-oscillation frequency. The drain-to-source LC branch attenuates the input frequency. The transistor is biased at $V_{GS} = -1.5$ V, $V_{DS} = 3$ V, near pinchoff, to take advantage of the quasiquadratic $i_{ds} \equiv i_{ds}(v_{gs})$ characteristic for an efficient mixing between the input frequency and the oscillation. This should provide the subharmonic frequency $\omega_{in}/2$. The nonlinear elements of the MESFET transistor, taken into account for the analysis, are the Schottky junction current $i_{gs} \equiv i_{gs}(v_{gs})$ and charge $q_{gs} \equiv q_{gs}(v_{gs})$; the drain-to-source current $i_{ds} \equiv i_{ds}(v_{gs}, v_{ds})$, which can be modeled through the Tajima equation [35]; and the drain-to-gate current $i_{dg} \equiv i_{dg}(v_{gs}, v_{ds})$, which can be modeled through a diodelike equation [29,30].

In the absence of external signal, a free-running oscillation takes place at $F_0 = 3$ GHz. Figure 3 shows the time-domain simulation of this oscillation, in terms of the voltage at the drain node. The oscillation startup required an initial condition to “escape” from the unstable DC solution. Note the long duration of the transient in comparison with the solution period (Fig. 3a). This duration is about 15 periods of the steady-state oscillation. The integration has been performed with the trapezoidal rule, with adjustable timestep. The minimum allowed timestep, along the integration interval, is $\Delta t = 1$ ps. Convergence fails when a larger value of this minimum step is chosen.

The criterion for the selection of the timestep is based on the number of iterations required to achieve convergence. If, for a time t_n , convergence is achieved with a smaller number of iterations than a certain prefixed value n_0 , the timestep for t_{n+1} is increased. The expanded view of Fig. 3b shows the steady-state waveform and the discrete timepoints. Figure 3c shows a comparison between the trapezoidal (solid line) and the backward Euler

Figure 2. Schematic of a frequency divider by 2, with 6 GHz input frequency.

Figure 3. Time-domain integration of the circuit of Fig. 2, elements operating as a free-running oscillator: (a) transient and steady state; (b) expanded view of the steady-state waveform, showing the adjustment of the timestep; (c) comparison between the Euler integration rule (dashed line) and the trapezoidal rule (solid line) for fixed timestep $h = 1$ ps. For $h = 0.25$ ps, there is a numerical oscillation, in both cases. The one obtained for the trapezoidal rule has been superimposed.

(dashed line) integration rules, for fixed timestep $h = 1$ ps. To test the validity of this method, the integration step has been reduced to the unnecessarily small value $h = 0.25$ ps. For this small step, a numerical oscillation is obtained in both cases. The one resulting from the trapezoidal integration rule is shown in Fig. 3c.

The abovementioned numerical oscillation indicates the possible instability of the integration algorithms. As seen in the previous example, the unstable behavior is independent of the accuracy. It depends on the timestep and the particular algorithm. For a same continuous-time system, each algorithm gives rise to a different discrete-time equation. The stable solution of the continuous-time system may become an unstable solution of a particular discrete-time system. The stability properties of the different algorithms have been compared by applying them to a continuous first-order linear system [1], with a stable solution.

Generally speaking, the stable or unstable behavior of a given algorithm depends on the time constants of the original continuous-time system and the timestep h . With λ as the time constant of the original system, the different algorithms have different stability regions, in terms of λh [1]. These stability regions are usually larger for the implicit algorithms, due to the effect of feedback. Typically, the stability is not critical for the stepsizes that are commonly used by the designer. However, in some systems, called *stiff systems*, the step to satisfy the accuracy constraint lies within the instability region [1]. This is typical of systems with time constants of very different orders of magnitude.

3. FAST TIME-DOMAIN TECHNIQUES

As has been shown, the direct-integration methods provide the entire time evolution of the circuit solution, from the initial point t_0, \bar{v}_0 , including the transient and steady state. Generally, most of the simulation time is devoted to the transient. However, the circuit designers are usually interested in the steady-state solution only. Taking this into account, the fast time-domain methods directly address the steady-state regime. These methods use time-domain descriptions for both the linear and nonlinear elements. Therefore, if the circuit contains the distributed elements, the use of frequency-domain techniques is usually more convenient. But the fast time-domain analysis is possibly the best option for the simulation of strongly nonlinear periodic regimes in lumped-element circuits. Two different techniques will be briefly outlined here: the shooting methods and the finite differences in time domain.

3.1. Shooting Methods

The shooting methods [8,11–13] provide, through an optimization technique, a vector of initial conditions \bar{v}_0 , from which the circuit operates in the steady-state regime. Thus, no transient is obtained when integrating the nonlinear system (6) from \bar{v}_0 . The initial conditions are difficult to establish in the case of distributed elements, since these conditions must be specified throughout the entire

devices, which is done through the use of functions [13]. In case of periodic regimes, the solution at the end of the period must match this initial condition. Assuming initial time $t_0=0$, the two-point constraint $\bar{v}(0) - \bar{v}(T)=0$ is imposed, where T is the period of the solution. Of course, this boundary value constraint cannot be applied to quasiperiodic regimes. The so-called mixed frequency-time methods are a generalization of the shooting method, enabling the simulation of these quasiperiodic regimes [12].

A periodic steady state will be assumed here. Let the solution $\bar{v}(t)$ be expressed in terms of the initial value $\bar{v}(t_0)$ as $\bar{v}(t) = \bar{v}(t_0) + \bar{\phi}(\bar{v}(t_0), t_0, t)$, where $\bar{\phi}$ is the so-called state transition function [8,11]. Then, the shooting equation system is given by $\bar{\phi}(\bar{v}_0, 0, T) = 0$, which contains P equations in P unknowns. To obtain the transition matrix, it must be taken into account that $\bar{v}(t_{n+1})$ in (6) is an implicit function of $\bar{v}(t_n)$, assuming that no convolution terms are present. Thus, recursively integrating Eq. (6) from \bar{v}_0 , it will be possible to obtain numerically the function $\bar{\phi}(\bar{v}_0, 0, T)$. If the time interval $[0, T]$ is discretized in M values, such that $t_0=0$ and $t_{M-1}=T$, then Eq. (6) will be fulfilled at each of these values, even when the shooting equations are not satisfied.

A Newton-Raphson algorithm is used to solve the shooting equations $\bar{\phi}(\bar{v}_0, 0, T) = 0$ in terms of the initial conditions \bar{v}_0 . This requires calculation of the state-transition matrix over the shooting interval and determination of the Jacobian matrix $[J\phi] \equiv \partial\bar{\phi}(\bar{v}_0, 0, T)/\partial\bar{v}_0$, also called the *sensitivity matrix*. Thus, the circuit is solved through a two-level Newton-Raphson algorithm. The outer level corresponds to the shooting equations. The inner level is applied to the integration of the system (6), which is required for determination of the transition matrix. Note that the computational rapidly increases with the size of the circuit, so matrix-implicit iterative algorithms are usually applied.

3.2. Finite Differences in Time Domain

In the finite-difference time-domain (FDTD) method [11], the system (6) is combined with the periodicity condition $\bar{v}(t_0) - \bar{v}(t_{M-1}) = 0$, to obtain a global system, whose unknowns are the M time samples $v_p(t_n)$ ($n=0$ to $M-1$) of each P state variable. For a circuit containing lumped elements only and assuming a backward-Euler integration rule, the $P \times M$ equation system is written

$$\begin{aligned}
 & \frac{2}{h}(\bar{q}(\bar{v}(t_1)) - \bar{q}(\bar{v}(0)) + \bar{i}(\bar{v}(t_1)) + \bar{g}(t_1)) = 0 \\
 & \vdots \\
 & \frac{2}{h}(\bar{q}(\bar{v}(t_{n+1})) - \bar{q}(\bar{v}(t_n)) + \bar{i}(\bar{v}(t_{n+1})) + \bar{g}(t_{n+1})) = 0 \\
 & \vdots \\
 & \frac{2}{h}(\bar{q}(\bar{v}(T)) - \bar{q}(\bar{v}(t_{M-2})) + \bar{i}(\bar{v}(T)) + \bar{g}(T)) = 0 \\
 & \bar{v}(0) - \bar{v}(T) = 0
 \end{aligned} \tag{7}$$

where equal spacing h between the time samples has been considered. Compared with (6), in the subsystem composed by the $M-1$ first equations of (6), there are P additional unknowns, which correspond to the initial condition $\bar{v}(0)$. However, the periodicity condition $\bar{v}(0) - \bar{v}(t_{M-1}) = 0$ adds P more equations to the system. Thus, (7) is a well-balanced system of $P \times M$ equations in $P \times M$ unknowns, which is solved through the Newton-Raphson algorithm [11]. As in the case of the shooting methods, matrix-implicit iterative algorithms must be used for the analysis of large-size circuits.

The two cases of an autonomous or a nonautonomous circuit give rise to a difference in the solution of (7). In the case of a nonautonomous circuit, the time-varying input generator or generators $\bar{g}(t)$ set the conditions for the first point $t_0=0$, as these generators take the specific value $\bar{g}(0)$. In the case of an autonomous circuit (free-running oscillator), there are no time-varying input generators. Thus, there is no external reference, providing the initial value of the circuit variables at $t_0=0$. On the other hand, the solution period T is an unknown of the system, since the oscillation frequency is autonomously generated.

The autonomous circuit must be solved for T , in addition to $\bar{v}(0), \dots, \bar{v}(t_n), \dots, \bar{v}(T)$. However, because no external reference exists, one of the components of $\bar{v}(0)$ may take any value in the expected variation range, specifically, $v^1(0) = v_x$, which is arbitrarily assigned [14]. Thus, in the case of an autonomous circuit, there are $MP-1$ unknowns of the form $\bar{v}(t_n)$, with $n=0$ to $M-1$, plus the oscillation period T . So the system (7), in the case of an autonomous circuit, is also a well-balanced system.

Note that since the FDTD method directly provides the periodic steady state of the circuit, without passing through the transient, the solution obtained could be an unstable mathematical solution, to which the circuit never actually evolves. Taking this into account, the system (7) must be complemented with a stability analysis of the solution obtained. In the case of oscillator circuits, a DC solution coexists with the steady-state oscillation, as a mathematical solution. Thus, the initial values of the Newton-Raphson algorithm must be relatively close to the oscillating solution to avoid undesired convergence to the DC regime [14].

4. HARMONIC BALANCE

The HB technique [8,16-19], to be presented in this section, uses frequency-domain descriptions for the linear elements, while keeping the necessary time-domain description for the nonlinear elements. The use of a Fourier frequency basis for the representation of the circuit signals limits its application to relatively mild nonlinear regimes. This is due to the difficulties in the representation of fast time variations in a sinusoidal basis. Because of the use of Fourier series expansions for the circuit variables, HB analyzes only the steady-state solution. Convergence may be obtained to either stable or unstable solutions, so a complementary stability analysis will be necessary, as in the case of the FDTD analysis.

4.1. Formulation of the Harmonic Balance System

The HB method can be applied to periodic or quasiperiodic solutions only. It is assumed that the circuit variables can be expanded in a Fourier series, having a finite set of NF nonrationally related fundamentals $F_1 \dots F_{NF}$. In most practical circuits, the number of fundamentals is one or two. Examples of circuits with one fundamental frequency are the amplifiers and oscillators. A circuit with two fundamental frequencies is a frequency mixer.

Physical circuits have an intrinsic lowpass behavior, so it will be possible to truncate the Fourier series expansions of the circuit variables and keep only a certain number of harmonic terms. Let N be the total number of positive frequencies, resulting from the intermodulation products of the fundamental frequencies. The Fourier series expansions will have the general form

$$\bar{a}(t) = \sum_{k=-N}^N \bar{A}_k e^{j\omega_k t}; \quad \omega_k \equiv \bar{\lambda}_k^t \bar{\Omega}; \tag{8}$$

$$\bar{\Omega}^t = (2\pi F_1, 2\pi F_2, \dots, 2\pi F_{NF})$$

where $\bar{a}(t)$ stands for any of the circuit variables. The vector $\bar{\lambda}_k^t \in Z^{NF}$ contains the integer coefficients of the intermodulation product k . The subindex k ranges the resulting frequencies in increasing order $\omega_1 < \omega_2 < \dots < \omega_N$. Note that since we are dealing with real variables (in the time domain), the Fourier coefficients of (8) fulfill $A_k = A_{-k}^*$.

The Fourier series of a quasiperiodic signal may be truncated using different criteria. Two of the most common are the box truncation and the diamond truncation [7,36,37]. In the box truncation, positive integers nl_j are specified such that $|\lambda_j| \leq nl_j$ $1 \leq j \leq NF$. In the case of two fundamental frequencies, the representation of the selected pairs of coefficients λ_1, λ_2 (one vs. the other) provides a rectangle, which justifies the term used for this truncation criterion. In the diamond truncation, the criterion is $|\lambda_1| + |\lambda_2| + \dots + |\lambda_{NF}| \leq nl$, where nl is a previously imposed nonlinearity order. For two fundamental frequencies, the representation of the selected pairs of coefficients λ_1, λ_2 provides a diamond. It is easily shown that, in this case, the total number of positive frequencies is $N = nl(nl + 1)$.

The diamond truncation is generally more efficient than the box truncation, since for the same total number of frequency components it neglects components with higher order than any fundamental. Other truncation schemes can also be used. For instance, it is possible to assign a different order nl_j $1 \leq j \leq NF$ to each fundamental, while still imposing an overall truncation order $|\lambda_1| + |\lambda_2| + \dots + |\lambda_{NF}| \leq nl$. This technique is especially useful when there are significant differences in magnitude at the different fundamentals. Note that the a priori determination of the optimum truncation order is generally difficult. A saturation criterion can be applied, increasing nl or (nl_j) until no appreciable changes are obtained in the circuit solution. The error in the fulfillment of the Kirchhoff laws at the circuit nodes, in the time domain, can also be used to verify the validity of the series truncation.

Two different HB formulations are possible and will be introduced in the following text. The first formulation results from the direct introduction of the Fourier series expansions of the vector $\bar{v}(t), \bar{q}(t), \bar{i}(t),$ or $\bar{g}(t)$ into Eq. (1), taking into account the orthogonality of the Fourier basis. This formulation is known as *nodal harmonic balance* [8]. The size of the system is equal to the number of circuit nodes, multiplied by the number $(2N + 1)$ of spectral lines. Thus, a nonlinear system with a great number of unknowns may be obtained. The second formulation, known as *piecewise harmonic balance* [18], is based on a strict separation of the circuit elements into linear and nonlinear. This allows one to limit the set of unknowns to the control variables of the nonlinear elements only (instead of having to determine all the node voltages). The number of unknowns is reduced, at the expense of using linear impedances or admittances of higher order in ω .

4.1.1. Nodal Harmonic Balance. Let Fourier series expansions of the vectors $\bar{v}(t), \bar{q}(t), \bar{i}(t),$ and $\bar{g}(t)$, with the form (8), be considered. These expansions will be introduced into the modified nodal equation (2). Taking into account the orthogonality of the Fourier basis $e^{j\omega_k t}$, it will be possible to obtain a relationship between the harmonic components of $\bar{v}(t), \bar{q}(t), \bar{i}(t),$ or $\bar{g}(t)$. For a compact expression of this relationship, the set of Fourier coefficients will be written in the vector form

$$\bar{v}(t) \rightarrow \bar{V} = (\bar{V}_{-N}, \dots, \bar{V}_k, \dots, \bar{V}_N); \tag{9}$$

$$\bar{V}_k = (V_k^1, \dots, V_k^p, \dots, V_k^P)$$

where k indicates the harmonic index and p , the index of the state variable. Similar expressions hold for $\bar{q}(t), \bar{i}(t),$ and $\bar{g}(t)$. Then, the relationship between the Fourier coefficients of the different sets of variables, constituting the HB equation, is

$$\bar{E}(\bar{V}) \equiv \bar{I}(\bar{V}) + [j\omega] \bar{Q}(\bar{V}) \tag{10}$$

$$+ [H(j\omega)] \bar{V} + \bar{G} = 0$$

where $[j\omega]$ is composed of diagonal matrixes of the form $j\omega_k [I_p]$, where $[I_p]$ is the identity matrix of P order. $\bar{E}(\bar{V})$ is an error function to be minimized in the solution process. Note that the convolution operation in (1) has become, in (10), a simple multiplication by the matrix $[H(j\omega)]$. This matrix contains the transfer functions of the different distributed elements. Provided the relationship $\bar{Q}(\bar{V})$ is globally invertible, it will be possible to express $\bar{I}(\bar{V}) \equiv \bar{I}(\bar{Q})$. Then the HB system can be reformulated using \bar{Q} as unknown. This technique ensures the charge conservation. Note that since the circuit variables are real, it is generally more convenient to limit the harmonic vectors $\bar{V}, \bar{I}, \bar{Q}, \bar{G}$ to the positive spectrum only. Then, real variables are used, instead of complex ones. The variables are given by the real and imaginary parts of each Fourier coefficient. The total number of unknowns (and equations) is $(2N + 1)P$.

As an example, Fig. 4 shows the nodal HB formulation of a simple nonlinear circuit. This circuit contains a

Nodal:
$$\begin{bmatrix} jC\omega_k & \frac{1}{R} \\ 1 & -1 - \frac{jL\omega_k}{R} \end{bmatrix} \begin{bmatrix} V_k^1 \\ V_k^2 \end{bmatrix} + \begin{bmatrix} I_{nk}(\bar{V}^1) \\ 0 \end{bmatrix} + \begin{bmatrix} -1 \\ jL\omega_k \end{bmatrix} I_{gk} = \bar{0}$$

Piecewise: $[1 - L\omega_k^2 + jRC\omega_k] V_k^1 + [R + jL\omega_k] I_{nk}(\bar{V}^1) - R I_{gk} = 0$

Figure 4. Comparison between the nodal and piecewise HB formulations of a simple nonlinear circuit.

one-port nonlinear element and an input generator. It has two nodes, so $P=2$. In turn, the subindex k goes from $-N$ to N , for N harmonic components. The number of HB unknowns is $2(2N+1)$. The same example will also be used later on to illustrate the piecewise HB formulation.

For a given value of the state variable vector \bar{V} , the corresponding $\bar{I}(\bar{V})$ and $\bar{Q}(\bar{V})$ are indirectly obtained through inverse (F^{-1}) and direct (F) Fourier transforms:

$$\begin{aligned} \bar{v} &= F^{-1}(\bar{V}) \rightarrow \bar{i} \equiv \bar{i}(\bar{v}), \bar{q} \equiv \bar{q}(\bar{v}) \\ &\rightarrow \bar{I} = F(\bar{i}), \bar{Q} = F(\bar{q}) \end{aligned} \quad (11)$$

For the practical calculation of the direct and inverse Fourier transforms, the time variable is discretized. Discrete Fourier transforms (DFTs) must be used. The algorithms for the calculation of these transforms, in the two cases of periodic and quasiperiodic signals, are the object of Section 4.2. The reader familiar with these algorithms can skip this section. The DFT algorithm requires a number M of discrete time samples in the vectors $\bar{v}(t)$, $\bar{q}(t)$, $\bar{i}(t)$, and $\bar{g}(t)$. The choice $M_{\min} = 2N + 1$, where N is the number of positive frequencies, gives rise to square transformation matrixes (see Section 4.2). However, oversampling is commonly used, to reduce aliasing. Then, the number of samples M is chosen between $2M_{\min}$ and $10M_{\min}$ [8]. The excess of time samples, with respect to the number $2N + 1$ of harmonic frequencies, gives rise to a rectangular Fourier transformation matrix, to which pseudoinversion techniques are applied.

The error function in (10) is usually minimized through the Newton–Raphson algorithm. Using this algorithm, the next-iteration vector \bar{V}^{j+1} is obtained from a linearization of the nonlinear system about the point \bar{V}^j , resulting from the iteration j . This is equated as

$$[JE]_j(\bar{V}^{j+1} - \bar{V}^j) = -\bar{E}^j(\bar{V}^j) \quad (12)$$

where $[JE]_j$ is the jacobian matrix of the error function in (10), evaluated at the previous iteration j . This Jacobian

matrix is given by

$$\begin{aligned} [JE] &\equiv \left[\frac{\partial \bar{E}}{\partial \bar{V}} \right] = \left[\frac{\partial \bar{I}(\bar{V})}{\partial \bar{V}} \right] \\ &+ [j\omega] \left[\frac{\partial \bar{Q}(\bar{V})}{\partial \bar{V}} \right] + [H(j\omega)] \end{aligned} \quad (13)$$

The algorithm requires an initial value \bar{V}^0 of the state variable vector. In a nonautonomous circuit, with low input generator amplitudes, \bar{V}^0 can be estimated by discarding the nonlinear effects in (10). This technique will not work properly in the case of input generators with high amplitude. A method to cope with this problem will be presented later.

To obtain the components of the matrixes $\partial I/\partial V$ and $\partial Q/\partial V$, the Fourier transformation matrix $[F]$ and the chain rule are used. As an example, let the element $i^r(\bar{v})$, $1 \leq r \leq P$, and the particular state variable v^p , $1 \leq p \leq P$, be considered. The box $\partial I^r/\partial V^p$, containing the derivatives of the harmonic components of i^r with respect to each harmonic component of v_p , is computed as follows

$$\frac{\partial \bar{I}^r}{\partial \bar{V}^p} = [F] \left[\frac{\partial i^r}{\partial v^p} \right] [F]^{-1} \quad (14)$$

Note that the calculation of $\partial I_N^r/\partial V_{-N}^p$ and $\partial I_{-N}^r/\partial V_N^p$ requires $4N + 1$ components in the Fourier series expansions of the derivatives. The box $\partial I^r/\partial V^p$ is full in the case of a nonlinear element $i^r(v^p)$. In the case of a linear element i^r , the box will be diagonal, since each harmonic component I_k^r depends only on the harmonic components of the same order k of the state vector \bar{v} . Since the vectors $\bar{i}(\bar{v})$ and $\bar{q}(\bar{v})$ include both linear and nonlinear elements, the calculations of the form (14) give rise to Jacobian matrix (13) with many zero terms. A matrix of this kind is called *sparse matrix* [38–40].

As already mentioned, the Newton–Raphson algorithm will have convergence problems in case of high input generator amplitude. A simple way to cope with this problem is to perform a general sweep in the amplitude of the RF generators, introducing a parameter η and expressing them as $\bar{G}_{RF}(\eta) = \eta \bar{G}_{RF}$. Then, the parameter η is varied between a very small value η_0 and 1, in discrete steps $\eta_n = \eta_0 + n\Delta\eta$ [3]. A complete HB resolution is carried out for each η_n , using the result of the previous analysis (for η_{n-1}) as the initial guess. Note that the circuit will operate in small signal for the initial parameter value η_0 . Thus, obtaining the HB solution for this initial value will be straightforward.

The Newton–Raphson algorithm (12) may be difficult to implement in the case of very large circuits, due to the large number of unknowns to be determined. This number of unknowns strongly increases in the case of quasiperiodic solutions. The matrix factorization required for the Jacobian inversion is very demanding in terms of computing time and memory storage. However, the natural sparsity of the system (14) enables the straightforward application of sparse matrix techniques for linear system

solution. This linear system is solved through preconditioned Krylov subspace methods [11,38]. If the GMRES [11] (generalized minimum residual) algorithm is applied, the Jacobian matrix $[JE]$ is not needed explicitly, since only matrix–vector products have to be computed.

4.1.2. Piecewise Harmonic Balance. In piecewise HB, the nonlinear elements of the circuit are initially identified [19]. These elements are considered as nonlinear controlled sources, and the set of all their control variables constitute the set of unknowns, to be determined in the solution process. As an example, in the circuit in Fig. 4, the only state variable is the voltage v_1 , controlling the nonlinear current i_{n1} . Compared to the nodal HB, the number of state variables has been reduced from two to one. Clearly, in piece-wise HB, the number of unknowns will be much lower than in the case of nodal HB. The Q different variables that control the nonlinear elements form the set of unknowns x_q , with $1 \leq q \leq Q$. The P nonlinear elements form a second set of variables y_p , with $1 \leq p \leq P$. Finally, the S independent generators of the circuit form a third set g_s , with $1 \leq s \leq S$.

Once the Fourier basis is established, three vectors \bar{X} , \bar{Y} , and \bar{G} , respectively containing the $2N + 1$ harmonic components of the different variables, x_q , y_p , and g_s , are defined. These vectors are organized in a manner similar to that for $\bar{v}(t)$ in (9). The HB system is easily obtained from the application to the circuit of the Kirchhoff laws, which provides a relationship between the three vectors $\bar{X}, \bar{Y}, \bar{G}$ [19]

$$\bar{H}(\bar{X}) = [A_x]\bar{X} + [A_y]\bar{Y}(\bar{X}) + [A_g]\bar{G} = 0 \tag{15}$$

where $[A_x]$, $[A_y]$, and $[A_g]$ are frequency-dependent linear matrixes, with respective orders $Q \times Q$, $Q \times P$, and $Q \times S$. These linear matrixes are block diagonal matrixes, at the different harmonic orders $-N \leq k \leq N$. The total number of equations is $(2N + 1)Q$, in $(2N + 1)Q$ unknowns. Using, again, the simple circuit of Fig. 4 as an example, it can be seen that the degree of the linear matrixes is 2 (in ω_k) in the piecewise formulation, while it was only 1 in the nodal formulation. In fact, the main advantage of the piecewise HB comes from the fact that the complexity of the linear network or the accuracy in the description of its elements may be arbitrarily increased, without increasing the number of unknowns of the nonlinear system.

Equation (15) is, in fact, a nonlinear equation, since the functions \bar{Y} and the state variables \bar{X} are nonlinearly related, through the (time-domain) transfer characteristics of the different nonlinear elements. The system (15) is numerically solved by minimizing the norm of the error function $\|\bar{H}\|$, through the Newton–Raphson algorithm. In contrast with the case of the nodal HB, the Jacobian matrix of the piecewise formulation is generally dense (not sparse). Artificial sparsity may be created by setting to zero selected elements of the matrix, according to a physical criterion [39]. However, a relatively high degree of sparsity is necessary for the sparse system solvers to operate efficiently. In a more recent work, an inexact Newton

approach enables the use of GMRES for the calculation of the inexact Newton update [40].

4.2. Algorithms for Calculation of the Discrete Fourier Transforms

From the point of view of the discrete Fourier transform (DFT) algorithms, two main types of signal may be distinguished: periodic and quasiperiodic. In the case of periodic signals, the techniques for the DFT are well known. In particular, the fast Fourier transform FFT reduces the number of operations involved in the transformation. These algorithms cannot be directly applied to quasiperiodic signals, and complementary approaches will be needed [36,41–45]. The main approaches are briefly summarized in the following paragraphs.

4.2.1. DFT of Periodic Signals. The case of a periodic signal $y(t)$, to be expressed in the form $y(t) = \sum_{k=-N}^N Y_k e^{jk2\pi f_0 t}$, will be considered initially. The $2N + 1$ coefficients Y_k may be calculated from the linear equation system that is obtained when considering $2N + 1$ timepoints t_n [41]. The resulting square system is as follows:

$$\begin{bmatrix} 1 & 1 & \dots & 1 & 1 & \dots & 1 \\ 1 & e^{j2\pi f_0 t_1} & \dots & e^{j2\pi N f_0 t_1} & e^{-j2\pi N f_0 t_1} & \dots & e^{-j2\pi f_0 t_1} \\ \vdots & \vdots & \dots & \vdots & \vdots & \vdots & \vdots \\ 1 & e^{j2\pi f_0 t_{2N}} & \dots & e^{j2\pi N f_0 t_{2N}} & e^{-j2\pi N f_0 t_{2N}} & \dots & e^{-j2\pi f_0 t_{2N}} \end{bmatrix} \times \begin{bmatrix} Y_0 \\ Y_1 \\ \vdots \\ Y_N \\ Y_{-N} \\ \vdots \\ Y_{-1} \end{bmatrix} = \begin{bmatrix} y(0) \\ y(t_1) \\ \vdots \\ y(t_{2N}) \end{bmatrix} \tag{16}$$

This system can be written in a more compact form: $[W]\bar{Y} = \bar{y}$. Provided the time instants t_n are calculated in such a way that $[W]$ is invertible, the Fourier transform of $y(t)$ will be given by $\bar{Y} = [W]^{-1}\bar{y}$. The timepoints t_n are

$$t_n = n \frac{1}{(2N + 1)f_0} \equiv nT_s \tag{17}$$

The frequency $f_s = (2N + 1)f_0$ is clearly the sampling frequency of the time-domain signal. With the point selection (17), the matrix $[W]$ is invertible and well conditioned. In order for a matrix to be well conditioned, its condition

number must be very close to unity. This number is calculated from the Euclidean norm of $[W]$ as $k_W = \frac{1}{\|W\|} \|W^{-1}\|$.

From the timepoint choice (17), and taking into account the harmonic relationship $f_k = kf_0$, the harmonic components of $y(t)$ can be written as

$$\begin{aligned} Y_k &= \frac{1}{2N+1} \sum_{n=0}^{2N} y(n) e^{\frac{-j2\pi}{2N+1} nk} \\ &= \frac{1}{M} \sum_{n=0}^{2N} y(n) (\Phi_M)^{nk} \end{aligned} \quad (18)$$

where $M=2N+1$ and $\Phi_M \equiv e^{-j2\pi/M}$. The fast Fourier transform (FFT) takes advantage of the periodicity of Φ_M , with respect to both n and k , to substantially reduce the number of operations involved in the calculation of the complete sequence Y_k .

4.2.2. DFT of Quasiperiodic Signals. In the case of periodic signals, the sample points are equally spaced within the signal period. Then the DFT has great accuracy since the rows of the transformation matrix $[W]$ are orthogonal and the matrix is well conditioned. In the case of quasiperiodic signals, the equally spaced timepoints give rise to the ill-conditioning of $[W]$. Thus, the DFT cannot be directly applied. Different methods for the calculation of the Fourier transform of quasiperiodic signals have been presented in the literature. The most efficient are summarized in the following paragraphs.

4.2.2.1. Almost-Periodic Fourier Transform. Kundert et al. [41], randomly obtain the timepoints t_n from a time interval equal to 3 times the period of the smallest nonzero frequency. Thus, a number M' of timepoints larger than M is generated. However, instead of oversampling, which would give rise to an increase in the computational cost, only M timepoints are selected from the original set of M' points. A variation of the Gram-Schmidt orthogonalization procedure is used for this selection. The selected M timepoints are those giving rise to the nearest-to-one condition number of the matrix $[W]$. However, the near orthogonality of $[W]$ can also be achieved using nonrandom selections of the sample points. Ngoya et al. [42] describe several strategies.

4.2.2.2. Frequency Remapping. The objective of the Fourier transform is determination of the frequency components of the nonlinear elements of the HB equations. Let the memoryless function $y \equiv y(\bar{x})$ be considered. It can be easily shown [43] that the Fourier coefficients of the nonlinear element Y_k , with $k = -N \dots N$, depend only on the Fourier coefficients of the state variables, grouped in the vector \bar{X} , and on the integer vector $\bar{\lambda}_k$ that generates the particular intermodulation product f_k , but do not depend on the frequency basis \bar{F} . They can actually be written $Y_k \equiv Y_k(\bar{X}, \bar{\lambda}_k)$. Thus, it will not be necessary to use the actual waveforms of the state variables $\bar{x}(t)$ to obtain the Fourier coefficients of $y(\bar{x})$. It will be possible to use simpler

artificial waveforms for the \bar{Y}_k calculation. A convenient choice for the frequency basis \bar{F}^{dl} would be one providing periodic artificial waveforms, to which the efficient FFT algorithm may be applicable. Thus, the actual fundamental frequencies $\bar{F}^t = (F_1 \dots F_{NF})$ are remapped to the artificial ones $(\bar{F}^{dl})^t = (F_1^{dl} \dots F_{NF}^{dl})$. Once the harmonic values \bar{Y}_k are determined, they will be assigned to the actual frequencies, given by $f_k = \bar{\lambda}_k^t \bar{F}$. For this calculation to be valid, the artificial basis \bar{F}^{dl} must generate $2N+1$ different frequencies $f_{kd} = \bar{\lambda}_k^t \bar{F}^{dl}$. These artificial frequencies are the *remapped frequencies*.

The value of the artificial fundamentals depends on the truncation criterion that is used for the Fourier series. For $NF=2$, the artificial fundamentals, in the two cases of box and diamond truncation, are respectively given by [36,37,43]

$$\left. \begin{aligned} F_1^{dl} &= \Delta f \\ F_2^{dl} &= (2nl+1)\Delta f \end{aligned} \right\} \text{box truncation}$$

$$\left. \begin{aligned} F_1^{dl} &= nl\Delta f \\ F_2^{dl} &= (nl+1)\Delta f \end{aligned} \right\} \text{diamond truncation} \quad (19)$$

where Δf is an arbitrary frequency, different from zero, and nl is the nonlinearity order.

4.2.2.3. Multidimensional Fourier Transform. Let a signal $x(t)$ and NF fundamental frequencies be considered. An artificial signal \tilde{x} can be defined, using a different time variable for each fundamental: $\tilde{x}(t_1, t_2, \dots, t_{NF})$. Then, the following equality is fulfilled: $x(t) = \tilde{x}(t, t, \dots, t)$. The artificial signal \tilde{x} is periodic in each time variable t_j . Considering a different truncation order nl_j , $1 \leq j \leq NF$ for each fundamental frequency, the NF -dimensional DFT is written [36,37,44]

$$\begin{aligned} X(\lambda_1, \lambda_2, \dots, \lambda_{NF}) &= \frac{1}{N_{\text{tot}}} \sum_{n_1=-nl_1}^{nl_1} \dots \sum_{n_{NF}=-nl_{NF}}^{nl_{NF}} x_{n_1} \dots x_{n_{NF}} \\ &\times \exp\left(-j2\pi \left(\frac{\lambda_1 n_1}{N_1} + \dots + \frac{\lambda_{NF} n_{NF}}{N_{NF}} \right)\right) \end{aligned} \quad (20)$$

where $N_j = 2nl_j + 1$, $1 \leq j \leq NF$, and $N_{\text{tot}} = \prod_{j=1}^{NF} N_j$.

Care must be taken in (20) to prevent aliasing when choosing the sampling orders. The multidimensional Fourier transform can be obtained through a sequential calculation of fast Fourier transforms, in the different time variables. However, the computational cost of these operations can be greatly reduced through the use of special algorithms [45]. For a nonlinear relationship $y = f(x)$, it is easily shown [36,37] that the samples of $y(t)$ can be obtained through $\hat{y}_{n_1, \dots, n_{NF}} = f(\tilde{x}_{n_1, \dots, n_{NF}})$, which is easily generalized to a nonlinear dependence on multiple state variables. Then, the Fourier coefficients of $y(t)$ can be determined through an expression formally identical to (20).

4.3. Analysis of Autonomous and Synchronized Circuits

As has been shown, the HB technique requires the provision by the designer of the set of fundamentals F_1, \dots, F_{NF} to be used in the Fourier series expansion of the circuit variables. In case of self-oscillations, the corresponding frequencies must be included in this basis. However, the existence or nonexistence of this oscillation and the value of the oscillation frequency depend on the circuit values, so the a priori determination of the frequency basis is not always an easy task. The designer might not even be aware of the existence of a self-oscillation in the circuit in question, as when simulating an unstable amplifier as if it operated in periodic regime.

But even when the entire frequency basis is correctly provided, there might still be problems for the simulation of autonomous or synchronized circuits. The reason is that, coexisting with the oscillating solution, there is always a mathematical solution, with no self-generated fundamentals. This mathematical solution is usually unstable and, thus, has no interest for the user. The most obvious example is the free-running oscillator, for which a DC solution always coexists with the oscillating one (see Fig. 1). In HB, the initial value \bar{X}^0 of the Newton–Raphson algorithm is essentially determined by the input generators. Therefore, the frequency terms involving self-generated fundamentals will have zero value in \bar{X}^0 and will remain so during the entire iterative procedure. Thus, the Newton–Raphson algorithm starting from \bar{X}^0 will converge to the nonoscillating solution, which is as mathematically correct as the other one.

The HB problems with autonomous and synchronized circuits can be circumvented through the use of complementary techniques, to avoid its undesired convergence to nonoscillating mathematical solutions. Then, HB becomes a very powerful method for the design of circuits such as oscillators and frequency dividers. To take full advantage of the technique, the designer must be aware of what he/she is actually facing. With this purpose, the dynamics of the forced oscillator is briefly outlined in Section 4.3.1, which will also allow a better understanding of the HB problems with the simulation of these circuits. The complementary analysis techniques will be presented in Section 4.3.2.

4.3.1. Dynamics of the Forced Oscillator. Let a free-running oscillator at the frequency F_0 be considered. The only fundamental F_0 of the circuit solution is an autonomous one. If an external periodic generator is connected to the circuit, different operation modes may be obtained, depending on the values of the frequency F_{in} and power P_{in} of the generator [3,46]. As an example, Fig. 5 shows the different operation regions of the forced oscillator of Fig. 4, in the plane defined by F_{in} and P_{in} . For small input power P_{in} , provided the input frequency F_{in} is not too close to F_0 , the two frequencies will coexist in the circuit, giving rise to a quasiperiodic regime at F_{in} , F_a . Note that the autonomous frequency F_a is slightly different from the free-running frequency F_0 , due to the influence of the input generator. The circuit operates like a self-oscillating mixer. If the input frequency F_{in} is relatively close to F_0 , then

Figure 5. Global behavior of forced oscillators, in terms of the forcing generator frequency and power. Operation regions about F_0 of the oscillator in Fig. 4. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the autonomous frequency F_a may be influenced by the input generator in such a way that both frequencies become the same and there is a constant phase relationship between the input signal and the self-oscillation. This phenomenon is called *synchronization*.

The synchronization band, in terms of the input frequency F_{in} , becomes wider as the power delivered by the input generator increases (see Fig. 5). The border of the synchronization region is a V-shaped curve in the plane defined by F_{in} and P_{in} , called the *Arnold tongue*. The lower vertex of the Arnold tongue is the free-running oscillation, occurring at the frequency F_0 , for zero input power P_{in} . The synchronized regime is a periodic regime with F_{in} as fundamental. Although the fundamental frequency is the same delivered by the input generator, the self-oscillation is still present in the circuit and, in general, gives rise to output power much higher than could be expected in a simple amplifier regime. Finally, note that for relatively high input power P_{in} at a frequency F_{in} not too close to F_a , the self-oscillation may be extinguished. This phenomenon, known as *asynchronous extinction*, gives rise to a simple forced regime.

The synchronization can also occur when the input frequency is close to any harmonic component, of k order, of the free-running frequency. Then $F_{in} = kF_a$, after synchronization. The harmonic synchronization principle is used for the design of analog frequency dividers. Thus, this kind of circuit operates in a synchronized regime in which the self-oscillation has become a subharmonic of the input signal. The synchronization is also possible when the input frequency is close to a subharmonic of the free-running oscillation frequency, that is, when $F_a = mF_{in}$. This is the principle of the subsynchronized oscillator, in which a stable subharmonic source is used to stabilize and reduce the phase noise of a noisier oscillator. The synchronization bands become narrower with the order k or m . Each

synchronization region in the plane F_{in}, P_{in} constitutes an Arnold tongue.

Figure 6a shows the periodic solution curves of the forced oscillator of Fig. 4, when represented in terms of the amplitude at the fundamental frequency. The point O indicates the free-running oscillation, obtained for zero input power. This solution coexists with a DC solution that, in the representation of the figure, would lie on the horizontal axis (abscissa). When the input generator power is injected, a synchronized solution curve is obtained around the free-running oscillation point. For small input power, this synchronization curve is closed. See, for instance, the curve obtained for $I_g = 7 \text{ mA}$, in the figure. This is in agreement with the fact that the synchronized solution has a limited bandwidth (see the Arnold tongue in Fig. 5).

The limits of the synchronization band are given by the infinite-slope points or turning points of this closed curve. Although the stability analysis is the object of the final

section (Section 6), it can be advanced that the turning points of a given solution curve always separate sections with different qualitative stability [3]. If the solution is originally stable, it becomes unstable after folding at a turning point. In Fig. 6a, only the upper section of the closed curve is stable. Note also that the closed curve coexists with a low-amplitude curve, obtained for the same input power and the same circuit values. It is an unstable solution, equivalent to the DC solution of the free-running oscillator. In this small amplitude solution, the circuit is not oscillating.

For higher input power, the closed synchronization curve widens, as gathered from the Arnold tongue of Fig. 5. For a certain input power, the upper curve and the lower curve merge. From that input power, only one curve is obtained. There is an intermediate range of input power for which the curve exhibits strong folding (see the curve for $I_g = 9 \text{ mA}$). For the lower input power values, the turning points will still be synchronization points. For higher input power, they will be simple jump points. At these points, the solution cannot continue evolving along the same section of the curve, due to its folding versus the parameter, and “jumps” to a different section. When the open periodic curves cross the locus, indicated with “asynchronous extinction” in Fig. 5, they become unstable. An autonomous frequency is generated and gives rise to a stable quasiperiodic regime. The autonomous frequency is, in fact, the self-oscillation frequency, reappearing in the circuit for input generator values of lesser influence.

In Fig. 6a, the circuit solution is quasiperiodic beyond the turning points (for the lower input power) and below the “asynchronous extinction locus” (for the higher input power). The quasiperiodic solution has two fundamental frequencies: the input frequency F_{in} and the oscillation frequency F_a . These quasiperiodic solutions have been represented in Fig. 6b, for the input current $I_g = 20 \text{ mA}$. Since there are two fundamentals, a path has been traced for each of them, showing the evolution of the corresponding harmonic amplitude. On the left-hand side, the synchronization is due to the asynchronous extinction of the autonomous fundamental, occurring at $F_{in} = 1.32 \text{ GHz}$. The solution is periodic in the input frequency interval 1.32–1.55 GHz. However, at $F_{in} = 1.55 \text{ GHz}$, it loses synchronization due to a turning point of the periodic curve (see Fig. 6a).

All the simulations in Fig. 6 have been carried through HB, using the techniques that will be presented in the following section. By default, the HB methods of Section 4.1 would miss many of the solutions represented in the figure. In the case of the free-running oscillator (zero input power), it would converge to the DC solution. When the input generator power is injected, two different cases must be distinguished. For low input power, it will converge to the low-amplitude curve, missing the actually synchronized solution. For higher input power, it will converge to the single periodic curve, but will not be able to circumvent the turning points for reasons that will be made clear later. The quasiperiodic solutions of Fig. 6b can never be obtained by default since convergence to the coexisting periodic solutions is much simpler, as these solutions are naturally forced by the input generators. In the case of low

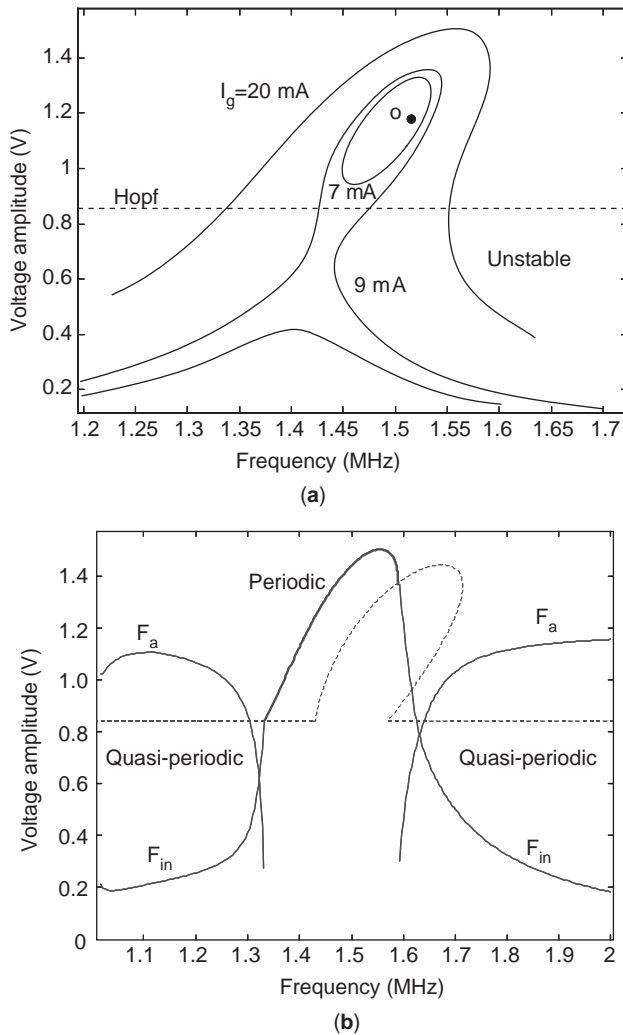

Figure 6. Solutions of the cubic nonlinearity oscillator: (a) for different values of the input generator current; (b) for the input current $I_g = 20 \text{ mA}$, including quasiperiodic simulations. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

input power, the periodic solution obtained will be the unstable low-amplitude curve. In the case of higher input power, the obtained periodic solution will be the unstable single curve.

4.3.2. Complementary Harmonic Balance Techniques. Different techniques have been proposed in the literature to cope with the HB difficulties when dealing with autonomous circuits [46–48]. In Ref. 46, taking into account the forced nature of ‘the HB method, an artificial generator is introduced at the self-generated fundamental. We shall refer to this artificial generator as the *auxiliary generator* [3,46]. Provided the auxiliary generator has a nonzero value, it will be able to initialize the harmonic components, involving the autonomous or synchronized fundamental. The solution obtained with the aid of this auxiliary generator must be the actual autonomous or synchronized solution, and must, of course, entirely agree with the one that would be obtained without the auxiliary generators.

Two different types of auxiliary generator are possible: voltage generators, connected in parallel at a circuit node, and current generators, connected in series at a circuit branch. The use of the voltage auxiliary generator is illustrated in Fig. 7, where it has been introduced in the frequency divider of Fig. 2. As formerly stated, the auxiliary generator operates at the autonomous or synchronized oscillation frequency. This will be written $F_{AG} = F_a$, where the subindex ‘a’ denotes, in general, ‘autonomous.’ We must also account for the fact that voltage generators and current generators are, respectively, short circuits and open circuits at frequencies different from those that they deliver. Thus, an ideal filter is necessary in each case, to avoid a major perturbation of the circuit, due to the short-circuiting/opening of the harmonic components. In the case of a voltage generator, the ideal filter is connected in series with this generator (see Fig. 7). The filter has a zero impedance value at the generator frequency $F_{AG} = F_a$ and infinite impedance at any other frequency (for which the generator will have no effect).

As already stated, to be of any use in determination of the circuit solution, the auxiliary generator must have no influence over this solution. To have zero influence, a voltage generator must exhibit a zero value of its current-to-voltage relationship at the delivered frequency. The non-perturbation condition will introduce additional constraints in the HB system. But there are also additional

variables. These variables depend on the type of regime, autonomous or synchronized, to be analyzed. Both cases are considered in the following text.

4.3.3. Autonomous Regime. In an autonomous regime, one of the fundamental frequencies is due to a self-oscillation of the circuit. As already indicated, for the analysis of this regime, an auxiliary generator is introduced at the frequency $F_{AG} = F_a$. Because the frequency F_a is autonomously generated by the circuit, its value will depend on the values of the circuit elements and the input generators, so it is not known a priori. It is, actually, one of the unknowns to be determined. The auxiliary generator will have an amplitude A_{AG} and a phase ϕ_{AG} . However, in an autonomous regime, the phase ϕ_{AG} can be anyone, in the sense that any phase value ϕ_{AG} gives rise, after the solution of the circuit, to the same waveforms of the circuit variables. For simplicity, the value $\phi_{AG} = 0$ will be considered.

As already mentioned, the auxiliary generator must not to perturb the steady state. The unknowns to be determined, in order to fulfill the nonperturbation condition, are the autonomous frequency, which is the same frequency delivered by the auxiliary generator, and the amplitude A_{AG} of this generator. In case of an auxiliary generator of voltage type, the nonperturbation conditions are the following:

$$\bar{Y}_{AG}(A_{AG}, F_{AG}) \equiv \begin{bmatrix} \text{Re} \left(\frac{I_{AG}}{A_{AG}} \right) \\ \text{Im} \left(\frac{I_{AG}}{A_{AG}} \right) \end{bmatrix} = \bar{0}, \tag{21}$$

$$V_{AG} \equiv A_{AG} e^{j0}$$

where I_{AG} is the current flowing through the auxiliary generator. The nonperturbation condition adds two more equations and two more unknowns to the HB system, which becomes

$$\bar{H}_B(\bar{X}, F_{AG}, A_{AG}) = \bar{0} \tag{22a}$$

$$\bar{Y}_{AG}(\bar{X}, F_{AG}, A_{AG}) = \bar{0} \tag{22b}$$

Note that a piecewise HB formulation has been considered, although the method can equally be applied when using a nodal formulation. The error function \bar{H}_B is the same function we have been dealing with in Section 5. Once the convergence is achieved, the voltage value at the auxiliary generator node (in case of a voltage generator) will be, at the oscillation frequency $V(F_A) = A_{AG} e^{j0}$. This value is independent of the presence or absence of the auxiliary generator, since, according to (22), this generator does not have any influence on the steady-state solution.

The auxiliary generator technique has been applied to the circuit of Fig. 2 in free-running oscillator regime. The fundamental frequency of the Fourier basis is $F_{AG} \equiv F_a$. The number of harmonic frequencies that has been taken into account is $N = 15$. Figure 8a shows the evolution of the real and imaginary parts of the admittance function Y_{AG} , versus the iteration number. Figure 8b shows the

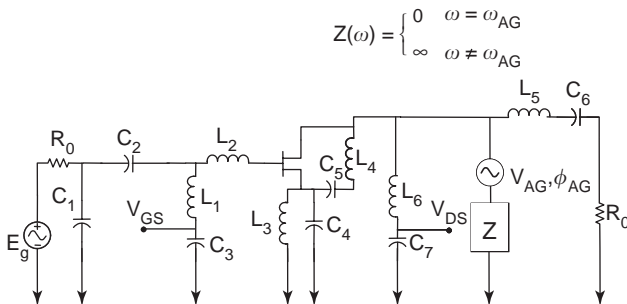

Figure 7. Auxiliary generators of voltage type, connected in parallel at a circuit node.

evolution of the frequency F_{AG} and the amplitude A_{AG} versus the iteration number. As can be appreciated, the initial values were relatively far from the actual solution. When the admittance function is equal to zero, F_{AG} agrees with the free-running oscillation frequency F_0 and A_{AG} with the node amplitude at the first-harmonic component. Figure 9 shows the resulting spectrum and waveform. As can be seen, the waveform (Fig. 9b) agrees with the one obtained through the time-domain analysis of Fig. 3.

4.3.4. Synchronized Regime. In the case of a synchronized regime, the self-oscillation frequency F_a is harmonically related to the input generator frequency F_{in} . There is also a constant-phase relationship between the two frequency components. For the analysis of this regime, an auxiliary generator will be introduced at the frequency at which the self-oscillation occurs. Since it is a synchronized regime, the frequency of the generator will be $F_{AG} \equiv F_a = F_{in}/k$. A similar relationship would hold in the case

$F_a = mF_{in}$. Since the frequency of the auxiliary generator is determined by F_{in} , it is no longer an unknown of the problem. In contrast, and as a result of the phase relationship between the oscillation and the input generator signal, the phase ϕ_{AG} of the auxiliary generator is no longer irrelevant and will be an unknown of the problem. The amplitude A_{AG} and phase ϕ_{AG} are unknowns to be determined through

$$\bar{H}_B(\bar{X}, \phi_{AG}, A_{AG}) = \bar{0} \tag{23a}$$

$$\bar{Y}_{AG}(\bar{X}, \phi_{AG}, A_{AG}) = \bar{0} \tag{23b}$$

with the auxiliary generator operating at the frequency $F_{AG} \equiv F_a = F_{in}/k$, in the case of a frequency divider or $F_{AG} \equiv F_a = mF_{in}$, in the case of a subsynchronized oscillator.

Figure 8. Application of the auxiliary generator technique to the circuit of Fig. 7, in free-running-oscillator regime, showing evolution of the (a) real and imaginary parts of the auxiliary generator admittance versus the iteration number and (b) auxiliary generator amplitude and frequency versus the iteration number.

Figure 9. Results of application of the auxiliary generator technique to the circuit of Fig. 7, in free-running oscillator regime: (a) magnitude spectrum of the node voltage; (b) waveform.

The analysis technique has been applied to the divider circuit of Fig. 2. Now the input generator is connected, at a frequency F_{in} , about $2F_0$. The input amplitude is $V_{in} = 0.25$ V. The fundamental frequency of the Fourier series expansion is $F_{in}/2$. Again, the number of harmonic components is $N = 15$. The synchronized solution curve, in terms of the drain amplitude, versus the input frequency, has been traced in Fig. 10. For this relatively low input amplitude, a closed curve is obtained about the free-running oscillation. In agreement with the qualitative behavior of Fig. 6, there will also be a low-amplitude curve, with no frequency division (not represented). The upper section of the curve (between the two turning points) is stable, while the lower section is unstable.

In Fig. 11, the circuit has been analyzed for constant frequency $F_{in} = 6$ GHz and the same generator amplitude $V_{in} = 0.25$ V. The low-amplitude waveform of Fig. 11a at the nondivided frequency 6 GHz is the solution obtained through standard HB. The frequency-divided waveform is the solution obtained through the auxiliary generator technique. Figure 11b shows the time-domain analysis of the frequency-divided regime, with a long transient, in comparison with the solution period. Note the agreement of the resulting steady-state waveform with the divided solution of Fig. 11a.

For the input frequency $F_{in} = 5.6$ GHz, the solution lies on the left-hand side of the ellipsoidal curve of Fig. 10. The solution is not synchronized for these input conditions, and this is way it has not been represented. The input generator frequency F_{in} and the self-oscillation frequency F_a coexist and the circuit behaves as a self-oscillating mixer. Because of the existence of F_a as an independent fundamental, the circuit behaves in an autonomous regime that has been analyzed through (22). Note that a multitone analysis at the two fundamental frequencies F_{in} and F_{AG} is necessary. Here a diamond truncation of the spectrum has been used, with $nl = 7$. Figure 12a shows the

Figure 10. Synchronized solution versus the output frequency for $V_{in} = 0.25$ V. The upper portion of the closed curve is stable. The lower section of the solution curve is unstable. The point inside the curve corresponds to the free-running oscillation.

Figure 11. Simulation of the circuit of Fig. 2, operating as a frequency divider by 2: (a) the frequency-divided solution, obtained through the auxiliary generator technique, coexists with a non divided solution, obtained through standard HB simulation, with no auxiliary generator; (b) time-domain simulation of the frequency-divided regime.

evolution of the auxiliary generator frequency and amplitude versus the iteration number. Figure 12b shows the resulting quasiperiodic spectrum of the drain voltage.

For too close values of F_{in} and $2F_a$, differing, for instance, in just a few megahertz, the multitone HB will not be accurate, since this represents three orders of magnitude less than F_{in} and F_a . This kind of operation is obtained for input frequencies close to the border of the synchronization region. As will be shown, the envelope transient is very well suited for the simulation of this regime.

5. ENVELOPE TRANSIENT

Obviously, the HB method cannot be applied to the analysis of circuits with modulated input signals. This is due to the impossibility of representing the modulated variables

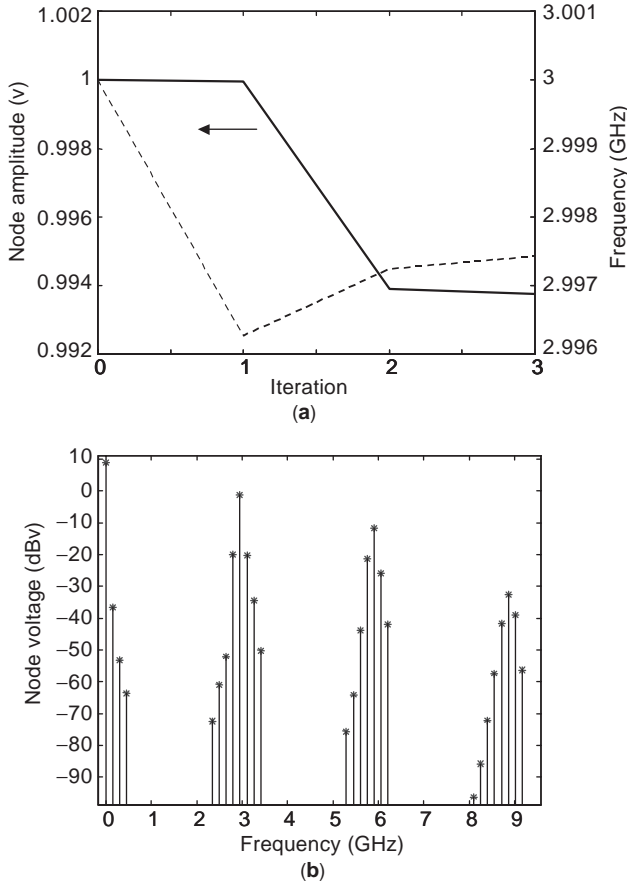

Figure 12. Auxiliary generator technique for analysis of the circuit in Fig. 2 in self-oscillating mixer regime: (a) evolution of the auxiliary generator amplitude and frequency versus the iteration number; (b) resulting quasiperiodic spectrum.

in a Fourier series. However, in most circuits with modulated inputs, it is possible to consider two different timescales. The faster timescale t_2 corresponds to the carrier, and the slower timescale t_1 corresponds to the modulation. The circuit is generally periodic in the “faster” time t_2 . Then, any state variable $a(t)$ can be expanded in a harmonic series of the form [20–25]

$$a(t_1, t_2) = \sum_{k=-N}^N A_k(t_1) e^{j\omega_k t_2} \quad (24)$$

where $A_k(t_1)$ are the slowly varying envelopes. In general, the frequencies ω_k will either be the harmonics of a single input frequency, in an amplifier, for instance, or the intermodulation products of an RF/IF input frequency and a local-oscillator frequency, in a frequency mixer.

According to (24), the circuit variables could be sampled using two different time rates t_1, t_2 . Of course, since the two timescales are fictitious, the variables $\bar{a}(t_1, t_2)$ will agree with $\bar{a}(t)$ only for $t_1 = t_2$. On the other hand, the envelopes must not overlap in order for the decomposition (24) to be unique in the basis $e^{j\omega_k t_2}$, $-N \leq k \leq N$.

When expressions of the form (24) are introduced in the HB system, the two time variables t_1, t_2 will require two

different derivative operators. However, as a result of the solution periodicity with respect to t_2 , for fixed t_1 , the derivative with respect to t_2 will simply be obtained through multiplication of the different harmonic terms by $j\omega_k$. This provides an algebraic system of differential equations in the harmonic terms $A_k(t_1)$, to be sampled (in the numerical integration) at a rate Δt_1 lower than that of the original system. This allows a significant reduction of the computational cost.

Two different cases may be considered, according to the type of HB formulation, nodal or piecewise, in which the expansions (24) are introduced. The two cases are analyzed in the following text.

5.1. Nodal Harmonic Balance

In the case of a nodal HB formulation [22,25], the envelope transient equation takes the form

$$\begin{aligned} \bar{I}(\bar{V}(t)) + [j\omega]\bar{Q}(\bar{V}(t)) + \frac{d}{dt}\bar{Q}(\bar{V}(t)) \\ + \int_{-\infty}^t \bar{H}(t-\tau)\bar{V}(\tau)d\tau + \bar{G}(t) = 0 \end{aligned} \quad (25)$$

where the subindex has been dropped from the time variable t_1 , for notation simplicity. For the numerical solution of (25), the time variable is discretized. Then the following system is obtained

$$\begin{aligned} \bar{I}(\bar{V}(t_{n+1})) + [j\omega]\bar{Q}(\bar{V}(t_{n+1})) \\ + \frac{\bar{Q}(\bar{V}(t_{n+1})) - \bar{Q}(\bar{V}(t_n))}{t_{n+1} - t_n} \\ + \sum_{i=0}^n \bar{H}(t_{n+1} - t_i)\bar{V}(t_i)\Delta t_i + \bar{G}(t_{n+1}) = 0 \end{aligned} \quad (26)$$

where a backward Euler integration rule has been considered. The system is integrated using the initial conditions $\bar{G}(t_0), \bar{V}(t_0)$. The initial condition may be obtained from a simple harmonic balance (with constant envelopes) at the initial time $t_0 = 0$. From this timepoint, the Newton-Raphson algorithm is applied to obtain the solution $\bar{V}(t)$ along the simulation interval $[0, T_s]$. Since Eq. (26) is a nonlinear harmonic relationship between $\bar{I}(t_{n+1}), \bar{Q}(t_{n+1}), \bar{V}(t_{n+1})$ and $\bar{G}(t_{n+1})$, the integration along $[0, T_s]$ involves a HB calculation for each timepoint t_{n+1} .

The major difficulty with the envelope transient, based on the nodal HB, comes from the need to compute the time-varying harmonic components of the impulsive responses $\bar{H}(t)$, which will necessitate, again, the use of Padé approximations, as in the case of the full time-domain analysis. However, the computation of the convolution products is much less demanding than in standard time-domain integration, since the models of the distributed elements can be narrowband about the harmonic frequencies ω_k .

5.2. Piecewise Harmonic Balance

When considering time-varying harmonic components in the piecewise HB equations, the following system is obtained [21,24]

$$\begin{aligned}
 & [A_x(jk\omega_0 + j\omega)]\bar{X}(t) + [A_y(jk\omega_0 + j\omega)]\bar{Y}(t) \\
 & + [A_g(jk\omega_0 + j\omega)]\bar{G}(t) = 0
 \end{aligned}
 \tag{27}$$

where ω is the frequency associated to the time variations in t_1 and, again, the subindex of this time variable has been dropped, $t_1 \equiv t$. Assuming slow variations of the harmonic components, the linear matrixes can be expanded in a Taylor series about $\omega = 0$. This Taylor expansion will necessarily limit the allowed envelope bandwidth. For $\omega \ll \omega_0$, a first-order Taylor expansion will be sufficient, providing the result

$$\begin{aligned}
 & [A_x(jk\omega_0)]\bar{X}(t) + \left[\frac{\partial A_x}{\partial jk\omega_0} \right] \frac{d\bar{X}(t)}{dt} \\
 & + [A_y(jk\omega_0)]\bar{Y}(t) + \left[\frac{\partial A_y}{\partial jk\omega_0} \right] \frac{d\bar{Y}(t)}{dt} \\
 & + [A_g(jk\omega_0)]\bar{G}(t) + \left[\frac{\partial A_g}{\partial jk\omega_0} \right] \frac{d\bar{G}(t)}{dt} = 0
 \end{aligned}
 \tag{28}$$

where the fact that the multiplication by $j\omega$ is equivalent to a time derivation in t_1 has been taken into account.

Because of the development of the linear matrixes in a first-order Taylor series, it will be valid only for slowly varying $\bar{X}(t), \bar{Y}(t), \bar{G}(t)$, that is, for narrowband harmonic components. This is a significant departure from the nodal formulation, which does not have this constraint. However, the formulation (28) requires neither the calculation of the distributed-element impulsive responses nor the computation of the convolution products. As a result, provided the envelopes are narrowband, which is usually the case, the piecewise formulation may be more efficient.

As an example, the envelope transient formulation has been applied to a transistor-based frequency mixer, with input frequency $F_{in} = 4$ GHz and local-oscillator frequency $F_0 = 3.5$ GHz. The input signal is CDMA-modulated, with 4 MHz bandwidth. Contrary to the previous examples, this circuit is forced. It is analyzed using a two-tone Fourier-series expansion, at F_{in} and F_0 , avoiding the harmonic relationship between the fundamentals. Diamond truncation is used, with $nl = 7$. The conditions for an accurate envelope transient simulation are fulfilled, since the envelope bandwidth, due to the CDMA modulation, is much narrower than the smallest frequency interval between the spectral lines $\Delta f/2 = (F_{in} - F_0) = 250$ MHz. Figure 13a shows the time-varying magnitude of the intermediate frequency component $F_{in} - F_0$, over the output 50 Ω load. Figure 13b shows the output power spectrum, in steady state. Note that this spectrum is centered about the frequency $f = 0$, since it has been calculated from the time varying envelope of the harmonic component $F_{in} - F_0$.

The envelope transient can be applied to the simulation of autonomous and synchronized regimes. However, as in

Figure 13. Frequency mixer with a CDMA input signal at $F_{in} = 4$ GHz. The frequency of the local oscillator is $F_0 = 3.5$ GHz: (a) magnitude of the time-varying envelope at the intermediate-frequency component $F_{in} - F_0$; (b) power spectrum about the frequency component $F_{in} - F_0$.

the case of standard HB, there may be simulation problems, due to the coexistence of the autonomous or synchronized solutions with a (generally unstable) mathematical solution, without self-oscillation. As in the case of the standard HB, the problem can be solved with the aid of auxiliary generators. This has been done in the bibliography in two different ways, indicated in the following text.

Assuming an auxiliary generator of voltage type, once the nonperturbation condition is fulfilled, the resulting generator voltage agrees with the node voltage. The same is true in terms of the branch current, in the case of a current generator. Thus, since we are dealing with the possibly modulated steady states, the value of the auxiliary generator should be time-varying. In the case of an autonomous regime, this generator would be represented by $A_{AG}(t), \omega_{AG}(t)$. In the case of a synchronized regime, it would be represented by $A_{AG}(t), \phi_{AG}(t)$. Taking this into account, Ngoya and coworkers imposed

the nonperturbation condition along the whole simulation interval $[0 - T_s]$ [21,24], as $\vec{H}_{AG}(A_{AG}(t), \zeta_{AG}(t)) = 0$, where $\zeta_{AG}(t)$ stands for either the auxiliary generator frequency or its phase, according to the type of regime. Thus, the auxiliary generator variables must be calculated at each timestep, along the simulation interval $[0 - T_s]$. This technique allows simulation of the oscillator transients [21,22].

A different technique has been developed [49] to avoid the computational complexity of the calculation of the time-varying values $A_{AG}(t), \zeta_{AG}(t)$, along $[0 - T_s]$. In this second technique, an auxiliary generator of constant value A_{AG_0}, ζ_{AG_0} is connected to the circuit at the initial point $t_0 = 0$ of the simulation interval only. The constant value A_{AG_0}, ζ_{AG_0} is determined from a HB analysis of the form (22) or (23), according to the type of regime. After $t_0 = 0$, the AG is disconnected from the circuit, letting it evolve according to its own dynamics, with no AG influence. In general terms, if the solution is stable, the circuit will evolve to it after removing the AG. In the case of an autonomous regime, the fundamental frequency of the frequency-series expansion (24) is kept constant to ω_{AG_0} , as this is the value resulting from the initial HB analysis, assuming constant harmonic terms A_k . When doing so, the frequency variation $\omega_a(t) - \omega_{AG}$ is naturally converted to phase variations of the harmonic terms $A_k(t)$ [3].

Two examples of application of the envelope transient to autonomous/synchronized circuits will be shown in the following paragraphs. The first example analyzes the effect of a modulated input phase at F_{in} , over the phase of the drain voltage, at the harmonic component $F_{in}/2$, in the frequency divider of Fig. 2. The input generator amplitude is $V_{in} = 0.25$ V, at the frequency $F_{in} = 6$ GHz. For these input generator conditions, the circuit operates in synchronized regime, as shown by the synchronization curve of Fig. 10. In the absence of any form of modulation, a constant value of the phase of the first-harmonic component $V[1]$ would be obtained. When the phase modulation is introduced, the phase of this harmonic responds to this modulation in the way shown in Fig. 14. The division by 2 of the phase increments should be noted. The same technique could be applied to more practical cases of modulated autonomous circuits.

The second example shows the application of the envelope transient technique to a near-synchronization regime, difficult to analyze through other techniques. According to Fig. 10, the circuit operates in this regime when the input frequency corresponds to values outside the ellipsoidal curve, but close to any of its two turning points. The input frequency and the oscillation frequency coexist in the circuit solution. Then, when using a frequency basis with ω_{in} as the only fundamental, the envelopes will oscillate at the difference frequency $|\omega_{in}/2 - \omega_a|$. Figure 15 shows the envelope transient simulation of the quasiperiodic solution for $F_{in} = 5.92$ GHz. The envelope oscillates at the difference frequency $F_a - F_{in}/2 = 8$ MHz (see Fig. 15a). The resulting dense spectrum about the first-harmonic component is shown in Fig. 15b. The demanding time-domain simulation of this regime is also shown in Fig. 15c, for comparison.

Figure 14. Effect of a modulated input phase on the solution of the circuit of Fig. 2, for $V_{in} = 0.25$ V, $F_{in} = 6$ GHz [dashed line—input modulation; solid line—phase of the harmonic component $V[1]$ of the drain voltage].

6. PARAMETRIC ANALYSIS AND STABILITY

Usually, the interest of the designer is not limited to obtaining the circuit solution for just a particular value of the input generator or generators, or the circuit elements. Instead, the designer generally wishes to know the circuit response versus a given parameter η , which may be the input generator power or frequency, or a bias voltage, for instance. In many cases, this parametric analysis is necessary in order to calculate the circuit operation ranges, in terms of frequency bandwidth, for instance, or to determine the possible coexistence of the desired regime with solutions of other type. As an example, the parametric analysis of the circuit of Fig. 2, versus the input frequency, allowed us to obtain its frequency-division band for $V_{in} = 0.25$ V (see Fig. 10).

The straightforward way to obtain the circuit response versus a parameter η is to carry out a sweep in this parameter. However, this direct sweep will generally lead to unsatisfactory results if the curve contains turning points. At the turning points (or infinite-slope points) the curve folds over itself, giving rise to a multivalued section, versus the parameter (see Fig. 6a). The turning points are intrinsic to the performance of frequency dividers and synchronized oscillators and are also commonly obtained in autonomous circuits of other nature, such as voltage-controlled oscillators.

The turning points of the solution curve can be circumvented using continuation methods. These methods assume that the solution is known for a particular value η_0 of the parameter. This initial point may have been obtained from a standard HB calculation or with the aid of auxiliary generators, in the case of an autonomous or synchronized regime. From this initial point, the solution variations versus η may be followed using different strategies. One of the most efficient techniques is the prediction–correction technique, with parameter switching [50].

Figure 15. Envelope transient simulation of a near-synchronization solution; (a) slow oscillation of the magnitude of $V[1]$; (b) dense spectrum about the first-harmonic component; (c) time-domain simulation, for similar conditions.

The prediction–correction technique, with parameter switching, is applied from the initial solution point (η_0, \bar{X}_0) , considering a discrete step $\Delta\eta = h$. In this technique, once a solution point (η_n, \bar{X}_n) has been determined, the next one $(\eta_{n+1}, \bar{X}_{n+1})$ is estimated through the linearization of the HB system about the previous point (η_n, \bar{X}_n) . This constitutes the *prediction* stage of the technique. The estimated point will be called here $(\eta_{n+1,p}, \bar{X}_{n+1,p})$. It is calculated by differentiating the error function \bar{H} of the HB system

$$\begin{aligned} \Delta\bar{H} &= [JH]_n(\bar{X}_{n+1,p} - \bar{X}_n) + \frac{\partial\bar{H}}{\partial\eta}\bigg|_n(\eta_{n+1} - \eta_n) = 0 \\ \rightarrow \bar{X}_{n+1,p} &= \bar{X}_n - [JH]_n^{-1} \frac{\partial\bar{H}}{\partial\eta}\bigg|_n(\eta_{n+1} - \eta_n) \end{aligned} \quad (29)$$

where the Jacobian matrix $[JH]_n$ and the derivative of \bar{H} with respect to the parameter are evaluated at the preceding solution point n . The predicted point $(\eta_{n+1,p}, \bar{X}_{n+1,p})$ is not the actual solution point since the actual system $\bar{H}(\bar{X}, \eta) = 0$, unlike Eq. (29), is nonlinear. The point obtained through (29) is a linear estimation (prediction) of the solution for η_{n+1} .

At the *correction stage* of the continuation technique, the Newton–Raphson algorithm is applied for correction of the estimated point n , which is done for constant parameter value $\eta = \eta_{n+1,p}$. The input of this algorithm is the estimated solution $(\eta_{n+1,p}, \bar{X}_{n+1,p})$, which is used as the starting point: $\bar{X}_{n+1}^0 \equiv \bar{X}_{n+1,p}$. Unlike $\bar{X}_{n+1,p}$, the point resulting from the Newton–Raphson convergence $\bar{X}_{n+1} = \bar{X}_{n+1}^c$ is an actual solution point.

It is easily seen from (29) that the Jacobian matrix $[JH]$ becomes singular at any point of the curve with infinite slope of the solution curve or turning point. Because of this, the Newton–Raphson algorithm fails to converge in the neighborhood of the turning point. To cope with this problem, a parameter-switching algorithm [3,50] can be used. In this algorithm, the continuation parameter is, at sections of the curve, different from the actual circuit parameter η . In fact, at each prediction stage $(\eta_{n+1,p}, \bar{X}_{n+1,p})$, the predicted increments of the different variables (including the parameter η), $|\text{Re} \Delta X_{0n+1}^1|$, $|\text{Im} \Delta X_{0n+1}^1|, \dots, |\text{Re} \Delta X_{Nn+1}^Q|$, $|\text{Im} \Delta X_{Nn+1}^Q|, |\Delta\eta_{n+1}|$ are compared, taking the variable with the biggest increment as new analysis parameter.

If the new parameter is, for instance, $\text{Re} X_k^j$, the increment h is assigned to this variable. Therefore, this variable not considered as an unknown. Instead, the parameter increment $\Delta\eta_{n+1}$ is an unknown of the problem, to be determined in the resolution process. Note that taking the variable with the biggest increment as parameter prevents any unbounded growth of the circuit variables. Through this technique, points of infinite slope (turning points) become points of zero slope. The synchronization curves of Figs. 6 and 10 have been traced through the described prediction–correction technique, with parameter switching.

When dealing with HB simulations, the stability analysis of the obtained steady-state solutions is essential. This is even more so when two or more steady-state

solutions coexist for the same parameter values. To show the principles of the stability analysis through HB, a general steady-state solution \bar{X}_s will be considered. It may be a DC solution or a periodic or quasiperiodic solution, with frequency components ω_k , with $k = -N \dots N$. As already stated, a stable solution must be able to recover from small perturbations. To verify whether this is the case, a small perturbation of complex frequency $\sigma + j\omega$ has been considered [3,17,19]. The need for a complex frequency in the perturbation comes from the fact that the perturbed solution is no longer in steady state. Taking into account the smallness of the perturbation, the HB system can be linearized about \bar{X}_s , which provides the following characteristic equation:

$$\left\{ [A_x(k\omega_0 + \omega - j\sigma)] + [A_y(k\omega_0 + \omega - j\sigma)] \frac{\partial \bar{Y}}{\partial \bar{X}} \Big|_s \right\} \times \Delta \bar{X} = 0 \tag{30}$$

where $\partial \bar{Y} / \partial \bar{X} \Big|_s$ is the Jacobian of the nonlinear elements, with respect to the state variables, evaluated at the steady-state solution. In order for the variable increment $\Delta \bar{X}$ to be different from zero, the associated determinant must be singular:

$$\det[JH(\sigma + j\omega)] = 0 \tag{31}$$

For stability, all the determinant roots must be located on the left-hand side of the complex plane. This means that the perturbation will vanish exponentially in time (due to the negative sign of σ), in agreement with the definition of stability. Because of the (usually) very high order of the HB system, the direct calculation of these roots is a nearly impossible task. Instead, the Nyquist stability criterion is applied to (31). The Nyquist plot is obtained by performing a sweep in ω and tracing $\text{Im}[\det(j\omega)]$ versus $\text{Re}[\det(j\omega)]$. The number of unstable poles of the linearized system (30) agrees with the number of encirclements of the Nyquist plot about the origin of the complex plane. Examples of the application of this technique can be found elsewhere in the literature [3,17,19].

NONLINEAR CIRCUIT DESIGN

ALMUDENA SUÁREZ
University of Cantabria
Santander
Cantabria, Spain

1. INTRODUCTION

Circuits based on semiconductor devices are intrinsically nonlinear. The superposition principle does not hold, and the response depends on the values of the input signals. The linear assumption is valid for small excitation levels; however, as the input power increases, nonlinear effects, such as the gain saturation, or the generation of harmonic components, are observed [1–4]. These effects are undesired in circuits such as power amplifiers. However, essential functions in communication systems, such as frequency generation and frequency conversion, can be achieved only by means of circuits operating in nonlinear regime. Four examples of nonlinear circuits are frequency mixers [1–3,5], used for frequency conversion; oscillators [3,4,6]; frequency dividers [7,8]; and frequency multipliers [9,10]. Essential differences exist between their operation principles and characteristics, so specific design techniques should be used for each of them.

The design of circuits operating in the nonlinear regime is demanding. In case of forced circuits, the input generator level must be carefully chosen. Because of the

intrinsic generation of harmonic components, the harmonic loads will also have an influence on the circuit behavior. In case of autonomous circuits, the introduction of feedback networks is usually required and the stability considerations will be essential. In the past, analytical techniques such as describing function [3,11] or Volterra series [1,12] were used for an approximate analysis of the nonlinear circuits. Nowadays, iterative methods, such as harmonic balance [13,14] or envelope transient [15] (see also article titled NONLINEAR CIRCUIT ANALYSIS this encyclopedia), have taken the lead for accurate nonlinear analysis. However, they may be impractical and provide little intuition for circuit design, which should be complemented with systematic synthesis procedures. In contrast, analytical techniques enable a comprehensive design, with a clear identification of the most influential circuit elements and an approximate prediction of their effects on the circuit response. As an example, Volterra series [1,10] has allowed an analytical determination of the influence of the transistor nonlinearities on the intermodulation distortion. The method has been applied to the analysis of power amplifiers and, more recently, analysis of frequency mixers [1,5]. In turn, the describing function [3,11] can be used for an approximate oscillator design, at a specified oscillation frequency and output power, to be corrected at a later stage through harmonic balance simulations.

In this contribution, nonlinear synthesis techniques for frequency mixers, oscillators, frequency dividers, and frequency multipliers will be provided. The objective is not to present an exhaustive review of the possible circuit configurations; instead, the principles and implementation of modern design techniques will be emphasized. They will be illustrated by means of their application to simple, although practical, microwave circuits. Volterra series and describing function will be introduced, together with computer-aided tools, based on harmonic balance (HB). The use of auxiliary generators for oscillator optimization [16] or multiharmonic load pull [10,17,18] for oscillator and multiplier design will also be presented. Each section will start with some background about the particular nonlinear circuit. Then, the detailed design procedures will be presented.

2. FREQUENCY MIXERS

2.1. General Concepts about Frequency Mixers

An ideal frequency mixer is a signal multiplier. This instantaneous multiplication is used for the frequency downconversion or upconversion of a modulated signal. In the case of a frequency downconverter, the mixer will perform the frequency translation of a RF signal about the frequency ω_{RF} to a lower frequency, known as the *intermediate frequency* ω_{IF} . The RF signal is written, in terms of its lowpass equivalent $v_{\text{lp}}(t)$ [19] in the form $v_{\text{RF}}(t) = 2 \operatorname{Re}[v_{\text{lp}}(t)e^{j\omega_{\text{RF}}t}]$, where $v_{\text{lp}}(t)$ depends on the particular type of modulation. For downconversion to ω_{IF} , the RF signal must be multiplied by the one delivered by a local oscillator at the frequency ω_{LO} . For simplicity, only the case $\omega_{\text{RF}} > \omega_{\text{LO}}$ will be considered here, so $\omega_{\text{LO}} = \omega_{\text{RF}} - \omega_{\text{IF}}$. The local-oscillator signal constitutes the second input of the mixer circuit. Then, the ideal mixer

operation can be defined by the following expression:

$$\begin{aligned} v_{\text{IF}}(t) &= [2v_{\text{lp}}^{\text{r}}(t) \cos(\omega_{\text{RF}}t) \\ &\quad - 2v_{\text{lp}}^{\text{i}}(t) \sin(\omega_{\text{RF}}t)]V_{\text{LO}} \cos(\omega_{\text{LO}}t) \\ &= \operatorname{Re}[v_{\text{lp}}(t)V_{\text{LO}}e^{j(\omega_{\text{RF}}-\omega_{\text{LO}})t}] \\ &\quad + \operatorname{Re}[v_{\text{lp}}(t)V_{\text{LO}}e^{j(\omega_{\text{RF}}+\omega_{\text{LO}})t}] \end{aligned} \quad (1)$$

where the superscripts “r” and “i” respectively indicate the real and imaginary parts. Thus, the ideal mixer gives rise to two frequency terms at the difference and sum frequencies $\omega_{\text{IF}} = \omega_{\text{RF}} - \omega_{\text{LO}}$ and $\omega_{\text{RF}} + \omega_{\text{LO}}$. The sum frequency is generally far from the desired intermediate frequency ω_{IF} , so it is easily eliminated through filtering.

The ideal multiplier does not exist in practice, but it can be replaced with a properly selected nonlinear element, at a suitable operation point. Actually, using a Taylor series development about the operation point v_0 , a nonlinear voltage-controlled current characteristic $i(v)$ can be approximated by means of a power series $i(v) = i(v_0) + g_1v + g_2v^2 + \dots + g_Nv^N$. Introducing the signal $v(t) = V_{\text{RF}} \cos(\omega_{\text{RF}}t) + V_{\text{LO}} \cos(\omega_{\text{LO}}t)$ in this expansion, the terms $\omega_{\text{RF}} + \omega_{\text{LO}}$ and $\omega_{\text{RF}} - \omega_{\text{LO}}$ are obtained, together with undesired intermodulation products $m'\omega_{\text{LO}} + n\omega_{\text{RF}}$, with m' and n . The resulting frequency components form clusters about the different harmonic components ω_{LO} . It is generally more useful to express the intermodulation products in terms of ω_{LO} and ω_{IF} . When doing so, the indices have to be reorganized. Expressing $\omega_{\text{RF}} = \omega_{\text{LO}} + \omega_{\text{IF}}$, the new indexes will be $m\omega_{\text{LO}} + n\omega_{\text{IF}} = (m' + n)\omega_{\text{LO}} + n\omega_{\text{IF}}$.

It is easily shown that the use of $V_{\text{RF}} \ll V_{\text{LO}}$, where V_{RF} is the amplitude of the RF signal carrier, reduces the number of relevant intermodulation terms [1]. This is also the most usual case, since the RF input will generally correspond to a low-power received signal. The amplitude difference between the RF signal and the LO signal allows the use of the periodic oscillator solution (in the absence of RF input) as the quiescent point of the Taylor series expansion of the nonlinearity $i(v)$ [1,2]. Thus, the strongly nonlinear function is transformed into mildly nonlinear one, with periodic coefficients

$$\begin{aligned} i(v) &= i(v_{\text{LO}}(t)) + g_1(t)v_{\text{RF}}(t) \\ &\quad + g_2(t)v_{\text{RF}}(t)^2 + \dots + g_N(t)v_{\text{RF}}(t)^N \end{aligned} \quad (2)$$

with

$$g_k(t) = \frac{1}{k!} \frac{\partial^k i}{\partial v^k}(v_{\text{LO}}(t)), \quad k = 1, \dots, N$$

For moderate amplitude of the RF signal, the frequency conversion will be due to the linear term $g_1(t)v_{\text{RF}}(t)$, with $g_1(t)$ periodic at ω_{LO} , which gives rise to the two mixing terms $\omega_{\text{RF}} - \omega_{\text{LO}}$ and $\omega_{\text{RF}} + \omega_{\text{LO}}$.

2.2. Characteristics of Frequency Mixers

When carrying out a mixer design, the main characteristics to take into account will be the conversion loss or gain,

the spurious power level, the noise figure, and the intermodulation distortion. Each of these will be briefly introduced in the following paragraphs:

1. *Conversion Gain.* The mixer conversion gain is defined as the ratio $G_c = P_{IF}/P_{RF}$, where P_{IF} is the power delivered to the output load at the intermediate frequency and P_{RF} is the available RF power. This gain saturates from a certain RF power.

2. *Spurious Frequencies.* The spurious frequencies are the undesired intermodulation products of the form $m\omega_{LO} \pm n\omega_{IF}$, with $m \neq 0, n \neq 1$ [1]. One of spurious frequencies with highest amplitude is the *image frequency*. Assuming $\omega_{RF} > \omega_{LO}$, the image frequency will be $\omega_{IM} = \omega_{LO} - \omega_{IF}$. The term is derived from the fact that, in the spectrum, ω_{RF} and ω_{IM} are located on opposite sides of the local-oscillator signal, with equal frequency spacing ω_{IF} . The mixing of the image frequency with the local-oscillator frequency ω_{LO} gives rise to the same frequency ω_{IF} , which can have negative effects on the circuit behavior.

3. *Noise Figure.* The single-sideband noise figure of the frequency mixer [3,20,21] is the quotient of the input signal-to-noise ratio at the RF frequency, and the output signal-to-noise ratio at the IF frequency: $F_{mix} = (SNR)_{RF}/(SNR)_{IF}$. The input signal-to-noise ratio is calculated with the standard noise power kT_0B , where k is Boltzmann’s constant, T_0 the standard noise temperature, and B the noise bandwidth. The output noise at the IF will have contributions due to the conversion to this frequency of the input noise in all the harmonic terms $m\omega_{LO} + n\omega_{IF}$, especially at the image frequency ω_{IM} . It will also have contributions from the transistor noise sources and the circuit resistive elements [3]. The different contributions to the F_{mix} are easily distinguished in the following expression [20]:

$$F_{mix} = 10 \log \frac{E_n^2/R + KT_0(G_1 + G_2 + \dots + G_p)}{KT_0G_1} \quad (3)$$

where $G_1 \dots G_p$ indicate the conversion gain of the different intermodulation products, R is the output resistance, and

E_n^2 is the spectral density of the equivalent noise voltage at the output port, when no contributions from the input and output terminations are considered. For an accurate calculation of F_{mix} , the noise input due to the local oscillator should also be taken into account. Its effect on the IF noise power is included in the term $E_n^2(f)$.

4. *Intermodulation Distortion.* The intermodulation distortion is generally analyzed by considering two input RF carriers close in value ω_{RF1} and $\omega_{RF2} = \omega_{RF1} + \Delta\omega$ [1,2]. Then, assuming a signal of the form $v_{RF}(t) = V_{RF1} \cos(\omega_{RF1}t) + V_{RF2} \cos(\omega_{RF2}t)$, the higher-order terms $g_2(t)v_{RF}^2(t), g_3(t)v_{RF}^3(t), \dots$ in (2) will give rise to the intermodulation tones $m\omega_{LO} + p\omega_{IF1} + q\omega_{IF2}$. At the IF output, the frequencies will be $p\omega_{IF1} + q\omega_{IF2}$. The so-called intermodulation order IO is defined as the sum of the absolute values of the integer coefficients $IO = |p| + |q|$. Because of the proximity between the values of ω_{RF1} and ω_{RF2} , the frequencies ω_{IF1} and ω_{IF2} will also be close in value. Thus, the most dangerous intermodulation products will be third-order terms $2\omega_{IF1} - \omega_{IF2} = \omega_{IF1} - \Delta\omega$ and $2\omega_{IF2} - \omega_{IF1} = \omega_{IF2} + \Delta\omega$, since these will be the closest to the desired downconverted frequencies ω_{IF1} and ω_{IF2} .

For a better understanding of the intermodulation distortion, Fig. 1 shows a typical output power spectrum of a mixer circuit, in which two close input carriers, at the frequencies $f_{RF1} = 3.5 \text{ GHz} - 500 \text{ kHz}$ and $f_{RF2} = 3.5 \text{ GHz} + 500 \text{ kHz}$, have been introduced. The local oscillator frequency is $f_{LO} = 3 \text{ GHz}$, so the IF frequencies should be $f_{IF1} = 0.5 \text{ GHz} - 500 \text{ kHz}$ and $f_{IF2} = 0.5 \text{ GHz} + 500 \text{ kHz}$. As expected, the highest-amplitude tones are those corresponding to ω_{IF1} and ω_{IF2} . On each side of these tones, there are intermodulation terms of increasing odd order n , given by $\omega_{IF1} - k\Delta\omega$ and $\omega_{IF2} + k\Delta\omega$, with $k = (n - 1)/2$.

2.3. Realization of Frequency Mixers

Frequency mixers have traditionally been based on Schottky diodes [2,3]. Those devices do not have the charge accumulation limitations of bipolar devices, such as the PN diode, and the mixing function relies on the junction current $i(v) = I_s(e^{v/V} - 1)$. Then, the terms in (2)

Figure 1. Typical mixer spectrum at the IF output.

are obtained by differentiating this function about the oscillator solution $V_{LO}(t)$. When using diodes as mixing elements, the amplitude of the downconverted signal is always smaller than that of the input RF signal, due to the diode passivity. The typical conversion loss is about 5 dB [3]. Balanced structures, based on hybrid couplers, are used for the isolation of the RF, LO, and IF signals. They also enable cancellation of the AM noise from the local oscillator and some undesired frequency terms, which are eliminated without filtering [3]. The singly balanced mixers are based on the use of two diodes connected to a 90° or 180° hybrid coupler. The doubly balanced mixers are based on the use of four diodes.

The transistors are active devices, so, under certain operation conditions, they can provide conversion gain. They also enable inherent input-output isolation. Both MESFET and bipolar transistors can be used for frequency mixing. The MESFET transistors are very common owing to the significant development of MMIC technology on GaAs substrate. Balanced structures, using two or four transistors, are also possible, to isolate the RF, LO, and IF signals and enable the cancellation of undesired frequency

terms. Different types of active FET mixer are possible [1,2], according to the port through which the LO and RF signals are injected.

In the *gate mixer*, the LO and RF signals are injected at the gate port. The IF signal is extracted through filtering from the drain port (see Fig. 2a). It is the most popular kind of FET mixer. Assuming that the amplitude of the RF input signal is small compared to the RF signal, the mixing will be mainly due to the product $g_m(v_{LO}(t))v_{RF}(t)$, where g_m is the transistor transconductance, evaluated with the local-oscillator signal as the only excitation. In turn, $v_{RF}(t)$ is the incremental voltage due to the input RF signal.

In the *resistive mixer*, the FET is biased in the triode region [2,5]. The mixing is due to the periodic variation of the channel conductance $g_{ds}(t)$ with the local-oscillator pumping (see Fig. 2b). Thus, the LO signal is introduced at the gate terminal, while the RF signal is introduced at the drain terminal. The mixing is due to the product $g_{ds}(t)v_D(t)$. The IF signal is extracted from the drain terminal. The main advantage of the resistive mixers is the low intermodulation level, due to the good linearity of the

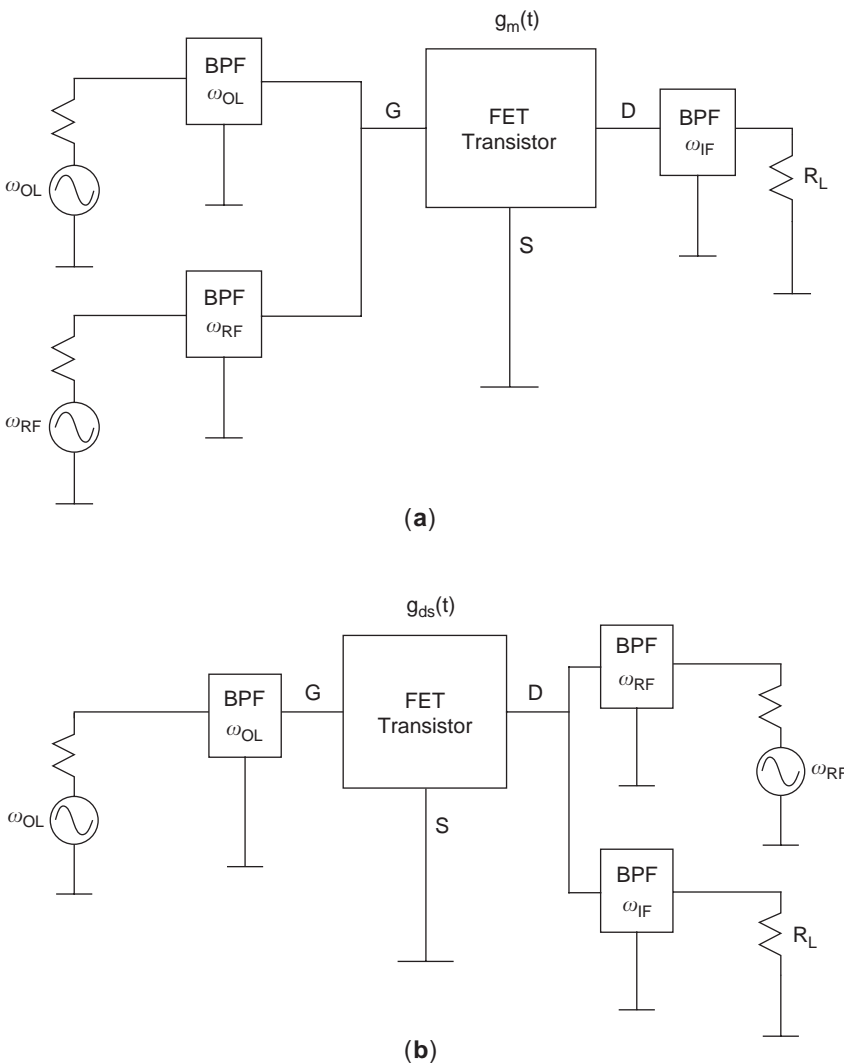

Figure 2. Two usual FET-based mixer configurations: (a) gate active mixer; (b) passive mixer.

channel resistance. The resistive mixers can also be realized in balanced topologies, with the same advantages as in the case of diodes.

2.4. Analysis of Frequency Mixers

Different techniques can be applied for the analysis and design of frequency mixers. The time-varying Volterra series, discussed in Section 2.5, enables an analytical evaluation of the influence of magnitudes such as the transistor bias voltages or the local-oscillator amplitude on the conversion gain and the intermodulation distortion. Thus, it is very helpful for an optimum selection of the operation conditions. However, its accuracy is limited to small amplitude of the input RF signal. For higher RF amplitude, iterative nonlinear analysis methods should be applied. Two-tone HB enables the accurate determination of the mixer conversion gain and spurious content [1] (see also NONLINEAR CIRCUIT ANALYSIS article). The envelope transient method enables an accurate analysis of the intermodulation distortion [1,22]. Next, the foundations of these two iterative methods are briefly summarized in order to provide an intuitive idea about their basic principles and to give the reader feeling for their circuit simulation capabilities.

2.4.1. Harmonic Balance. The HB method [15] uses frequency-domain representations for the linear elements and time-domain descriptions for the nonlinear devices. The circuit state variables are expressed in a Fourier series, with typically one or two fundamental frequencies. In the case of a frequency mixer, the two fundamentals will be ω_{LO} and ω_{IF} . The variables are written $v(t) = \sum_{m,n} V_{mn} e^{j(m\omega_{LO} + n\omega_{IF})t}$. Assuming a diamond truncation of this Fourier series [1] (again, see also NONLINEAR CIRCUIT ANALYSIS article), all the intermodulation products up to a certain nonlinearity order $nl = \max(|m| + |n|)$, by the user, will be considered. The direct and inverse Fourier transforms translate the circuit variables from one to another domain, which enables the frequency-domain expression of an error equation system $\bar{E}(\bar{V}) = 0$, where \bar{V} is the vector containing the harmonic components of the state variables. This technique enables an accurate prediction of the solution spectrum, with as many spurious terms as allowed by the nonlinearity order.

When the mixer circuit is analyzed through HB, the noise figure $F_{mix} = (SNR)_{RF} / (SNR)_{IF}$ can be determined using the conversion matrix approach [23]. Linear behavior with respect to the RF signal is assumed. When the noise perturbations are introduced, the HB equations are linearized about the nonlinear solution, at ω_{LO} , in the absence of RF input. The nonlinear current $\bar{I}(\bar{V})$ and charges $\bar{Q}(\bar{V})$ are replaced by their conversion matrixes, $[\partial \bar{I} / \partial \bar{V}]_0$, $[\partial \bar{Q} / \partial \bar{V}]_0$, evaluated at the solution at ω_{LO} [24]. These conversion matrixes are determined from the Fourier transforms of $g(t) = \partial i(t) / \partial v(t)$ and $c(t) = \partial q(t) / \partial v(t)$ [1]. The resulting perturbed system can be written

$$[Y(m\omega_{LO} + \omega_{IF})]_0 \Delta \bar{V}(m\omega_{LO} + \omega_{IF}) = \bar{I}_n(m\omega_{LO} + \omega_{IF}) \quad (4)$$

where the matrix $[Y]$ is easily calculated from the transistor conversion matrixes and the linear networks, evaluated at the sideband frequencies $m\omega_{LO} + \omega_{IF}$. The vector \bar{I}_n contains the equivalent noise current sources, obtained from their spectral power descriptions, in a normalized noise band of 1 Hz.

The perturbed state variables $\Delta \bar{V}$ are determined from the matrix inversion $[Y]_0^{-1}$. To obtain the power spectral density at the different harmonic terms, the noise correlation matrix $\bar{I}_n \bar{I}_n^*$, where the asterisk denotes *adjoint*, must be considered. The transistor intrinsic noise sources are correlated [21], which must be taken into account in the calculation of $\langle |\Delta V_{IF}|^2 \rangle$. The noise figure is determined from $F_{mix} = N_{IF} / (N_0 G_T)$, where N_{IF} is the noise output power. An example of application of this technique will be shown in Section 2.6.

2.4.2. Envelope Transient. The analysis of intermodulation distortion requires the consideration of two close input carriers ω_{RF1} and ω_{RF2} . The use of three-tone HB for this analysis is computationally expensive. The relatively recently introduced envelope transient method can be applied instead [15] (see also NONLINEAR CIRCUIT ANALYSIS article). This method relies on the use of two different time scales, one for the carrier frequencies and the other for the modulation signals. For the analysis of intermodulation distortion [22], the spacing between the two RF frequencies $\omega_m = \omega_{RF2} - \omega_{RF1}$ is taken as the modulation frequency of a unique carrier $\omega_{RF0} = (\omega_{RF1} + \omega_{RF2})/2$. The circuit variables are expressed in a Fourier series, with ω_{LO} and $\omega_{IF0} = \omega_{RF0} - \omega_{LO}$ as fundamentals, and slowly varying harmonic components, at the modulation rate, $v(t) = \sum_{m,n} V_{mn}(t) e^{j(m\omega_{LO} + n\omega_{IF0})t}$. When introducing this expression for the circuit variables in the HB equations, a differential equation system is obtained in the slowly varying components $\bar{V}(t)$. This system is efficiently integrated in much larger timestep than the one that would be required for a standard time-domain analysis.

As already stated, the dynamic Volterra series allows a comprehensive and optimized design and is less time-consuming than multitone HB and the envelope transient method. Because of its practical interest, the dynamic Volterra series will be presented in the next section. On the other hand, both harmonic balance and the envelope transient method are discussed in detail in the NONLINEAR CIRCUIT ANALYSIS article.

2.5. Volterra Series Analysis

The output of a linear, time-invariant system is related to its input through the impulse response $h(t)$, which characterizes the particular linear system [20]. For an input signal $i_g(t)$, the system output (circuit solution) is written $v_0(t) = \int_{-\infty}^{\infty} h(\tau) i_g(t - \tau) d\tau$. This kind of representation can be generalized to weakly nonlinear time-invariant systems. However, the superposition principle does not hold in nonlinear systems, and the overall effect of impulses applied at different time values must be taken into account [12]. The system output is expressed as

$v_0(t) = \sum_{n=1}^{\infty} v_{\text{on}}(t)$, where $v_{\text{on}}(t)$ is the n th-order solution:

$$v_{\text{on}}(t) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_n(\tau_1, \dots, \tau_n) i_g(t - \tau_1) \dots i_g(t - \tau_n) d\tau_1 \dots d\tau_n \quad (5)$$

The expression $v_0(t) = \sum_{n=1}^{\infty} v_{\text{on}}(t)$ constitutes the Volterra series representation of the solution, and the different functions $h_n(t_1, \dots, t_n)$ are the Volterra kernels [12]. The Volterra analysis is usually more convenient in terms of the transfer functions $H_n(\omega_1, \dots, \omega_n)$, associated with the different kernels $h_n(t_1, \dots, t_n)$. When these functions are used, the solution output, for an arbitrary input $i_g(t) = \sum_{p=-P}^P I_g^p e^{j\omega_p t}$, is given by

$$\begin{aligned} v_0(t) &= \sum_{n=1}^N v_{\text{on}}(t) \\ &= \sum_{n=1}^N \sum_{p_1=-P}^P \dots \sum_{p_n=-P}^P H_n(\omega_{p_1}, \dots, \omega_{p_n}) \\ &\quad I_g^{p_1} \dots I_g^{p_n} e^{j(\omega_{p_1} + \dots + \omega_{p_n})t} \end{aligned} \quad (6)$$

The Volterra series analysis can also be extended to time-varying weakly nonlinear systems. As evidenced by (2), this is the case of the mixer circuits, since their RF input signal usually has an amplitude much smaller than that of the local oscillator. The time-varying Volterra series is expressed as

$$\begin{aligned} v_{\text{on}}(t) &= \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_n(t, \tau_1, \dots, \tau_n) \\ &\quad \times i_g(t - \tau_1) \dots i_g(t - \tau_n) d\tau_1 \dots d\tau_n \end{aligned} \quad (7)$$

where the Volterra kernels have an extra time dependence on the variable t . The local oscillator solution is taken as the quiescent point and the kernels are periodic in t , with the same period as this local oscillator.

In the calculation of intermodulation distortion, two close RF signals, at ω_{RF1} and ω_{RF2} , are considered. As shown in (2), Taylor series developments, with the local-oscillator solution as the quiescent point, are used for the description of the nonlinear elements. The product of the nonlinearities by the RF inputs will generate current components at $m\omega_{\text{LO}} + p\omega_{\text{IF1}} + q\omega_{\text{IF2}}$, which are transformed to voltages at the circuit linear elements. Then, the independent voltages of the mixer solution can be expressed as [1]

$$\begin{aligned} v_0(t) &= \sum_{n=1}^N v_{\text{on}}(t) \\ &= \sum_{n=1}^N \sum_{p_1=-P}^P \dots \sum_{p_n=-P}^P H_n(t, \omega_{p_1}, \dots, \omega_{p_n}) \\ &\quad \times I_g^{p_1} \dots I_g^{p_n} e^{j(\omega_{p_1} + \dots + \omega_{p_n})t} \end{aligned} \quad (8)$$

where the transfer functions, associated with the different Volterra kernels, have been introduced. The input $i_g(t)$ represents an IF signal, with the general form $i_g(t) = \sum_{p=-P}^P I_g^p e^{j\omega_p t}$, where ω_p takes the values $-\omega_{\text{IF1}}$, $-\omega_{\text{IF2}}$, ω_{IF1} , ω_{IF2} . Because of their periodicity, it is possible to expand the transfer functions $H_n(t, \omega_{p_1}, \dots, \omega_{p_n})$ in a Fourier series at $m\omega_{\text{LO}}$ with m integer and varying between $-M$ and M . Then, the n th-order solution can be written [1] as follows:

$$\begin{aligned} v_{\text{on}}(t) &= \sum_{m=-M}^M \sum_{p_1=-P}^P \dots \sum_{p_n=-P}^P V_{mp_1 \dots p_n}^n \\ &\quad \times e^{j(m\omega_{\text{LO}} + \omega_{p_1} + \dots + \omega_{p_n})t} \end{aligned} \quad (9)$$

It should be noted that the frequencies ω_{p_1} to ω_{p_N} are not harmonically related to $m\omega_{\text{LO}}$. Each ω_{p_i} , with $i = 1 \dots N$, will take the values $-\omega_{\text{IF1}}$, $-\omega_{\text{IF2}}$, ω_{IF1} , ω_{IF2} .

In the harmonic input method, signals $I_g(t)$ of the form $e^{j\omega_{p_1} t}$, $e^{j\omega_{p_2} t}$, \dots , $e^{j\omega_{p_N} t} + \dots + e^{j\omega_{p_N} t}$ are introduced, in order to recursively determine the terms $V_{\text{on}}(t)$, from which the Volterra kernels are calculated. The calculation of $v_{01}(t)$ (sketched in Fig. 3a) requires the previous determination of the conversion matrixes of the different nonlinear elements. As is well known, this conversion matrix is obtained from the Fourier series expansion at $m\omega_{\text{LO}}$ of the derivatives $g(t) = \partial i / \partial v(v_{\text{LO}}(t))$ and $c(t) = \partial q / \partial v(v_{\text{LO}}(t))$, in case of capacitive nonlinearities. In Fig. 3a, a single nonlinear resistive-type element has been considered, with the first-order conversion matrix $[G_1]$. The direct application of Kirchhoff's laws provides a linear system in the frequency domain, from which the harmonic components of $v_{01}(t)$ are easily determined.

In order to determine the second term of the series $v_{02}(t)$, an input, of the form $e^{j\omega_{p_1} t} + e^{j\omega_{p_2} t}$, will be considered (see Fig. 3b). This calculation requires second-order derivatives of the nonlinear elements, of the form $g_2(t) = \partial^2 i / \partial v^2(v_{\text{LO}}(t))$. In time domain, this derivative should be multiplied by $v_{01}^2(t)$. This can easily be done, since the term $v_{01}(t)$ is already known from the preceding step. The resulting current $i_2(t) = g_2(t)v_{01}^2(t)$ will be considered as an external source (see Fig. 3b), and the second-order term $v_{02}(t)$ will be the new unknown. The system is linear in this term, which ensures a straightforward resolution.

The frequency-domain expression of $v_{02}(t)$ will contain the components $m\omega_{\text{LO}} + \omega_{p_1} + \omega_{p_2}$, with both ω_{p_1} and ω_{p_2} taking the values $-\omega_{\text{IF1}}$, $-\omega_{\text{IF2}}$, ω_{IF1} , ω_{IF2} . For the frequency-domain analysis of the circuit, a generalized conversion matrix of second order, obtained from the Fourier series expansion of $g_2(t) = \partial^2 i / \partial v^2(v_{\text{LO}}(t))$, must be used. Applying Kirchhoff's laws, a linear system is obtained in the harmonic components of $v_{02}(t)$.

The analysis above can be generalized up to the N^{th} order, with an input signal $e^{j\omega_{p_1} t} + e^{j\omega_{p_2} t} + \dots + e^{j\omega_{p_N} t}$ and requiring the Fourier series expansion of $g_N(t)$, to obtain the corresponding conversion matrix. As already stated, the most dangerous intermodulation terms are $2\omega_{\text{IF1}} - \omega_{\text{IF2}}$ and $2\omega_{\text{IF2}} - \omega_{\text{IF1}}$, so the Volterra series must be calculated up to a minimum order $N = 3$. The order should be higher for higher amplitude of the RF input signal.

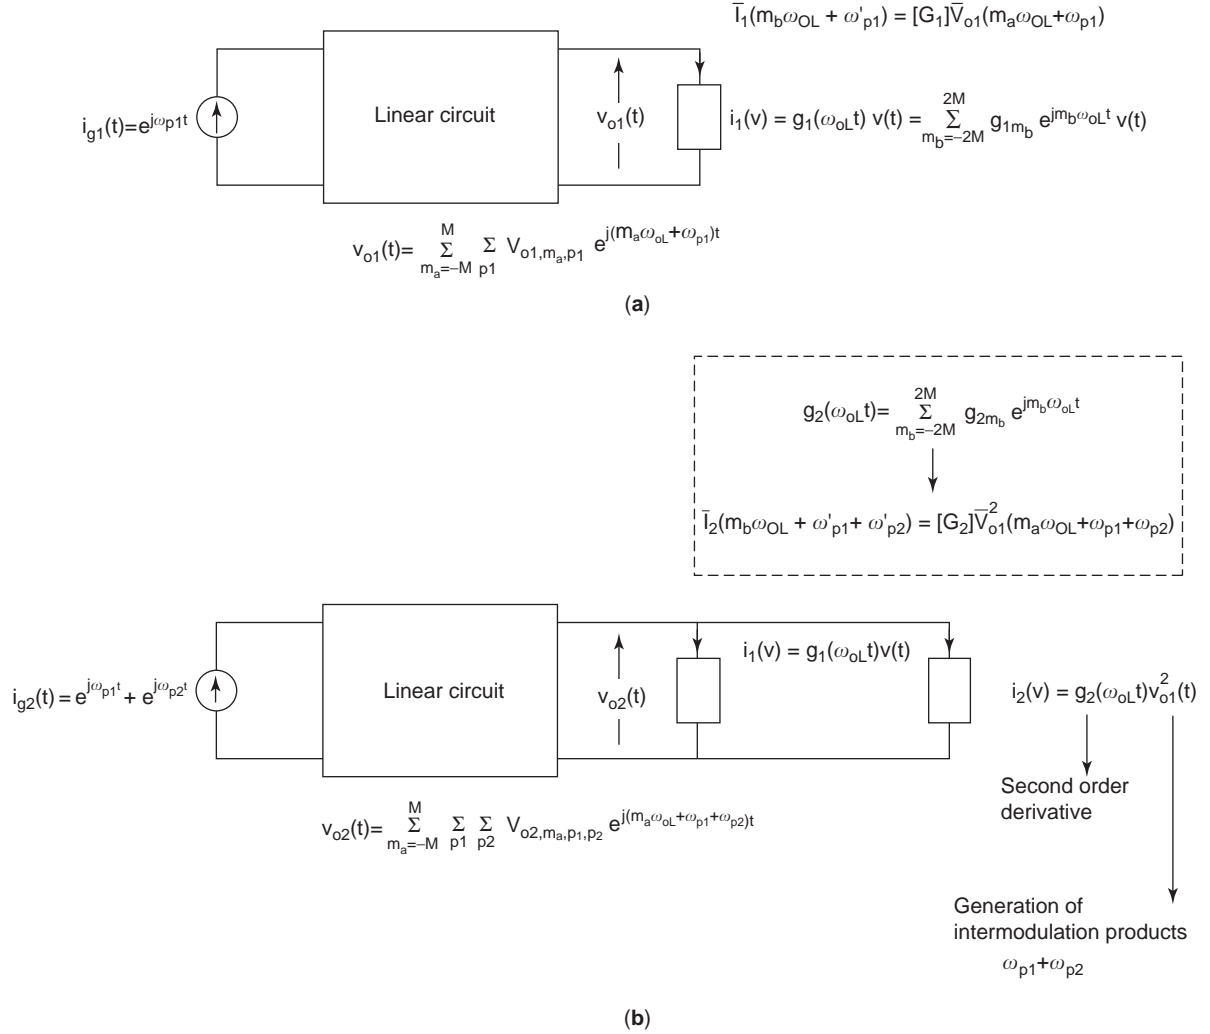

Figure 3. Calculation of the dynamic Volterra series up to second order.

The Volterra series enables the analytical evaluation of the influence of the bias point or the local-oscillator amplitude on the intermodulation distortion. Because of the complexity of this symbolic calculation, some circuit simplifications are necessary. For a given type of mixer, only the essential nonlinearities will be taken into account and most of the transistor parasitics will be ignored. The linear embedding of the mixer circuit is also simplified, assuming, for instance, that the input matching networks provide short circuits at all frequencies different from ω_{RF} and ω_{IM} , and that the output circuit provides short circuits at all frequencies different from ω_{IF} . This symbolic analysis has been carried out by other authors on both active and resistive mixers [1,5]. In the following example, the main results from this analysis are used for the design of a gate frequency mixer.

2.6. Gate Mixer Design

In the gate mixer, the LO and RF signals are injected at the gate port, while the IF signal is extracted through filtering from the drain port. The mixing will be due mainly to the periodic modulation of the transistor transconduc-

tance $g_m(t)$ by the LO signal. As already mentioned, a manageable analysis through time-varying Volterra series requires some circuit simplifications. Only the i_{DS} nonlinearity will be considered, assuming constant capacitances C_{gs} , C_{gd} , and C_{ds} . In the gate mixer, the transistor is usually biased in the saturation region, so, in most cases, the dependence of i_{DS} on the drain voltage may be ignored [1], which considerably reduces the complexity of the study. Regarding the linear embedding circuit, some additional assumptions are possible.

At the drain port, short circuits are imposed at both the RF and LO frequencies. At the gate port, a short circuit is considered at the IF frequency, which reduces the output noise. Under these assumptions, a simplified schematic is obtained in which the output power is directly proportional to the square of the I_{ds} current at the IF frequency. This can be determined from the first-order Volterra analysis [1]:

$$I_{ds}(\omega_{IF}) = G_{m1}V_{gs}(-\omega_{IM}) + G_{m,-1}V_{gs}(\omega_{RF}) + G_{dso}V_{ds}(\omega_{IF}) \quad (10)$$

The i_{DS} current has small dependence on the drain voltage, so the conversion gain will be optimized by maximizing of the harmonic term G_{m1} of the Fourier series expansion of $g_m(t) \equiv \partial i_{DS} / \partial v_{GS}(v_{LO}(t))$. The value of these terms will depend on the mixer bias point and the local-oscillator amplitude.

The second-order intermodulation terms $\omega_{IF2} - \omega_{IF1}$ and $\omega_{IF1} + \omega_{IF2}$, originating mainly from the second order derivative g_{m2} , will typically be far from the desired output frequencies ω_{IF1} , ω_{IF2} . In turn, the third-order intermodulation distortion, coming mainly from the third-order derivative g_{m3} , gives rise to the dangerous frequencies $2\omega_{IF1} - \omega_{IF2}$ and $2\omega_{IF2} - \omega_{IF1}$. The drain current at these intermodulation frequencies is obtained from a third-order Volterra series analysis of the circuit. It is approximately given by [1]:

$$I_{ds3}(2\omega_{IF1} - \omega_{IF2}) = G_{m3,-1} V_{gs1}^3 (2\omega_{RF1} - \omega_{RF2}) \quad (11)$$

Thus, in order to reduce the third-order intermodulation distortion, the first-harmonic component of the Fourier series expansion of $g_{m3}(t) \equiv \partial^3 i_{DS} / \partial v_{GS}^3(v_{LO}(t))$ must be minimized.

The results presented above have been applied to the design of a gate mixer, using the FET transistor CFY30. For the input network, a simple circuit topology has been chosen (see Fig. 4), with a power combiner, enabling the introduction of the RF and local-oscillator signals. The input frequencies considered here are $f_{RF} = 3.5$ GHz and $f_{OL} = 3$ GHz, with $f_{IF} = 0.5$ GHz. At the drain terminal, an open-circuited quarter-wave $\lambda/4$ line, at the local-oscillator frequency, is introduced, in order to suppress this frequency component from the mixer output. In addition, this $\lambda/4$ line reduces the variation of the drain-to-source voltage $v_{DS}(t)$ and thus ensures the mixer operation in the saturation region for all time values [1,3].

To take advantage of the analytical results (10) and (11), an accurate transistor model, enabling a reliable calculation of the nonlinear element derivatives up to third order, will be necessary. The Angelov model [24] has been used here, which is continuously differentiable. Using this model, the derivatives $g_1(t), g_2(t), g_3(t)$ are analytically calculated. The periodic quiescent point and its evolution versus each parameter of interest (e.g., V_{GS} or P_{LO}) are

initially determined through HB simulations. The waveforms $v_{gs}(t), v_{ds}(t)$, corresponding to each parameter value, are obtained through the inverse Fourier transform. This double set of waveforms (vs. the parameter) is introduced in the derivatives of the Angelov model. Different harmonic components of the Fourier transforms of these derivatives provide the factors in (10) and (11).

Initially, the influence of the gate bias voltage V_{GS} is considered, while setting the drain voltage to the constant value $V_{DS} = 2.5$ V and the local-oscillator power to the moderate value $P_{LO} = 0.8$ dBm. Figure 5 shows the variation of the amplitude of G_{m1} [first-harmonic component of $g_m(t)$] with this bias voltage. As can be seen, a maximum is obtained for $V_{GS} = -1$ V. Thus, maximum conversion gain should be expected for this gate bias. To verify this, a two-tone HB simulation has been carried out, obtaining the conversion gain from the direct calculation $G_c = P_{IF}/P_{RF}$. For this analysis, the RF power $P_{RF} = -18$ dBm has been considered, below the 1-dB gain compression, which occurs for $P_{RF} = 1.5$ dBm. The resulting G_c variation is also shown in Fig. 5, with good agreement with the Volterra series analysis, in terms of G_{m1} . After selection of the gate bias, input matching is carried out, by means of the transmission line and stub, represented in Fig. 4. This will increase the conversion gain.

In the case of FET devices, two different kinds of noise contributions can be considered: the intrinsic noise, modeled with two current sources i_g and i_d ; and the thermal noise, associated with parasitic resistive elements [21]. The i_g source is in parallel between the intrinsic gate and source terminals and has the mean-square value $\overline{i_g^2} = 4kTB\omega_{LO}^2 C_{gs}^2 S/g_m$. The i_d source is in parallel between the intrinsic drain and source terminals and has the mean-square value $\overline{i_d^2} = 4kTBg_m P$. The coefficients P and S depend on the drain current i_{ds} . Both g_m and C_{gs} are time-periodic at the local-oscillator period. For strong oscillator amplitude, P and S are also periodic. The two noise sources are thus cyclostationary. In the frequency domain, they give rise to harmonic terms $m\omega_{OL} + \omega_{IF}$. The two noise sources are frequency-correlated [22].

In Fig. 6, the conversion matrix approach has been applied for determination of the noise figure versus the LO power. As can be appreciated, it decreases with this power, because of the increase of conversion gain. In a detailed analysis, it was found that the largest noise contribution

Figure 4. Classical topology of a gate mixer.

Figure 5. Variation of the mixer conversion gain with the gate bias voltage V_{GS} ; comparison with $G_{m,1}$ obtained through Volterra series analysis.

was due to the conversion to IF of the input noise, through the different gains in (3). The second largest contribution was the transistor source i_d . Next were the transistor resistive elements.

Figure 7 shows the mixer output power spectrum for $P_{RF} = -18$ dBm and $P_{LO} = 0.8$ dBm. It has been obtained through two-tone HB, using a diamond truncation of the Fourier series, with nonlinearity order $nl = 7$. The different spurious-frequency terms can be appreciated.

As already stated, the intermodulation distortion is analyzed by considering two closely spaced input carriers. For the gate mixer studied here, the two carriers are centered about $f_{RF} = 3.5$ GHz, with a frequency spacing of

$\Delta f = 100$ kHz. At the circuit output, two tones should be obtained about the intermediate frequency $f_{IF} = 0.5$ GHz, with the same frequency spacing $\Delta f = 100$ kHz. The frequency-translated carriers will be designed f_{IF1} and f_{IF2} , with $f_{IF1} < f_{IF2}$. As already seen in previous sections, the circuit nonlinearity gives rise to intermodulation tones of the form $pf_{IF1} + qf_{IF2}$, with p, q integers.

For the envelope transient analysis of Fig. 8, a two-tone HB formulation was used at the two fundamentals $f_{RF} = 3.5$ GHz and $f_{LO} = 3$ GHz. The frequency spacing between the tones $\Delta f = 100$ kHz was taken as the modulation frequency. The spectrum of Fig. 8 is centered about $f = 0$, because it is actually calculated from the Fourier transform of the harmonic component $V_{IF}(t)$. Thus, the line $f = 0$ represents the intermediate frequency f_{IF} , in similar manner to the low-pass equivalents of bandpass systems.

As already seen, the intermodulation distortion is highly dependent on the circuit operation point. The third-order intermodulation distortion, giving the two closest tones to the downconverted frequencies ω_{IF1} and ω_{IF2} , is determined mainly by $G_{m3,1}$, specifically, the first-harmonic component of the third-order derivative $g_{m3} = \partial^3 i_{ds} / \partial v_{gs}^3$ [see (11)]. The evolution of this harmonic component versus V_{GS} is shown in Fig. 9. As can be seen, a maximum of the $G_{m3,1}$ amplitude is obtained for $V_{GS} = -0.8$ V, while a substantial reduction is achieved for $V_{GS} = -0.4$ V. The results of this analysis have been verified through a sequential application of the envelope transient method. The third-order intermodulation tone $\omega_{IM3,1}$ has been followed along the entire V_{GS} interval, to obtain the curve superimposed in Fig. 9. As can be seen, there is very good agreement between the maximum and minimum of $G_{m3,1}$ and those corresponding to the tone $\omega_{IM3,1}$. The advantage

Figure 6. Variation of the conversion gain and noise figure versus the local-oscillator power, for $V_{GS} = -1$ V.

Figure 7. Output power spectrum of the frequency mixer.

of the Volterra series analysis is the short simulation time, compared to the envelope transient sweep, which is computationally very expensive.

3. OSCILLATOR SYNTHESIS

3.1. General Concepts about Oscillator Circuits

The oscillator circuit provides a time-varying, generally periodic solution, from DC sources only. In contrast to forced circuits, the fundamental frequency of the solution depends on the values of the circuit elements, bias sources, and other parameters, since it is not delivered to the circuit by any external source [4]. For this reason, the oscillation frequency will be an unknown of the circuit

equations. In the synthesis procedure, the values of the circuit elements will have to be determined in order to obtain the desired oscillation frequency and power.

The oscillator circuit is often modeled as the connection of a linear network and a nonlinear network [3,11]. The nonlinear network contains the active-device, feedback, and terminal elements, while the output resistive load is included in the linear network. With respect to this output load, the rest of the circuit must behave as an energy source at the desired oscillation frequency. Thus, the nonlinear network must exhibit negative resistance at the oscillation frequency, which is determined by the circuit resonance. To achieve this, a negative-resistance diode or a transistor is used in the oscillator design.

Since no RF generators are present in the oscillator circuit, its equations can always be solved for a DC solution. In a well-behaved oscillator, this solution will be unstable, that is, *nonrobust* versus perturbations [4]. Under any small perturbation, an oscillation of growing amplitude will begin as a result of the circuit resonance and the energy excess. The equilibrium state is enabled by the decrease of the negative resistance in all physical devices when the current amplitude increases beyond a certain level. Actually, it is the nonlinearity of the negative-resistance element that allows the establishment of the steady-state oscillation.

As already stated, even when the circuit oscillates, it can always be solved for a DC solution, besides the desired periodic solution [4]. The stability considerations for these two solutions are essential. From a mathematical point of view, the DC solution of this oscillator circuit must be unstable, having a pair of complex poles $\sigma \pm j\omega$, with $\sigma > 0$ and ω , in the order of the desired oscillation frequency ω_0 [4]. In turn, the steady-state oscillation must be stable, or robust versus perturbations, to be physically observed. No generators exist at the oscillation frequency ω_0 , so, in order for this frequency to be self-sustained, a pair of complex conjugate

poles $\pm j\omega_0$ of the linearized system must be located on the imaginary axis. For stability, all the rest of the poles must be located on the left-hand side of the complex plane.

Another essential fact in oscillator circuits is that, since there is no external time reference for the self-oscillation (i.e., there exist no time varying generators in the circuit), the oscillating solution is invariant with respect to time translations. Any arbitrary timeshift to the oscillating solution obtained provides another solution of the oscillator equations [4]. There is a singularity in the system, corresponding to the existence of a pair of complex conjugate poles, located on the imaginary axis $\pm j\omega_0$. The invariance with respect to the time origin gives, in turn, an invariance of the phase reference. Thus, when a stable oscillator is perturbed, perturbations affecting the oscillator phase will remain in the steady-state solution [25].

The oscillator phase noise may be understood as the result of the phase shift accumulation, versus continuous perturbations, coming from the noise sources. The oscillator spectrum is not a delta at ω_0 [3], since the noise perturbations give rise to a power distribution about this frequency. When only phase noise is considered, the total power of the spectral distribution is the same as the one of the ideal line. The single-sideband phase noise spectral density at a certain frequency offset Ω is defined as the ratio between the sideband power at Ω , measured in 1 Hz bandwidth, and the carrier power.

3.2. Design Procedure

The oscillator circuits are most efficiently designed in the frequency domain, where impedance/admittance analysis can be easily applied for the evaluation of the oscillation startup and steady-state conditions. The distributed

elements of the linear networks are also more easily described in this domain. The oscillator design requires an initial choice of the active device. This device may be a negative-resistance diode or a transistor [3]. The three main types of negative-resistance diodes are tunnel, IMP-ATT (impact avalanche transit time), and Gunn diodes [26]. They allow higher oscillation frequencies than the transistor devices; however, at frequencies where the two types of devices are possible, the transistor-based oscillators are generally preferred. They usually enable lower phase noise values and have better stability properties. The diodes can also be difficult to match to the impedance values commonly used at microwave frequencies.

In the following, a systematic design procedure for oscillator circuits is presented. It will be illustrated by means of its application to the design of an oscillator, based on the MESFET CFY30, at the frequency $f_0 = 4.5$ GHz.
