In a quasioptical power combiner, an array of solid-state devices is distributed over a planar radiating structure and interacts directly with an electromagnetic beam. The spacing between devices scales with frequency: the higher the frequency, the closer the spacing, and therefore the more devices can be packed per unit area. As in the

Figure 2. Power-handling capacity of solid-state and vacuum devices [1]. The Gunn and impact-ionization-avalanche-transit-time (IMPATT) devices are solid-state diodes. The silicon bipolar, metal-semiconductor field-effect transistor (MESFET), and high-electron-mobility transistor (HEMT) devices are transistors.

Figure 3. Analogy between a (a) gas laser and (b) quasioptical power combiner [1].

laser, the total output power can be substantial, even though the power from an individual device is small.

Since the publication of Mink's paper, quasioptical applications have evolved beyond just power generation to more functional circuits such as amplifiers, mixers, phase shifters, switches, frequency multipliers, modulators, and beamsteerers. All of these quasioptical circuits share the following advantages:

- The array's unit cell primarily determines the driving-point impedances seen by the active devices, while the output power scales with the total number of devices incorporated. This allows a designer to optimize for gain through the unit cell and to select the array size independently to meet the system power requirement. In many arrays already demonstrated, 100 low-power devices have been spatially power-combined.
- Quasioptical circuits are compact, lightweight, and amenable to monolithic integration. The antenna is an integral part of the circuit design, which reduces the size of the circuit-antenna module since the feedlines are eliminated. The biasing scheme is also simple, since often all of the devices in the array are biased in parallel.
- The noise from each unit cell is usually uncorrelated, so the noise figure for the array will be no worse than the noise figure of a single device, leading to a high signal-to-noise ratio at the receiver.
- The total output power is a result of combining a large number of devices. Therefore, the reliability of quasioptical components is high; a fraction of the devices can fail before the component fails, resulting in graceful degradation of the component.

Millimeter-wave power can be generated quasioptically in three basic ways: by direct conversion of direct current (DC) power to radiofrequency (RF) power with an oscillator array; by amplifying a low-power source with an amplifier array; or by cascading a low-frequency source with a frequency-multiplier array. Each of these techniques will be discussed in the following sections.

2. OSCILLATORS

An oscillator is essentially a device that converts DC power to RF power. In quasioptical architectures, the RF power must also be radiated efficiently into free space. Quasioptical oscillators can be divided into two categories: grid oscillators and coupled-oscillator arrays.

2.1. Grid Oscillators

In the grid approach, solid-state devices are embedded in a metal grating supported by a dielectric substrate (Fig. 4). The horizontal lines of the grid serve as DC bias lines, and the vertical lines as antennas. The mirror, substrate, and grid dimensions are chosen to resonate the devices at the oscillation frequency. The devices are typically spaced a small fraction of a wavelength apart. An oscillation is

Figure 4. Schematic of a grid oscillator. The radiated power is combined in free space. (Courtesy of IEEE [10].)

triggered by any noise or transient on the DC bias. RF currents on the vertical leads cause an electromagnetic wave to be radiated away from the grid. Feedback from the mirror provides the injection-locking between devices, resulting in a single-frequency, self-locked oscillation.

Grid oscillators have been demonstrated at both microwave and millimeter-wave frequencies, up to 43 GHz [4–10]. Oscillators using up to 100 transistors have been developed, demonstrating the feasibility of large-scale power combining. Active grids can also be cascaded, as demonstrated in Ref. 11, where four transistor grids were placed in a cavity so that the final configuration resembled that of Fig. 3b. Other cascaded grids include a quasioptical voltage-controlled oscillator, which was composed of back-to-back transistor and tuning-diode arrays [12].

2.2. Coupled-Oscillator Arrays

In the grid approach, the oscillator can be interpreted as an active frequency-selective surface with the spacing between devices a small fraction of a wavelength apart. In contrast, in the coupled-oscillator array, each element is independent and contains a conventional planar antenna, and elements are not as closely spaced apart as they are in a grid. Mutual coupling between devices can be enforced using transmission-line interconnections, as shown in Fig. 5. A wide variety of coupled-oscillator arrays have been demonstrated in recent years [13–21], owing to the flexibility of this approach.

Electronic steering of the radiated beam, which is important for radar applications, can be accomplished by enforcing a prescribed phase shift between elements in the array. Typically this is done by associating a phase shifter with each oscillator element; the result is known as a phased array. Two types of steering techniques have been demonstrated in quasioptical oscillator arrays that do not require individual phase shifters for each antenna. In the first method, two coherent signals with a predetermined phase shift are injected into two opposite ends of the array [22]. The phase shift is divided equally along the chain. In the second method, the constant phase progression is established by detuning the frequencies of the end elements in the array [23]. When all of the oscillators are set to the same free-running frequency, the array is uniformly phased and a broadside beam results. When the frequencies of the end elements are slightly detuned from the

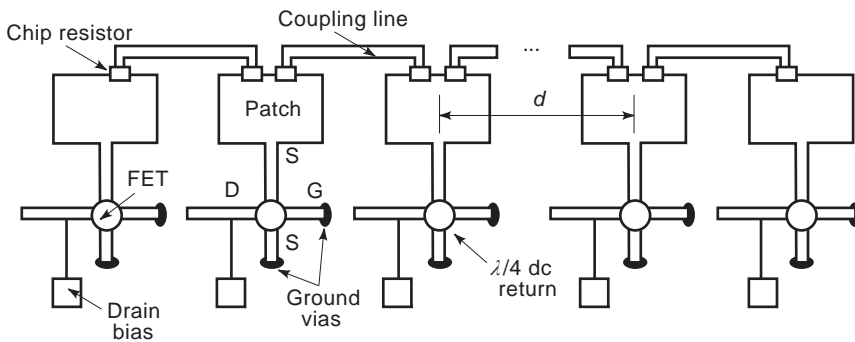

Figure 5. Coupled-oscillator array using patch antennas and field-effect transistors (FETs). (Courtesy of IEEE [24,53].)

others, a constant phase progression is established along the array. A scanning range from -15° to 30° from broad-side was reported for an X-band array [24].

3. AMPLIFIERS

Quasioptical amplifiers have been the object of considerable attention since their development in the early 1990s. Because of their immediate applicability to both military and industrial radar and communications systems, these amplifiers have been the focus of several coordinated academic, government, and industrial research efforts. Several possible amplifier configurations are illustrated in

Figure 6. (a) Free-space, (b) waveguide, and (c) lens-focused quasioptical amplifier configurations [25]. Successful amplifiers have been demonstrated using all three configurations [1].

Figure 7. Unit cell and gain of a 100-element pHEMT grid amplifier [28]. This grid produced 3.7 W of saturated output power. (Courtesy of IEEE.)

Fig. 6 [25]. The amplifier arrays consist of many unit cells, each cell containing input and output antennas connected by an amplifier. The arrays are excited by an input microwave or millimeter-wave beam. The amplified output is reradiated into free space. The input and output beams are usually orthogonally polarized to provide isolation and thus reduce mutual coupling. Wire-grid polarizers are often used to help confine the signal path to the forward direction. Several amplifier arrays may be cascaded to increase the gain.

Quasioptical amplifiers are often labeled as being either *grid amplifiers* or *active arrays*. Grid amplifiers have smaller unit cells, typically less than $\lambda_0/4$. A differential transistor pair usually provides the gain. The input and output antennas are short dipoles that are strongly coupled because of the close spacing. Grid amplifiers are usually modeled by defining an equivalent waveguide unit cell based on symmetry and then developing a transmission-line equivalent circuit. Active arrays, on the other hand, have larger unit cells, usually near $\lambda_0/2$. Because of the larger cells, multitransistor MMIC: monolithic microwave integrated circuit amplifiers can be employed. More conventional resonant slot or patch antennas are often used.

Figure 8. Photograph and gain of a 36-element pHEMT monolithic grid amplifier [30]. The unit cell size is 0.52mm. (Courtesy of IEEE.)

Modeling of active arrays is more straightforward because the larger cell reduces coupling between elements. At this point, both the grid amplifier and active-array approaches have been quite successful.

3.1. Grid Amplifiers

The first quasioptical amplifiers were grids developed in the early 1990s by Rutledge and coworkers at the California Institute of Technology [26,27]. A unit cell for a 100-element hybrid X-band array using pHEMT: pseudomorphic high-electron-mobility transistor transistors is shown in Fig. 7 [28]. A horizontally polarized input beam excites RF currents on the horizontal leads of the grid. These currents drive the gates of the transistor pair in the differential mode. The output currents are redirected along the vertical leads, producing a vertically polarized output beam. Thin meandering lines provide the transistor bias. These bias lines are intended to present a rather high impedance to the input wave. The peak gain is 12 dB at 9 GHz with a 15% 3 dB bandwidth. The minimum noise figure is 3 dB, which is less than 2 dB greater than the minimum noise figure available from a single HEMT. Finally, this 100-element grid provided 3.7 W of saturated output power.

Grid amplifiers are among the few successful monolithic millimeter-wave quasioptical amplifiers. A 36-element heterojunction bipolar transistor (HBT) grid produced 5 dB of gain at 40 GHz with a saturated output power of 670 mW [29]. Figure 8 shows a photograph of a 36-element pHEMT grid amplifier [30]. This amplifier could be tuned to operate at frequencies between 44 and 60 GHz by repositioning the external wire-grid polarizers. Continued efforts are underway to develop monolithic grids further.

3.2. Active Arrays

Active-array amplifiers have also been very successful. The approaches vary, but usually involve larger unit cells with more conventional antennas [31–39]. Amplifiers using back-to-back integrated horn antennas, patch

Figure 9. Unit cell and gain of a 16-element active array using folded slot antennas [1,32]. The folded slot antennas are designed to match to 50Ω.

Figure 10. A 24-element lens-amplifier array using patch antennas [33]. The input and output patch antennas are on opposite sides of the dielectric substrate, isolated by interleaving ground strips [1].

antennas, slot antennas, and probe antennas have been demonstrated. Figure 9 illustrates an approach pursued by York and coworkers at the University of California at Santa Barbara [32]. Orthogonally polarized folded slot antennas are used to provide $50\ \Omega$ input and output feeds. A commercial HBT MMIC amplifier is used as a gain stage. Coplanar waveguide transmission lines connect the amplifier to the antennas. A 16-element array produced about an 8 dB gain at 11 GHz with a 5% bandwidth.

Another very successful approach is the lens–amplifier configuration developed by Popović and others at the University of Colorado [33]. Figure 10 shows the idea. Patch antennas are used at the input and output. The two antennas are on opposite sides of a dielectric substrate, isolated by interleaving ground strips. Gain is provided by a single transistor, although multistage amplifiers may also be used. Microstrip lines connect the antennas to the amplifier. Through careful selection of the electrical lengths of these microstrip lines, the array can be designed to focus a plane wave to a spot much like a lens. This particular array demonstrated a peak gain of 8 dB at 9.8 GHz. Other lens amplifiers have also been developed with considerable success [34], including bi-directional amplifiers that can be used for both transmission and reception [35].

Figure 11 illustrates yet another very promising approach developed by York and others [38]. MMIC amplifiers are integrated with tapered slot antennas forming an amplifier “card.” Several cards are stacked into a conventional metal waveguide to form the active array. This approach has been very successful with an X-band array; a 2×4 array has achieved 10 dB of gain over the entire waveguide band from 8 to 12 GHz. Furthermore, the array generated 20 W of output power.

Monolithic active-array amplifiers have also shown success in the millimeter-wave band. An array of 112 pHEMT amplifiers achieved a gain of 9 dB at 39 GHz with an output power of 630 mW [39]. Researchers are continuing to develop active-array technology for millimeter-wave applications.

4. FREQUENCY CONVERSION AND BEAM CONTROL ARRAYS

Quasioptical technology shows great promise for many other applications in addition to direct power generation and amplification. Quasioptical mixers, frequency

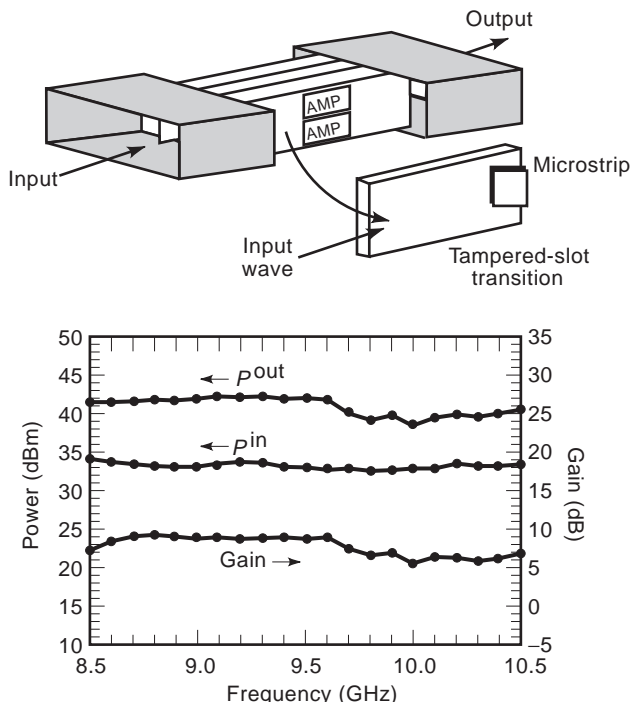

Figure 11. Configuration and gain of an eight element waveguide active array [38]. This array produced 20 W using eight high-power MMICs. (Courtesy of IEEE.)

multipliers, beam switches, and beamsteering components have been investigated. While these components are interesting alone, they are integral components in any quasi-optical transmitter or receiver.

4.1. Frequency Conversion Arrays

A quasi-optical grid periodically loaded with diodes will act as a nonlinear surface. When illuminated with an incident beam of radiation, the nonlinearities in the diode array will generate radiation not only at the fundamental frequency but at higher-order harmonics as well. Diode grids can therefore be used to generate very-high-frequency signals by multiplying a lower fundamental frequency. Luhmann and others at the University of California at Davis have demonstrated a 760-element doubler grid that generated 0.5 W at 66 GHz when illuminated with a 2.5 W input at 33 GHz [40]. This group has also reported a 5 W 99 GHz output tripler grid using 3100 diodes [41]. Multiplier grids have proved extremely successful at terahertz frequencies; a 144-element doubler produced 5.5 mW output at 1 THz [42,43]. This output power is almost two orders of magnitude more than that available using competing non-quasi-optical techniques. The terahertz doubler array is shown in Fig. 12. The success of these grids is a testament to the utility of quasi-optics.

Diode mixer grids have also been demonstrated. The local-oscillator (LO) and RF signals illuminate a diode grid quasi-optically. The intermediate-frequency (IF) signal is

the difference between the RF and LO frequencies. Due to the nature of quasi-optical arrays, the mixer’s conversion loss and noise figure are comparable to those of a single-diode microstrip mixer. On the other hand, the array’s power-handling capability increases with the number of elements, thereby increasing the dynamic range. A 100-element mixer grid [44] had a third-order intercept nearly 20 dB greater than that of a single-diode microstrip mixer. This feature makes quasi-optical receivers very attractive for high-dynamic-range wireless communications applications.

4.2. Beam Control Arrays

Diode grid arrays have also shown promise as beam-control arrays. Quasi-optical phase shifters [45,46] and switches [46–48] are among the many successful beam control components. Figure 13 shows a millimeter-wave monolithic p-i-n-diode switching array [48] developed by Stephan and others. The p-i-n diodes act as switches; depending on the DC diode bias, the array will either reflect or transmit an incident beam. This array switched a 94 GHz beam with an insertion loss of 4 dB and an isolation of 22 dB. An array of varactor diodes will behave in a similar way. By varying the varactor bias, and thus the junction capacitance, the phase of a quasi-optical beam can be shifted.

Figure 12. (a) A monolithic terahertz multiplier grid [42] and (b) unit cell detail. This grid produced 5.5 mW at 1 THz. (Courtesy of IEEE.)

Figure 13. A p-i-n-diode switch array with measured and modeled transmission loss. (Courtesy of IEEE [48].)

One very intriguing application of quasioptical phase shifters is for beamsteering. Progressively shifting the phase of an incident beam across the surface of the quasioptical array will cause the beam to change directions. These quasioptical beamsteerers could one day replace the slow, heavy mechanical systems or the complicated phased-array systems used in many radar transmitters. One particularly promising approach is to use tiny microelectromechanical (MEMS) switches to provide the phase shift [49] without the parasitic losses associated with millimeter-wave diodes.

5. CHARACTERIZATION OF QUASIOPTICAL ARRAYS

Quasioptical components are both active circuits and antenna arrays. These components must be characterized with this unique property in mind. Researchers have developed several figures of merit useful for quasioptical characterization. Gouker [50] has attempted to standardize some of these figures. In this section, characterization of quasioptical oscillators and amplifiers will be discussed.

5.1. Oscillator Characterization

Consider the quasioptical oscillator or transmitter array illustrated in Fig. 14. This array, with active area A and directive gain G_t is located a distance R from a receiving horn antenna with directive gain G_h . The quasioptical array transmits a total power of P_t . λ_0 is free-space wavelength. The power received by the receiving horn antenna P_r will be given by the Friis transmission equation:

$$P_r = G_t P_t G_h \left(\frac{\lambda_0}{4\pi R} \right)^2 \tag{1}$$

G_h , R , and λ_0 are usually well-known quantities. This measurement directly reveals the array’s effective isotropic radiated power (EIRP), which is the product of the actual radiated power P_t and the array’s directive gain G_t :

$$\text{EIRP} = P_t G_t = \frac{P_r}{G_h} \left(\frac{4\pi R}{\lambda_0} \right)^2 \tag{2}$$

To compute the array’s total radiated power, the directive gain G_t must be computed from a complete measurement

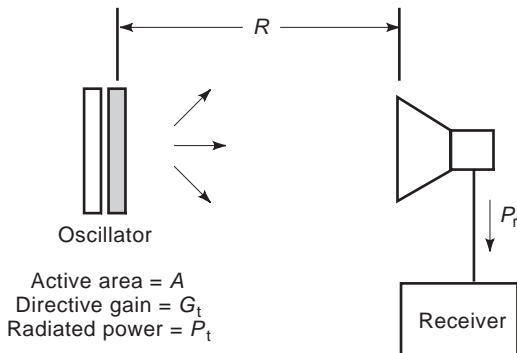

Figure 14. Measurement setup used to characterize a quasioptical oscillator.

of the array’s three-dimensional radiation pattern. Often, one can estimate the array’s the directive gain using the active area A :

$$G_t \approx \frac{4\pi A}{\lambda_0^2} \tag{3}$$

This approximation is most valid for larger arrays with dimensions of several wavelengths on a side. This gives an estimate of the radiated power from the measured EIRP.

5.2. Amplifier Characterization

Several techniques have been used to measure the gain of quasioptical amplifiers. One popular method is a far-field approach shown in Fig. 15. The first step is to calibrate the system. This is done with the two horn antennas copolarized, as shown in Fig. 15a. The calibrated power P_c is related to the transmitted power P_t using the Friis transmission equation

$$\frac{P_c}{P_t} = \left(\frac{G_h \lambda}{4\pi(2R)} \right)^2 \tag{4}$$

where G_h is the directive gain of the transmitting and receiving horn antennas and R is the distance between the amplifier and each horn. Then, the amplifier gain is measured using the setup shown in Fig. 15b. In this case, the received power is related to the transmitted power by

$$\frac{P_r}{P_t} = \frac{G_h A}{4\pi R^2} G \frac{G_h A}{4\pi R^2} \tag{5}$$

where G is the power gain of the amplifier and A is the physical area of the active array. This allows us to express the amplifier gain as

$$G = \frac{P_r}{P_c} \left(\frac{\lambda R}{2A} \right)^2 \tag{6}$$

This simple formula reveals that the gain of the amplifier can be computed from a relative power measurement and three well-known parameters.

Another method used to measure gain is the lens-focused approach shown in Fig. 16. This is a modified version of the quasioptical reflectometer reported by Gagnon [51]. The system is calibrated by placing an absorbing screen at the focal plane, as depicted in Fig 16a. The screen has an aperture cut in it, matching the physical area A of the amplifier. The gain is measured in the cross-polarized setup illustrated in Fig. 16b. For this method, the amplifier gain is simply the ratio of the power received from the grid P_r to the calibration power P_c .

A third method of measuring amplifiers involves placing the array in a large, overmoded waveguide [36,39]. Like the lens-focused approach, this method has the advantage of being very straightforward—the gain can be measured directly using a network analyzer. Care must be taken, however, to avoid exciting higher-order waveguide modes. Furthermore, the edges of the overmoded waveguide must be loaded with a dielectric in order to uniformly illuminate the array.

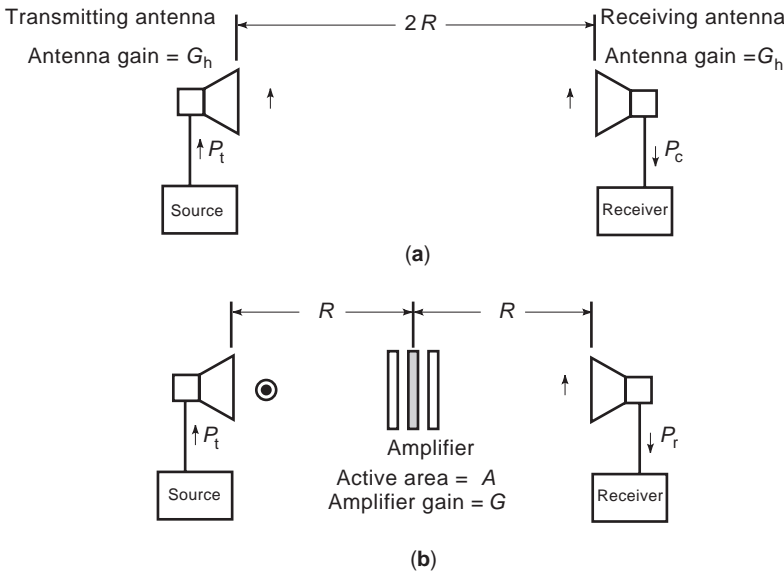

Figure 15. Far-field setup used to measure the gain of a quasioptical amplifier: (a) the calibration step is performed with the horns copolarized; (b) the measurement is performed with the horns cross-polarized [1].

At this point, it should be stressed that the far-field arrangement of Fig. 15 is not how a quasioptical amplifier is ultimately intended to be used—the high path losses between the grid and the horns would result in a very inefficient system. Instead, a quasioptical amplifier would be

employed in a system where the microwave beam is confined, such as in an overmoded waveguide or a lens-focused system like Fig. 16. Much of the diffraction losses are eliminated, possibly resulting in a system with appreciable flange-to-flange gain. On the other hand, the far-field method is simpler to set up in the laboratory, as there are no lenses to focus or align or metal waveguide to machine. Any of the methods should give similar results; the gain of a 100-element HBT grid amplifier was measured using both far-field and lens-focused approaches, with nearly identical results [28].

Figure 16. Lens-focused setup used for gain measurement. (a) The calibration step is performed with copolarized horns and an aperture cut into an absorbing screen. (b) The measurement is performed with the horns cross-polarized [1].

6. PASSIVE QUASIOPTICAL COMPONENTS

Passive components are used to characterize the active arrays described above, and are also necessary building blocks for quasioptical subsystems. Goldsmith [52] summarizes the extensive work on passive quasioptical devices, including their use in Gaussian beam waveguide systems. Frequency-dependent components include path-length modulators, polarization processing components, polarization transducers, hybrids, attenuators, power dividers, ferrite devices, absorbers, and calibration loads. Frequency-dependent components include planar frequency-selective surfaces and grids, perforated plates, interferometers, layered dielectrics, diffraction gratings, and resonators.

7. QUASIOPTICAL SUBSYSTEMS AND MODELING TECHNIQUES

One of the attractive features of the quasioptical approach is the ability to form systems by cascading surfaces that perform different analog signal processing functions, such as the transceiver front end shown in Fig. 17. Numerous

Figure 17. Quasi-optical transceiver front end consisting of cascaded quasi-optical arrays. (Figure courtesy of J. C. Chiao, University of Hawaii.)

individual components have already been developed, and a demonstration of an end-to-end quasi-optical subsystem could occur soon.

To characterize the various components that constitute a quasi-optical subsystem, one must understand the complicated interactions among the semiconductor devices, the antenna element, dielectric substrate, and the radiated and evanescent fields. Determining the driving-point impedance presented to the device at each feedpoint of the array is thus a nontrivial task. Further complications

arise from edge effects and the mutual coupling between array elements. One of the simplest techniques for making this problem more tractable is to assume an infinite array with identical cells. Based on symmetry, a unit cell can be defined with prescribed boundary conditions.

An example of a transmission-line model arising from this approximation is that of a diode-loaded grid shown in Fig. 18 [45]. The vertical metal leads of the grid are represented by a shunt inductor, and the substrate is represented by a section of transmission line whose characteristic impedance is equal to the wave impedance in the dielectric. A system such as the one in Fig. 17 can be characterized in a similar manner by cascading equivalent transmission-line models. For more complex array geometries, full-wave methods must be used to more accurately design these systems.

For a more detailed discussion of quasi-optical circuits, the interested reader is referred to Ref. 1.

RADAR ALTIMETRY

R. KEITH RANEY
Johns Hopkins University
Laurel, Maryland

1. INTRODUCTION

Satellite-based radar altimetry over the world's oceans is the main theme of this article. Rather than measure the unknown clearance of the radar above potentially hazardous topography (which is one rationale for an aircraft radar altimeter, for example), satellite-based altimeters are designed to measure the height of the ocean's surface relative to an objective reference such as Earth's mean ellipsoid. Such sea surface height measurements have become essential for a wide variety of applications in oceanography, geodesy, geophysics, and climatology [1]. A satellite-based altimeter circles Earth in about 90 min, generating surface height measurements along its nadir track. These measurements accumulate, providing unique synoptic data that have revolutionized our knowledge and understanding of both global and local phenomena, from El Niño to bathymetry. A satellite-based radar altimeter also provides measurements of significant wave height and wind speed along its nadir track.

Although one might view these altimeters as relatively simple instruments, their phenomenal measurement accuracy and precision requires elegant microwave implementation and innovative signal processing. This article provides an overview of the applications that drive these requirements, and a description of the resulting state-of-the-art design concepts.

A nadir-viewing altimeter in a repeat-track orbit is constrained by a fundamental tradeoff between temporal coverage (revisit period D days) and spatial coverage (track separation at the equator W kilometers): $DW = \text{constant}$ for a given inclination and altitude. If more than one altimeter is under consideration, as either independent assets or a preplanned constellation, then the spacetime trade space is enlarged, and more measurement objectives may be satisfied. The limitations imposed by this constraint have motivated "multibeam" or "wide swath" altimeter concepts, although all such architectures imply a compromise on height measurement accuracy. The leading example of this genre is reviewed at the end of this article.

The sea surface height (SSH) measurement objectives of space-based altimeters can be grouped into three broad categories: large-scale dynamic sea surface topography, mesoscale oceanic features, and the cryosphere—near-polar sea ice and continental ice sheets. Satellite altimeters dedicated to determining the ocean's large-scale dynamic surface topography are characterized by absolute SSH measurement accuracy on the order of centimeters along tracks of more than 1000 km, and orbits that retrace their surface tracks every 10–20 days. In contrast,

mesoscale missions focus on SSH signals of less than ~ 300 km in length. This application requires measurement precision sufficient to sustain relative height measurements, and for geodetic data, relatively dense track-to-track spacing. Geosat is the leading example of this category, for both geodetic (nonrepeat) and mesoscale (exact-repeat) orbits. Observation of oceanic and polar ice sheets requires that the altimeter have robust range and spatial resolution, accuracy, and precision in response to the nonzero average surface slope in both the along-track and cross-track directions of the continental glaciers. Suitable orbits must have near-polar inclination, and multi-year relative accuracy. Cryosat is reviewed as the first example of this class of radar altimeter mission.

Radar altimeters must provide accurate and precise SSH measurements from a spacecraft whose roll and pitch attitudes are not known exactly. These requirements can be satisfied by the pulse-limited altimeter paradigm, which is characterized by (1) large time-bandwidth pulse modulation, (2) antenna directivity that illuminates a surface area larger than the spatially resolved footprint, and (3) extensive noncoherent (postdetection) waveform averaging. The design of the TOPEX altimeter is described as an example. Footprint resolution and measurement precision can be improved by combining coherent and increased incoherent processing, exemplified by the delay-Doppler altimeter, which borrows applicable techniques from synthetic aperture radar (SAR). The article closes with an overview of future developments and advanced mission concepts.

2. RADAR ALTIMETER SATELLITES

All satellite radar altimeters to date (Table 1) are incoherent pulse-limited instruments, as described in a later passage. Since 1973 height measurement accuracy has improved, due primarily to dedicated effort and increasing skill applied to estimation and correction of systematic errors. Performance also has benefited from improved on-board hardware and algorithms, and improved orbit determination. The Jason-1 altimeter represents the state of the art in absolute SSH measurement accuracy (as of the year 2003). Online access to descriptions of most of these radar altimeter missions may be found at the Website given in Ref. 2.

2.1. Orbits

An altimeter's SSH accuracy on large scales depends to first order on how well the height of the altimeter itself can be determined. Given the state of the art in satellite tracking systems, the dominant error in satellite (radial) position determination is uncertainty in knowledge of the gravity field (often expressed in terms of geoid height) [3]. At lower orbit altitudes, the higher-frequency components of the gravity field are enhanced. The impact can be significant. For example, gravity variations of about 400 km

Table 1. Summary of Satellite Radar Altimeters

Altimeter	Agency	Year	Orbit Repeat (days)	Inclination (degrees)	Altitude (km)	Equatorial Spacing (km)	Band	Propagation Measurements	Accuracy
Skylab (3)	NASA	1973	No	~48	435	—	Ku	None	50 m
GEOS-3	NASA	1975–1978	No	115	845	~60	Ku	None	50 cm
Seasat	NASA	1978	~17, 3	108	800	160, 800	Ku	H ₂ O	20 cm
Geosat	USN	1985–1989	~3, 17.05	108	800	~4, 160	Ku	None	10 cm
ERS-1	ESA	1991–1997	3, 35, 176	98.5	785	20–800	Ku	H ₂ O	7 cm
TOPEX ^a	NASA	1992–	9.916	66	1336	315	C, Ku	H ₂ O, e ⁻	2 cm
Poseidon ^a	CNES	1992–	9.916	66	1336	315	Ku	H ₂ O	5 cm
ERS-2	ESA	1995–	35	98.5	781	80	Ku	H ₂ O	7 cm
GFO	USN	1998–	17.05	108	800	160	Ku	H ₂ O	5 cm
RA-2	ESA	2002	35	98.5	800	80	S, Ku	H ₂ O, e ⁻	7 cm
Jason-1	CNES	2001	9.916	66	1336	315	C, Ku	H ₂ O, e ⁻	1.5 cm
Cryosat	ESA	(2004)	369	92	720	—	Ku	None	(5 cm)
Jason-2	CNES	(2007)	9.916	66	1336	315	C, Ku	H ₂ O, e ⁻	(1.5 cm)

^aTOPEX/Poseidon was a joint NASA/CNES mission on the same spacecraft.

wavelength are 100 times larger at an altitude of 500 km than they are at 1000 km. In general, the accuracy of precision orbit determination is better for higher altitudes.

Atmospheric drag is approximately 10 times greater at 800 km than at 1200 km [4]. For example, over one orbit at 1200 km altitude, drag imposes a 1-cm decay on the orbit radius. At 800 km altitude, the effect is 10 times greater, resulting in a 10-cm decay per orbit. Atmospheric drag increases significantly during periods of higher solar flare activity, the peaks of which occur approximately every eleven years.

Whereas a 10-cm decay in radius per orbit may not seem like much for a satellite at 800 km altitude, these decreases accumulate. Smaller orbit radii induce higher spacecraft velocities. Thus, orbit decay accelerates the satellite, shifting its ground track away from its exact-repeat path. An altimeter's repeat pattern can be maintained only by replacing the energy removed by drag forces. Active intervention is required, usually in the form of thruster firings of controlled strength, duration, and direction. Orbit maintenance maneuvers are required more frequently when the altimeter's orbit is subject to larger perturbations. A review of the orbit maintenance histories of radar altimeter satellites may be found in Ref. 5.

2.2. Review of Missions

The first satellite radar altimeter was the proof-of-concept S-193 instrument (General Electric) that flew on three Skylab missions. The objectives were to verify predicted waveform response to wind and waves, measure the radar cross section of the sea at vertical incidence, measure interpulse correlation properties, and observe the effect of off-nadir antenna orientation. Geos-3 (General Electric) provided the first geodetic and geophysical results of significance within the National Geodetic Satellite Program, including the first maps of sea-level variability and the marine geoid. Geos-3 and the S-193 altimeters used conventional pulse compression techniques.

The Seasat altimeter (Johns Hopkins University Applied Physics Laboratory) was the first to use full-deramp pulse compression, which opened the way for the very

small range resolution required for many oceanographic applications. The deramp technique (described below) has been adopted by all radar altimeters since then. Seasat was designed to measure global ocean topography and the marine geoid, as well as wave height and surface wind-speed. The Geosat (Johns Hopkins University Applied Physics Laboratory) altimeter's design was patterned closely after that of the Seasat altimeter. Geosat was a U.S. Navy military satellite whose primary mission was to map Earth's marine geoid to then-unprecedented accuracy (drifting orbit). Since their declassification in 1995, data from the first 18 month geodetic mission have become the backbone of the global bathymetric chart that is the industry standard [6,7]. Geosat's secondary mission was to observe dynamic oceanographic phenomena, for which it was maneuvered into an exact-repeat orbit (period 17.05 days) [8]. The Geosat follow-on (GFO) altimeter (E-Systems) is meant to replicate as much as possible the Geosat exact-repeat mission, leading toward an operational capability for the U.S. Navy. There has been no dedicated geodetic radar altimeter mission since Geosat, although a new mission known as "Abyss-Lite" is being actively promoted.

In the late 1980s, planning for satellite radar altimeter missions split into two themes, determined by the relative priority of their measurements. If the altimeter is the prime payload instrument, then the orbit and mission design can be optimized accordingly. This theme was initiated by TOPEX/Poseidon (T/P), a joint United States (NASA) and French (CNES) mission. TOPEX (Johns Hopkins University Applied Physics Laboratory) was designed to measure and map the dynamic ocean topography with sufficient accuracy to determine large-scale circulation patterns [1]. TOPEX' most famous contribution is early observation and near-real-time monitoring of El Niño events, whose height signature over the equatorial eastern Pacific ocean typically is an increase on the order of 10–20 cm with respect to the mean. Poseidon (Alcatel Espace), contributed by France, is a small proof-of-concept instrument that has a solid-state transmitter. Poseidon is the precursor of the Jason altimeters, and the SIRAL instrument aboard Cryosat. Cryosat (described

below) will be the first radar altimeter designed to observe polar and continental ice sheets from space.

The T/P orbit repeat period (9.916 days) was chosen carefully to satisfy adequate observation of the dominant aliased tidal constituents. All solar tidal constituents would be ambiguous with other height signals if the repeat period were an integral number of days (20). For T/P, the time of day for each subsequent observation slips by about 2 h. The T/P repeat pass footprint location accuracy is better than ± 1 km, a requirement that is bounded by the cross-track gradient of the oceanic geoid. The T/P instrument package includes a three-frequency radiometer to measure and compensate for propagation delays due to atmospheric moisture (H_2O). TOPEX is the first altimeter to use two frequencies to estimate and compensate for propagation delays imposed by ionospheric electrons (e^-). The Jason-1 altimeter (Alcatel Espace) [9] is designed to follow in the footsteps of TOPEX, figuratively and literally. Following the launch of Jason-1 into the T/P orbit, TOPEX was maneuvered into a “tandem” phasing so that the measurements of the two altimeters could be cross-calibrated. The follow-on mission Jason-2 will be identical to Jason-1, and may also include an experimental wide-swath ocean altimeter (outlined in the closing sections of this article).

If the altimeter is not the primary payload, then the resulting mission and orbit are likely to be determined by other requirements, which may compromise altimetry. The European Space Agency’s satellite altimeters (Selenia Spazio) on ERS-1 and ERS-2, as well as the advanced radar altimeter RA-2 [10] (Alenia Spazio) on ESA’s Envisat, are of second priority with respect to the other instruments on their respective spacecraft. Their sun-synchronous orbits are less than optimum for precision altimetry. The orbit of ERS-1 was adjusted during its mission to a long repeat period (176 days). That long repeat period generated a relatively dense surface sampling grid useful for estimating sea ice cover, geodesy, and bathymetry, but is less than optimum for most other applications.

3. GLOBAL DYNAMIC TOPOGRAPHY—ACCURACY

The principal objective of an oceanographic satellite radar altimeter designed to observe the dynamic sea surface topography over very large spatial scales is to measure the absolute height h_S of the sea surface (Fig. 1) with respect to the standard reference ellipsoid. The keyword here is *accuracy*: the mean bias error of the measurements with respect to an absolute reference. Height measurement accuracy depends, among other factors, upon the accuracy of accounting for variations in the speed of microwave propagation between the radar and the surface. The absolute SSH measurement problem is challenging because the geophysical signal is small, at most on the order of tens of centimeters, yet that signal has to be derived from a satellite altimeter at altitude of 1400 km or so, whose raw range measurement is subject to corrections as large as several tens of meters, and corrections for the geoid of many tens of meters. The accuracy of estimating the dynamic topographic signal is limited by the corrections

Figure 1. A satelliteborne radar altimeter measures the round-trip time delay of transmitted signals, from which is deduced the altimetric height h between the satellite’s orbit and the reflecting surface. For most geophysical interpretations, the altimetric height is converted to the surface’s height, which is described using the standard ellipsoid of Earth as the reference.

for variations in the speed of light (nominally c) and other perturbations, as well as the height accuracies of the orbit, marine geoid, tides, and atmospheric pressure. The implied errors have been reduced over the years, after considerable focused effort. State-of-the-art height accuracy (Jason-1) is better than 3 cm (10-day average) or 1.5 cm (1 month average computed with multi-orbit crossover data), which is a remarkable achievement.

The mean sea level, governed primarily by the marine geoid, differs from the reference ellipsoid by ± 50 m or more, approaching $+100$ m in parts of the Indian Sea. Often, the geophysical signal of interest is the dynamic topography ζ , defined as the distance between the marine geoid h_G and the physical sea surface, corrected for systematic offsets due to tides and atmospheric pressure, for example. The dynamic topography would be zero if the sea were at rest relative to Earth. The dynamic topography reflects small surface slopes associated with geostrophic currents, of which the Gulf Stream is a well-known example. Cross-stream surface slopes are proportional to the mean current flowrate; the resulting slope signals are indicative of large-scale oceanic circulation patterns.

3.1. The Altimeter’s Measurements

Whereas the objective is determination of the distance between the radar and the sea surface, the altimeter

actually measures round-trip delay t_T . The altimeter’s relative height h is derived from the measured time delay by $h = t_T c/2$, where c is the speed of light. At the accuracy required of an oceanographic altimeter, this deceptively simple proportionality must take into account the small but significant retardation of the radar’s microwaves as they propagate through the atmosphere and the ionosphere.

In addition to sea surface height, the satellite radar altimeter’s waveform supports two other oceanographic measurements: significant wave height (SWH) and surface windspeed (WS). Over a quasiflat sea, a pulse-limited altimeter’s idealized mean waveform is a step function whose risetime is equal to the compressed pulselength, and whose position on the time-delay axis is determined by the altimeter’s height (Fig. 2). If the sea surface is modulated by gravity waves, the altimetric depth of the surface increases, which reduces the slope of the waveform’s leading edge. Hence, SWH is proportional to the waveform risetime. If the sea surface is under stress from wind, the resulting fine-scale roughness decreases the power of the pulse reflected back to the altimeter. Hence, WS is inversely related to mean waveform power. In practice, the inflections of the idealized flat-surface response function waveform are softened by the pulse weighting, and the waveform plateau is attenuated over time by the weighting of the antenna pattern.

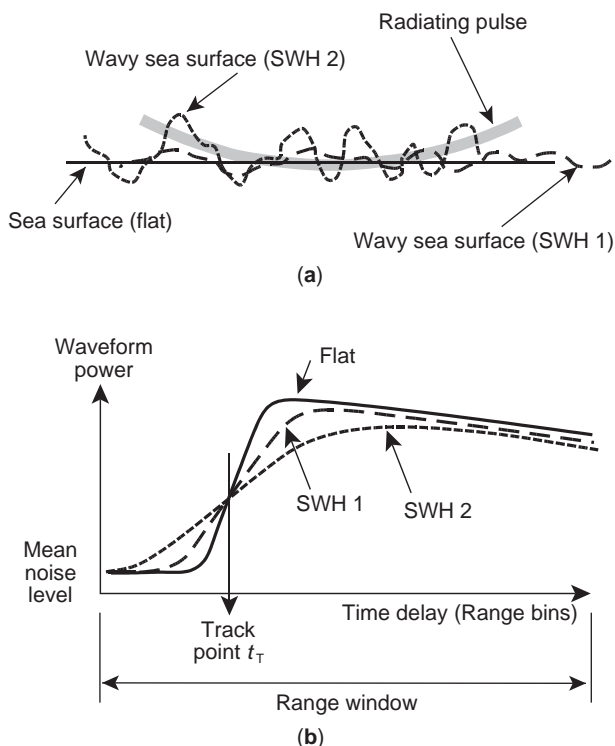

Figure 2. A pulse-limited altimeter’s radiated signal intersects the wavy surface of the ocean from above (a). The output (averaged) waveform is the altimeter’s response to the surface (b). Waveform (round-trip) time delay t_T and leading-edge slope indicate height above the surface and the large-scale roughness (SWH) of the surface, respectively.

To extract SWH and WS from waveform data, finely tuned algorithms have been developed and validated against *in situ* buoy measurements. For example, the TOPEX Ku-band altimeter measures SWH to within ± 0.5 m up to more than 5.0 m, and WS within ± 1.5 m/s up to more than 15 m/s. These figures correspond to averages over 1 second, or about 6 km along the subsatellite path of the altimeter’s footprint, which typically is 3–5 km wide, determined by mean sea state.

3.2. Height Error Budget

The ultimate accuracy of an altimeter depends critically on estimation and removal of the systematic errors inherent to the measurement. Once recovered from the altimetry data, sea surface height h_S is used to derive the signal ξ of the dynamic sea surface topography by

$$\xi = h_S - h_G - \delta h_S$$

in which the independent variables imply geophysical corrections: geoid determination (h_G), and Earth tides, oceanic tides, inverse barometer corrections and so on (δh_S).

An oceanographic altimeter collects radar ranging data that are reduced to sea surface height h_S according to

$$h_S = h_O - h - \delta h_A - \delta h_B - \delta h_h \tag{1}$$

where the last three terms on the right-hand side of Eq. (1) entail corrections to be derived from electromagnetic (EM) reflection and propagation phenomena. Orbit radial height (h_O) is determined through extensive instrumentation and analysis, with a net uncertainty. The magnitude of the uncorrected height errors, and the TOPEX postcompensation residual height uncertainties that remain in h_S , are summarized in Table 2.

3.2.1. Instrument Corrections δh_A . Height errors that arise in the altimeter and spacecraft environment may be driven close to zero by careful design and calibration [11,12]. Range delay has to be adjusted to account for the electronic distance from the antenna phase center, through the transmitter, receiver, and processor, to the

Table 2. TOPEX Height Accuracy

Uncertainty Source	Height Error	Residual Uncertainty (cm)
Instrument δh_A		
Noise	~25 cm	2
Waveform bias	~25 cm	3
Timing bias	~1 m	1
Surface interaction δh_B		
EM bias	~0.05 × SWH	2
Skewness	∝ SWH	1
Propagation δh_h		
Ionosphere	5–25 cm	1.3
Dry troposphere	~2.2 m	0.7
Wet troposphere	5–50 cm	1.2
Orbit h_O	(Large)	3.5
RSS error	>2.5 m	<5

satellite's center of mass. The required timing correction is a function of spacecraft attitude, temperature, and age, among other perturbations. The waveform leading-edge delay is tracked dynamically on-board, but not perfectly. After calibration and compensation, the combined equivalent distance root-sum-squared (RSS) uncertainty of TOPEX from all on-board sources is about 3.7 cm, less than two Ku-band wavelengths.

3.2.2. Surface Corrections δh_b . The radiated wave front impinges on the sea surface, and then is reflected. In the presence of waves, the mean EM surface sensed by the reflection deviates from the physical sea surface. The resulting height measurement bias occurs because ocean waves tend to reflect more strongly from their troughs than from their crests. Ocean waves also tend to be asymmetric in their height distribution, described by skewness. This causes the area of the reflecting surface that lies above the mean sea level to be larger than the area below. If scattering were simply proportional to area, this skewness would bias the height measurement. Both EM bias and skewness bias are reduced through empirically derived algorithms that depend on the local significant wave height.

3.2.3. Propagation Corrections δh_h . EM propagation is retarded by free electrons in the ionosphere, by the air mass of the troposphere, and by the water content of the troposphere. If uncorrected, the height measurement error from these three sources would be about 2.5 m, intolerable for oceanic radar altimetry. The largest error is due to the dry troposphere, but this contribution varies slowly over the planet, and is not problematic. It can be removed almost completely through application of standard models that depend simply on atmospheric pressure and Earth latitude.

Atmospheric water content may vary considerably with location. The resulting pathlength changes, if uncorrected, could imply the presence of large but false oceanic height signals. The only reliable way to counteract its effect is to measure the water content directly along the altimeter's propagation path. Atmospheric water content may be estimated rather well with radiometric techniques. TOPEX carries a three-frequency (18, 21, and 37 GHz) water-vapor radiometer (WVR) whose data are used to reduce the wet troposphere pathlength error to 1.2 cm [13].

The altimeter's radiation is delayed also by the total count of free electrons [i.e., total electron content (TEC)] found in the layer above about 70 km [14]. Depending on the solar cycle, solar illumination, and other parameters, the TEC varies widely, causing an apparent increase in pathlength up to 25 cm. The optical pathlength delay due to TEC depends on frequency f as f^{-2} . Hence, simultaneous altimeter heights h_1 and h_2 obtained at two different frequencies $f_1 > f_2$ can be combined as

$$h = \frac{f_1^2}{f_1^2 - f_2^2} h_1 - \frac{f_2^2}{f_1^2 - f_2^2} h_2$$

to offset the unwanted ionospheric delay error. The TOPEX altimeter operates at Ku band (13.6 GHz) and

C band (5.2 GHz), generating height estimates h_K and h_C , respectively. The TOPEX algorithm that corrects for the ionospheric pathlength delay is $h = 1.18h_K - 0.18h_C$.

3.2.4. Orbit Determination h_O . The dominant error in absolute height measurements from a radar altimeter is the uncertainty of the satellite's instantaneous radial distance from the reference ellipsoid. The perturbations on a satellite in low-Earth orbit, in order of importance, include: variations in the gravity field; radiation pressures; atmospheric pressure; tides, both oceanic and solid Earth; and the troposphere. Real-time observation of the satellite's orbital perturbations is subject to errors also, compounded by insufficient knowledge of the Earth's geoid, and location uncertainties for the tracking systems.

The principal methods used by T/P for precision orbit determination (POD) rely on its global positioning system (GPS) receivers and the "Doppler orbitography and radio-positioning integrated by satellite" (DORIS) data system. DORIS instantaneous navigation is better than 4 m on all axes, a tolerance that reduces to less than 5 cm (radial) after precision processing. T/P carries a set of optical retroreflectors (corner cubes) mounted around the circumference of the altimeter antenna. When within view of ground stations equipped with precision range measurement lasers, the corner cubes can be illuminated. The resulting laser ranging measurements are used to calibrate the onboard orbit determination systems.

The radial orbit determination error for TOPEX/Poseidon has been reduced to less than 3.5 cm when averaged (RSS) over its orbital repeat period [15]. The predominant errors have 2–3 cm peaks, concentrated at a once-per-orbit frequency. Orbit determination residuals can be reduced through analysis of height measurements at locations at which the ascending and descending satellite orbits cross. After removal of all geophysical signals and adjustment for changes in the orbit, the measured heights at each crossover point should be equal. Comparison of the actual crossover differentials helps refine the orbital models. For TOPEX, crossover analysis of many orbits over a period of 30 to 60 days reduces the residual to about 2 cm. At this level of precision, inaccuracies in Earth's tide and geoid models dominate the remaining error. Improvements in these models are expected to lead to 1 cm radial orbit accuracies for the Jason series of altimeters.

Such tight orbit determination is unlikely to be achieved in the near future for the radar altimeter satellites at 800 km altitudes. For example, the working objective for POD on GFO is 5 cm, based primarily on GPS tracking and dynamic modeling (although it was better than 7 cm only rarely during 1998–2002).

4. THEORETICAL FOUNDATIONS

Altimeters generally fall into one of two kinds, determined by their beamwidth and range resolution. Radar altimeters illuminate the surface through an antenna pattern of width β , which typically is less than a few degrees. As a part of the onboard processing, the received energy is

processed into resolved range shells. Beamwidth determines the width βh of the surface illuminated by the antenna. As it intersects the surface, each range of resolved length ρ also determines a surface area of width $2r_P$ [16]. Beam-limited radar altimeters are those for which $\beta h < 2r_P$. Conversely, $2r_P < \beta h$ for pulse-limited altimeters. The altimeters cited in Table 1 are all pulse-limited.

4.1. Pulse-Limited Altimeters

Figure 3 illustrates the pulse-limited condition. The height accuracy of a pulse-limited altimeter is much less sensitive to (small) angular pointing errors than is the case for a beam-limited altimeter.

Figure 3. Elevation (a) and plan view (b) of a pulse-limited radar altimeter’s illumination geometry. The surface area simultaneously illuminated within the duration of the compressed radar pulseshift dominates the height measurement. This pulse-limited area expands for larger significant wave height (SWH).

The pulse-limited radius r_P of a quasiflat surface on Earth of mean radius R_E is

$$r_P = \sqrt{\frac{c\tau h}{\alpha_R}} \tag{2}$$

where $\alpha_R = (R_E + h)/R_E$ is a consequence of the spherical observation geometry. For typical satellite radar altimeters, the pulse-limited footprint over a quasiflat surface is on the order of 2 km in diameter. The pulse-limited area is

$$A_P = \pi r_P^2 = \frac{\pi c\tau h}{\alpha_R} \tag{3}$$

As the pulse continues to impinge on and spread over the surface, the resulting pulse-limited annuli all have areas equal to that of the initial pulse-limited footprint. Hence, the received power tends to maintain the level corresponding to the peak of the initial response. The pulse-limited areas expand in response to increasing large-scale surface roughness, which in the oceanographic context is expressed as significant wave height (SWH).

4.2. Radiometric Response

The classical single-pulse radar equation that describes the postprocessing peak power P is

$$P = \frac{P_T G^2(\theta) \lambda^2 C_R \sigma}{(4\pi)^3 h^4} \tag{4}$$

where σ is the effective radar cross section, P_T is the transmitted power, $G(\theta)$ is the one-way power gain of the antenna as a function of off-boresight angle, λ is radar wavelength, h is height, and the range pulse processing gain (compression ratio) is C_R . In the altimetry literature, the radar cross section usually is interpreted to mean $\sigma = \sigma^0 A_\sigma$, where σ^0 (sigma 0) is the normalized scattering coefficient (dimensionless) of the terrain and A_σ is the area of the resolved footprint. The peak power observed within a conventional radar altimeter, at the instant that the pulse-limited area at nadir is fully illuminated, is given from Eqs. (3) and (4) by

$$P_P = \frac{P_T G^2 \lambda^2 C_R \pi c \tau \sigma^0}{(4\pi)^3 h^3 \alpha_R} \tag{5}$$

The power described by Eq. (5) is proportional to compressed pulseshift τ and to the inverse cube of height h^{-3} .

4.3. Flat-Surface Response

Under reasonable conditions, the expected output $g(t)$ from any linear sensor is given by the convolution $g(t) = p(t) * s(t)$ of the sensor’s impulse response $p(t)$ over the distribution $s(t)$ that describes the input data source. A pulse-limited radar altimeter is an example of a linear system, but its response to input data takes on a special form due to the relatively strange geometry through which it views surface height variations. As a function of time, the

radiating pulse first strikes the surface, and then spreads out over it. The so-called *flat-surface response* is the altimetric counterpart to the generic impulse response function. It serves as the primary analytical basis for description of a radar altimeter’s waveform from a variety of surface topographies.

In the altimetry literature two closely related “flat surface” functions appear, denoted here as $p_I(t)$ and $p_F(t)$. The (idealized) flat surface response $p_I(t)$ was introduced originally [16] as a system function to account for the effects of antenna pattern, illumination geometry, and incoherent surface scattering. As an extension, Brown’s [17] flat-surface response $p_F(t)$ includes the impact of the compressed pulshape and signal processing as well as the functional dependencies captured in $p_I(t)$. Brown’s model is used most widely.

The difference between these two flat-surface functions is subtle but significant. The average input data distribution presented to a conventional radar altimeter is accurately modeled by $s(t) = p_I(t) * q(t)$, which is a convolution of the (idealized) flat-surface response $p_I(t)$ with the topographic distribution $q(t)$ of the surface. The resulting radar altimeter linear model is the convolution $g_A(t) = p_F(t) * q(t)$, where $p_F(t) = p(t) * p_I(t)$ is Brown’s flat-surface response function and $p(t)$ is the conventional linear system impulse response of the altimeter. The output $g_A(t)$ is known as the *altimeter waveform*, examples of which are sketched in Fig. 2.

The flat-surface response function (averaged) of a conventional satellite radar altimeter is

$$\begin{aligned}
 p_F(t) &= 0 && \frac{1}{\tau} \left[t - \frac{2h}{c} \right] \leq 0 \\
 &= \frac{t}{\tau} && 0 < \frac{1}{\tau} \left[t - \frac{2h}{c} \right] \leq 1 \\
 &= 1 && 1 < \frac{1}{\tau} \left[t - \frac{2h}{c} \right]
 \end{aligned} \tag{6}$$

under the simplifying condition of a perfectly rectangular compressed unity pulse of length τ . The defining characteristic of this response is that it is essentially a step function; following its linear rise over the duration of the compressed pulse, its maximum value is supported for many subsequent delay intervals. In practice, this waveform is attenuated in time, due primarily to weighting of the antenna pattern away from boresight. Also, the waveform itself is more rounded, as a consequence of the weighted shape of the compressed pulse produced by a realistic altimeter.

5. DERAMP ON RECEIVE

A satellite-based radar altimeter needs to measure the distance accurately, but only for an essentially planar surface, oriented orthogonally to the radar’s line of sight. Conservative design suggests that all radar resources should be concentrated near the reflection from that surface. Hence, ocean-viewing altimeters have a small range window that tracks the delay and strength of the surface

reflection. The ocean’s surface has a significant wave height of less than 20 m or so, and its radar backscatter coefficient spans 3–20 dB, to cite parameters used in the testing of the TOPEX altimeter. In practice, range gate delay and backscatter tracking are met with two servo-regulator feedback loops (Fig. 4). The first loop is a second-order height tracker consisting of range position (alpha tracker) and range rate (beta tracker). The second loop is the receiver gain control (AGC). Altimeter height measurement is given by the setting of the range delay coarse and fine values, corrected by the remaining height error measured from the waveform’s position in the tracker. Surface windspeed and significant wave height are derived from the AGC values and the waveform’s shape, respectively.

The precision of an individual height measurement is determined by range resolution. If a simple short pulse were transmitted, then the height resolution would equal the pulselength. The principal disadvantage of a short pulse is that it contains little energy. The inherent resolution of a pulse is inversely proportional to its bandwidth. Most radar altimeters use some form of modulation on the transmitted signal to maintain a large bandwidth within a longer pulse, thus increasing the transmitted energy at no loss of resolution. A well-established modulation technique used in many airborne radar altimeters is frequency-modulated continuous wave (FMCW), from which height is

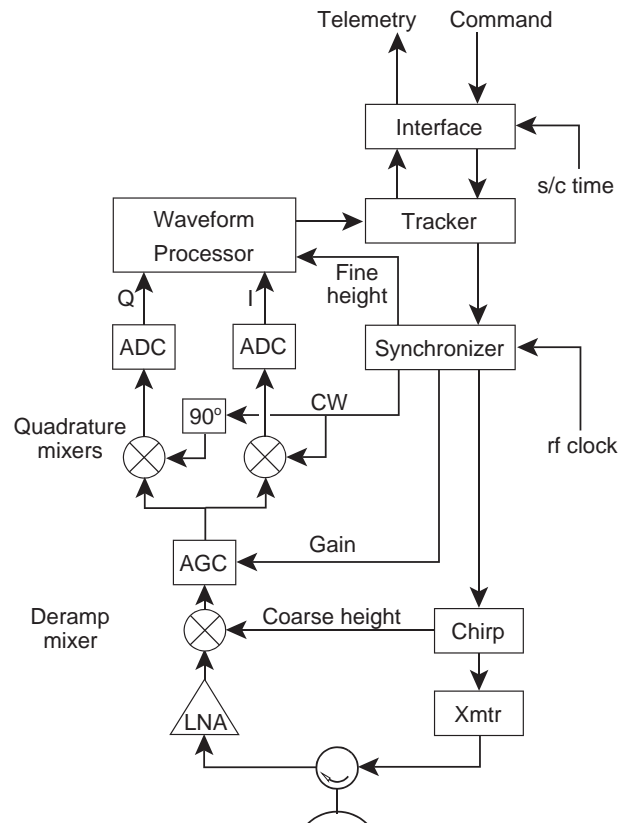

Figure 4. The functional diagram of a modern satellite altimeter is centered on the waveform tracker, whose outputs are (1) translated into science data to be returned via telemetry and (2) transformed into closed-loop timing and gain controls for the radar.

proportional to the frequency difference between the transmitted and received signals. An alternative approach is pulse compression, whereby a relatively long large time-bandwidth pulse is transmitted, and then processed (compressed) after reception to a simple short pulse of unity time-bandwidth.

Satellite-based radar altimeters use a different and specialized form of modulation and demodulation. The relatively distant and narrow range window typical of an ocean-viewing satellite radar altimeter is ideal for the full-deramp (stretch) technique [18], which was first applied to altimetry by MacArthur [19] in the Seasat altimeter. The defining feature of the full-deramp technique is that the transmitted pulselength is longer than the depth of the range window.

The full-deramp (dechirp) technique employs a transmitted chirp (linear FM signal) of duration T_P , bandwidth B_P , chirp rate k_P , and center frequency f_0 . For a pulse initiated at $t = 0$, the transmitted frequency is $f_0 + k_P t$, $t \in T_P$, as shown in Fig. 5. The bandwidth is $B_P = k_P T_P$, and the associated time-bandwidth product is $k_P T_P^2$. Pulse bandwidths and the time-bandwidth products for satellite radar altimeters are large, on the order of 300 MHz and 30,000, respectively. The compressed pulselength τ is given by the inverse bandwidth of the transmitted pulse, or alternatively, by the original pulselength T_P divided by the time-bandwidth product. Thus, a fully deramped altimeter's height resolution is

$$\tau = \frac{1}{k_P T_P} \text{ seconds or } \rho = \frac{c}{2k_P T_P} \text{ meters} \quad (7)$$

The altimeter tracking system anticipates the time t_0 when the reflected signals will arrive back at the radar; to meet them, another chirp is generated, at time $t_C \approx t_0$ and center frequency $f_0 - f_1$, where f_1 is to become the receiver's intermediate frequency (IF). (The deramp chirp

time t_C in general is slightly different from t_0 , as explained in the tracking discussion below.) The deramp chirp is mixed with the incoming signals, after which their difference frequencies are retained, to produce the set of deramped data signals shown in the figure.

The key to many characteristics unique to a radar altimeter lies in this deramp domain. The deramped signal from the m th individual scatterer at time delay t_m is a CW segment of length T_P and frequency

$$f_m = 2k_P(t_m - t_C), \quad t_m \in T_R \quad (8)$$

where T_R is the time spanned by the received signals. For a range window R_H meters deep, $T_R = 2R_H/c$. The IF bandwidth B_I is determined by the FM rate and the range window, $B_I = 2k_P R_H/c$. If the range depth of the scene is small, as is the case with radar altimeters meant to operate over the ocean, then the corresponding IF bandwidth is small, typically less than 5 MHz. Clearly, the full-deramp technique offers a considerable savings in system bandwidth at all subsequent stages, and at no cost in range resolution.

The deramped window duration $T_D \geq T_P + T_R$ must be larger than the pulse duration to accommodate the extra time induced by the range window timespan. The full-deramp technique works best when $T_P \gg T_R$, a condition that is very well satisfied for oceanographic altimeters for which T_R is less than 1% of T_P . *Alert:* There is a conceptual pitfall lurking in the deramped signal domain. Time and frequency reverse their customary roles. In this domain, time delay is no longer a measure of the radar range to reflectors. Rather, the signals' time duration T_P determines their compressed pulse resolution according to Eq. (7), and thus "time" behaves as a bandwidth. Conversely, each scatterer's round-trip time delay, relative to the trackpoint, is proportional after deramp to the CW frequency given by Eq. (8), relative to the IF center frequency. Thus "frequency" behaves as delay time, which is proportional to radar range.

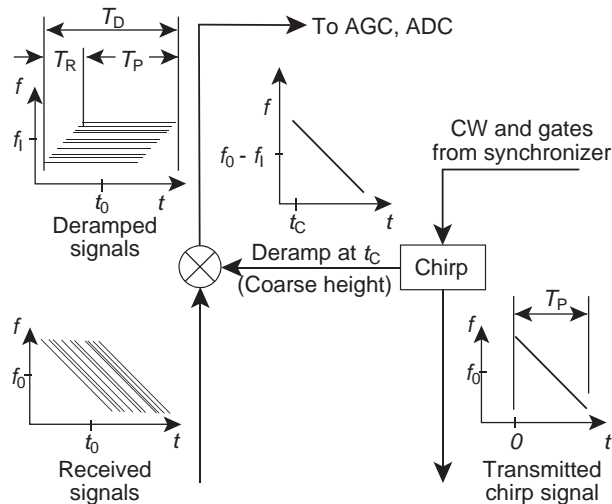

Figure 5. A long linearly frequency-modulated (chirp) pulse is transmitted (as in Fig. 4), followed by full-deramp demodulation on receive to produce a relatively narrowband set of CW data signals at intermediate frequency f_1 .

6. THE TOPEX DESIGN

The TOPEX Ku-band altimeter [11,12,19] illustrates the essential features of conventional space-based radar altimeters (Fig. 4). The TOPEX altimeter is controlled by a synchronizer whose inputs are derived from the tracker outputs, slaved to a master radiofrequency clock at 80 MHz. The tracker and synchronizer control the altimeter in all seven of its operational modes: test, calibrate, standby, coarse track acquisition, fine track acquisition, coarse-resolution track, and fine-resolution track. Table 3 lists values for selected TOPEX parameters.

In the fine-resolution track mode, the radar transmits a linear FM (chirp) pulse of length 102.4 μ s and bandwidth 320 MHz. The signal generator consists of a digital section that creates 40-MHz chirps at baseband, followed by RF sections that multiply and mix the signals to meet the final bandwidth and center frequency. The chirped pulses at 13.6 GHz are amplified in a traveling-wave tube (TWT) to

Table 3. TOPEX Chirp Parameter Values

Parameter	Symbol	Value	Units
Chirp rate	k_P	-3.125	MHz/ μ s
Pulse duration	T_P	102.4	μ s
Pulse bandwidth	B_P	320	Hz
Time \times bandwidth	—	32768	(Nil)
Pulse resolution	ρ	0.469	m
Pulse resolution	τ	3.125	ns
Carrier (Ku-band)	f_0	13.6	GHz
Carrier (C band)	f_0	5.2	GHz
IF frequency	f_1	500	MHz
IF bandwidth	B_I	3	MHz
Range timespan	T_R	400	ns
Deramp timespan	T_D	~ 103	μ s

20 W (peak), and transmitted at 4.5 kHz pulse repetition frequency (PRF) through an antenna 1.5 m in diameter.

The received pulses are amplified and then mixed with a delayed chirp signal, centered at 13.1 GHz to produce an ensemble of CW data signals spread over a band of ~ 3 MHz about an intermediate frequency of 500 MHz. The deramped data signals are further amplified, subject to gain control in the AGC attenuator, mixed down to in-phase and quadrature video, lowpass-filtered and digitized. At this stage, the lowpass filter has the effect of removing echoes from ranges that are well outside the desired range gate window. The signals are magnitude-squared, and summed to produce smoothed height waveforms. Extensive waveform averaging over statistically independent samples is essential to suppress the speckle noise that otherwise would dominate the waveforms. The smoothed waveforms are processed to extract the data of interest, and the tracking outputs are fed back to close the control loops of the radar.

The Ku-band and the C-band channels are time-multiplexed, which impacts system timing from the PRF to the processor.

6.1. Sampling and Waveform Processing

The mean amplitude of the deramped signals is normalized through an AGC amplifier. The receiver gain is set by the level observed in the waveform processor. Signal level is proportional to the scattering coefficient (σ_0) of the water's surface, which in turn is a function of surface windspeed. The normalized signals in the TOPEX altimeters are mixed down to in-phase (I) and quadrature (Q) video channels and passed through 625-kHz lowpass filters prior to analog-to-digital sampling at a 1.25 MHz rate. This produces a set of 128 complex samples uniformly spaced over the 103.2- μ s deramp interval T_D .

The tracker and synchronizer control the position of the altimeter height settings through two paths: coarse, and fine. The coarse height feedback depends on the deramp trigger t_C that is slaved to the 80 MHz clock, which has a period of 12.5 ns. Thus, choice of t_C is restricted to a set of discrete delays separated by 12.5 ns, corresponding to height intervals of 1.875 m each. The fine height feedback is exercised in the digitized deramp domain (Fig. 6). In the deramp domain, a small frequency shift is equivalent to a

Figure 6. The waveform processor (see Fig. 4) of a pulse-limited radar altimeter performs three basic functions: (1) application of a frequency shift to effect the fine range delay correction, (2) an inverse FFT applied to each return to transform the CW signals into a power distribution as a function of altimetric height (relative to the trackpoint), and (3) summation over many of these individual power waveforms to form the averaged waveform that is sent to the tracker.

small time delay Δt . For a fine time shift interval $-12.5 \text{ ns} < \Delta t < 12.5 \text{ ns}$, the corresponding frequency shift is $k_P \Delta t$, bounded by $\pm 39.0625 \text{ kHz}$. The 25-ns fine time shift adjustment interval is large enough to accommodate anticipated range rates without having to reset the course height feedback selection within one waveform-processing cycle.

Following frequency shift, the data are inverse fast Fourier transformed (IFFT) and magnitude-squared detected. The IFFT converts CW to time shift (relative to the trackpoint), and compresses the data to its individual pulse resolution, 0.469 m. Each resulting waveform is a distribution of power across the bins within the range window (as suggested in Fig. 2).

As is true for most radars, the received waveform produced by an individual pulse is corrupted by speckle noise. Speckle is created by the coherent interference within a given echo between unresolved and competing elementary scatterers, and causes the signal's standard deviation to be large. (In the limit, the standard deviation equals the signal's mean value for an individual waveform drawn from a Gaussian ensemble). The standard deviation of the speckle can be reduced by summing (averaging) many statistically independent waveforms together. Statistical independence between sequential returns observed by a radar altimeter depends primarily on the radar pulse repetition rate (PRF), the antenna size, the spacecraft velocity, and sea surface conditions [20]. The pulse-to-pulse statistical independence threshold for TOPEX is about 2.5 kHz, yet its PRF = 4.5 kHz. The pulse rate above the threshold improves the additive SNR, but does not contribute to speckle reduction.

6.2. Tracking

The TOPEX Ku-band channel averages 228 pulses over a so-called track interval of about 50 ms to produce the smoothed waveforms delivered to the tracker at a 20 Hz rate. For each waveform, the range window (Fig. 2) is partitioned into 128 sample positions or bins, each of size equal to the radar's range resolution. Groups of bins are

organized into *tracking gates* of various sizes whose outputs are used to calculate the parameters that control the altimeter's feedback loops, and to provide the first-order science data from the instrument [21]. The tracking algorithm, based on an Intel 80186 microprocessor, iterates at the waveform input rate of 20 Hz. Each tracking gate is normalized so that its gain is inversely proportional to its width, which is the number of samples that it spans. The range width of each gate is a power of 2 times the intrinsic range resolution of the altimeter.

The noise gate estimates the mean noise level from samples 5–8, which occur well before the waveform begins to respond to surface reflections. The mid-point of the waveform's leading edge is tracked to keep it centered between samples 32 and 33. The AGC gate spans samples 17–48, which are centered on bin 32.5, the so-called *trackpoint*.

The output of the AGC gate is fed back to control the altimeter's gain loop. TOPEX is required to measure waveform power (proportional to σ_0) with an accuracy of ± 1 dB and a precision of ± 0.25 dB. In response to the waveform levels observed in the AGC gate, the receiver attenuator is adjusted in 1 dB steps. To meet the accuracy and precision requirements, from pulse to pulse the attenuator setting is dithered between neighboring steps. This has the effect of interpolating the mean AGC setting to an effective accuracy of less than 0.1 dB when averaged over all 228 input waveforms. Waveform power (σ_0) returned as science data is equal to the mean AGC level plus the AGC tracking gate level.

To summarize, the altimeter's measurements are: SSH—the position of the trackpoint, plus the trackpoint offset; SWH—proportional to the width of the waveform leading edge of the waveform; and WS—proportional to a function (empirically determined) of $1/(\text{waveform power})$, hence derived from the AGC setting.

7. GRAVITY AND BATHYMETRY—PRECISION

Radar altimetric data are the basis for state-of-the-art geodesy expressed through the ocean's surface, and consequently, global bathymetry. The principal objective of a geodetic satellite radar altimeter [22] is to measure the (along-track) slope of the sea surface caused by gravity deflections over spatial scales less than a few hundreds of kilometers (Fig. 7). Sea surface slope is derived by taking

Figure 7. The ocean's bottom topography causes subtle variations in the local gravity field, which are expressed as small tilts in the ocean's surface. These are observable by satellite altimetry.

the difference between two neighboring height measurements, where the slope tangent equals "rise over run." The keyword for these measurements is *precision*: the standard deviation (noise) of the sea surface height measurement about its mean value. Height measurement precision is determined by the radar altimeter's postprocessing range resolution, and by the amount of averaging available for each estimate. Note that a precision measurement may still have poor accuracy, if its mean value is biased away from the correct value. When comparing two neighboring height measurements, any constant bias is canceled by differentiation as long as the error is the same for both measurements. The sea surface slope measurement problem is challenging because the desired slope signals are as small as 6 mm height differential (rise) for each 6-km along-track separation (run). Such a slope corresponds to one microradian of gravity deflection, or about a one milligal gravity anomaly.

In addition to height precision, geodetic altimetry requires smaller along-track resolution than does a conventional altimeter, and a suitable orbit. The altimeter's footprint resolution should be smaller than about 6 km, which corresponds to the minimum half-wavelength scale of the observable gravity anomaly spectrum. The orbit should not repeat for ~ 1.2 years, to yield an average ground track spacing of 6 km, again in respect of the anomaly spectrum. The orbit's inclination should be near $50\text{--}63^\circ$ (or $113\text{--}120^\circ$ retrograde) to resolve north and east slopes nearly equally, and to cover the lower latitudes where existing data are inadequate. Note that oceanographic radar altimeter missions (TOPEX/Poseidon, Jason-1, ERS1/2, Envisat, and Geosat ERM/GFO) normally are placed into exact-repeat orbits (10–35 days), and as a consequence have widely spaced (80–315-km) ground tracks. Such orbits cannot resolve the short-wavelength two-dimensional surface slopes required for useful bathymetry.

Since absolute height accuracy is not required, geodetic radar altimeters can be relatively basic instruments. They do not need to compensate for propagation delays; hence they need only one frequency, and they do not need a water-vapor radiometer. Indeed, such an instrument is preferred; it has been shown that efforts to correct for path delays usually add noise to slope estimates [23]. Geodetic measurements provided by the Geosat and ERS-1 (both single-frequency altimeters with no WVR) furnish the best resolution oceanic gravity from space to date. Their resulting bathymetric resolution is limited to about 25 km north-south, with poorer resolution of east-west slope components. These results reflect the less-than-optimum resolution, waveform precision, and orbit inclination of those two altimeters. Geodetic resolution at the ocean's surface can be no finer than about 6 km (half wavelength), a limit that is determined by the average depth of the ocean, which is about 4 km.

Gravity anomalies are caused by topographic relief on an interface between two volumes of differing mass density. In the deep ocean, sediments are thin, and the basaltic seafloor crust is internally flat-layered, and so gravity anomalies at the surface reflect the topography of the ocean floor. Conversely, at continental margins the

seafloor is nearly flat and sediments are generally thick. Beneath these sediments there may be basins or other geologic structures of interest. In such regions, surface slope signals are due primarily to topographic variations at the interface between crystalline rocks and their sedimentary overburden. The sediment–basement interface provides essential reconnaissance information for petroleum exploration. The correlation between slope and existing depth soundings readily distinguishes these two environments [24].

The slope signals required to estimate bathymetry are bandlimited (12–300 km full wavelength), as determined by fundamental physical principles. Hence, the height measurements of a geodetic altimeter need to maintain relative accuracy—precision—only over this relatively narrow band. Within this band, precision turns out to be the dominant limiting condition. Sea surface slope measurements are derivatives of the altimeter’s natural measurements, height. Taking derivatives eliminates constant and longwave height errors, but it amplifies noise at short wavelengths. Using a simple model in which height errors are assumed to be a Gaussian white-noise process over the geodetic band, the one-sigma slope error is about $1.8 \mu\text{rad}$ if the altimeter’s one-sigma height precision is 1 cm for a one-second averaged height value. Experience teaches that height precision degrades with increasing significant wave height (SWH). One of the factors that motivated the development of the delay–Doppler approach to radar altimetry was to improve measurement precision.

8. DELAY–DOPPLER

The delay–Doppler technique leads to better measurement precision, a smaller effective footprint at nadir, and increased tolerance of along-track surface gradients typical of continental ice sheets. The central innovation in the delay–Doppler concept [25,26] is that it combines the benefits of coherent and incoherent signal processing, rather than relying exclusively on incoherent averaging as is the case for all conventional satellite radar altimeters. The coherent processing stages, patterned after well-established methods developed for synthetic aperture imaging radar (SAR), allow much more of the instrument’s radiated power to be converted into height measurement data. One consequence of delay–Doppler signal processing is that less transmitted power is required than with a conventional altimeter. The delay–Doppler technique also enjoys the benefits of the pulse-limited range measurement geometry.

The coherent processing transforms groups of data into the Doppler frequency domain, where delay corrections are applied, analogous to SAR range curvature correction [27]. Doppler processing determines the size and location of the along-track footprint, which is (1) smaller than the pulse-limited diameter, (2) a constant of the system, and (3) relatively immune to surface topographic variations. Waveforms are incoherently summed corresponding to each surface position as the altimeter progresses along track. One direct result is that each height measurement from a delay–Doppler altimeter has more incoherent

averaging than is possible from a conventional radar altimeter.

The delay–Doppler technique exploits coherence between pulses, in contrast to the pulse-to-pulse incoherence that is the norm for conventional pulse-limited altimeters. Pulse-to-pulse coherence requires that the PRF be above the interpulse correlation threshold, rather than below it as is normal for conventional incoherent radar altimeters [20]. To assure correlation, the PRF must be high enough so that at least two pulses are emitted while the satellite’s forward motion equals the along-track aperture size of the altimeter’s antenna.

8.1. Delay–Doppler Domain

The objective of delay compensation is to remove the extra delay (Fig. 8) that is induced by the spherical curvature of the radar’s ranging wavefront as it impinges on the ocean’s surface. At each along-track angular offset θ_D from nadir, there is an extra range distance $\Delta h = h(\sec \theta_D - 1)$ due to range curvature. As it is received, the signal includes returns from scatterers at many different angles. Hence, the problem is multivalued; in the signal domain compensation for wavefront curvature is impossible. This is the situation for conventional incoherent radar altimeters. In the delay–Doppler altimeter, however, along-track coherent processing circumvents this dilemma. Transformation from the signal domain to the frequency (Doppler) domain reduces delay compensation to a single-valued problem: at each Doppler frequency f_D the extra range delay increment is unique, and known.

The delay increment, in terms of Doppler frequency f_D as its independent variable, is

$$\Delta h(f_D) \approx \alpha_R \frac{\lambda^2 h}{8V^2} f_D^2 \quad (9)$$

where V is the velocity of the spacecraft along its orbit. Recall that the deramped data in the range direction appear as constant (CW) frequencies. Each range delay increment translates into an equivalent CW frequency shift. These unwanted frequency shifts may be nullified by multiplying the data field by equal and opposite CW signals prior to the range IFFT, analogous to the fine tracking frequency shift of a conventional radar altimeter. The result is evident in Fig. 9, which compares the flat-surface response waveform (as it would appear in the delay–Doppler domain) before and after delay compensation.

8.2. Implementation

The delay–Doppler altimeter introduces additional along-track processing steps (Fig. 10) after the range deramp and before the range IFFT. The net effect of the extra processing is to transform the signal space from one to two dimensions. A Fourier transform is applied to these data in the along-track dimension, implemented in real time onboard as a set of parallel FFTs that span the range window width. Signals in the resulting two-dimensional deramp/Doppler domain are phase-shifted to eliminate the unwanted range.

Figure 8. Elevation (a) and postcompensation plan view (b) of a delay/Doppler radar altimeter’s illumination geometry. The resolved along-track footprint X_D is Doppler-limited. The cross-track footprint is pulse-limited. Although the footprint is smaller than the pulse-limited area, more averaging is available at each Doppler bin position.

The delay correction phase functions are

$$\Phi(f_D, t) = \exp \left\{ +j2\pi k_P \frac{2}{c} \Delta h(f_D) t \right\} \quad (10)$$

which are CW signals whose frequency is matched to the delay increment given by Eq. (9). The data at this stage consist of an ensemble of two-dimensional CW signals. Frequency in the time-delay direction is proportional to (minimum) delay relative to the range trackpoint, and

Figure 9. Simulated height waveforms, as they would appear in a compressed pulse (delay) and Doppler data array before (a) and after (b) curvature compensation, illustrate how delay/Doppler processing shifts more of the reflected energy into the pulse-limited region, thus improving the height estimates.

frequency in the along-track direction is proportional to the scatterer’s along-track position relative to the zero-Doppler position.

The remaining data processing is carried out in parallel, consisting of a range IFFT at each Doppler frequency bin, detection, and assignment of the height estimates to their respective along-track positions. The process is repeated over subsequent blocks of data, from which many statistically-independent waveforms are accumulated at each along-track position. As the altimeter passes over each scatterer, the corresponding height estimates move in sequence from the highest Doppler filter to each lower frequency filter, until the scatterer is out of sight. Thus, the final waveform at each along-track position is the average (incoherent sum, normalized) of estimates from all Doppler filters. If the Doppler filters are designed to span the along-track antenna beamwidth, then all along-track data contribute to the height estimates.

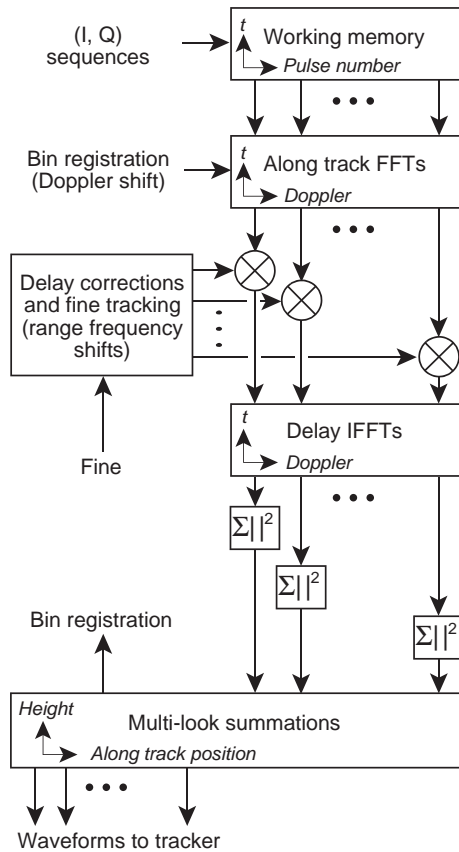

Figure 10. A delay/Doppler radar altimeter waveform processor (see Fig. 4) must be augmented with a cache memory to store the deramped returns from a sequence of transmitted pulses. FFTs are applied across these data to derive their Doppler frequency spectra, which then are corrected for curvature delay by phase multiplication.

8.3. Footprint

Delay–Doppler processing may be interpreted as an operation that flattens the radiating field in the along-track direction. In this transformed data space (Fig. 8b), the (x, y) cells have constant along-track length, but their cross-track widths decrease as the square root of delay time. The cross-track footprint is determined by the pulse-limited condition.

The along-track impulse response is set up by the Doppler filters. Along-track impulse position is determined by the zero-Doppler position for each burst of data. Along-track position can be adjusted by artificial Doppler shifts to maintain registration of subsequent Doppler bins, which is the along-track analog of the fine height adjustment in an incoherent radar altimeter.

Ideally, the along-track zero-Doppler position is equivalent to the geometric subsatellite point, nadir. The along-track location of the zero-Doppler plane is independent of satellite attitude, and also is independent of terrain slope. Thus, the height measurements at all Doppler frequencies can be located along track with respect to zero Doppler. In practice, the zero-Doppler bin location may not coincide with nadir. A vertical spacecraft velocity component adds

a Doppler shift to the signals. Vertical velocity and its implied Doppler error can be estimated. Offsetting Doppler shifts can be applied in response to a spacecraft vertical velocity component to assure registration of the Doppler bins with their corresponding along-track positions defined with respect to nadir.

8.4. Unfocused Condition

The foregoing is predicated on a simple isometry between Doppler frequency and along-track spatial position. This equivalence is valid for an along-track resolution that is comparable to or larger than the first Fresnel zone. In synthetic aperture radar parlance, this zone is known as the *unfocused SAR resolution*. Using the classic quarter-wavelength criterion, the radius a_0 of the first Fresnel zone is

$$a_0 = \sqrt{\frac{h\lambda}{2}}$$

which for a Ku-band altimeter leads to an along-track (unfocused) dimension of 180 m from an altitude of 800 km (or about 230 m from an altitude of 1334 km). As these quantities are less than the nominal delay–Doppler along-track cell size of 250 m, the processing task is trivial—no focusing is required. Focus operations would be required if the Fresnel radius were larger than the along-track cell dimension. If a smaller cell size is desired such as for altimetry over land, or if a very high satellite altitude or longer radar wavelength were chosen, then the along-track processor would have to incorporate phase matching to focus the data.

8.5. Incoherent Averaging

There are two stages in a delay-Doppler altimeter at which incoherent averaging takes place: within each Doppler bin and across neighboring bins. Detected returns from many pulses are averaged together to build the waveform within each bin. For a typical satellite altimeter, these waveforms would accumulate within each 250-m bin at about a 26 Hz rate. Subsequent averaging (incoherent integration) over adjacent waveforms typically extends over 0.1 s (or 1.0 s), during which time the antenna illumination pattern progresses in the along-track direction by an appreciable distance, approximately 0.6 km (or 6 km). *Alert:* the relative location of each delay–Doppler-derived height estimate is synchronized to coincide with the forward motion of the instrument, thus eliminating along-track elongation of the footprint, as is the case for a conventional altimeter. The result is that a delay–Doppler altimeter generates significantly more incoherent averaging than does a conventional altimeter, and at less compromise in along-track footprint size.

One immediate benefit is better measurement precision. Consider the case of height precision in the context of geodetic requirements. Figure 11 shows a plot of height precision *versus* SWH for a delay–Doppler altimeter (DDA) and a conventional radar altimeter (RA). The plot shows that the DDA meets the height precision requirement of 1 cm at 3 m SWH, a result that is consistent with

Figure 11. Height precision of a delay-Doppler radar altimeter (calculated for a Ku-band system in an 800-km Earth orbit) compared to that of a conventional altimeter, as a function of significant wave height. The requirements derived from state-of-the-art oceanic geodesy, and the nominal performance of the Geosat altimeter are included, for reference.

previous analyses [28]. The figure also shows that the DDA is about half as sensitive as an RA to increasing SWH. This is important for geodetic applications, as measurement precision degraded by larger significant wave heights is a major source of noise in Geosat surface slope estimates [7].

8.6. Flat-Surface Response

The customary concept of flat surface response applies only to the delay time dimension for a delay-Doppler altimeter. This means that the inherent delay/elevation ambiguity characteristic of pulse-limited altimeters is reduced from two spatial dimensions to only one dimension. The cross-track ambiguity that remains is suggested in Fig. 8, which shows that at any given Doppler frequency, there are two possible sources for reflections having a given (relative) time delay. These arise from either side of the minimum delay locus, which nominally is the subsatellite track. Of course, the point of first reflection (at zero relative delay time) may be to one side of the subsatellite track, as would be true in general when there is a nonzero cross-track terrain slope. The cross-track ambiguity and the delay/elevation ambiguity both may be at least partially resolved through application of other means such as the monopulse phase-sensing technique.

The flat-surface delay time response (after processing) of the delay-Doppler altimeter has the functional form

$$\begin{aligned}
 f_D(t) &= 0 & \frac{1}{\tau} \left[t - \frac{2h}{c} \right] &\leq 0 \\
 &= \sqrt{\frac{t}{\tau}} & 0 < \frac{1}{\tau} \left[t - \frac{2h}{c} \right] &\leq 1 \\
 &= \sqrt{\frac{t}{\tau}} - \sqrt{\frac{t}{\tau} - 1} & 1 < \frac{1}{\tau} \left[t - \frac{2h}{c} \right] &
 \end{aligned} \quad (11)$$

where τ is the compressed pulselength (Eq. (7)). The curve of Eq. (11) represents the (average) strength of the altimeter's response to illumination of a quasiflat surface as a function of time delay, just as in the conventional case. Note that the response to a flat surface for all regions $t < \tau$ have much less relative power for the delay-Doppler altimeter than for the conventional radar altimeter

described by Eq. (6). The cross-track (time-delay) width of $f_D(t)$ is approximately equal to τ .

8.7. Radiometric Response

The delay-Doppler altimeter can take advantage of reflections from the entire length of the antenna illumination pattern in the along-track direction to estimate the height of each resolved patch of subsatellite terrain. This implies that substantially more integration is possible than in a pulse-limited altimeter. Under the assumption that the dominant scattering mechanism is nonspecular, the integration gain is linear in power. It follows that the total power arising from each resolved cell is larger for the delay-Doppler altimeter than for a conventional pulse-limited altimeter, even though the postprocessing footprint size is smaller.

Height estimation for each resolved scattering cell benefits from integration as long as that cell is illuminated by the antenna pattern. For each scattering cell, the equivalent along-orbit integration is governed by the length βh of the antenna footprint, expanded by the orbital factor α_R . The along-orbit integration may be interpreted in terms of an equivalent along-track area A_D that contributes to the received signal power for a delay-Doppler altimeter on a single-pulse basis. The cross-track dimension is set by the pulse-limited condition. Thus

$$A_D = 2h\beta\sqrt{c\tau\alpha_R} \quad (12)$$

The postprocessing power of the delay-Doppler flat-surface response function is

$$P_D = \frac{P_T G^2(\theta) \lambda^2 C_R \sigma^0}{(4\pi)^3 h^{5/2}} 2\beta\sqrt{c\tau\alpha_R} \quad (13)$$

which has an $h^{-5/2}$ height dependence, and a square-root dependence on compressed pulselength. The height dependence in Eq. (13) is the geometric mean between (h^{-3}) for the pulse-limited case described by Eq. (5) and (h^{-2}) for the beam-limited case. Reduced sensitivity to compressed pulselength τ in comparison to the pulse-limited case may be helpful in system optimization.

From Eqs. (4) and (13), the relative power efficiency of the two altimeters is given by the ratio

$$\frac{P_D}{P_P} = \alpha_R \frac{A_D}{A_P}$$

in which it is assumed that all other factors (such as average transmitted power and antenna gain) are equal in the two cases. The areas A_D and A_P are given by Eqs. (3) and (12), respectively. To first order, the relative radiometric advantage of the delay-Doppler altimeter over the pulse-limited altimeter is given simply by the ratio of the equivalent areas over which the signals are integrated. For example, the delay-Doppler technique would require only about one-tenth of the transmitter power of TOPEX to support the same SNR performance, yet it yields waveforms with reduced speckle due to increased incoherent summation.

8.8. Cross-Track Interferometry

Pulse-limited radar altimeters work best over relatively mild topographic relief of mean slope zero, such as the ocean's surface. Over ice sheets or terrestrial surfaces, performance is degraded. Unwanted characteristics include footprint dilation over rougher terrain, height errors in proportion to surface mean slope, and the tendency of the footprint location to hop from one elevated region to another (without the control or knowledge of the data analyst). Beam-limited techniques, of which laser altimeters are extreme examples, circumvent these problems, but may imply their own set of disadvantages.

A major potential application of radar altimetry is to monitor the height of extensive ice sheets, as found in Greenland or Antarctica. Approximately 95% of these surfaces have slopes less than $\sim 3^\circ$, which is sufficient to trick a conventional altimeter into very large height errors. For example, an unknown one-degree slope would lead to a 120-m surface height error, which is unacceptable. Although the delay-Doppler technique helps overcome errors induced by surface slope components in the along-track direction, that is not sufficient.

Error due to an unknown cross-track slope component can be mitigated if its slope is known. Radar interferometry, as an adjunct to a delay-Doppler altimeter, can be used to measure such cross-track surface slopes. The phase monopulse technique uses this principle to estimate the angle of arrival of reflections from a tilted surface collected through two antennas separated in the cross-track direction of the altimeter (Fig. 12). In a radar altimeter that uses phase monopulse [29], a scatterer at cross-track distance Δy away from nadir precipitates a pathlength difference Δh , observable through the cross-channel differential phase. The cross-track phase monopulse technique can measure the presence of small (mean) cross-track surface slopes. Once measured, the slope data can be applied to recover accurate estimates of the height h of (gently) sloping surfaces. The cross-track phase monopulse technique complements the delay-Doppler technique, which is an along-track enhancement.

8.9. D2P Airborne Testbed

The first embodiment of the delay-Doppler altimeter combined with a phase monopulse cross-track receiver is the D2P radar developed at the Johns Hopkins University Applied Physics Laboratory [30]. The D2P is a coherent airborne radar altimeter that operates from 13.72 to 14.08 GHz (Ku band). The system transmits a linear FM chirp signal at 5 W peak power, with pulselengths ranging from 0.384 to 3.072 μs . The system uses two receiver channels and a pair of antenna arrays, separated by a 14.5-cm baseline, to provide for angle measurements in the cross-track direction. The system provides real-time display of the delay-Doppler spectrum and cross-track phase of a burst sequence (typically 16 consecutive pulses). The D2P system typically is installed into a P-3 research aircraft. More recent campaigns include flights to Greenland, Svalbard, and Antarctica, and over sea ice.

Figure 12. The cross-track (mean) surface slope can be estimated by a measurement of the phase difference between the same return observed through two separated antennas. The range difference ΔR is proportional to their phase difference, from which the slope-induced height correction δh can be calculated.

9. FUTURE DIRECTIONS

9.1. Cryosat

Cryosat [31] is the first satellite of the European Space Agency's Living Planet Programme to be realized in the framework of the Earth Explorer Opportunity Missions. The mission concept was selected in 1999 with launch anticipated in 2004. The Cryosat orbit will have high inclination (92°) and a long repeat period (369 days, with a 30-day subcycle), designed to provide dense interlocking coverage over the polar regions. Its aim is to study possible climate variability and trends by determining the variations in thickness of Earth's continental ice sheets and marine sea ice cover.

The Cryosat altimeter will be the first of its kind: SAR/Interferometric Radar ALtimeter (SIRAL), whose advanced modes are patterned after the D2P altimeter [32], and whose flight hardware has extensive Poseidon heritage. Unlike previous radar altimeter missions, Cryosat will downlink all altimetric data. These data will support three modes: conventional, interferometric, and synthetic aperture. The conventional (pulse-limited) mode will be used for open ocean (for calibration and sea surface height reference purposes) and the central continental ice sheets that are relatively level. The interferometric mode will be used for the more steeply sloping margins of the ice sheets. The synthetic aperture mode will be used primarily over sea ice, where its sharper spatial resolution and better precision will support

measurement of the freeboard for floating sea ice. These measurements can be inverted to estimate ice thickness.

9.2. WSOA

The wide-swath ocean altimeter (WSOA) [33] has been promoted by the Jet Propulsion Laboratory as a means to overcome the dominant timespace coverage dilemma that confronts ocean altimetry. The standard altimeter measurement geometry is strictly nadir-viewing; only one subsatellite height profile is gathered during each pass of the spacecraft. Whereas nadir heights can be very accurate, the surface heights of all regions between nadir tracks remain unobserved, and hence unknown. Many applications would prefer a substantially wider swath of simultaneous height measurements.

Several altimeters have been proposed over the years that would scan the surface below with a set of altimetric beams arrayed orthogonally to the subsatellite path. The goal is reasonable—to generate a wide swath of height measurements, rather than the single subsatellite line of data points typically available. However, there are problems with this general approach. The predominant difficulty is that the measurement is based on triangulation, rather than the much more robust (minimum) range measurement of nadir altimetry. Off-nadir triangulation is extremely sensitive to the satellite's roll angle error $\delta\theta$. Height accuracy within a beam-limited paradigm, at an off-nadir measurement angle θ , depends to first order on $h(\tan\theta \sec^2\theta)\delta\theta$, which increases rapidly from zero as the off-nadir angle is increased. In contrast, a pulse-limited nadir altimeter's height measurement accuracy is not degraded in response to small attitude errors at the spacecraft. The height accuracy requirements typical of oceanographic applications of a few centimeters cannot be met by a single-pass multibeam or wide-swath system given the state of the art of controlling or determining spacecraft (roll) attitude control.

The WSOA concept promises to overcome this roadblock by combining swaths from ascending and descending passes. The accurate nadir heights from one pass will be applied to remove systematic cross-track height errors in the intersecting swath. This approach is expected to provide useful height measurements across the swath for those oceanic features whose height signals are highly correlated over the time between the two passes, typically a few days.

The WSOA is designed to measure ocean surface height within a 200-km swath centered on the nadir track. In a suitable orbit, such an instrument could observe nearly all the ocean's surface with a spatial resolution of ~ 15 km. This WSOA is under negotiation as a demonstration instrument on the Jason-2 mission, post 2007.

9.3. WITTEX

WITTEX, named in honor of E. Witte, who in 1878 first discovered the geostrophic current equation, is an acronym for "water inclination topography and technology experiment." A WITTEX constellation would consist of three coplanar small-satellite radar altimeters [34,35]. The satellites would be spaced apart by several hundred kilome-

ters along their orbit. Earth rotation will cause their subsatellite tracks to be laterally separated. Along-orbit spacecraft spacing will determine the separation and temporal coverage of the resulting surface tracks. The measurements along each set of three near-parallel tracks occur within minutes of each other.

In principle, WITTEX data would support measurement of the cross-track surface gradient as well as the usual along-track gradient. Hence, two orthogonal components of the surface gradient could be observed, from which can be derived the two-dimensional geostrophic current. In practice, height biases will exist between the cross-track measurements. Even if small, such differential biases would compromise the track-to-track height comparisons. One means of offsetting these systematic errors is to cross-calibrate the respective altimeters. This is easily done, since the altimeters are in the same orbit plane. Their surface tracks cross each other at maximal latitudes. When these crossovers occur over the ocean, coincident height measurements from the different instruments can be cross-calibrated.

9.4. Dual-Use Altimetry

To date, the two themes of dynamic mesoscale ocean topography and geodesy have remained disjoint. Geodesy requires a nonrepeating orbit, whereas traditional oceanographic altimetry, including mesoscale observations, relies on exact-repeat orbits. More recent investigations suggest that the two objectives could be satisfied by one altimeter in a nonrepeating orbit, if adequate near-simultaneous ancillary data were available from a more conventional mission such as Jason. The feasibility of dual-use altimetry is a work in progress [36]. If verified, such a mission could be very appealing, since it would attract more potential users (and sponsors), and would require relatively low-cost space-based assets (single frequency, and no WVR, as long as the resolution and precision requirements imposed by geodesy were satisfied). Adoption of this paradigm would require users to think outside traditional boundaries.

RADAR ANTENNAS

TIE JUN CUI
 WENG CHO CHEW
 FU-CHIARNG CHEN
 University of Illinois at
 Urbana—Champaign

Although the principle of radar has been known and advocated by many scientists since the early 1900s, it did not come into its own until its widespread development and application in World War II when the word *radar* was coined. Since then, the use of radar has expanded prodigiously. Important applications are found not only in numerous military problems but also in many public and commercial areas (e.g., civil air-traffic control, aircraft navigation, ship safety, spacecraft, ground detection, and remote sensing of the environment). It is even applied to law enforcement when police use radar to check the speed of cars.

The major types of radar are pulse radar, high-range-resolution radar, continuous-waveform (CW) radar, moving-target indication (MTI) radar, airborne radar, tracking radar, pulse Doppler radar, ground penetrating radar, synthetic aperture radar (SAR), and inverse SAR. Each of these radar types employs a different characteristic waveform, which is determined by the corresponding radar antenna and signal-processing method.

The radar antenna is an important component of radar. For different radar types, the requirement for antenna performances and functions is varied. Because the subject of radar antennas is very extensive, only selected types and performances of radar antennas are discussed in this

article. The reader should consult the bibliography for further details [1–5].

Radar antennas serve as transducers to couple electromagnetic (EM) energy into the atmosphere. A simple description of the antenna in a radar system is shown in Fig. 1. The functions of the antenna when transmitting are to concentrate the radiated energy from the transmitter into a shaped directive beam in a predetermined direction. When receiving, the antenna again forms a beam in a particular direction and collects the energy contained in the reflected target echo signals. Received energy is sent to the receiver via transmission lines. Therefore, the primary purpose of the antenna is to determine accurately the angular direction of the target in both transmit and receive modes. For this purpose, a highly directive beamwidth is required, not only to achieve accurate angular targets but also to resolve closely located targets. This important feature of radar antennas can be quantitatively expressed in terms of the beamwidth, gain, and sidelobes.

Generally, the functions of radar antennas can be classified into beamscanning and target tracking. Beamscanning fulfills the search or surveillance function of a radar. It requires that the narrow directive beam be scanned rapidly and repeatedly over the region where the detected target may appear. Target tracking, however, requires that the narrow beam follow the target once it has been detected. In some radar systems, particularly airborne radars, the antenna is designed to perform both searching and tracking functions.

The preceding functional description of radar antennas implies that a single antenna is used for both transmitting and receiving via the duplexer, a device that permits both transmission and reception of EM waves with the single antenna. This is true for most radar systems, but there are exceptions (e.g., the bistatic radars in which separate transmit and receive antennas are used). This article considers only the single antenna.

Radar antennas are mainly classified into two types: quasioptical antennas, which can be analyzed by optics methods like geometric optics and physical optics, and array antennas. In some cases, small antennas are used (e.g., in ground penetrating radars). Quasioptical antennas include reflector antennas and lens antennas. The former are still widely used for radar, whereas lens antennas, although still used in some communication and

military applications, are no longer used in modern radar systems. Therefore, because of limited space, we discuss only reflector antennas and array antennas.

1. BASIC PARAMETERS AND REQUIREMENTS

Consider a radar antenna located at the origin of a spherical coordinate system as shown in Fig. 2. The observation point is on a sphere having a very large radius R , which is located in the far field of the antenna. Assuming that the antenna is reciprocal, so that the transmit and receive patterns are identical. When the antenna is transmitting, its radiation efficiency is defined as

$$\eta = \frac{P_r}{P_0} \tag{1}$$

where P_0 is the total power consumed by the antenna, and P_r is the power radiated by the antenna. The later can be expressed by the radiation intensity $\Phi(\theta, \phi)$

$$P_r = \int_0^{2\pi} \int_0^\pi \Phi(\theta, \phi) \sin \theta d\theta d\phi \tag{2}$$

in which ϕ is the azimuth angle and θ is the elevation angle, as shown in Fig. 2. From Eq. (2), the average radiation intensity is easily obtained:

$$\langle \Phi \rangle = \frac{P_r}{4\pi} \text{ (watts/steradian)} \tag{3}$$

From Eqs. (1)–(3), we can define some basic parameters of an antenna. Directivity is a measure of the ability of the antenna to concentrate the radiated power in a particular direction. Thus it can be defined as the ratio of the achieved radiation intensity in the direction to the average:

$$D(\theta, \phi) = \frac{\Phi(\theta, \phi)}{\langle \Phi \rangle} \tag{4}$$

In practice, one is usually interested in the maximum directivity of the mainlobe.

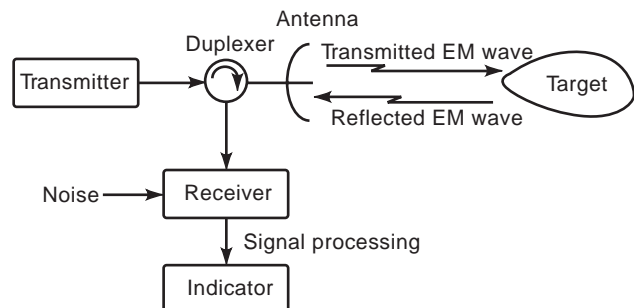

Figure 1. Basic elements in a radar system in which the antenna is an important part. It can be served as transmitting and receiving.

Figure 2. Spherical coordinate system. The azimuth angle ϕ and elevation angle θ are adopted by most antennas.

Gain is another important parameter of an antenna. It represents the ability to concentrate the power accepted by the antenna in a particular direction:

$$G(\theta, \phi) = \frac{\Phi(\theta, \phi)}{P_0/4\pi} = \eta D(\theta, \phi) \quad (5)$$

Thus antenna gain is always less than directivity except for a lossless and reflectionless antenna ($\eta = 1$). Again, the peak value of the gain, G_0 , is of more interest in practice.

The aperture of an antenna is its physical area projected on a plane perpendicular to the desired direction. If the antenna is lossless and the aperture of area A is uniformly illuminated with equiphase, the directivity is given by

$$D_0 = \frac{4\pi A}{\lambda^2} \quad (6)$$

which is the maximum available gain from an aperture A . Practical antennas are not uniformly illuminated, but they have a maximum in the center of the aperture and are less tapered toward the edges in order to reduce the sidelobes of the pattern. In this case, an effective aperture is defined from the directivity:

$$A_e(\theta, \phi) = \frac{\lambda^2}{4\pi} D(\theta, \phi) \quad (7)$$

The concept of effective aperture is very useful when considering the antenna in its receiving mode, which measures the effective absorption area of the antenna to an incident plane wave. Let A_e be the peak value of $A_e(\theta, \phi)$. Clearly, the effective aperture A_e is always less than the physical aperture A by a factor η_a

$$A_e = \eta_a A \quad (8)$$

which is usually called the aperture efficiency. From the definitions in Eqs. (6)–(8), we can see that the aperture efficiency measures only how effectively a given aperture is used, but does not involve the EM energy loss. Therefore, the efficiency of the antenna should be the multiplication of η_a and antenna losses η_L .

When the power radiation intensity $\Phi(\theta, \phi)$, the directivity $D(\theta, \phi)$, the gain $G(\theta, \phi)$, and the effective aperture $A_e(\theta, \phi)$ are normalized to their peak values, they will be identical and are called the antenna radiation pattern, which in fact represents the EM-energy distribution in three-dimensional (3D) angular space. There are several ways to plot the radiation pattern: rectangular or polar, voltage intensity or power density, absolute value or dB value, or power per unit solid angle. However, the 3D plots of radiation pattern require extensive data. Thus two-dimensional (2D) plots are usually adopted as a result of the ease in measurement and plotting. Generally, the two cuts of 3D plots in the principal elevation and azimuth planes are sufficient to describe the pattern performance of an antenna, which is much less costly.

Instead of azimuth and elevation, E - and H -plane patterns are usually used in actual radar antennas because the terms *azimuth* and *elevation* imply the Earth-based

reference coordinates, which are not applicable to some space-based systems like airborne and satellite.

The mainlobe of the radiation pattern is in the direction of maximum gain; all other lobes are called sidelobes. In addition to the peak gain of the main lobe, two other important features of an antenna pattern are the beamwidth of the mainlobe, which is usually specified at the half-power level (3 dB), and the maximum sidelobe level. The half-power beamwidth (HPBW) is usually a measure of the resolution of an antenna. Therefore, if two identical targets at the same range can be separated by the HPBW, they are said to be resolved in angle.

The beamwidth of an antenna is determined by the size of the antenna aperture as well as the amplitude and phase distributions across the aperture. For a given distribution, the half-power beamwidth in a particular plane is inversely proportional to the size of the aperture in that plane

$$\text{HPBW} = K \frac{\lambda}{L} \quad (9)$$

where L is the aperture dimension and K is a constant for the given distribution, which is known as the beamwidth factor. Accurate estimate of the beamwidth factor must take into account the aperture illumination function. However, $K = 70^\circ$ can give a rough estimate in most cases. For reflector-type antennas, a good estimation to K is given by [6]

$$K = 1.05238I + 55.9486 \text{ (deg)} \quad (10)$$

in which I is the absolute value of edge illumination in decibels.

From the half-power beamwidths in two orthogonal principle planes, one can obtain a practical formula for predicting the gain of a relatively lossless antenna

$$G_0 = \frac{C}{\theta_1 \theta_2} \quad (11)$$

where C is a unitless constant and θ_1 and θ_2 are HPBWs in degrees. The accurate value of C depends on the antenna efficiency, but the rough estimate can be taken from 26,000 to 35,000 [1,7].

Ideally, an antenna radiation pattern would consist of a single mainlobe and no sidelobes. However, for all practical radar antennas, it contains numerous sidelobes. These sidelobes can be a source of problems for the radar system. For example, a radar for detecting low-flying aircraft targets can receive strong ground or ocean echoes, which is called the clutter, through the sidelobes. This signal will interfere with the desired echoes coming from the low radar-cross-section targets through the mainlobe. Another fatal problem of the sidelobes is coming from jamming, which threatens most military radars. Therefore, it is often (but not always) desirable to design radar antennas with sidelobes as low as possible to minimize such problems. However, low sidelobes and high gain are competing requirements. Thus, the tradeoff between sidelobes level, gain, and beamwidth is an important consideration for designing radar antennas.

2. REFLECTOR RADAR ANTENNAS

Reflector antennas are one of the most important radar antennas and are widely used in practical radar systems. They provide an economical way to distribute energy over a large aperture area and produce shaped or pencil beams with high gain. In accordance with different demands, there are many types of reflector antennas with different shapes and feed systems.

2.1. Types of Reflectors

A wide variety of reflector antennas have been used in radar system. Figure 3 shows the most common reflector antennas.

2.1.1. Paraboloidal Reflector Antennas. The paraboloidal reflector antenna shown in Fig. 3a is a classical one with a round aperture. The theory and design of this kind have been well developed and discussed in the literature [1,5]. In this antenna, the feed is placed at the focus of the paraboloid. Then the spherical wave emerging from the feed strikes on the reflector and is transformed into a plane wave after reflection to form a pencil beam. Usually, the paraboloidal antenna provides a high gain and a minimum beamwidth with the simplest and smallest feed.

An important parameter for this paraboloid is the ratio of the focal length f to the aperture diameter D . For fixed aperture, when f increases, the reflector becomes flatter and introduces less distortion for polarization and off-axis beam. However, a narrow primary beam that leads to a larger feed is also required. For example, the size of the horn to feed a reflector of $f/D = 1.0$ is approximately four times that of $f/D = 0.25$. In general, most reflectors are chosen to have a ratio between 0.25 and 0.5.

Besides the round aperture, a variety of reflector outlines are also used in practice (2, 5). For example, an oblong shape is chosen when the azimuth and elevation beamwidths have different requirements.

2.1.2. Parabolic Cylinder Antennas. It is very common that only one of the azimuth and elevation beams must be steerable or shaped while the other is not. In this case, a parabolic cylinder reflector fed by a line source shown in Fig. 3b can meet the requirement at a modest cost. The line source feed may be a parallel-plate lens, a slotted waveguide, a phased array, and so on [1]. Of course, the parabolic cylinder antenna is not limited to these applications. It can even be applied when both patterns are fixed in shape (e.g., the AN/TPS-63).

Parabolic cylinders suffer from large blockage if they are symmetric; thus they are often built offset. Properly designed, however, a cylinder fed by an offset multiple-element line source can have excellent performance [8].

2.1.3. Shaped-Reflector Antennas. A good method of shaping the beam in one plane is using shaped reflectors [9], as shown in Fig. 3c, in which the surface itself is no longer a paraboloid. From Fig. 3c, each portion of the reflector is aimed in a different direction, making the analysis complicated. However, with modern computers, arbitrary beam shapes can be approximated accurately by direct integration of the reflected primary pattern.

A disadvantage of the shaped reflector is that its effective aperture is very small because a large fraction of its energy is radiated to a wide angle. However, it can reduce the blockage from the feed. In most shaped reflectors, the feed is usually placed outside the secondary beam. Then the blockage can be virtually eliminated even though the feed appears in front of the reflector, as shown in Fig. 3c.

Comparing shaped-reflector antennas with parabolic cylinder antennas, the shaped reflector is cheap and simple to construct. But it has less control over the beam shape because only the phase of the wave across the aperture is changed, whereas both phase and amplitude can be adjusted in the linear array for the parabolic cylinder.

2.1.4. Multiple-Beam Reflector Antennas. Very often the radar designer needs multiple beams to provide extended

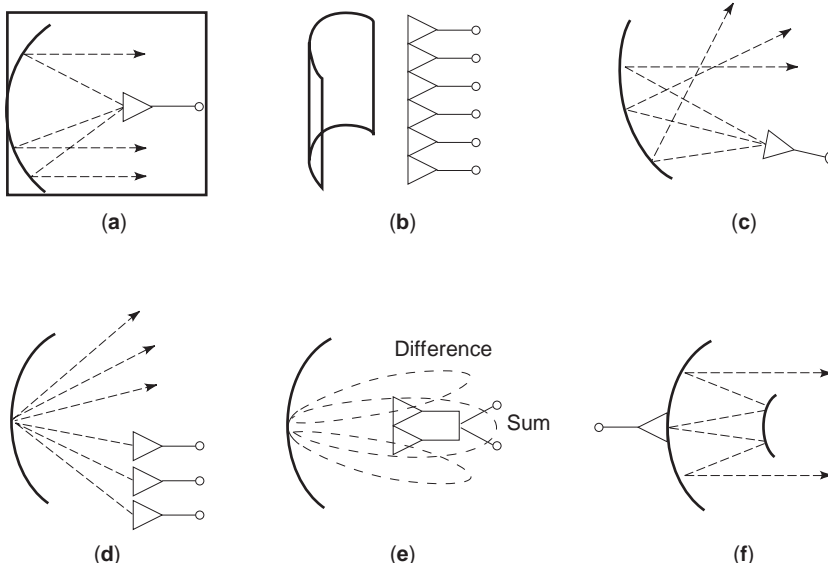

Figure 3. Common reflector antenna types: (a) paraboloid; (b) parabolic cylinder; (c) shaped reflector; (d) multiple beam; (e) monopulse; (f) Cassegrain.

coverage. This requirement can be achieved by using a reflector with multiple feeds [10], as shown in Fig. 3d. As we know, a feed at the focal point of a paraboloid forms a beam at the direction parallel to the focal axis. The feeds displaced from the focal point, however, will form additional beams at distinct angles from the axis with nearly full gain. Therefore, the coverage range of the radar can be increased. However, when the feed is off the focus, a distortion occurs on the antenna pattern. As the angular displacement increases, the beamwidth becomes larger, and additional sidelobes arise. The other limitation of this kind of antennas is that the extended feeds increase the blockage of the aperture.

2.1.5. Monopulse Reflector Antennas. An especially common multiple-beam radar antenna is the monopulse reflector illustrated in Fig. 3e. In fact, the illustration shows an amplitude comparison system, which is far more prevalent than the phase comparison system. In the amplitude system, the sum of the even-numbered source outputs fed by a single pulse forms a high-gain and low-sidelobe beam, and the difference forms a precise deep null at the peak value direction of sum pattern. The sum beam is used on bolt transmit and receive to detect the target, whereas the difference beams provide angle determination in both azimuth and elevation angles. Therefore, the monopulse reflector is normally used in tracking systems in which the antenna is removable and keeps the target near the null in difference pattern.

A tradeoff to design the monopulse radar antenna is the choice of feed size. The conflict arises between the goals of high sum-beam gain and large difference-beam slopes. For example, for a four-horn feed, the former requires a small overall horn size to reduce the blockage, whereas the latter requires large individual horns. Also, high difference sidelobes are required for tracking purpose in the design. To overcome these problems, many methods have been presented and several suggested configurations of the feed are given in Ref. 11.

2.1.6. Multiple-Reflector Antennas. Multiple-reflector systems can offer more degrees of flexibility by shaping the primary beam and then overcoming some of the shortcomings of single reflector. Figure 3f shows the most common type of multiple reflector, the Cassegrain antenna [12], in which the feed system is conveniently located behind the main reflector. In the Cassegrain system, the subreflector is a hyperboloid. The feed is placed at the left focus of the hyperboloid, and the paraboloid focus coincides with the right focus. From geometry optics, the spherical wave radiated by the feed and then reflected to the main reflector by the hyperboloid is equivalent to the one emerging directly from the right focus. Therefore, the wave reflected from the main reflector is also a plane wave that forms a pencil beam. A similar antenna to Cassegrain is the Gregorian antenna, which uses an ellipsoidal subreflector rather than a hyperboloidal one.

Aperture blockage can be very large for symmetric Cassegrain antennas, as illustrated in Fig. 3f. There are two ways to reduce blockage. The first method is to make the diameter of the subreflector equal to that of the feed,

Figure 4. Offset dual reflector. The blockage of the subreflector can be virtually eliminated.

but the reduction is limited. The second method, which is generally used, is achieved by offsetting both the feed and subreflector. For example, Fig. 4 shows an offset dual reflector with blockage and supporting struts virtually eliminated. This antenna usually has very low sidelobes.

The geometry of the Cassegrain antenna is especially attractive for monopulse tracking radar because the radiofrequency (RF) plumbing can be placed behind the reflector to avoid blocking of the aperture. Also, the long runs of transmission line out to the feed at the focus of a conventional monopulse reflector are avoided. Therefore, the Cassegrain antennas usually have a low noise temperature.

2.2. Feeds for Reflector Antennas

In the previously discussed antennas, a spherical wave from the focus of the paraboloidal reflectors will be transferred into a plane wave to form a pencil beam at the transmit mode, while the incoming plane wave will be converted into spherical phase fronts centered at the focus on their receive mode. Thus the feeds for reflector antennas must be point-source radiators so that they can radiate spherical waves. Other requirements for reflector feeds include the proper illumination of the reflector with a prescribed amplitude distribution, a minimum spillover, and the correct polarization with no or minimum cross-polarization. These are the basic factors chosen to design a feed. For a different application of the antennas, other considerations must be included.

The most common feeds for reflector antennas are the flared waveguide horns, which are very suitable for microwave-frequency radar systems (L band and higher). At lower frequencies, dipole feeds, Yagi-Uda, or logperiodic feeds are sometimes used. For example, a linear array of dipoles can feed a parabolic cylinder reflector. Rectangular waveguide horns propagating the dominant TE_{01} mode are widely adopted because they meet the high-power and other requirements, although in some cases circular waveguide horns propagating TE_{11} mode have also been used. These single-mode horns provide just one linear polarization. When such additional requirements as polarization diversity, multiple beams, high beam efficiency, or ultra-low sidelobes are needed, the design for feeds becomes

Figure 5. Various types of feeds used in radar antennas.

more complicated. In these cases, segmented horns, finned horns, multimode horns, and corrugated horns must be used. Figure 5 illustrates some of the types, which have been well studied [1,13].

In addition, the sitting of the feeds has also a great influence to the performance of the reflector antennas. Figure 6 shows several placement styles of the feeds.

2.3. Reflector Antennas Design and Analysis

The analysis and design of conventional paraboloidal reflectors are well developed [1,5] and not stated here. However, most of the rotating search radars require that the antenna patterns have a narrow azimuth beamwidth for angular resolution and a shaped elevation beam for multiple requirements, for example, the ARSR-3 radar for air-traffic control and the AN/TPN-19 for ground control. Thus, a shaped reflector is nearly always the practical choice. In this section, we will consider the analysis and design of such kinds of antennas.

2.3.1. Requirements. When a search radar works, small nearby targets like birds and insects may clutter the output of the radar because of the inverse fourth-power

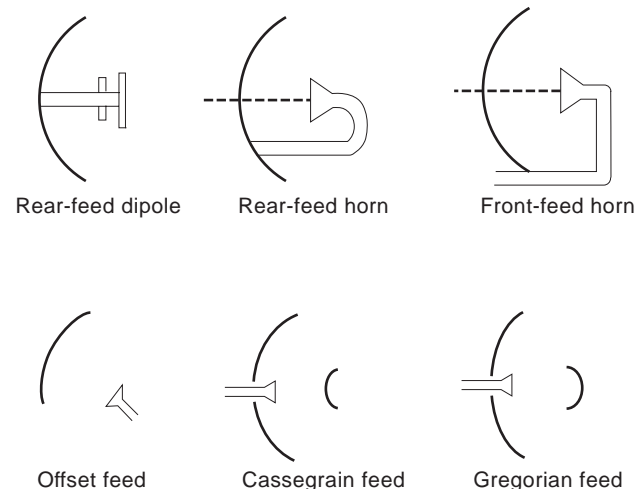

Figure 6. Various placements of the feeds in radar antennas.

variation of signal strength with range. For example, the radar that can detect a 1 m^2 target at 100 nmi can detect a 10^{-4} m^2 target at 10 nmi. [Nautical mile (nmi), where $1 \text{ nmi} = 1852 \text{ m}$ is usually used as the range unit.] To avoid the clutter, the receiver gain should be reduced at short range and increased at distant range so that the received signal from a target of constant size remains unchanged with range. The programmed control of the receiver gain to keep a constant echo signal strength is called sensitive time control (STC), which is an effective method of eliminating the radar echoes from unwanted objects. Therefore, STC is usual requirement for designing the search radar.

A typical range coverage requirement for the rotating search radars is shown in Fig. 7, which is an idealized simplification of the STC requirement [14]. It gives a relationship between the radar range, height, and elevation angle. From Fig. 7, at low elevation angles ($0.5\text{--}3.5^\circ$), the maximum range is the critical requirement. When the elevation angle increases ($3.5\text{--}9.5^\circ$), however, the height becomes the governing requirement. In this period, the corresponding pattern is a cosecant square. At high elevation angles ($9.5\text{--}30^\circ$), the STC is used.

The two-way coverage requirement shown in Fig. 7 is inconvenient for antenna design. It can be converted into a pattern requirement if we plot only the range against angle because the range is directly proportional to the pattern amplitude, as shown in Fig. 8 (the solid line).

2.3.2. Analysis. Antenna analysis is very important not only in analyzing a given antenna but also in antenna design. Because the accurate design is usually an iterative procedure, in each iterative cycle, an analysis is needed.

There are two methods to analyze a given antenna: current distribution method and aperture field method [5]. For shaped antennas, however, the first one is more suitable. From the magnetic field H radiated by the feed, one can get the induced current on the reflector surface

Figure 7. Typical two-way coverage requirement of the search radar, in which a relationship between the radar range, height, and elevation angle is given.

Figure 8. Coverage requirement (solid line) and realizable pattern (dashed line).

$\mathbf{J} = 2\hat{\mathbf{n}} \times \mathbf{H}$. Then the radiated fields by the reflector can be obtained by integration.

This type of accurate analysis is quite time-consuming. In practical design, the antenna pattern and gain are usually approximated in the first several iterative cycles. For rotating search radars, the antenna pattern can be obtained directly from the coverage requirement; however, the designer must realize that the range-angle plot represents the minimum range requirement. If some ripple is anticipated (normally about ± 1 dB), the design curve should be raised 1 dB in the height limit and STC coverage regions. For the range limit region, a reasonable situation is achieved by assuming that a section or several sections of the reflector are shaped so that the -3 dB points of the resulting pattern will coincide with the two corners of the range limit portion, as shown in Fig. 8 (dashed line), which is just the realizable elevation pattern of the antenna.

For the gain of shaped beam considered here, we assume that the azimuth and elevation power patterns are separable. Then, using the definition in Eq. (5), the maximum gain (in mainbeam direction) can be expressed as

$$G = \frac{4\pi}{\int \int f_{az}(\phi) f_{el}(\theta) d\phi d\theta} = \frac{4\pi}{\int f_{az}(\phi) d\phi \int f_{el}(\theta) d\theta} \quad (12)$$

where $f_{az}(\phi)$ and $f_{el}(\theta)$ are azimuth and elevation power patterns. For simplicity, the azimuth power pattern can be approximated by a Gaussian function: $f_{az}(\phi) = \exp[-2.7726(\phi/BWAZ)^2]$. Then

$$\int f_{az}(\phi) d\phi = 1.0645BWAZ \quad (13)$$

in which BWAZ is the azimuth half-power beamwidth. For the other integral in Eq. (12), it can be easily found from Fig. 8.

2.3.3. Design. For shaped-beam antennas, the shaping is generally in one plane (elevation), with a narrow pattern of conventional design in the orthogonal plane (azimuth). The parabolic cylinder antenna fed from a line source is convenient for obtaining independent control of the patterns. However, it is much more expensive and heavier than a reflector fed from a point source. In order to obtain a shaped beam, the antenna with a point source feed requires a reflector surface with double curvature. An easy but efficient way to do this is to use an offset paraboloidal antenna by adding several shaped sections. Each successive section points slightly higher than the preceding section, as shown in Fig. 9. Clearly, the projections of added sections are virtually missing the feed. So there is no feed blockage. The design of the added sections can be done iteratively by using a computer. However, the antenna's width and height can be directly approximated from the antenna patterns [14]

$$\text{Width} = \frac{65\lambda}{BWAZ} \quad (14)$$

$$\text{Height} = \frac{65\lambda}{BWEL} \frac{\int f_{el}(\theta) d\theta}{\Delta \int f_{el}(\theta) d\theta} \quad (15)$$

in which BWEL is the elevation half-power beamwidth, and $\Delta \int$ is the integral in the range-limit region.

2.4. Practical Considerations

In the analysis and design of radar antennas, some practical considerations must be taken into account because they can affect the performances of the antennas. There are a lot of practical details for different radar antennas, but here we consider only four common effects: feed support blockage, surface leakage, surface tolerance, and radomes.

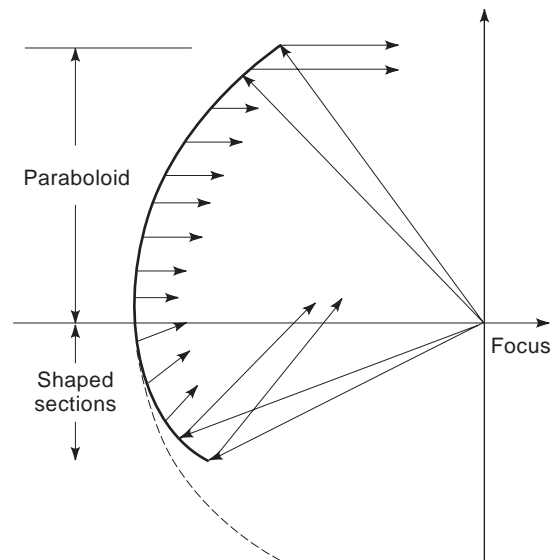

Figure 9. An example of shaped-beam antenna design.

Figure 10. Some common feed supports used in radar antennas.

2.4.1. Feed Support Blockage. No matter whether the feed is placed in the front or rear, there is always blockage from the feed supports. In the case of Cassegrain or Gregorian, the blockage comes from the support of the subreflector. Like the blockage of feeds, the supports have two effects on the antenna's performance: they put a shadow in the desired distribution, and they scatter the intercepted power. Both effects can reduce the gain and increase the sidelobe level.

The effective size of the blockage may be larger than its projected area depending upon the material and polarization. For conducting supports, the effective size equals the actual dimension in the E plane, whereas the effective width becomes $W + \sqrt{0.5\lambda d}$ (where W and d are the width and thickness of a strut) in the H plane [15]. Therefore, the blockage of a strut of 0.125λ square in cross section will be three times larger when it is parallel to the E field than when it is parallel to the H field. In addition, various ways of sitting the supports have different effects. Figure 10 shows three common ways of supporting the feeds. Note that the tripod arrangement produces sidelobe ridges that are broader but 6 dB lower than those of the quadrapods [15]. The feed support blockage can be reduced by using a dielectric strut.

2.4.2. Surface Leakage. Many reflectors are designed with a tubular grid or wire mesh instead of a solid metal surface in order to reduce the wind resistance and the antenna's weight. To accomplish this, the opening area in the structure should be as large as possible. However, the openings lead to surface leakage, from which backlobe is produced. The larger the area of the opening is, the higher the backlobe is. Therefore, a suitable design of the surface structure is important to the antenna's performance. Figure 11 illustrates some of the common reflector surfaces, in which the gap S between conductors must be much smaller than a half-wavelength in the H plane so that the passage of EM energy will be below cutoff [14].

2.4.3. Surface Tolerance. Mechanical consideration to design reflector antennas is very important in a radar system. In most cases, it is even more difficult and complicated than the electrical design, especially for a high-performance radar. The surface tolerance is one important part of the mechanical design. The reflector surface must be smooth enough so that it remains within close tolerances of the ideal surface. Typically, the surface error must be less than $\lambda/28$.

The roughness of reflector surface can cause small phase error on the aperture. From the antenna tolerance

Figure 11. Common types of reflector surfaces that can reduce the wind resistance.

theory, the loss of gain due to phase error is approximated by

$$\frac{G_1}{G_0} \approx 1 - \bar{\delta}^2 \quad (16)$$

where G_1 and G_0 are gains with and without phase error, and $\bar{\delta}^2$ is the mean square phase error. From Eq. (16), one clearly sees that for 1 dB loss of gain the phase error $\sqrt{\bar{\delta}^2}$ must be less than 0.45 rad, which means the reflector surface error must be less than $\lambda/28$.

2.4.4. Radomes. Antennas for ground-based radars are often subjected to high winds, icing, and temperature extremes so they must be sheltered if they are to survive and perform under adverse weather conditions. The shelter to protect antennas is called a radome. Antennas mounted on aircraft must also be housed within a radome to offer protection from large aerodynamic loads. An ideal radome should be perfectly transparent to the RF radiation from (or to) the antenna but mechanically strong if they are to provide the necessary protection. These two requirements are usually competing, thus the design of radomes must be compromised [17].

The design of radomes for antennas can be divided into two separate classes, depending on whether the antenna is for airborne or ground-based (or ocean-based) applications. The airborne radome is characterized by smaller size than ground-based radomes because the antennas that can be carried in an aircraft are generally smaller. The airborne radome must be strong enough to form a part of the aircraft structure and usually it is designed to conform to the aerodynamic shape of the aircraft, missile, or space vehicle in which it is to operate. If the antenna scans inside the streamlined radome, the incident angle may be

varied around the normal direction. This will lead to great degradation of antenna performance.

A properly designed radome should distort the antenna pattern as little as possible. The presence of a radome can affect the gain, beamwidth, sidelobe level, beam direction, the voltage standing-wave ratio (VSWR), and antenna noise temperature. Sometimes in tracking radars, the change rate of the beam direction can be very important.

3. PHASED-ARRAY RADAR ANTENNAS

Besides reflectors, phased-array antennas are also important in radar systems. An attractive advantage of the phased-array antenna for radar applications is that it can steer a beam without having to move a large mechanical structure. For example, when a single radar simultaneously carries out the functions of surveillance and tracking, it must pause for an instant to confirm or disprove a possible alert as a surveillance radar, however, it is required to follow several targets by pointing at each of them successively without any loss of time as a tracking radar. In this case, a phased-array antenna is the best choice because it can steer the beams rapidly by means of electronic control.

The first large steerable directive phased-array antenna for the reception of trans-Atlantic shortwave communication was developed and installed by the Bell Telephone Laboratories in the late 1930s. However, it was limited because the beam was scanned by mechanically actuated phase shifters. A major advance in phased-array technology was made in the early 1950s with the replacement of the mechanically actuated phase shifters by electronic phase shifters, from which the scanning in one angular coordinate can be electronically controlled. The introduction of digitally switched phase shifters employing either ferrites or diodes in the early 1960s made a significant improvement in the practice use, in which a phased array could be electronically steered in two orthogonal angular coordinates. With the development of modern computer and solid-state microwave devices, multifunction phased-array antennas have been developed.

Array antennas can take many different forms for various applications. However, they always include some common components. Figure 12 shows a basic schematic of the phased-array antennas. Clearly, a phased-array system contains an element array composed of many similar radiating elements, a power splitter, the phase shifters, the transmitter and receiver, and a central computer. The radiating elements might be dipoles, open-ended waveguides (or small horns), slots cut in waveguide, printed-circuit patches, or any other type of antennas. On its transmission mode, the power splitter divides the energy from the transmitter to the various elements of the array via the phase shifters. Then the phases and amplitudes of the array can be controlled by the computer. Generally, the amplitude characteristic does not vary during scanning except for adaptive and optimum arrays. Therefore, one can adjust the phase and amplitude taper on array by using the phase distribution and the amplitude distribution to meet different uses.

3.1. Basic Characteristics

See ANTENNA ARRAYS for a detailed analysis of phased-array antennas. Here we give only some general characteristics important to the analysis and design of radar antennas.

For a general planar array, when the elements are spaced by a half-wavelength to avoid the generation of grating lobes, the number of the radiating elements N for a pencil beam can be approximated from the broadside beamwidth by [18]

$$N \approx \frac{10000}{\text{HPBW}^2} \text{ or } \text{HPBW} \approx \frac{100}{\sqrt{N}} \quad (17)$$

where HPBW is the 3 dB beamwidth (in degrees) of the antenna pattern. When the beam points in the broadside direction to the aperture, the corresponding antenna gain is

$$G_0 \approx N\pi\eta \quad (18)$$

Figure 12. General structure of a phased array in which the phase shifter driver provides different phases to the array.

where η is the antenna efficiency, which accounts for antenna losses (η_L) and reduction in gain caused by weighting the elements with a nonuniform amplitude distribution (η_a).

When the antenna is scanning to an angle θ_0 , the scanned beamwidth is increased from the broadside beamwidth

$$\text{HPBW}(\theta_0) \approx \frac{\text{HPBW}}{\cos \theta_0} (\theta_0 \neq 90^\circ) \tag{19}$$

whereas the gain of the planar array is reduced to that of the projected aperture:

$$G_0(\theta_0) \approx N\pi\eta \cos \theta_0 \tag{20}$$

These characteristics can provide an easy way to estimate quickly when analyzing and designing array antennas.

3.2. Types of Arrays

The arrays used in radar systems can be classified by such different means as geometry and functions. This subsection will discuss several typical arrays.

3.2.1. Linear Arrays. The linear array generates a fan beam when the phase relationships are such that the radiation is perpendicular to the array. If the radiation is at some other angles, the antenna pattern is a cone-shaped beam. The broadside linear-array antenna may be used where broad coverage in one plane and a narrow beamwidth in the orthogonal plane are required. An active application of linear array is that it can act as the feed for a parabolic cylinder antenna, as discussed earlier.

3.2.2. Planar Arrays. The two-dimensional planar array is capable of steering the beams in two angular coordinates. It is probably the array of most interest in radar applications because of its versatility. Generally, a rectangular aperture can produce a fan-shaped beam, whereas a square or a circular aperture can generate a pencil beam. The array may also be made to produce simultaneously many search and or tracking beams with the same aperture. Most of arrays discussed later will be the planar arrays.

3.2.3. Conformal Arrays. Sometimes, a radar designer is required to place array elements on an arbitrary surface to achieve a directive beam with good sidelobe level and efficiency, which can be easily scanned electronically. For example, on an aircraft, arrays arranged along the nose, on the wings, or on the fuselage would be attractive options. In this case, a conformal array, which conforms to the geometry of a nonplanar surface, should be used [1].

In principle, the array on any surface can be made to radiate a beam in some given direction by applying the proper phase, amplitude, and polarization at each element. In practice, however, it is very difficult to control the beam shape and obtain low sidelobes from an arbitrary surface when the beam is electronically scanned. Further-

more, the mechanisms for feeding the elements and generation of the phase shifter command are also more complicated than those of a planar array. Therefore, the application of conformal array is possible only for some simple shapes like cylinder and cones.

Most of the work on conformal arrays has been with the cylinder because it has a geometry suitable for antennas that scan 360° in azimuth. Although it is of a relatively simple shape compared with others, the properties of the cylindrical array are not as suitable as those of planar array. In the cylindrical array, the radiation pattern cannot be separated into an element factor and an array factor as they can in the planar array. Considering the additional difficulties in the practical control, the conformal arrays are not widely used in the radar systems.

3.2.4. Thinned Arrays. Most array antennas have equal spacings between adjacent elements. In order to obtain a given beamwidth with considerably fewer elements, a thinned array has sometimes been considered. Generally, the shape of the main beam has little distortion after thinning. However, the average sidelobes are degraded in proportion to the number of elements removed. Figure 13 shows an example of thinned arrays, in which 77.5% of the elements are randomly removed from a regular grid [19].

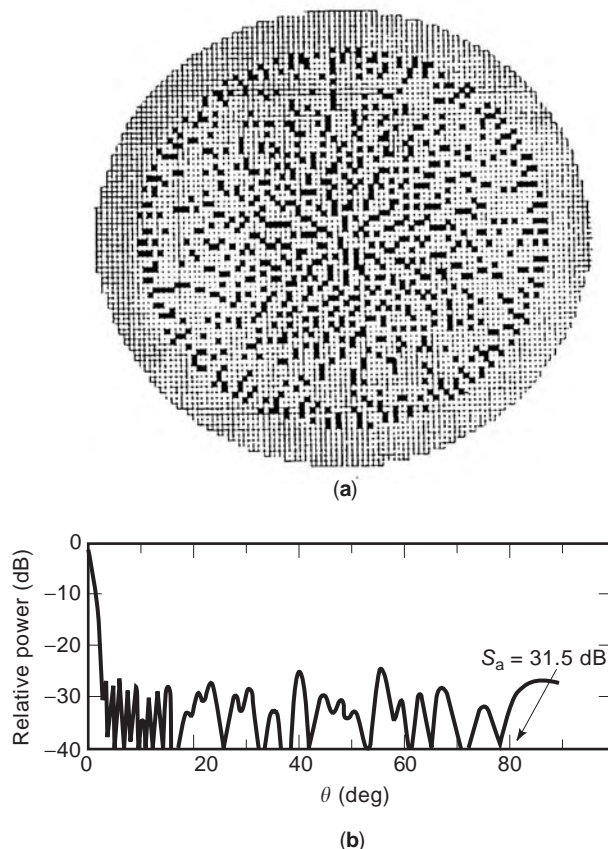

Figure 13. (a) Thinned array with a 4000-element grid containing 900 elements; (b) typical pattern for thinned array in which S_A is the average sidelobe level. (From Wiley [15, Figs. 5 and 6] courtesy of Bendix Radio Div., Bendix Corporation.)

Then the gain, which is caused by the actual element number, will drop by 6.5 dB, while almost 77.5% of the power is delivered to the sidelobes because the main beam is nearly unchanged.

Therefore, the design of a thinned array consists of selecting the size of the aperture to give the desired beamwidth, selecting the number of actual elements to give the desired gain, and arranging the element distribution to obtain some required properties of the sidelobes.

The thinned arrays have seen only limited applications in radar system because of the reduction in gain and the increases in sidelobes. Instead of thinning elements, the number of phase shifters can also be thinned, in which some of the phase shifters in the array can be used to adjust the phase of more than one element. A 50% saving of the phase shifters might be possible [20].

3.2.5. Phase-Scan Arrays. The beam of an antenna points to the direction perpendicular to the phase front. In phase-scan arrays, the phase front is adjusted by controlling the phase of each radiating element to steer the beam, as shown in Fig. 14a. The phase shifters are electronically actuated to perform rapid scanning and are adjusted in phase to a value between 0 and 2π rad. If the spacing between two adjacent elements is S , the incremental phase shift ψ will be $\psi = (2\pi/\lambda)S \sin \theta_0$, in which θ_0 is the scan angle. Because the phase shifters have phase shift that is virtually independent of frequency, the scan angle θ_0 is frequency-dependent.

3.2.6. Time-Delay-Scan Arrays. Phase scanning was seen to be frequency-sensitive. Time-delay scanning provides a way that is independent of frequency. Instead of the phase shifters, delay lines are used in the time-delay-scan arrays, as illustrated in Fig. 14b. For the spacing distance between two adjacent elements S , the incremental time delay from element to element is $t = (S/c) \sin \theta_0$, in which c is the velocity of propagation of wave and θ_0 is

again the scan angle. The time-delay circuits accompanied by all radiating elements are normally too cumbersome. A reasonable compromise solution is to share one time-delay network by a group of elements in which each element has its own phase shifter. However, this will cause a grating lobe problem.

3.2.7. Frequency-Scan Arrays. A change in frequency of an EM signal propagating along a transmission line produces a change in phase. This provides a simple way for obtaining the electronic phase shift, as shown in Fig. 14c. In this case, the incremental phase shift is

$$\psi = (2\pi/\lambda)l = (2\pi/\lambda)S \sin \theta_0 + 2\pi m \quad (21)$$

in which l is the length of line connecting adjacent elements. When the beam points broadside ($\theta_0 = 0$), Eq. (21) yields $m = l/\lambda_0$, where λ_0 is the wavelength corresponding to the beam position at broadside. Then the direction of beam pointing can be obtained from Eq. (21):

$$\sin \theta_0 = \frac{l}{S} \left(1 - \frac{\lambda}{\lambda_0} \right) \quad (22)$$

Comparing with other ways, the frequency-scanning system is relatively inexpensive and easy to implement. Frequency-scan arrays have been developed and used to provide elevation-angle scanning. Combined with the mechanical horizontal rotation, it served as 3D radars in the past.

3.2.8. Multiple-Beam-Forming Arrays. One of the properties of the phased array is the ability to generate multiple independent beams simultaneously from a single aperture. In principle, an N -element array can generate N independent beams. Multiple beams allow parallel operation and can obtain a higher data rate than a single beam. The multiple beams may be fixed in space, steered

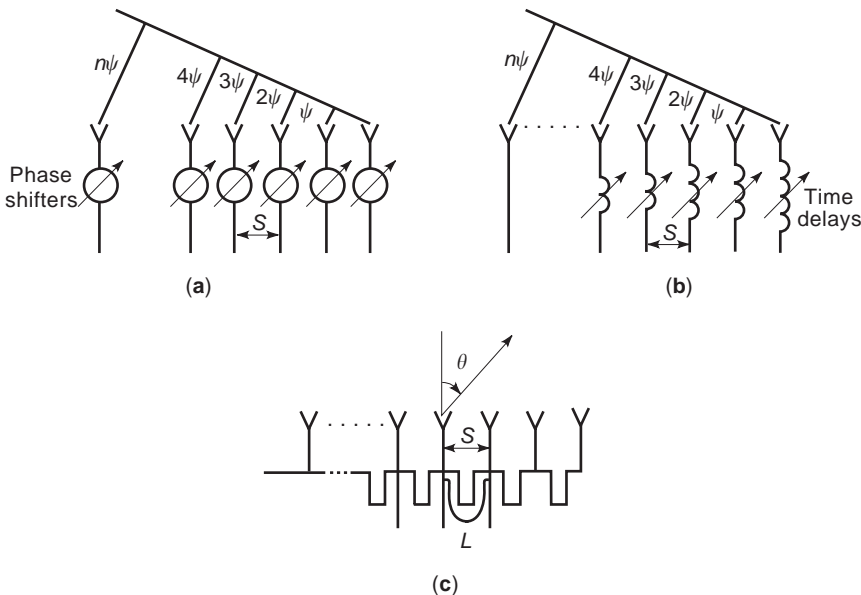

Figure 14. Scanning of arrays: (a) phase scan; (b) time-delay scan; (c) frequency scan.

independently, or steered as a group. In some applications, multiple beams are generated on receive and connected to separate receivers, whereas only one wide radiation pattern is needed on transmit so that it can cover all the received beams. Such multibeam systems have found application with mechanical rotation for 3D coverage.

3.2.9. Low-Sidelobe Arrays. A low sidelobe level is one of the most important requirements for the radar antennas, especially for military radars that may be threatened by the jamming. Therefore, the low sidelobe level has been and will be of great interests to radar designers. By modern technology, an ultralow sidelobe has been achieved in the Airborne Warning and Control System (AWACS) radar, which now supports sidelobe levels of more than 50 dB below the mainbeam peak [21]. However, as mentioned earlier, the low sidelobe and high gain are competing requirements. Thus the cost to achieve low sidelobe is a reduction in gain and an increase in beamwidth. Considering the practical implementation, the low sidelobes also require a high-tolerance control and a good environment free from obstructions that could increase the sidelobes so low-sidelobe antennas are usually expensive. In spite of these drawbacks, the trend toward low-sidelobe arrays has accelerated because low sidelobes provide an excellent deterrent to electronic countermeasures (ECM).

From the aperture theory, antenna sidelobes are related to the aperture amplitude distribution. For phased arrays, the amplitude taper is generally fixed and does not change. However, the amplitude of each radiating element can be controlled individually by the computer, which makes it possible to achieve very low sidelobes.

The relation between the antenna pattern and the aperture illumination has been studied extensively in many literatures. It has been shown that the far-field pattern is just the Fourier transform of the aperture distribution. Some typical illumination functions and their corresponding gains, sidelobes, and beamwidths can be found in Refs. 5 and 18. For low-sidelobe arrays, the Taylor illumination for the sum patterns and the Bayliss illumination, a derivative form of the Taylor illumination, for the difference patterns are usually chosen because they can provide low sidelobes at a minimum loss in gain. Note that the sidelobes predicted by the aperture illuminations are suitable for perfect phase and amplitude distributions (error-free). In practice, aperture illuminations must be chosen to provide peak sidelobes below the requirements to allow for errors. The effect of errors on the design will be mentioned next.

3.3. Practical Considerations

The array theory gives only the theoretical analysis and design of the phased arrays. For practical use in radar systems, a lot of details must be considered. In this subsection, some important considerations are addressed.

3.3.1. Phase Shifters. As already stated, there are three basic techniques to steer the beam electronically: frequency scanning, time-delay scanning, and phase scanning with phase shifters. In practice, the use of phase shifters

is the most popular technique, but many other techniques have been developed for a variety of phase shifters [22]. Generally, the phase shifters can be classified into two categories: reciprocal and nonreciprocal. For reciprocal phase shifters, the phase change does not depend on the direction of propagation. Therefore, it is not needed to switch the phase states between transmit and receive if the reciprocal phase shifters are used. For a nonreciprocal phase shifter, however, it is necessary to change the phase states between transmit and receive. Typically, it takes a few microseconds to switch the nonreciprocal phase shifters. During this period, the radar cannot detect targets.

A perfect phase shifter could change its phase rapidly; handle high power; require control signals of little power; be of low loss, light weight, small size, and reasonable cost; and have a long life. But in practice, no one device is universal enough to meet all the requirements. Various phase shifters possess these properties in varying degrees. Presently, three types of phase shifters are used in the phased-array antennas: the diode phasers, which are all reciprocal; the nonreciprocal ferrite phasers; and the reciprocal ferrite phasers. Each of the three types has its own advantage. The choice of phase shifters is highly dependent on the radar requirements.

3.3.2. Array Elements and Matching. Almost any type of radiating antenna element can be considered for an array antenna. In practice, the dipole, open-ended waveguide (or small horn) and slotted waveguide have found wide applications. Detailed descriptions of these antennas have been investigated in the standard textbooks [1,5]. However, note that the properties of a radiating element in an array is significantly different from its properties when in free space. For example, the radiation resistance of a half-wavelength dipole in free space is $73\ \Omega$, but when it is in an infinite array with half-wavelength spacing and a back screen of quarter-wave separation, it will be $153\ \Omega$ when the beam is broadside. The impedance also varies with scan angles.

The change of impedance with scan angle makes the matching of an array antenna difficult. There are conditions where an antenna that is well matched at broadside may have some angles at which most of the power is reflected. Unlike a conventional antenna, the mismatch of array antennas will affect both the level of the radiated power and the shape of the antenna pattern.

3.3.3. Mutual Coupling. If two radiating elements are widely separated, the energy coupled between them is small, and the influence of one to the other on the current excitation and pattern can be negligible. However, when the elements are placed closer, their coupling will increase. Generally, the strength of the coupling in a phased array is related to the distance between elements, the pattern of the elements, and the structure of the array. For example, the radiation pattern of a dipole has a null at $\theta = \pm 90^\circ$ and a peak value at $\theta = 0^\circ$. Thus, the dipoles in a straight line are loosely coupled, whereas the dipoles parallel to each other have a strong coupling.

For a phased array, the effect of coupling between elements is focused mainly on the pattern and impedance of

the element, which are usually called the active element pattern and the active element impedance. The exact analysis of coupling in practical arrays is rather complicated. A convenient way is to assume that the array is infinite in extent and has a uniform amplitude distribution and a linear phase taper from element to element. Under such an assumption, every element in the array has the same environment; thereby a significant simplification in the calculations can be made. It has been shown that the infinite-array model has a good prediction to the actual arrays. Even for a modest array that has fewer than 100 elements, the predicted results can also give reasonable agreement [23].

3.3.4. Errors in Arrays. As indicated in Section 3.2.9, the errors in the amplitude and phase of the current at individual elements of the array may cause distortion of the radiation pattern. Additional factors of the error include the missing or inoperative elements, rotation or translation of an element from its correct position, and variations in the individual element patterns. These errors can result in a decrease in gain, increase in sidelobes, and shift in the direction of the main beam.

When errors occur in the phase and amplitude of the aperture, the energy will be removed from the main beam and distributed to the sidelobes. If the errors are purely random, they will produce random effects on the main beam and all sidelobes. When the errors are correlated, the sidelobe energy will be lumped at discrete locations in the far field. Usually, the correlated errors provide higher sidelobes than do the random errors, but they are located at some certain directions only. Both of the correlated and random errors should be considered in the practical design of phased arrays [18,24].

3.4. Applications

In many cases, phased-array antennas have been of considerable interest in the radar systems because they have different properties from those of reflector antennas. Hence, a number of phased-array radar systems have been built for different uses [18,25]. Examples include the AN/SPS-33 radar for the purpose as aircraft surveillance from onboard ship; the AN/FPS-85 for satellite surveillance; the PAR and MSR for ballistic missile defense; the AN/SPY-1 and PATRIOT for air defense; the EAR (Electronically Agile Radar) for airborne bomber; the AN/TPN-19 and AN/TPS-32 used in aircraft landing systems; the AWACS and AN/TPS-70 for airborne warning and control systems; the MESAR as a multifunction electronically scanned adaptive radar; the AN/TPQ-37 Firefinder radar; the PAVE PAWS for providing early warning of ballistic missiles and performing satellite tracking; the COBRA DANE for tracking of ballistic missile; and the COBRA JUDY for collecting data on foreign ballistic missile tests [18,25].

Although the array antennas have many unique characteristics that make them candidates for use in radar systems, they are expensive. As technology advances, the costs can be reduced, particularly in the areas of phase shifters and drivers. In the meantime, the high demand for better performance with lower sidelobes and wider bandwidth

makes the costs high. In the future, the great potential for cost reduction may be the application of solid-state systems with a transmit/receive module at each element.

RADAR APPLICATIONS

GEORGE A. TSIHRINTZIS
 University of Piraeus
 Piraeus, Greece

1. INTRODUCTION

Radar (*radio detection and ranging*) systems attempt to infer information about remotely located objects from reflections of deliberately generated electromagnetic waves at radio frequencies. Typically, a radar system operates in the environment depicted in Fig. 1 and the information sought is *detection* of the presence of target objects in the midst of *clutter*, *recognition* (classification) of targets, and *estimation* of target parameters such as *range* (distance from the radar antenna), *bearing* (azimuth and

elevation), *orientation*, *velocity*, *acceleration*, or *backscattering cross section* (reflectivity) distribution.

Early radar systems could only scan the environment, to detect an aircraft when it appeared in their beam and to measure its range and bearing. The range resolution cell was determined by the length of the unmodulated transmitted pulse and was much larger than the aircraft. Thus, it was reasonable to model the aircraft as a point target and the system interference as white Gaussian thermal noise. Subsequently, the detection problem was reduced to that of detecting a point target in white Gaussian noise. Modern radar systems, however, are expected to perform the much more sophisticated tasks stated above for multiple targets simultaneously, at the finest possible target *resolution* and with the highest possible *accuracy*. Additionally, the domain of utilization of radar techniques has expanded beyond the traditional aircraft detection and ranging to applications such as estimation of the parameter (range, velocity, acceleration, and backscattering cross section) distribution of *spread* targets, aerial imaging, and ground or foliage penetrating radar imaging. To achieve their expanded tasks, modern radar systems combine high-quality hardware with sophisticated signal design and processing algorithm development and implementation based on statistical descriptions of both the target characteristics and the clutter distributions.

Figure 1. Typical environment in which a radar system needs to operate.

Applications of modern radar can be found in the military, the civilian, and the scientific regimes. Military applications include search and surveillance of enemy targets; navigation, control, and guidance of weapons; battlefield surveillance; and antiaircraft fire control. Among civilian applications, prominent are those in air, water, and land transportation, including aircraft navigation; collision avoidance with both other aircraft and terrain obstacles; detection and avoidance of weather disturbances and clean-air turbulence; altimetry; air traffic control; shore-based ship navigation; collision avoidance for ships and small boats; harbor and waterway traffic control; collision avoidance of land vehicles; tracking of vehicles; and traffic law enforcement, as well as space applications in detection and tracking of satellites and control of rendezvous and docking of space vehicles. Finally, scientific applications include remote sensing of Earth's environment from aircraft and satellites for planetary observation; weather radar for study and monitoring of precipitation, clouds, and major weather disturbances; ground mapping; ground-penetrating radar for detection of buried objects; foliage-penetrating radar for detection of hidden targets; and high-resolution imaging of objects and terrain via synthetic aperture imaging radars.

2. RADAR TARGET MEASUREMENT ELEMENTS

2.1. Point-Target Measurements

Assume that the radar antenna transmits the narrowband pulse

$$s_T(t) = u(t)e^{i2\pi f_0 t}, \quad 0 < t < T \tag{1}$$

where f_0 is the carrier frequency at which the radar operates and $u(t)$ is a pulse of duration T and bandwidth B smaller than the carrier frequency. Typical transmitted radar pulses are illustrated in Fig. 2. Specifically, Figs. 2a and 2c illustrate square pulses of duration $T = 10^{-2}$ ms modulating the amplitude of sinusoids of carrier frequency $f_0 = 0.25$ MHz and $f_0 = 1$ MHz, respectively. In Fig. 2d, a sinusoid of carrier frequency $f_0 = 1$ MHz is amplitude-modulated by a Gaussian rather than a square pulse of duration $T = 10^{-2}$ ms. Finally, in Fig. 2b, a sinusoid of carrier frequency $f_0 = 0.25$ MHz is frequency-modulated by a square pulse of duration $T = 10^{-2}$ ms with a rate of change of transmitted frequency $\beta = 1.5 \times 10^2 \text{ ms}^{-2}$. Signals, such as the linear frequency-modulated sinusoid in Fig. 2b, are also referred to as *chirps* and are used to increase the range resolution of the radar system.

The pulse illuminates a point target and is reflected back toward the antenna. Let Δ be the round-trip delay between the time at which the rising edge of the pulse leaves the radar antenna, is reflected by the target, and is received back at the antenna. Since the target is moving, this delay will be a function $\Delta(t)$ of time. Ignoring amplitude attenuation and constant phase shifts due to reflection, the received pulse will be

$$s_R(t) = u[t - D(t)]e^{i2\pi f_0 [t - \Delta(t)]} \tag{2}$$

The information about the target motion is contained in the round-trip delay $\Delta(t)$ as a function of time and the distortion it causes on the received pulse $s_R(t)$. The delay $\Delta(t)$ depends on the target position at the instant of reflection, which for a signal received at time t , occurs at

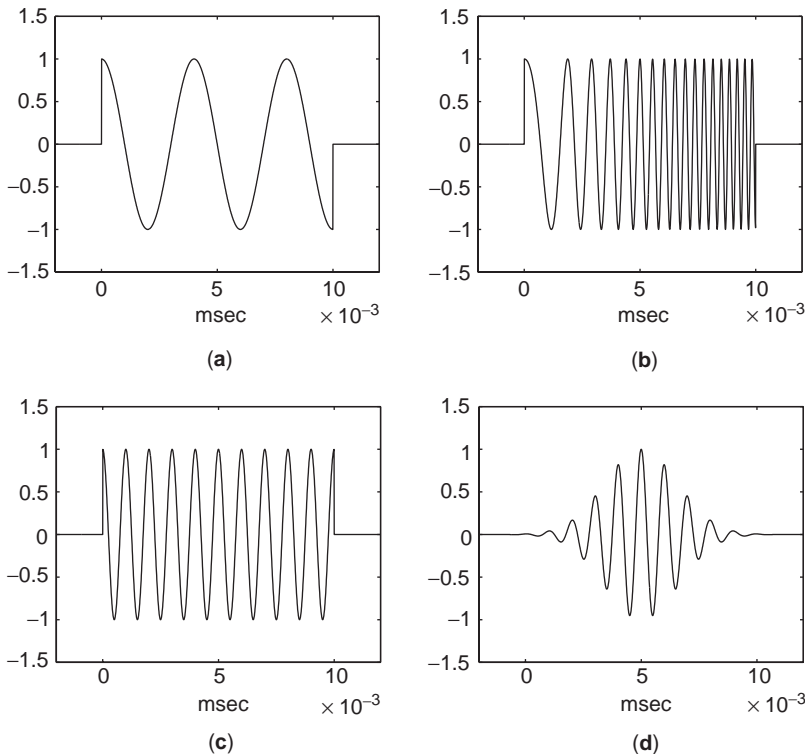

Figure 2. Typical transmitted radar pulses of various modulation formats.

time $t - [\Delta t/2]$. Thus

$$\Delta(t) = \frac{2}{c} R \left[t - \frac{\Delta(t)}{2} \right] \quad (3)$$

where $R(t)$ is the target *range*, that is, the distance from the radar antenna to the target, as a function of time.

If the target moves slowly enough for the delay $\Delta(t)$ to be approximately constant within the duration T of the illuminating pulse, then the target can be regarded as stationary. However, it is often the case that the target moves very fast in comparison with the pulse duration and different instants of the pulse are differently delayed. In the general case, the relation between the target motion, the round-trip delay, and the received pulse is too complicated to be tractable. Several simplifications can lead, however, to tractable mathematical relations. Assume that the delay $\Delta(t)$ is a smooth enough time function to be expandable into a Taylor series around the time instant $t_0 = \Delta(t=0) \equiv \Delta_0$ at which the leading pulse edge is received back at the receiver:

$$\begin{aligned} \Delta(t) = & \Delta_0 + \Delta_0^{(1)}(t - t_0) + \frac{\Delta_0^{(2)}}{2}(t - t_0)^2 \\ & + \frac{\Delta_0^{(3)}}{6}(t - t_0)^3 + \dots \end{aligned} \quad (4)$$

where $\Delta_0^{(k)} = (d^k \Delta / dt^k)(t_0)$ is the k^{th} derivative of the round-trip delay evaluated at the time instant t_0 .

Define now the target parameters of interest:

$$\begin{aligned} t_0 = \Delta_0 & \quad \text{delay coefficient} \\ v_0 = -f_0 \Delta_0^{(1)} & \quad \text{Doppler (velocity) coefficient} \\ \gamma_0 = -f_0 \frac{\Delta_0^{(2)}}{2} & \quad \text{acceleration coefficient} \\ \varepsilon_0 = -f_0 \frac{\Delta_0^{(3)}}{6} & \quad \text{hyperacceleration coefficient} \end{aligned}$$

and use Eqs. (3) and (4) to relate them to the target range and its derivatives. Algebraic manipulation gives the target parameters as the following functions of the range $R_0 = R(t_0/2)$ and its derivatives $R_0^{(k)} = (d^k / dt^k) R(t_0/2)$ at time $t_0/2$:

$$t_0 = \frac{2R_0}{c} \quad (5)$$

$$v_0 \approx -f_0 \frac{2R_0^{(1)}}{c} \quad (6)$$

$$\gamma_0 \approx -f_0 \frac{R_0^{(2)}}{c} \quad (7)$$

$$\varepsilon_0 \approx -f_0 \left[\frac{R_0^{(3)}}{3c} - \left(\frac{R_0^{(2)}}{c} \right)^2 \right] \quad (8)$$

The approximations in Eqs. (6)–(8) are valid simplifications for the practical cases of $R_0^{(1)} \ll c$ of the exact expressions in Ref. 16 (p. 59).

From Eq. (8), it is seen that even the simplified expression for the target hyperacceleration ε_0 is still a complicated function of target range derivatives. Higher order terms in Eq. (4) have coefficients that are nonmanageable functions of target range derivatives. Fortunately, practical radar systems need deal only with targets moving sufficiently smoothly for only the delay and Doppler and, occasionally, the acceleration coefficient (and, rather rarely, the hyperacceleration coefficient) to be significant in the expansion in Eq. (4). Additionally, only the delay term t_0 is significant in the complex envelope $u[t - D(t)]$, while the higher order terms affect only the phase in the exponential in Eq. (2); that is, the pulse received by the radar from a single target illuminated with the pulse of Eq. (1) is

$$s_R(t) \approx u(t - t_0) e^{i2\pi[f_0(t-t_0) + v_0(t-t_0) + \gamma_0(t-t_0)^2 + \varepsilon_0(t-t_0)^3]} \quad (9)$$

where t_0 , v_0 , γ_0 , and ε_0 are the target delay, Doppler (velocity), acceleration, and hyperacceleration parameters. Typical return pulses are shown in Fig. 3. The pulses are computed from Eq. (9) for various values of the parameters t_0 , v_0 , γ_0 , and ε_0 , assuming that the transmitted pulse was the pulse in Fig. 2a.

2.2. Matched-Filter Response to Received Pulse

The received pulse is processed through a bank of filters, each matched to a different set of values of the target parameters. The filter matched to the set of parameter values $(\tau, v, \gamma, \varepsilon)$ has impulse response

$$\begin{aligned} h(t; \tau, v, \gamma, \varepsilon) = & u^*(-t - \tau) e^{-i2\pi[f_0(-t-\tau) + v(-t-\tau) + \gamma(-t-\tau)^2 + \varepsilon(-t-\tau)^3]} \\ = & u^*(-t - \tau) e^{i2\pi[f_0(t+\tau) + v(t+\tau) - \gamma(t+\tau)^2 + \varepsilon(t+\tau)^3]} \end{aligned} \quad (10)$$

Assume now that the input to this matched filter is the received pulse in Eq. (9), multiplied by an unknown complex-valued amplitude $Ae^{i\delta}$ and corrupted by additive noise: $Ae^{i\delta} s_R(t) + n(t)$. The output of the filter will be

$$\begin{aligned} \eta_{\tau, v, \gamma, \varepsilon}(t) = & \int_0^{T_0} [Ae^{i\delta} s_R(\xi) + n(\xi)] h(t - \xi) d\xi \\ = & Ae^{i\delta} e^{i2\pi f_0(t+\tau-t_0)} \chi(t + \tau - t_0, v - v_0, \gamma - \gamma_0, \varepsilon - \varepsilon_0) \\ & + \int_0^{T_0} n(\xi) h(t - \xi) d\xi \end{aligned} \quad (11)$$

where T_0 is the time interval during which the radar is in receive mode (e.g., the time interval between two successive pulse transmissions). Equation (11) consists of two terms, a term due to noise and a signal term containing the *ambiguity function*

$$\begin{aligned} \chi(\tau, v, \gamma, \varepsilon) = & \int_{-\infty}^{\infty} u(\xi) u^* \\ & \times (\xi - \tau) e^{-i2\pi[v(\xi-\tau) + \gamma(\xi-\tau)^2 + \varepsilon(\xi-\tau)^3]} d\xi \end{aligned} \quad (12)$$

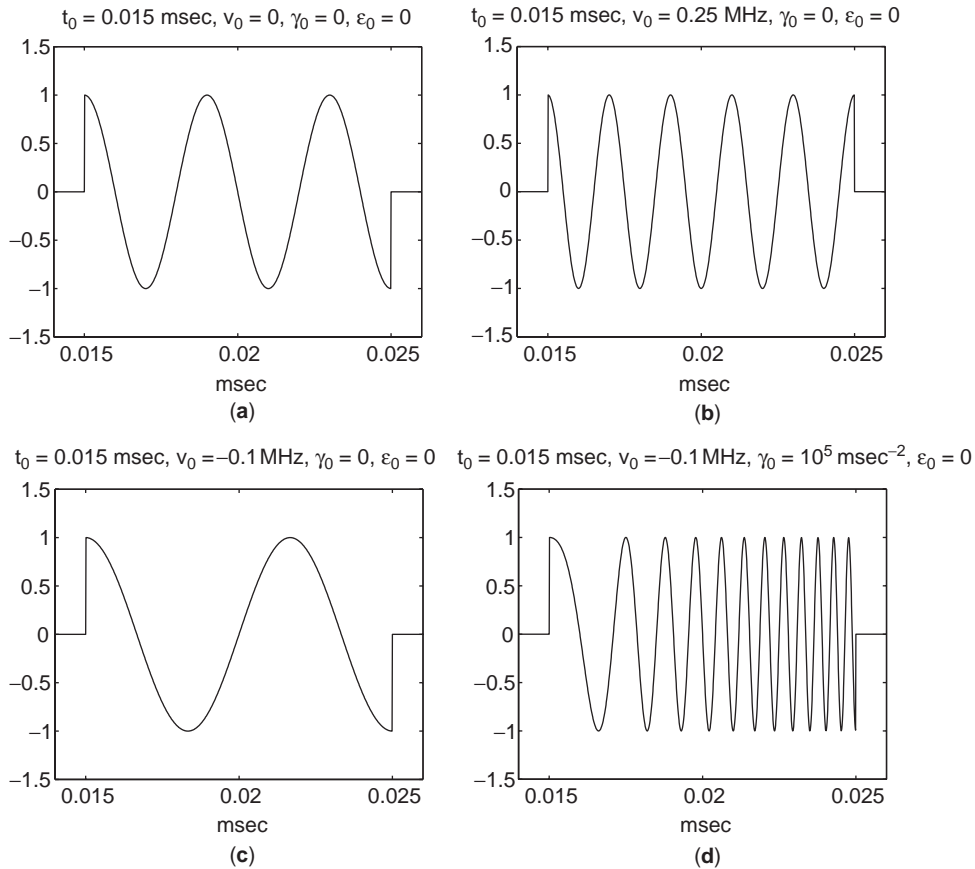

Figure 3. Typical radar return pulses. The pulses are computed from Eq. (9) for various values of the delay, Doppler, acceleration, and hyperacceleration parameters, assuming that the transmitted pulse was the pulse in Fig. 2a.

Clearly, the magnitude of the signal term at any time t is maximized if the filter parameters are selected equal to the target parameters, that is, if $\tau = t_0$, $v = v_0$, $\gamma = \gamma_0$, and $\varepsilon = \varepsilon_0$. Target *detection* can be performed by monitoring the matched-filter outputs at each instant t and examining whether they exceed a preset threshold. If the threshold is exceeded, then target detection is declared. If a target is thus detected, its parameters are subsequently *estimated* as the parameters of the matched filter that produces maximum output. A simplification to this target detection/estimation rule can be achieved by noticing that the matched-filter delay τ is not significant in that it corresponds only to a shift in the time instant of occurrence of the maximum of the matched-filter output. Indeed, a change in the round-trip delay t_0 changes only the time at which the maximum occurs. Thus, only a bank of matched filters need to be used, in which the delay τ is fixed to zero and the target range is estimated from the time instant of occurrence of the maximum of the matched-filter output. If, however, the other target parameters are significant, an entire bank of filters need to be used, with each filter matched to different target parameter values. In summary, the criterion for declaring target detection is

$$\max_{t,v,\gamma,\varepsilon} |\eta(t)| \geq \text{threshold} \quad (13)$$

and the set of values $(\hat{t}, \hat{v}, \hat{\gamma}, \hat{\varepsilon})$, which provide the maximum constitute the target parameter estimates. The threshold is set so as to keep the probability of a *false alarm* below a specified maximum tolerance. Since the complex amplitude $Ae^{i\delta}$ is unknown and varying, *constant false-alarm rate* (CFAR) techniques need to be utilized to adaptively set the threshold. Figure 4 depicts typical CFAR *receiver operating characteristics*, which have been experimentally computed for three different foliage-penetrating radar receivers (reprinted with permission from Ref. 10).

2.3. Distributed-Target Measurements

The theory of single-target measurements needs to be modified and extended if the radar is to operate at a resolution that is sufficiently high for the *spread* of one or more target parameters to exceed the corresponding resolution bin. Examples of such targets include the terrain, vegetation foliage, extended manmade objects such as buildings with more than one smooth surfaces, or even aircraft when the resolution bin is significantly smaller than its typical dimensions. In these cases, the pulse received at the radar antenna can be considered as the superposition of a small or large or even infinite number of reflections from individual scattering centers on the target.

Figure 4. Typical CFAR radar receiver operating characteristics that have been computed experimentally for three different foliage-penetrating radar receivers (reprinted with permission from Ref. 10, © 1999 IEEE).

Serious difficulties in extending the theory of single-to multiple- (distributed-) target measurements arise if the scattering centers of the target are not stationary during illumination with the radar pulse or new ones emerge or several disappear as a result of target motion. Additionally, the target may be dispersive; that is, its significant scattering centers may vary with frequency, making the target behavior rather complex. For the theory of distributed-target measurements to remain tractable, the assumption needs to be made that the target is represented by a possibly infinite, yet fixed, set of scattering centers. Additionally, no dispersion can be allowed; that is, the scattering centers need to be frequency-independent.

With these assumptions in mind, consider a target consisting of N scattering centers illuminated with the pulse of Eq. (1). The reflected pulse measured at the radar antenna will be

$$s_R(t) = \sum_{n=1}^N A_n e^{i\delta_n} u(t - t_n) \times e^{2\pi i [f_0(t-t_n) + v_n(t-t_n) + \gamma_n(t-t_n)^2 + \varepsilon_n(t-t_n)^3]} \quad (14)$$

producing the signal part at the output of the matched filter of Eq. (10)

$$\eta_{\tau,v,\gamma,\varepsilon}(t) = \sum_{n=1}^N A_n e^{i\delta_n} \chi(t + \tau - t_n, v - v_n, \gamma - \gamma_n, \varepsilon - \varepsilon_n) \quad (15)$$

Under the assumptions of stationarity of the target scattering centers during illumination with the radar pulse and their independence, cross-terms in the signal part of the magnitude square of the matched-filter output will be

relatively small. Thus

$$|\eta_{\tau,v,\gamma,\varepsilon}(t)|^2 \approx \sum_{n=1}^N |A_n|^2 |\chi(t + \tau - t_n, v - v_n, \gamma - \gamma_n, \varepsilon - \varepsilon_n)|^2 \quad (16)$$

Considering the limit of $N \rightarrow \infty$ densely packed scattering centers, the magnitude square of the matched-filter output becomes

$$|\eta_{\tau,v,\gamma,\varepsilon}(t)|^2 = \iiint\limits_{v-v_0, \gamma-\gamma_0, \varepsilon-\varepsilon_0} |A(t_0, v_0, \gamma_0, \varepsilon_0)|^2 |\chi(t + \tau - t_0, v - v_0, \gamma - \gamma_0, \varepsilon - \varepsilon_0)|^2 dt_0 dv_0 d\gamma_0 d\varepsilon_0 \quad (17)$$

In Eq. (17), $|A(t_0, v_0, \gamma_0, \varepsilon_0)|^2$ is the target *backscattering cross-section distribution* as a function of the delay, Doppler (velocity), acceleration, and hyperacceleration parameters. Clearly, if the magnitude square of the ambiguity function consists of a single central spike with very narrow width, that is, if

$$|\chi|^2 \approx \delta(t + \tau - t_0, v - v_0, \gamma - \gamma_0, \varepsilon - \varepsilon_0) \quad (18)$$

then

$$|\eta_{\tau,v,\gamma,\varepsilon}(t)|^2 \approx |A(t + \tau, v, \gamma, \varepsilon)|^2 \quad (19)$$

In words, the matched-filter response represents (and measures) the target backscattering cross section for the particular values of delay, Doppler, acceleration, and hyperacceleration to which the filter is matched. Consequently, a bank of matched filters, each adjusted to a different delay, Doppler, acceleration, and hyperacceleration, yields the entire target cross-section distribution. A simplification can be obtained by considering only matched filters corresponding to delay $\tau=0$ in the bank and utilizing the entire matched-filter output for parameter distribution estimation.

3. SEARCH (SURVEILLANCE OR ACQUISITION), TRACKING, AND NAVIGATION RADAR

3.1. Search Radar

A *search* (also known as *surveillance* or *acquisition*) radar uses an efficient scan pattern to cover an angular sector with a narrow pencil beam in order to detect the presence of a suspected target. Typical scan patterns include the *helical* (Fig. 5a), the *Palmer* (Fig. 5b), the *spiral* (Fig. 5c), the *raster* (or *TV*) (Fig. 5d), and the *nodding* (Fig. 5e) patterns. In the *helical* pattern, the beam is continuously rotated in azimuth while it is simultaneously raised or lowered in elevation. The *Palmer* pattern consists of a rapid circular scan about the antenna axis, combined with a linear movement of the axis of rotation, and is suited to a search area which is larger in one dimension than the other. The *spiral* scan covers an angular search volume with circular symmetry. Both the Palmer and the spiral scans need to vary the scanning speed during the scan cycle for all parts of the scan volume to receive the same

Figure 5. Depiction of the helical (a), Palmer (b), spiral (c), raster (d), and nodding (e) scan patterns of a surveillance radar.

energy. The *raster* scan is produced by oscillating the antenna beam fast in azimuth and slowly in elevation, while the *nodding* scan is produced by oscillating the antenna fast in elevation and slowly in azimuth. Both

the raster and the nodding scans cover a rectangular area, but can also be used to obtain hemispherical coverage. Hemispherical coverage can also be obtained by the helical pattern.

3.2. Tracking Radar

A *tracking* radar measures the coordinates of a target found by a search radar and provides data that can be used to determine the target path and predict its future position. All or part of the available data (range, elevation and azimuth angle, Doppler frequency shift, acceleration, and hyperacceleration) may be used in predicting future target position. Correspondingly, the radar may track in range, in angle, in Doppler, in acceleration, in hyperacceleration, or in any combination of those. Tracking radars either supply continuous tracking data on a particular target (*continuous tracking radar*) or supply sample data on one or more targets (*track-while-scan*) radar. The target parameters in a continuous tracking radar are tracked by a servocontrol loop activated by an error signal generated at the radar receiver. The information available from a tracking radar can either be displayed on a cathode-ray-tube (CRT) display for action by a human operator, or may be supplied to a digital computer and automatically processed to determine the target path and predict its probable future course. The latter is usually called *automatic detection and track* mode or *integrated automatic detection and track* mode when the outputs from more than one radars are automatically combined.

3.2.1. Sequential Lobing Radar. The difference between the target angular position and a reference direction, usually the antenna axis, is the *angular error*. The tracking radar attempts to position its antenna to make the tracking error zero and, thus, locate the target along the reference direction. One method used to obtain the direction and the magnitude of the angular error in one coordinate is to alternately switch the antenna beam between two positions. This is called *lobe switching*, or *sequential switching*, or *sequential lobing*. The difference in amplitude between the voltages in the two switched positions is a measure of the angular displacement of the target from the switching axis. The sign of the difference determines the direction that the antenna must be moved in order to align the switching axis with the direction of the target. Two additional positions are needed to obtain the angular error in the orthogonal coordinate. Thus, a two-dimensional sequentially lobing radar might consist of a cluster of four feed horns illuminating a single antenna, arranged so that the right-left up-down sectors are covered by successive antenna positions. Both transmission and reception are accomplished at each position.

3.2.2. Conical Scan Radar. Conical scan tracking radar uses continuous rotation of an offset antenna beam rather than discontinuous stepping between four discrete positions. The angle between the rotation and the antenna axes is called the *squint angle*. The echo signal is modulated at the frequency of the beam rotation. The phase of the modulation depends on the angle between the target and the rotation axis and can be used to locate the target and continuously position the rotation axis on it.

3.2.3. Monopulse Tracking Radar. The sequential lobing and conical scan tracking radars require a train of echo

pulses in order to extract the angular error signal. This echo train must contain no amplitude modulation components other than the modulation produced by the scanning, otherwise the tracking accuracy will be degraded. On the other hand, pulse-to-pulse amplitude modulations have no effect on tracking accuracy if the angular measurement is based on a single pulse rather than several. If two or more antenna beams are used simultaneously, it is possible to extract angular error information from a single pulse from the relative phase or the relative amplitude of the echo signal received in each beam. Tracking radars that derive angular error information from a single pulse are known as *simultaneous lobing* or *monopulse* radars. An example of a simultaneous lobing technique is *amplitude comparison monopulse*, in which the echoes received from two offset antenna beams are combined so that both the sum and the difference signals are obtained simultaneously. The sum signal provides range information, while the difference signal provides angular error information in one angular direction.

3.2.4. Track-While-Scan Radar. A search radar can obtain the track of a target by marking the coordinates of the target from scan to scan. Such a radar is called *track-while-scan* radar and either requires a human monitor to manually mark the target path or uses a digital computer to perform *automatic detection and tracking*. The automatic detection is achieved by quantization of the range into intervals equal to the range resolution. At each range bin, the detector integrates the number of pulses expected to be returned from a target as the antenna scans past and compares them with a threshold to indicate the presence or absence of a target. When a new detection is received, an attempt is first made to associate it with an existing track. When the detection is declared independent of existing tracks, the radar attempts to make a smooth estimate of the target's present position and velocity, as well as a predicted position and velocity. One method to achieve this is to use either the so-called α - β tracker or a Kalman filter that utilizes a dynamic model for the trajectory of a maneuvering target and the disturbance or uncertainty of the trajectory.

3.3. Navigation Radar

Navigation radar is used to provide the necessary data for piloting an aircraft from one position to another without any need for navigation information transmitted to the aircraft from a ground station. A self-contained aircraft navigation system utilizes a continuous-wave Doppler radar to measure the drift angle and true speed of the aircraft relative to Earth. The drift angle is the angle between the centerline (heading) of the aircraft and the horizontal direction (ground track). A navigation radar requires at least three noncoplanar beams to measure the vector velocity, that is, the speed and its direction, of the aircraft. Such a radar measures the vector velocity relative to the frame of reference of the antenna assembly. This vector velocity can be converted to a horizontal reference on the ground by determining the direction of the vertical and the aircraft heading by some auxiliary

means. Usually, the radar uses four beams that are initially disposed symmetrically about the aircraft axis, with two facing forward and two facing rearward. If the aircraft vector velocity is not in the direction of the aircraft heading, the two forward-facing beams will not read the same Doppler frequency. This Doppler difference can be fed in a servomechanism that will align the axes of the antennas with the ground track of the aircraft. The angular displacement of the antennas from the aircraft heading is the drift angle, and the magnitude of the Doppler frequency is a measure of the speed along the ground track. The uses of the two rearward beams are similar, but improves the accuracy considerably by reducing the errors caused by vertical motion of the aircraft and pitching movements of the antennas.

4. HIGH-RESOLUTION IMAGING RADAR

A *radar image* is a visual representation of the spatial microwave reflectivity distribution of a target illuminated by the electromagnetic radiation emitted by the radar. Equivalently, a radar image represents a collection of reflection coefficients assigned to an array partitioning the target space. Thus, a radar image is generated by the same physical mechanism that generates an optical image observed by a human observer, in which the optical reflectivity distribution is reconstructed. In humans, however, the aperture size of the imaging system is on the order of 10,000 wavelengths, orders of magnitude (in wavelengths) greater than the aperture size of the corresponding radar imaging systems. Since the resolution of an imaging system, namely, its ability to represent distinctly two closely spaced elements, is inversely related to its aperture size, radar imaging systems would appear primitive when compared to their optical counterparts and, whereas a single optical image is usually sufficient for target recognition, several radar images of the same target, corresponding to various viewing angles, are usually required. However, the usefulness of radar imaging systems is not undermined by their lower-resolution capabilities. Advantages of radar imaging systems over their optical counterparts include their day or night capability, since they supply their own illumination, or their all-weather capability, since radiowaves propagate through clouds and rain with only limited attenuation. Additionally, larger aperture sizes (and, thus, higher resolution) can be *synthesized* from the given physical aperture using techniques such as those described later in this article.

4.1. Direct-Imaging Radar

Direct imaging radar systematically scans a three-dimensional volume in angle and range with short pulses emitted from a pencil-beam antenna and range gating and displays the intensity of the received signals as a function of the spatial coordinates interrogated. The spatial resolution is established by the angular (beamwidth) and range (pulse duration) resolution of the sensor without subsequent processing. If range gating is not used, then range is not resolved and the radar image is a

two-dimensional projection of the reflectivity distribution along the radar line of sight. Direct imaging is the simplest form of radar imaging, requiring minimal data processing and allowing the target to be stationary. However, it requires very large aperture and subnanosecond pulses for a high degree of spatial resolution, while, as a result of beam widening, its cross-range resolution degrades as the range increases.

4.2. Synthetic Imaging Radar

Synthetic imaging radar attempts to overcome the limitations of direct imaging radar and create fine spatial resolution by synthetic means in which results from many observations of the target at different frequencies and illumination angles are coherently combined. The term “synthetic” here refers to the synthesis of resolution commensurate with short-pulse, large-aperture illumination from a number of elemental measurements of illumination with not-as-short pulses and not-as-large aperture.

4.2.1. Range Processing Radar. The first task of imaging radar involves discrimination on the basis of range. High resolution in the determination of range is achieved when the transmitted pulse duration T is narrowed down and the corresponding system bandwidth B is increased, so that the time-bandwidth product (TB) is constant. Maximum sensitivity is accomplished when the time-bandwidth product is set to unity, $TB = 1$. Thus, the required range resolution can be achieved when target reflections are measured over a band of frequencies. Any radar waveform that supports an extended bandwidth can be used; the specific type of waveform determines only the necessary implementation of the receiver for coherently processing the wideband signal.

In contrast to direct-imaging methods, in which all the spectral components of the signal must be present simultaneously, synthetic imaging methods require that the spectral components be present sequentially. In the simplest implementation of high range resolution by synthetic means, several narrowband measurements are made at discrete frequency increments. Such radars are called *stepped-frequency* systems and can be either *continuous-wave* (CW), at each frequency emitting an unmodulated sinusoid, or *pulsed*, amplitude-modulating each frequency sinusoid. Stepped-frequency continuous-wave systems are susceptible to aliased responses and transmitter coupling, shortcomings alleviated by pulsing the transmitter and time-gating the receiver as in a pulsed, stepped-frequency system. Although individual narrowband responses have insignificant resolution potential, the coherent combination of the responses provides the resolution allowed by the total bandwidth spanned. Alternatively, high range-resolution can be accomplished using *swept-frequency* (*linear FM*) systems and corresponding wideband receivers. Range resolution in swept-frequency systems is achieved by measuring the difference in instantaneous frequency between the instant of emission of the radar pulse by the transmitter and the instant of its reception back at the receiver.

4.2.2. Synthetic Aperture Processing Radar. High resolution in the cross-range direction can be obtained by scanning a focused beam across the object. If the aperture that forms the scanning beam is focused at the target plane, the minimum lateral extent of the focused spot is approximately

$$\Delta = \frac{\lambda R}{D} \quad (20)$$

where λ is the wavelength, R is the observation distance, and D is the aperture dimension. Resolution of two adjacent object points on a plane perpendicular to the line of sight of the radar is possible if their distance is greater than the spot dimension. Thus, for a fixed wavelength and observation distance, the resolution is increased by increasing the aperture size. High-resolution direct-imaging radars would, therefore, need to have physically large aperture.

Synthetic imaging radars synthesize equivalent large aperture for high-resolution cross-range imaging by sequentially stepping a sensor through small incremental distances and storing samples of the amplitudes of the corresponding received signals. The stored signals are coherently summed to produce signals equivalent to those that would be received by the corresponding large physical aperture. In effect, *synthetic aperture radars* (SARs) coherently process signals scattered from the same target for various viewing angles by utilizing relative motion between the sensor and the target. Depending on the type of relative motion between sensor and target, synthetic aperture radars can be linear, spotlight, or inverse.

Linear Synthetic Aperture Radar. In linear SAR, also called *stripmap* SAR, the radar sensor is moved along a linear path and images stationary targets in its line of sight. Linear SAR is widely used for mapping terrain features and ground-based objects from airborne platforms.

Spotlight Synthetic Aperture Radar. Spotlight SAR involves observing a target with the radar antenna fixed on it while the viewing angle is changed.

Inverse Synthetic Aperture Radar. Inverse SAR involves a stationary radar viewing targets rotating about an axis perpendicular to the line of sight.

4.2.3. Doppler Processing Radar. Spatial resolution in cross-range, that is, along an axis perpendicular to the radar line of sight, can be obtained if a target rotates relative to the radar sensor and the target reflections are Doppler-processed. This is possible since the Doppler frequency shift in waves reflected by a rotating target is proportional to the lateral offset of the reflector along an axis normal to the axis of rotation and the line of sight. Indeed, if d and R_0 ($R_0 \gg d$) are the distances of a reflecting point and the radar sensor, respectively, from the center of a target rotating at an angular velocity Ω , then the distance of the reflecting point from the radar sensor at time t is approximately

$$r(t) = R_0 - d \sin(\Omega t) \quad (21)$$

According to Eq. (6), the Doppler coefficient at time t in the received wave will be

$$v_0(t) = \frac{-2}{c} \frac{dr(t)}{dt} = \frac{2d\Omega}{c} \cos(\Omega t) \quad (22)$$

From Eq. (22), it is clear that the Doppler coefficient for every reflecting point in a target rotating with angular velocity Ω is a harmonic function of time, the amplitude of which is proportional to the instantaneous lateral distance of the reflecting point from the center of rotation. Doppler processing of the received signal for cross-range resolution can be done online by either a bank of contiguous filters or first sampling it and then analyzing it with Fourier transform processors of sufficiently high speed. Offline processing, on the other hand, can be performed by recording the received signal for later processing. In either case, the signal is usually frequency translated to retain only its complex envelope.

4.2.4. Holographic Processing Radar. Optical holography records the spatial distribution of the intensity of the interference of lightwaves diffracted by an object and a reference beam in a *hologram*. This overcomes the difficulty associated with lack of optical phase-sensitive storage media. Later, the hologram can be used to reconstruct the lightwaves associated with the original object by illumination with the reference beam used in the recording step. A holographic reconstruction allows a viewer the perception of a *virtual image* of the original object.

Microwave holography follows recording and reconstruction procedures analogous to optical holography. In microwave holography, the field amplitude scattered from an object coherently illuminated from a transmitter is mapped over a prescribed recording aperture by a coherent detector that is scanned over the aperture. The detected bipolar signal, representing the complex envelope of the time-varying field, is added to a bias level sufficient to make the resultant always positive. The resulting signal is used to produce a film transparency with an amplitude transmittance function that is real and positive. The area probed by the detector represents the hologram aperture, the reference signal for the coherent detector represents the reference beam, and the signal scattered from the object is the object beam. A variation, known as *scanned holography*, of the (conventional) procedure described above attempts to scan the transmitter and the receiver independently and offers some advantages in resolution.

5. WEATHER OBSERVATION RADAR

Radar is a powerful research instrument in meteorology and also for telecommunications at frequencies higher than 1 GHz, since it allows for the gathering of considerable quantities of data on the three-dimensional structure of the atmosphere in a flexible, efficient, and rapid manner. Radar applied to hydrometeor observation provides two types of information: (1) quantitative information on

the local distribution of the reflectivity and speed distribution in the scattering medium and (2) qualitative information on the small- and medium-scale structure of the targets, their evolution and movement, and other information heuristically extracted by expert analysts. This information can be used to describe atmospheric phenomena and study radiowave propagation, such as the provision of various statistics on precipitation and attenuation.

5.1. Precipitation Measurements

The most frequent quantitative application of the radar observation is to distinguish ice and liquid phases of precipitation. This task is particularly challenging in convective storms, where liquid water can exist at temperatures colder than 0 °C and ice can be found at temperatures warmer than 0 °C. Equally important and challenging is the task of quantifying rain, snow, or hail precipitation rates, where the difficulty lies in the dependence of the rates on detailed knowledge of the drop size distributions. Although radar techniques have practical limitations and their accuracy is highly suspect, they offer important advantages over conventional methods based on pluviometer array measurements—they allow for spatial continuity of the observations and improved access to the observation of the variability of the precipitation; and make it possible to observe the three-dimensional structure of the system generating the precipitation, as well as survey over a wide area from a single measurement point in real time; data acquisition, storage, and processing is simple. Radars capable of measuring multiple parameters (e.g., vertical and horizontal reflectivities and/or a spectrum of terminal velocities) in each resolution cell, in combination with satellites, rain gauges, and other instruments, may give the desired accuracy in measuring rainfall rates and discriminating rain from frozen precipitation.

5.2. Storm and Wind Observation

A pulsed Doppler radar can estimate the reflectivity and range velocity distribution inside a storm's shield of clouds. If a single beam is used, a three-dimensional picture of a storm typically requires 2–5 min of data collection time. This delay is imposed not only by antenna rotation limitations but also by the requirement for collection of a large number of radar echoes for reduction of the statistical uncertainty in the reflectivity and velocity estimates. Although the storm can change significantly during this period, with subsequent distortion of the reflectivity and velocity radar images, the returned estimates are considered highly valuable.

In practice, more significant than the reflectivity and velocity distributions are estimates of the rainfall rate and wind velocity. Doppler radar, however, measures the range velocity of hydrometeors rather than air, and often this differs significantly from the range component of wind. Nevertheless, since hydrometeors quickly respond to wind forces, their terminal velocities give negligible bias estimates of the range component of the wind.

5.3. Turbulence Measurement

The mean velocity and spectrum width measured by Doppler radar are weighted averages of point velocities. Therefore, they are sufficient to depict motion on scales larger than the resolution cell, but cannot infer the details of the flow inside the cell. Nevertheless, Doppler radar offers the possibility of measurement and study of turbulence on scales smaller than the resolution cell if a firm connection between the statistical and physical properties of the atmosphere and Doppler-derived measurements is established.

5.4. Clean-Air Observation

A radar designed to identify and track precipitating storms can also detect echoes from scatterers in fair weather. In such cases, the distribution of spatial reflectivity in clean air can be associated with meteorological phenomena such as turbulent layers, waves, and fronts, flying birds and insects, or atmospheric pollutants. Clean air echoes not related to any visible scatterers have been conclusively proved to emanate from refractive index irregularities.

Waves reflected by sharp, quasipermanent changes in the dielectric permittivity of the atmosphere form the coherent component in the echo received by the radar. Coherent echoes exist if the scattering medium does not time-modulate the amplitude or phase of the transmitted radar pulses, even though spatial variations may exist. Coherent echoes appear as peaked and narrow components in the Doppler spectrum. On the other hand, incoherent components are contained in the echo signal if time-varying (turbulent) scatter is present. Incoherent echoes demonstrate themselves as broad components in the Doppler spectrum.

6. LASER RADAR SYSTEMS

It is natural to attempt to extend radar techniques to the optical portion of the electromagnetic spectrum. The fact that optical wavelengths are orders of magnitude smaller than their radio counterparts allows for very fine resolution in the estimation of target parameters, such as angular position, range, and tangential and radial velocities. The first optical radar systems investigated used incoherent light from xenon or other flashlamps. With the invention of the *laser* (light amplification by stimulated emission of radiation), however, they were replaced by systems that employed coherent laser light. Such systems were initially called *lidar* (light detection and ranging) and, in more advanced, higher performance versions, *ladar* (laser detection and ranging) in complete analogy to radar.

The development of practical ladar systems followed a path similar to the development of radar systems: Reflectivity and backscattering cross-section data were collected and tabulated for a number of targets at available laser operating wavelengths; laser pointing could be accomplished by mounting the laser on existing radar platforms; the scan patterns of radar were employed in ladar systems

as well; the signal design and processing techniques of radar were also applicable to ladar systems.

When compared to radar, ladar systems exhibit advantages and disadvantages, both due to their use of very short wavelengths. On one hand, very short wavelengths result in very high information bandwidths and very fine resolution. Exploitation of the bandwidth can be achieved with today's advanced signal-processing techniques and hardware. Additionally, unlike the use of solid-state lasers in early ladars, which allowed only for signal envelope processing, today's ladars use gas lasers, which also allow for signal phase processing. On the other hand, however, very short wavelengths result in low power efficiency and high atmospheric propagation losses. As a result, ladar is preferable to microwave and millimeter-wave radar for long-range ground-to-space and space-to-space applications or short-range atmospheric applications, where the propagation loss penalty does not outweigh fine resolution.

6.1. Ladar Information Processing

A ladar measures a target's range, position, velocity, and motion by modulating its laser beam, detecting the reflected return, and processing the return signal to derive the desired information. Methods have been developed for amplitude, frequency, and phase modulation and for modulation by polarization. Laser radiation can be modulated both by direct action on coherent signals inside the laser during their generation (internal modulation) and through action on the radiated light outside the laser (external modulation). A number of electrooptical, acoustooptical, and mechanical beam modulation devices are available with different inherent modulation rates, yielding amplitude or frequency modulation of the transmitted beam.

Solid-state lasers cannot provide the necessary spectral purity to utilize phase processing of ladar signals. Gas lasers, such as helium–neon and carbon dioxide, however, have high spectral purity and can be modulated in amplitude or frequency with bandwidths of up to 525 MHz

(yielding a resolution of approximately one foot) with relatively low drive powers. Ladar signal processing techniques are similar to those used in microwave radar. In fact, the same circuits for signal-envelope processing may be employed in many cases. The use of ladar allows the exploitation of highly precise and unique methods for angle estimation and tracking.

7. GROUND/FOLIAGE-PENETRATING RADAR

In the recent years (as of 2003), an attempt has been made to use radar systems to detect and map "targets" buried under Earth's surface or obscured by foliage. Primarily, interest arises from a number of potential applications, such as detecting and locating unexploded ordnance in a battlefield, manmade objects in landfills, buried hazardous waste, subsurface plumes of refined hydrocarbons, or military equipment hidden in forest vegetation. The radar is either spaceborne, airborne, or ground-towed and possibly operates in SAR mode. In Fig. 6, a typical configuration is shown in which a ground-towed, ground-penetrating radar is utilized for excavation planning. The task of the radar in this application is to map (image) the location of buried pipes and discriminate them from other unwanted buried objects, such as rocks and small metal pieces (*volume clutter*).

A ground/foilage-penetrating radar needs to utilize *ultrawideband* (UWB) signals, containing both low- (for deeper penetration) and high- (for higher resolution) frequency components. This can be achieved in two ways: (1) by emission of very short in duration (and, subsequently, ultrawide in bandwidth) pulses or (2) by sequential emission of narrowband signals whose carrier frequency increases in steps, covering a wide frequency band.

Even though the perspective of ground/foilage-penetrating radar from initial tests has been encouraging, a number of difficulties have delayed the development of this technology. These include:

Figure 6. Typical configuration of a ground-towed, ground-penetrating radar utilized for excavation planning. The task of the radar in this application is to map (image) the location of buried pipes and discriminate them from other unwanted buried objects, such as rocks and small metal pieces, (*volume clutter*).

- High electromagnetic wave absorption, especially under moist soil conditions
- Random distributions of soil particles, such as rocks, that tend to scatter the electromagnetic energy, increase propagation losses, and reduce the image contrast
- High clay content to which water binds and, thus, dipolar relaxation loss mechanisms are encouraged
- Roughness of the air–soil interface that tends to increase backscattering that interferes with the penetrating radar signature

Similar factors affect the development of foliage-penetrating radar systems.

To date, the success of ground/foilage-penetrating radar surveys seems to be absolutely site-dependent. A thorough understanding of a site's geology, hydrology, and topography is of paramount importance. Before undertaking a radar survey, it is necessary to obtain as much information as possible about the physical characteristics of the specific site. If log-boring log or well-monitoring data are available, they should be analyzed to determine soil stratigraphy and hydrology. If such data are not available, it is prudent to gather representative soil samples.

The applications for radar in subsurface target detection seem to fall into two broad categories, depending on the scale of the system, target, terrain structures, and search volumes. The case of large scales is made if the targets sought are large relative to the average wavelength and the soil inhomogeneities. In this case, imaging would play a (secondary) role in reducing the number of false alarms of the detection procedure. If small targets, such as mines or weapons, are of interest, they would be hard to distinguish from clutter and the role of imaging would be enhanced. Thus, it is difficult or perhaps pointless to develop a single radar system for the detection of both large/deep and small/shallow targets. The wide frequency range requirement imposes stringent requirements in the range of both the electronics and the size of the relevant antennae and contributes to the delay of development of this significant radar application. However, ground/foilage-penetrating radar technologies are presently an area of significant research investigation.

8. CURRENT TRENDS

Besides research in ground/foilage penetrating radar technologies, significant research is also conducted in the development of *spacetime adaptive processing* (STAP) algorithms. STAP refers to multidimensional adaptive filtering algorithms that simultaneously combine the signals from the elements of an array antenna and the multiple pulses of a coherent radar waveform. STAP can improve the detection of low-velocity targets obscured by mainlobe clutter, detection of targets masked by sidelobe clutter, and detection in combined clutter and jamming environments.

Significant research is also conducted into the use of signal processing tools other than the traditional Fourier transform-based ones for target detection and recognition. Such tools are, for example, based on the theories of

wavelet-induced multiresolution analyses (WIMAs) of signals. A WIMA allows for the decomposition and simultaneous representation of a signal in time and scale and, therefore, is capable of processing signals at different scales. WIMA-based radar target detection and recognition have been actively researched.

RADAR CROSS-SECTION

DAVID C. JENN
Naval Postgraduate School

Radar cross section (RCS) is a measure of the magnitude of the scattered electromagnetic wave from a body relative to the magnitude of the wave incident on the body. To many people RCS is synonymous with stealth. Stealth technology has become an integral part of all military systems since it was first employed in the 1970s. However, RCS is just one aspect of stealth, the design philosophy that seeks to make a platform (such as an aircraft, ship, or ground vehicle) undetectable to a wide range of sensors. Such a platform is referred to as low-observable (LO). In addition to radar, the infrared, acoustic, and visible signatures must be controlled. In the past, the RCS has received the most attention because the detection range of radar is generally much greater than that of other sensors. Undetectability does not necessarily imply a very low signature, only that the target must be indiscernible against the background. In the visible region (wavelengths visible to the eye) stealth has been used since World War II in the form of camouflage.

A typical radar and target arrangement is shown in Fig. 1. The transmitter illuminates the target from a distance R_t . If the body is sufficiently far from the transmitting antenna, the incident spherical wavefront will be approximately planar across the target. The incident wave induces currents on the surface of the body, and even within its volume if the material is not a perfect electric conductor. The induced currents give rise to a scattered field, which is detected by the receiver at a distance R_r .

The arrangement shown in Fig. 1 is referred to as *bistatic*; the directions of the transmitter and receiver are different as viewed from the target. The *monostatic* case is more common; that is, the directions of the transmitter and receiver are the same as viewed from the target. For a truly monostatic radar the transmit and receive channels should use the same antenna. Frequently the radar will use separate antennas for transmit and receive, but they will be closely spaced on the same platform. This configuration is referred to as *quasimonostatic*, and can be considered as monostatic for the purpose of specifying the RCS of a distant target.

Figure 1. *Bistatic* RCS refers to an arrangement where the transmitting and receiving antennas are at different locations as viewed from the target. For the monostatic case the transmitting and receiving antennas are collocated.

static, and can be considered as monostatic for the purpose of specifying the RCS of a distant target. The majority of radars currently in use for both military and civilian applications are monostatic.

Most radars are designed to provide information on the target's location and velocity. Location is given in terms of the range (radial distance) from the radar along with direction. The range to the target is obtained by a time-delay measurement. An electromagnetic wave is transmitted in the direction of the target, and the round-trip travel time is converted to distance using the known velocity of propagation of the wave. The direction of the wave is obtained from antenna pointing. Velocity can be measured using the frequency shift due to the Doppler effect or two range measurements at closely spaced times to obtain the target's range rate. Any measurement of the target parameters assumes that the reflected wave is strong enough to be detected and processed by the radar. Search radars are specifically designed for this purpose. They are used to scan large volumes of space for targets at great distances (hundreds or even thousands of kilometers). Once a target has been detected it is handed over to a tracking radar. Modern multifunction radars are designed to perform both search and track functions.

Although both the search and track operations are more difficult for targets with low RCS, the primary objective of RCS reduction is to defeat search radars (i.e., avoid detection). The role of the RCS in the detection of a target is demonstrated by the basic form of the radar equation derived later. It shows that when all other radar system parameters are fixed, the maximum detection range of a target varies as the fourth root of RCS. Thus, by reducing the target RCS, the range at which it is first seen by the radar is also reduced.

The RCS of modern aircraft and ships has been significantly reduced, but in response to the lower cross sections, more sensitive radars have evolved. The RCS designer is at a disadvantage in this respect because a truly LO platform must be designed from the start. Stealth cannot simply be added on after all other design tradeoffs have been made. The entire design and test cycle of an aircraft can be a decade, and its operational life several decades. On the other hand, the radar designer may be able to significantly increase the capability of a radar by simply replacing a system component such as an antenna or signal processor. These are relatively minor changes and can be integrated into deployed radars in a

Table 1. Frequency Band Designations

Band Designation	Frequency Range
HF	3–30 MHz
VHF	30–300 MHz
UHF	300–1000 MHz
L	1–2 GHz
S	2–4 GHz
C	4–8 GHz
X	8–12 GHz
Ku	12–18 GHz
K	18–27 GHz
Ka	27–40 GHz
MM	40–300 GHz

couple of years, thereby decreasing the effectiveness of the LO platform for the rest of its operational lifetime.

The scattering properties of the target are only one of several considerations that enter into the selection of the operating frequency of a radar [1,2]. Others are size constraints, antenna gain and beamwidth, transmitter power, ambient noise, Doppler shift, and atmospheric attenuation. The frequency spectrum is divided into bands with letter designations as shown in Table 1. A few long-range ballistic missile defense radars operate in the 300-MHz region (UHF), but most others use frequencies greater than 1 GHz (L band and above). Devices at low frequencies are larger than similar devices at a higher frequency, and therefore the system’s components require more volume. Likewise the antenna must be larger at a low frequency than at a high frequency to achieve the same beam width and gain. Low frequencies are capable of handling more power because the applied voltages can be higher without causing breakdown. Finally, ambient noise is lowest in the 1–10 GHz range, and low-altitude atmospheric attenuation favors frequencies below 18 GHz.

The function of the radar also influences the choice of frequency. For instance, an airborne imaging radar must be compact and lightweight, but also have a narrow antenna beam for resolving scatters. These all favor a high frequency. On the other hand, a ground-based search radar must radiate high power to achieve a large detection range. In this case the larger and heavier equipment that is necessary for high-power operation is not a problem.

1. DEFINITION OF RADAR CROSS SECTION

Radar cross section is defined as [3]

$$\frac{\text{Power reflected towards receiver per unit solid angle}}{\text{Incident power density}/4\pi}$$

In general it is dependent on many parameters. They include

1. The size, shape, and material composition of the body
2. The frequency and polarization of the incident electromagnetic wave

3. The direction from which the wave illuminates the body, as well as that at which the observer is located (the angle at which the target is viewed is referred to as the *aspect angle*)

These factors are taken into consideration when a radar is designed to detect a specific target. On the other hand, if a vehicle is to face a radar with known specifications, the target can be designed with the radar’s performance in mind. For example, if an aircraft will be flying directly at a radar in most mission scenarios, then it will be wise to put extra effort into reducing the nose-on RCS, perhaps even at the expense of raising it at broadside aspect angles. Furthermore, if the frequency of the radar is known, then the RCS reduction effort need only concentrate on that frequency.

The conventional symbol for RCS is σ and it has units of square meters. As evident in Table 2, typical values of the RCS range from 0.0005 m² for insects to 100,000 m² for a large ship. The decibel unit is convenient when working with quantities that extend over several orders of magnitude. The RCS in decibels relative to a square meter (dBsm) is defined as

$$\sigma_{\text{dBsm}} = 10 \log_{10} \sigma$$

Implicit in the definition of RCS is the assumption that the frequency is fixed.

Mathematically the RCS is given by

$$\sigma(\theta, \phi, \theta_i, \phi_i) = \lim_{R_r \rightarrow \infty} 4\pi R_r^2 \frac{|\mathbf{E}_s(\theta, \phi)|^2}{|\mathbf{E}_i(\theta_i, \phi_i)|^2} \tag{1}$$

where

\mathbf{E}_i = plane-wave electric field intensity incident from the direction (θ_i, ϕ_i)

\mathbf{E}_s = scattered spherical wave electric field intensity observed from the direction (θ, ϕ)

R_r = distance from the target to the observer as shown in Fig. 1

At first glance it may appear that RCS is a function of range because of the R_r^2 in Eq. (1). However, the scattered field is a spherical wave whose electric field has a $1/R_r$ dependence, which, when squared, cancels the factor in the denominator. Hence RCS is a range-independent quantity.

Electromagnetic scattering and radiation problems can be formulated in either the time domain (TD) or the

Table 2. Typical Values of RCS

Target	RCS (m ²)
Insects	0.0005
Small birds	0.01
People	0.5
Cars (front)	5–10
Fighter aircraft nose on broadside	10–50
Bomber aircraft	500–1000
Ships	1000–100000

frequency domain (FD) [4,5]. In fact, the scattering body can be represented as a linear system with impulse and frequency responses. The RCS as a function of time is related to the RCS as a function of frequency by the Fourier transformation. There are advantages and disadvantages to working in each domain. Early radar systems operated over narrow frequency ranges, and the need to compare calculated and measured data dictated that calculations also be done in the frequency domain. Modern radars operate over wide frequency ranges, and in order to characterize their performance adequately, the target RCS must also be determined over the same wide range of frequencies. For a large, complex target, the calculation of the RCS at each frequency is potentially a time-consuming task. It may be more efficient to compute the target's response to a waveform in the time domain and then perform a Fourier transformation to obtain the RCS at many frequencies simultaneously. Thus the measurement or calculation of RCS can be performed by either of two procedures:

1. *Frequency Domain.* The received power is obtained as the target is rotated through a range of angles while a continuous wave (CW) fixed-frequency source is radiating. The frequency can be changed and another plot of RCS versus angle obtained, and so on. At any fixed angle the RCS from a large number of frequencies can be Fourier transformed to obtain the time-domain response of the target at that particular angle.
2. *Time Domain.* The received power as a function of time is obtained at each aspect angle of interest. The time histories are inverse Fourier transformed to yield the frequency response of the target at each angle. If the Fourier transform of the waveform and the impulse response of the radar system are known, then the target's frequency response can be converted to RCS.

There are several aspects of the RCS that enter into the design of an LO platform, and therefore the discussion of the RCS logically falls along similar lines. They include the following topics:

1. Electromagnetic (EM) scattering mechanisms and the physical aspects of scattering
2. Analytical and computational methods
3. Reduction methods
4. Measurement techniques

A brief overview of each of these four topics is given, followed by mathematically based discussions of RCS prediction and reduction.

2. BASIC SCATTERING CHARACTERISTICS OF BODIES

2.1. Frequency Regions

The scattering characteristics of a target are strongly dependent on the frequency of the incident wave. There

are three frequency regions in which the RCS of a target is distinctly different. They are referred to as the (1) low-frequency, (2) resonance, and (3) high-frequency regimes [6]. The labels are somewhat misleading in that low and high are defined relative to the size of the target when normalized to the incident wavelength, rather than to its physical size. If the target is smooth and it can be roughly described by a characteristic length L , then the three frequency regimes can be defined in terms of the quantity βL , where

$$\beta = 2\pi/\lambda \quad (2)$$

and λ is the wavelength.

Low-Frequency Region ($\beta L \ll 1$). At these frequencies the phase variation of the incident plane wave across the extent of the target is small. Thus the induced current on the body is approximately constant in amplitude and phase. The particular shape of the body is not a factor in the RCS pattern shape. For example, both a small sphere and a small cube have essentially isotropic (direction-independent) scattering patterns. In general, σ versus βL is smooth and varies as λ^{-4} . This region is also called the Rayleigh region.

Resonance Region ($\beta L \approx 1$). When βL is on the order of 1, the phase variation of the incident field across the body is significant and all parts contribute to the scattering pattern. A plot of σ versus βL is oscillatory. This region is also referred to as the Mie region.

High-Frequency Region ($\beta L \gg 1$). There are many cycles in the phase variation of the current across the body, and consequently the scattered field will be very angle-dependent. The peak scattering levels are primarily due to isolated points. For example, the peak scattering from large flat plates originates from specular points on the surface. (They are the mirrorlike reflection points for which the angle of reflection equals the angle of incidence.) A plot of σ versus βL is smooth in this region and may be independent of λ . This is also called the optical region.

The RCS of a sphere, which is plotted in Fig. 2, clearly illustrates the three frequency regions. The appropriate characteristic dimension of the sphere is its radius; therefore, let $L = a$. (One could argue that based on the previous discussion that $L = 2a$ should be used. However, the boundaries between the frequency regions are defined by orders of magnitude; they are not sharp. Hence either choice for L is acceptable. For a sphere quantities are generally normalized to the radius, and therefore $L = a$ is the most convenient choice.) For $\beta a < 1$, the curve is almost linear, but above 1 it begins to oscillate. This is the resonance region. The oscillations die out at higher values, and above $\beta a \leq 10$ the curve approaches a constant equal to πa^2 .

2.2. Polarization and the Scattering Matrix

In addition to frequency, polarization plays a major factor in determining the scattering characteristics of a body. Polarization refers to the orientation of the electric field vector. The incident wave polarization is determined by the orientation of the transmit antenna, while the receive

Figure 2. The RCS of a sphere illustrates the three frequency regions: (1) Rayleigh (linear region at low frequencies), (2) resonance (oscillatory region), and (3) optical (flat high frequency region).

antenna determines the receive polarization. If the antennas are linearly polarized and their electric field vectors are aligned, then the copolarized scattered field is measured. On the other hand, if linear transmit and receive antennas are orthogonal (electric field vectors crossed at 90°), then the cross-polarized component of the scattered field is sensed.

The copolarized scattered field is generally used, for several reasons. First, the copolarized scattered field component is usually much higher than the cross-polarized component. Second, for monostatic radars it is more efficient to use the same antenna for transmit and receive, and hence the transmit and receive polarizations are identical. However, measuring both components provides the most information available from the scattered field and may assist in target identification.

A polarization-specific RCS can be expressed as

$$\sigma_{qp} = \lim_{R_r \rightarrow \infty} 4\pi R_r^2 \frac{|\mathbf{E}_{sq}|^2}{|\mathbf{E}_{ip}|^2} \quad (3)$$

where p denotes the polarization of the incident wave and q the polarization of the receiver. Common polarization designations are defined with regard to a reference such as the ground or surface. They include horizontal and vertical (H and V); parallel and perpendicular (\parallel and \perp); rectangular (x and y). A scattering matrix relates the scattered field components to the incident field components:

$$\begin{bmatrix} \mathbf{E}_{s\theta} \\ \mathbf{E}_{s\phi} \end{bmatrix} = \begin{bmatrix} S_{\theta\theta} & S_{\theta\phi} \\ S_{\phi\theta} & S_{\phi\phi} \end{bmatrix} \begin{bmatrix} \mathbf{E}_{i\theta} \\ \mathbf{E}_{i\phi} \end{bmatrix} \quad (4)$$

The elements of the scattering matrix can be determined by computation or measurement.

The RCS of a cylinder illustrates the effect of polarization on scattering level and pattern shape. As shown in Fig. 3, a relatively strong copolarized RCS exists even for thin wires, whereas the cross-polarized RCS tends to zero.

Figure 3. A cylinder illustrates how a target's RCS can depend on the incident wave polarization. At low frequencies the cylinder becomes a thin wire that is transparent to a perpendicularly polarized wave.

At high frequencies the cross sections for both polarizations asymptotically approach the same value.

2.3. Monostatic versus Bistatic RCS

The vast majority of radars currently in use are monostatic, because most systems must operate from a single platform. However, the monostatic RCS (backscatter) of electrically large smooth flat targets is very small unless the radar is positioned normal to the surface. Besides the normal, large cross sections are observed in the specular ($\theta = \theta_i$) and forward ($\theta = \theta_i + \pi$) scattering directions.

Bistatic radars have the transmit and receive antennas in two separate locations. Thus a bistatic radar with a receiver at either of these two locations would have the advantage of larger target RCS. However, there are also disadvantages such as reduced operational flexibility because of the restricted transmit–receive relationships, and maintaining a coherent reference for the transmitter and receiver.

3. SCATTERING MECHANISMS

The RCSs of targets encountered by most radars are complicated geometric shapes. There are a few exceptions such as weather balloons and buoys. However, simple shapes such as plates, spheres, cylinders, and wires are useful in studying the phenomenology of RCSs. Furthermore, complex shapes can be decomposed into basic geometric building blocks (primitives) that can be assembled to form a more complex shape. Figure 4 shows an aircraft represented by cylinders, plates, cones, and hemispheres. The RCS of the model in Fig. 4 is shown in Fig. 5. A collection of basic shapes gives an acceptable RCS estimate that can be used during the initial design stages of a platform. The locations and levels of the largest RCS lobes are of most concern at this stage of the design process. The accuracy of the RCS estimate at other angles depends on how the interactions between the various shapes are handled. These are more difficult to include, as will be seen later. Even when they are included, the agreement

Figure 4. Simple geometric shapes such as plates, cylinders, and spheres can be used to build more complicated targets. The interaction between the individual parts is important in determining low-level RCS.

with the measured RCS may not be particularly good if the interactions are not modeled accurately. For an LO target more sophisticated numerical techniques must be used.

As evident from the pattern in Fig. 5, the RCS of a large, complex target is a rapidly varying function of angle. However, as complicated as it looks, isolated features of the pattern shape and level can be associated with the behavior of the currents induced in and on the scattering body. For example, the high narrow spikes result from mirrorlike specular reflections from large flat surfaces. Other lobes can be associated with surface waves, multiple reflections, diffraction, and so on. These so-called scattering mechanisms are depicted in Fig. 6.

The lines in the figure are ray representations for propagating waves. They denote the direction of power flow and are normal to the planes of constant phase.

For any particular aspect angle, frequency, and polarization, if one scattering mechanism dominates over all others, then it may be possible to express the total scattered field as a combination of scattered fields E_{s1} , E_{s2} , E_{s3} , ..., each due to a separate scattering mechanism:

$$E_s \approx E_{s1} + E_{s2} + E_{s3} + \dots$$

Figure 5. An azimuth plot of the RCS of the aircraft in Fig. 4 is shown. The two large lobes are due to the fuselage, which is modeled as a cylinder.

Figure 6. The total RCS of a target can often be decomposed into a sum of contributions from distinct scattering mechanisms. Some important mechanisms for electrically large targets are depicted in this figure.

and if one of these terms is much greater than all others, then

$$|E_s|^2 \approx |E_{s1}|^2 + |E_{s2}|^2 + |E_{s3}|^2 + \dots$$

It follows from Eq. (1) that the total RCS can be written as a sum of RCSs, each attributed to a separate scattering mechanism:

$$\sigma \approx \sigma_{s1} + \sigma_{s2} + \sigma_{s3} + \dots \tag{5}$$

Note that Eq. (5) is a convenient way of decomposing the scattered field for the purpose of assisting the RCS modeling and reduction efforts. First, if sufficiently accurate models exist for the individual scattering mechanisms, then Eq. (3) suggests that they can be combined under the appropriate circumstances to model their collective effects for a complex target. Second, since the largest terms in Eq. (3) correspond to the source of the most intense scattering, it may be possible to determine which scattering mechanism dominates, and thereby choose an appropriate reduction technique.

3.1. Reflection

This is the mechanism that yields the highest RCS peaks, but they are limited in number because Snell's law must be satisfied. When multiple surfaces are present, multiple reflections are possible. For instance, the incident plane wave could reflect off of the fuselage of an aircraft, hit a fin, and then return to the radar.

3.2. Diffraction

Diffracted fields are those scattered from discontinuities such as edges, corners, and vertices. The waves that are diffracted from these shapes are less intense than reflected waves, but they can emerge over a wide range of angles. At aspects requiring low RCS, the diffracted waves can be significant.

3.3. Surface Waves

The term *surface wave* refers to the current traveling along a body and includes several types of waves [7]. In general, the target acts as a transmission line, guiding the

wave along its surface. If the surface is a smooth closed shape such as a sphere, the wave can circulate around the body many times. Such waves are called *creeping* waves because they appear to creep around the back of a curved body. On curved bodies the surface wave continuously radiates. Radiating surface waves on flat bodies are usually called *leaky waves*. *Traveling waves* appear on slender bodies and along edges, and suffer little attenuation as they propagate [8]. If the surface is terminated with a discontinuity such as an edge, the traveling wave will be reflected back along the surface and radiate toward its origin.

3.4. Ducting

Also called waveguide modes, ducting occurs when a wave is trapped in a partially closed structure. An example is an air inlet cavity on a jet. Once the wave enters the cavity, many bounces can occur before a ray emerges. There are many paths that the ray can take, and therefore rays emerge at almost all angles. The result is a large, broad monostatic RCS lobe. An optical analogy of this is the glowing of a cat's eye when it is illuminated by a light.

3.5. Interactions

It is possible that these mechanisms will interact with each other. For example, a wave reflected from a flat surface can subsequently be diffracted from an edge or enter a cavity. For a complex target the interactions are not always obvious and the decomposition of the scattered field no longer makes sense.

4. PREDICTION METHODS

The analytical methods used to calculate RCSs are similar to those used in antenna analysis. A radar target is essentially acting as an antenna. The incident wave induces a current on the target, and the induced current radiates a field just as an antenna would. However, in the radar case it is called a scattered field as opposed to a radiated field. A good example is a reflector antenna or "satellite dish." The incident field from a feed horn excites currents on the reflector, which in turn give rise to a radiated field. In the radar analogy, the feed horn represents the radar's transmit antenna, while the reflector is the target. If the distribution of current is known for a target, then the currents can be used in the radiation integrals (Stratton–Chu integrals) to determine the scattered field. Once the scattered field is known, the RCS can be computed.

Of course, the problem is that the induced current on the target is unknown and generally very difficult to determine. An analytical solution is possible in only a few simple cases. In other cases it is feasible to solve Maxwell's equations or integral equations for the current numerically. These solutions are rigorous in that there are no assumptions or restrictions imposed. The only error in the solution is due to the numerical evaluation of the integral or differential equations. The alternative to a numerical solution is to take an intuitive guess at

the current, in which case the resulting RCS is only approximate.

Several methods of RCS prediction are described below. The classical solution techniques are not discussed in this list, because most are limited to one- or two-dimensional structures or simple three dimensional ones. The methods of interest here are those that can be applied to complex three-dimensional targets. The methods most commonly encountered are physical optics, microwave optics (ray tracing), the method of moments, and finite-difference methods.

4.1. Physical Optics

The physical optics (PO) approximation [9] provides a means of estimating the surface current induced on an arbitrary body. On the portions of the body that are directly illuminated by the incident field, the induced current is simply proportional to the incident magnetic field intensity. On the shadowed portion of the target the current is assumed to be zero. The current is then used in the radiation integrals to compute the scattered field far from the target.

PO is a high-frequency approximation that gives best results for electrically large bodies ($L \geq 10\lambda$). It is most accurate in the specular direction. Since PO assumes that the current abruptly decays to zero at a shadow boundary, the computed field values at angles far from the specular directions and in the shadow regions are inaccurate. Furthermore, surface waves are not included. PO can be used in either the time or the frequency domain. It can be supplemented by the physical theory of diffraction (PTD), which provides corrections to PO approximation that improve the accuracy of the current distribution near edges.

4.2. Microwave Optics

Microwave optics refers to a collection of ray-tracing methods that can be used to analyze electrically large targets of arbitrary shape. The rules for ray tracing in a simple medium (linear, homogeneous, and isotropic) are similar to reflection and refraction in optics. Geometric optics (GO) [10] is the classical theory of ray tracing used since the days of Newton. It provides a formula for computing the reflected and refracted fields. In addition, the geometric theory of diffraction (GTD) is used in conjunction with GO to include diffraction. Diffracted rays originate from the scattering of the incident wave at edges, corners, and vertices. The formulas are derived on the basis of infinite frequency ($\lambda \rightarrow \infty$), which implies an electrically large target. Ray optics is frequently used in situations that severely violate this restriction and still yields surprisingly good results. The major disadvantage of ray tracing is the bookkeeping required for a complex target. It is used primarily in the frequency domain.

4.3. Method of Moments

The method of moments (MM) is a technique used to solve an integral equation [11]. Integral equations are so named because the unknown quantity appears in an integrand.

In electromagnetics they are derived from Maxwell's equations and the boundary conditions. The unknown quantity can be a combination of volume or surface current (either electric or magnetic). The MM reduces the integral equations to a set of simultaneous linear equations that can be solved using standard matrix algebra. The size of the matrix involved depends on the size of the body; current computer capabilities allow bodies on the order of 10 or 20 wavelengths to be modeled.

Most MM formulations require a discretization (segmentation) of the body. Therefore, they are compatible with finite-element methods used in structural engineering, and the two are frequently used in tandem during the design of a platform. The MM can be used to solve both time- and frequency-domain integral equations.

4.4. Finite-Difference Methods

Finite differences are used to approximate the differential operators in Maxwell's equations in either the time or the frequency domain [5,6]. As with the MM technique, the target and surrounding space must be discretized. Maxwell's equations and the boundary conditions are enforced on the surface of the target and at the boundaries of the discretization cells. This method has found extensive use in computing the transient response of targets to various waveforms. Finite-difference methods do not require the large matrices that the MM does, because the solution is stepped in time throughout the scattering body.

5. REDUCTION OF RADAR CROSS SECTIONS

RCS reduction techniques are traditionally classified as geometric shaping, materials selection, and passive and active cancellation. The boundaries between these categories are not always distinct, and a reduction approach may draw on all of these simultaneously.

5.1. Shaping

Target shaping is the first step in RCS reduction. The first rule of shaping is to avoid presenting large flat surfaces to the radar. For large surfaces specular reflection is the dominant scattering mechanism. The direction of strongest reflection for a smooth surface is given by the law of reflection. Therefore, by examining the relationship between the direction of incidence and the surface normal, the direction of maximum scattering can be predicted. If a target is composed of several surfaces and one could visualize a plot of the normals of the surfaces, then it is expected that there would be few normals pointed in directions of low RCS.

It will be shown that the maximum monostatic RCS of a large flat surface occurs when the incident wave and observer are located normal to the surface. The maximum value is

$$\sigma_m = \frac{4\pi A^2}{\lambda^2} \quad (6)$$

where A is the area of the surface. Thus the RCS can be minimized by minimizing the area presented to the radar.

If it is not possible to tilt a large surface sufficiently, then it can be broken into a number of smaller surfaces, each tilted in a slightly different direction.

These approaches have led to rather unconventional aircraft shapes such as that of the F-117 Nighthawk (commonly referred to as the "Stealth Fighter") [12]. To date, shaping has not been applied extensively to ships and ground vehicles, although that is beginning to be done. Modern ship designs are making some concessions to RCS control, such as canting deckhouse walls and enclosing mast structures.

Another aspect of shaping is edge alignment. Once the specular reflections have been controlled, the contributions from edges (such as traveling waves and diffraction) may become important. Aligning edges is one way of maintaining low-RCS spatial sectors. For example, in plan form it is seen that the edges of the B2 bomber fall along only a couple of fixed angles.

The second rule of shaping is to avoid or hide retroreflectors. Retroreflectors are simple geometric structures that tend to redirect the incident radar wave back in the direction from which it arrives. Surfaces that meet at a 90° angle are strong retroreflectors, and therefore the angles between the tail rudder and elevator surfaces of a stealthy aircraft are always canted. New designs such as the tailless McDonnell Douglas X-36 have no vertical surfaces at all.

Cavities are another type of retroreflector. They have a very broad scattering pattern. Thus jet intakes are often located above the wing or else employ an electromagnetic screen to prevent penetration by the incident wave.

Obviously there is a limit to the degree of shaping that can be incorporated while simultaneously meeting other operational requirements. For example, extreme shaping applied to an aircraft degrades its aerodynamic performance and control characteristics. Another disadvantage of low-RCS shapes is that they have slim profiles, which reduces the useful enclosed volume relative to a conventional shape.

5.2. Materials and Coatings

Obviously the material composition of a body affects its RCS. For example, a metal plate has a higher RCS than a glass plate. Similarly, a plastic aircraft body has a lower RCS than one with a metal skin. The electrical characteristics of a material are defined by its constitutive parameters [13]:

1. Permittivity, $\varepsilon = \varepsilon_0 \varepsilon_r = \varepsilon' - j\varepsilon''$ (F/m)
2. Permeability, $\mu = \mu_0 \mu_r = \mu' - j\mu''$ (H/m)
3. Conductivity, σ_c (Ω/m)

where ε_0 and μ_0 are the permittivity and permeability of free space. The imaginary parts are associated with dissipation (attenuation) of the fields in the medium.

The permittivity determines the fundamental relationship between the electric field intensity \mathbf{E} and flux density \mathbf{D} . For the vast majority of materials that occur in nature

one can write

$$\mathbf{D} = \boldsymbol{\varepsilon} \mathbf{E} \quad (7)$$

where the boldface $\boldsymbol{\varepsilon}$ denotes a matrix. Expanding Eq. (7) and explicitly including the spatial and frequency dependences gives

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \begin{bmatrix} \varepsilon_{xx}(x, y, z, f) & \varepsilon_{xy}(x, y, z, f) & \varepsilon_{xz}(x, y, z, f) \\ \varepsilon_{yx}(x, y, z, f) & \varepsilon_{yy}(x, y, z, f) & \varepsilon_{yz}(x, y, z, f) \\ \varepsilon_{zx}(x, y, z, f) & \varepsilon_{zy}(x, y, z, f) & \varepsilon_{zz}(x, y, z, f) \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (8)$$

Likewise, the permeability determines the fundamental relationship between the magnetic field intensity \mathbf{H} and magnetic flux density \mathbf{B} , which for most materials can be written as

$$\mathbf{B} = \boldsymbol{\mu} \mathbf{H}$$

or

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \begin{bmatrix} \mu_{xx}(x, y, z, f) & \mu_{xy}(x, y, z, f) & \mu_{xz}(x, y, z, f) \\ \mu_{yx}(x, y, z, f) & \mu_{yy}(x, y, z, f) & \mu_{yz}(x, y, z, f) \\ \mu_{zx}(x, y, z, f) & \mu_{zy}(x, y, z, f) & \mu_{zz}(x, y, z, f) \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} \quad (9)$$

The following special cases occur frequently:

1. *Isotropic.* The diagonal components of the permittivity and permeability matrices are equal, and the off-diagonal elements are zero; that is, $\varepsilon_{pp} = \varepsilon_r \varepsilon_0$ and $\mu_{pp} = \mu_r \mu_0$; $\varepsilon_{pq} = 0$ and $\mu_{pq} = 0$ if $p \neq q$ ($p, q = x, y, \text{ or } z$).
2. *Nondispersive.* The constitutive parameters are independent of frequency. Most materials exhibit some dispersion (frequency dependence) if the frequency change is great enough. However, we define a nondispersive material as one whose ε_r and μ_r are sufficiently constant within the frequency band of the radar illuminating the material.
3. *Homogeneous.* The constitutive parameters are independent of location in the material. Almost all materials are inhomogeneous on a microscopic scale. For our purpose a homogeneous material is one that has a sufficiently small variation in ε_r and μ_r throughout its volume.

To examine the dependence of the RCS on the constitutive parameters, consider an infinite interface between free space and a half-space of material with ε_r and μ_r . The Fresnel reflection coefficient for a plane wave normally incident on the interface is

$$\Gamma = \frac{\eta - \eta_0}{\eta + \eta_0} \quad (10)$$

where the intrinsic impedances are defined by

$$\eta_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}}$$

and

$$\eta = \sqrt{\frac{\mu_r \mu_0}{\varepsilon_r \varepsilon_0}} = \eta_0 \sqrt{\frac{\mu_r}{\varepsilon_r}}$$

From Eq. (1) the RCS is proportional to the square of the scattered electric field intensity. Since the scattered field intensity (in this case the reflected field) is proportional to Γ , it follows that $\sigma \propto |\Gamma|^2$. Thus the RCS will be reduced in direct proportion to the reduction in reflection coefficient squared. This is an ideal limit, because in practice the material thickness is finite, and there will likely be some reflection from its back face and scattering from its edges.

Unfortunately, in most applications the target materials cannot be selected solely on the basis of the electromagnetic properties ε_r and μ_r . Mechanical properties such as strength, weight, and thermal conductivity have a higher priority. In the drive to reduce weight and increase strength, composite materials have found widespread military and civilian application [14].

Composites are formed from multiple constitutive materials in a manner that yields a final product having desirable properties from each material. Graphite is an example of a composite that is used extensively in the aircraft industry. Although the primary motivation for the use of composites has been structural, the reflection from most composite materials is lower than that for conductors. However, the majority of the incident field that is not reflected from the composite's surface is transmitted through the material, and the transmitted field can potentially be scattered from internal metallic objects. The use of nonconductors also complicates other electrical design issues such as the grounding of electrical systems and lightning protection.

An absorbing layer is another example of the application of materials for RCS reduction. A layer of absorbing material is deposited on the surface of the target. As the incident wave propagates through the material, energy is extracted from the field and its intensity diminishes [15]. Thus a weaker field is reflected at the target surface, and the reflected wave is attenuated further as it travels back through the material. The circuit analog of this type of material is a resistor.

A material that performs the function just described is referred to as a radar absorbing material (RAM). High absorption is desired, yet the material thickness and weight must be minimized. Unfortunately, many materials with high loss also have high reflection coefficients. Thus there is significant reflection of the incident wave at the absorbing-layer face, and little energy enters the material where attenuation takes place.

There are some materials that possess more complicated or exotic electromagnetic properties that can potentially be exploited for RCS reduction. For example, since the ε_{pq} affect the velocity of propagation along the coordinate axes of the material, it may be possible to construct $\boldsymbol{\varepsilon}$ for a material so that the polarization of the scattered field is different from that of the incident field. Thus the polarization of a wave rotates as it propagates through the medium, and scattered energy is converted to a field component that the radar is not capable of sensing.

Another example is a spatially dispersive medium. The electric flux density depends on both the electric field intensity and the magnetic flux density. A *chiral* material [16] has the constitutive relationship

$$\mathbf{D} = \epsilon \mathbf{E} + j\zeta \mathbf{B}$$

This type of behavior is associated with materials that have a helical molecular structure. It is possible to produce this type of behavior artificially by dispersing small helical coils throughout a bulk material.

In the past, the reduction of RCSs has focused on treating each scattering source, or hotspot, individually. For instance, an absorbing layer might be installed to reduce scattering from a wing edge. The layer will reduce the edge scattering, but will also introduce new scattering sources at the perimeter. For a useful reduction method, the new scattering sources must be much weaker than those of the original edge. But as the scattering intensities of the sources become smaller, one quickly reaches the point where the new scattering sources introduced by the treatments are comparable to those being treated. At this level the interaction between scatterers becomes important, and this complicates the design and application of RCS treatments.

5.3. Cancellation Techniques

Cancellation refers to RCS reduction methods that are based on the introduction of a secondary scatterer whose scattered field is adjusted to cancel the reflection of the primary target [17,18]. The total field at the radar receiver is the vector sum of the fields scattered by the target and the cancellation element. Therefore, if the cancellation field can be made equal and opposite to the field scattered from the body at the angle, polarization, and frequency of interest, then destructive interference occurs. The secondary scatterer is referred to as the *cancellation element*, and its scattered field the *cancellation field*.

The cancellation element can be a detached body located near the original target, or an attached protrusion. Both are referred to as *parasitic* elements. The combination of the target with the scattering element is frequently called the *loaded body*. If the cancellation field is fixed, then the system is a *passive* one. On the other hand, if the system can respond to changes in the incident field, then it is an *active* one. A fair amount of information about the radar and the target is required for an active system: the threat radar frequency, its direction and polarization, and the target's RCS in the direction of the radar.

5.3.1. Passive Cancellation. Since the cancellation of the two fields is essentially a tuning method, this technique is only effective over a narrow frequency band and usually limited to a small spatial sector. If large parasitic elements are to be avoided, then the magnitude of RCS that can be canceled is small. Thus passive cancellation is usually used to supplement shaping and absorbers.

The most common cancellation elements are slots and wires. Two orthogonal elements are required to cancel an incident wave of arbitrary polarization. The elements can

Figure 7. A Dallenbach layer is used to reduce the RCS of a conductor. The material electrical characteristics and thickness are chosen to provide a reflection coefficient of zero.

be increased in size or number so as to provide sufficient gain to cancel the RCS in the direction of interest.

Two examples of passive cancellation are the Salisbury screen and Dallenbach layer [19]. A Salisbury screen consists of a resistive film located a distance d in front of the target surface. The film resistivity is chosen so that the reflection from its surface is exactly canceled by the field that passes through the film, is reflected from the target, and then is transmitted back through the film.

The Dallenbach layer shown in Fig. 7 is similar to the RAM coating discussed earlier, except that the layer thickness is chosen to provide destructive interference between the fields scattered from the top of the layer and the boundary at the back of the layer, rather than absorption within it. Thus the top of the layer serves the same purpose as the resistive film does for the Salisbury screen.

5.3.2. Active Cancellation. Active cancellation (also known as adaptive cancellation) is the extension of passive cancellation to handle dynamic threat scenarios. In the context used here, it does not include *deception*, which comprises techniques of modifying and retransmitting a signal. For the present discussion, the source of RF energy is the radar's signal. Two levels of sophistication are considered:

1. *Fully Active.* The cancellation network receives, amplifies, and retransmits the threat signal in such a way that it is out of phase with the static (skin) RCS of the target. The transmitted signal amplitude, phase, frequency, and polarization can be adjusted to compensate for changing threat parameters.
2. *Semiactive.* No amplification of the incident signal energy is provided by the cancellation network, but adjustable devices in the network allow the reradiated signal to compensate for limited changes in the radar signal parameters.

The demands for a fully active system are almost always so severe as to make it difficult to implement. It requires amplifiers and antennas that cover the anticipated threat angles, frequencies, incident power densities, and polarizations. A knowledge of the radar's direction is required, as well as the target's own RCS. A semiactive system is not as complicated with regard to hardware, but the use of adjustable devices still requires bias lines, controller units, and a computer with the appropriate databases.

Because of the growing importance of low-level scattering sources (in particular, manufacturing-induced errors that differ from platform to platform), adaptive cancellation techniques are receiving increased attention. Adaptive cancelers have the ability to modify the amplitude and phase of the new scattering source to compensate for changes in the original scattering source that may occur with frequency or observation angle. In principle, adaptive techniques are capable of adjusting to changing physical and electrical conditions brought on by exposure to the environment. However, cancellation is most effective when there are a small number of coherent scattering sources rather than a large number of random sources.

5.3.3. Treatments for Surface Waves. Surface waves, and in particular traveling waves, present a special challenge as far as RCS reduction is concerned [6]. The target acts as a combination of antenna and transmission line, collecting incident energy and guiding it along the surface. As depicted in Fig. 8, when a discontinuity (such as a termination) is encountered, the surface wave is reflected. As it propagates in the reverse direction, it loses energy by radiation. A dielectric-coated ground plane can support a surface wave for incident plane waves having a component of \mathbf{E} normal to the surface; a magnetic-coated ground plane can support a surface wave for incident plane waves having a component of \mathbf{H} normal to the surface.

The most common technique for treating surface-wave reflections that arise from surface discontinuities is one borrowed from transmission line theory: the use of transformer sections. Typically a quarter-wave matching section is appended to the termination of the surface, and the surface characteristics of the matching section are chosen to allow the wave to continue propagating in the forward direction, thereby eliminating the reflected field.

6. SPECIAL STEALTH ISSUES

To achieve and maintain low observability requires careful design, manufacturing and maintenance procedures to a level that may seem trivial to the nonspecialist. Instances of bird droppings, loose screws, and pebbles kicked up from the takeoff roll having resulted in increased RCS have been reported [12]. Some special stealth-related issues are discussed below.

6.1. Integration of Sensors and Sensor RCS

Active sensors that transmit energy, such as microwave and laser radars, need to have a low probability of inter-

Figure 8. Traveling waves along a surface are treated using a transmission line matching method: the quarter-wave transformer.

cept (LPI). One aspect of LPI involves controlling the spatial distribution of radiation by using narrow antenna beams and low sidelobes. Another is to control the power distribution in the frequency spectrum, which is directly related to the transmitted waveform. For example, wide-bandwidth spread-spectrum pseudorandom waveforms distribute their power almost uniformly over a wide frequency band and hence appear like noise, making detection extremely difficult.

The RCSs of sensors installed on an LO platform, especially antennas in the radar frequency bands, are an area of concern. Unlike cavities, antennas cannot always be hidden from the radar's field of view without degrading the performance of the accompanying system. Ideally, if the incident wave frequency is in the operating band of the antenna (where the antenna is efficient), then its RCS is low because most of the incident wave is collected and appears at the antenna terminals.

The antenna scattering occurs when the frequency of the radar wave is outside the antenna's operating band. Large reflection sources may occur inside the antenna at frequencies out of its operating band, resulting in scattering characteristics similar to those of a cavity. Furthermore, if the antenna is composed of widely spaced (relative to wavelength) periodic elements, Bragg diffraction can occur. Bragg lobes are high-RCS spikes that result at multiple angles when the round trip path length differences between adjacent elements are an integer multiple of 2π . (This is similar to array grating lobes in the radiation case.)

The obvious antenna RCS reduction methods, such as adding lossy materials to attenuate out-of-band reflections, also decrease the antenna's gain in its operating band. The preferred approach is to incorporate a frequency-selective surface (FSS) into the design. An ideal FSS permits radiation in the antenna's frequency band to pass through unattenuated while all other frequencies are reflected or absorbed. FSS shielding has been applied to antennas on ship masts [20] and as missile radomes [21].

In the drive to reduce the number of low-level scattering sources, continuity of the platform external surface should be maintained. The number of apertures (openings) must be kept to a minimum. Apertures are needed for radar and communication antennas, which operate at microwave frequencies, and infrared and optical sensors. By integrating the infrared and optical sensors into the antennas, two or three apertures can be replaced by a single one.

6.2. Computational Advances

The need to predict the mutual interactions between many low-level scattering sources has fueled research in the area of computational electromagnetics (CEM). Numerical solutions of the rigorous equations of scattering from complex bodies have existed since the early 1960s. They involve reducing the electromagnetic equations to a set of simultaneous linear equations, which are solved by matrix methods. The dimension of the matrix increases as the size of the target measured in wavelengths increases (that is, all target dimensions are scaled by the

wavelength of the incident wave). It has only been in recent years that the dramatic increase in computer memory and speed has made this approach practicable for aircraft and ships. Even so, rigorous methods are still limited to low frequencies for targets that are physically large.

Approximate solutions have been developed based on the assumption that scattering is localized, so that interactions between distant parts of the structure can be neglected. The approximations have constantly been improved by adding higher-order corrections based on ever more detailed electromagnetic models as well as empirical data. Both the rigorous and the approximate computer models have incorporated geometry builders that can utilize computer-aided drawing (CAD) files generated by commercially available drawing programs. This capability allows for *concurrent engineering*—the ability to make a structural change and immediately assess its effect on the RCS.

6.3. Effect of Imperfections and Flaws

An important limitation in achieving low RCS is the imperfections introduced during the manufacture and assembly of the platform and the installation of its systems. Their effect on RCS performance depends on whether the imperfections are periodic or random in nature. Most error sources are nearly random, and their net effect on RCSs is to shift energy from the scattering mechanisms discussed previously to diffuse scattering. Diffuse surfaces reflect uniformly in all directions, independent of the angle of incidence; they are electrically rough surfaces. The magnitude of the diffuse scattering increases with the extent of the surface roughness (imperfection). Since diffuse scattering is not angle-dependent, shaping is not a practical way of reducing the RCS for it, and therefore very close tolerances must be maintained to keep the diffuse scattering to acceptable levels. Maintaining close tolerances is one of the primary cost drivers in the manufacture of LO platforms. Eventually a point is reached where the question must be asked: How much money is an additional RCS reduction of a few percent worth?

6.4. Maintenance and Testing

A second important cost driver is the maintenance of an LO platform. The natural elements, along with the harsh operating environment, stress and degrade the electrical and mechanical properties of materials. Special testing methods are required to determine if and when the RCS has been affected by exposure to the environment. So-called go-no-go tests compare a set of measured data from the platform under test with a reference dataset obtained from a known “clean” one of identical configuration. A significant deviation in the data sets would signify a correspondingly significant change in RCS. A test of this type does not require a high level of precision, and therefore can be conducted using portable test equipment. Data can be taken by probes located close to the platform surfaces, that is, in the near-field region of the scatterers.

If a platform fails the go-no-go check in the field, then it will be sent to a test and repair facility for further evaluation. Specialized facilities and repair techniques are required because of the uncommon materials involved and the exacting tolerances that must be satisfied. The integrity of localized repairs can be checked using hand-held reflection devices that verify local surface reflection characteristics.

6.5. Tradeoff between Stealth and Electronic Warfare

Low observability demands the most of technology and forces concessions in many other aspects of platform design and performance. At some point the burden of increasing stealth may become unacceptable. Electronic warfare (EW) techniques (now referred to as *electronic attack* and *electronic protect* in the United States) are a complement to low RCS. Common EW techniques currently in use around the world include jamming, decoys, and chaff [22]. The major disadvantage of EW is that the radar is aware of the target's presence. However, the radar is denied information on the target's range and velocity. Even though the radar is not completely disabled, a combination of EW and low RCS can cause the radar to lose lock, forcing it to reacquire a target repeatedly. This is a time-consuming process that ties up valuable radar resources. With all other factors constant, chaff, deception, and jamming are more effective for low-RCS targets than for conventional ones.

Some older platforms currently in the field are being retrofitted or upgraded to reduce the RCS and other signatures. All new aircraft, ships, and ground vehicles are incorporating some degree of stealth design and technology. However, it appears that the complete dominance of stealth in all aspects of design, as seen in the F-117, has been abandoned. Programs like the F-22, the Comanche helicopter, and the Euro-fighter are opting for a balance between stealth and other performance measures.

7. THE RADAR EQUATION

Consider the situation shown in Fig. 1 with the radar operating at a frequency f . The corresponding wavelength is $\lambda = c/f$, where $c \approx 2.998 \times 10^8$ m/s is the speed of light in free space. Define the following quantities:

- P_t = transmitter power delivered to the transmit antenna
- G_t = transmit antenna gain, a measure of how efficiently the antenna concentrates power in the direction of the target
- G_r = receive antenna gain
- A_{er} = effective area of the receive antenna, which can approach the physical area of the antenna aperture for a very efficient antenna

From antenna theory, antenna gain and effective area are related by

$$G_r = \frac{4\pi A_{er}}{\lambda^2} \quad (11)$$

The power scattered by the target that is delivered to the receive antenna terminals is given by

$$P_r \frac{P_t G_t}{4\pi R_t^2} \sigma \frac{1}{4\pi R_r^2} A_{er}$$

The first factor on the right-hand side is the power density incident on the target. Multiplying this factor by σ gives the fraction of incident power scattered in the direction of the receiver. The product of the first three factors represents the scattered power density at the receive antenna. Finally, multiplying by A_{er} gives the scattered power collected by the antenna.

Specializing to the monostatic case ($G_t = G_r \equiv G$ and $R_t = R_r \equiv R$) and using the relationship between effective area and gain give the result

$$P_r = \frac{P_t G^2 \sigma \lambda^2}{(4\pi)^3 R^4}$$

This form of the radar equation is too simple to be of practical use in predicting a radar's performance. However, two important features are evident. The first is the R^4 in the denominator, which is a disadvantage to the radar system designer, whose goal is to increase the detection range of the radar. The second is that the received power is linearly related to σ , which is a disadvantage to the RCS engineer.

If the minimum scattered power that the radar receiver can detect is P_m , then the corresponding maximum detection range is obtained by solving the radar equation for R :

$$R_m = \sqrt[4]{\frac{P_t G^2 \sigma \lambda^2}{(4\pi)^3 P_m}} \quad (12)$$

Therefore, to halve the maximum detection range requires that the RCS be reduced by a factor of $2^4 (= 16)$.

Finally, note that the radar equation was derived for a single-frequency wave. Typical radar waveforms, such as pulse trains, occupy a band of frequencies. The radar equation may have to be evaluated at several frequencies in the radar band if the quantities in the equation are not constant.

8. CALCULATION OF RADAR CROSS SECTION

RCS prediction methods can be broadly categorized as either rigorous or approximate. Rigorous methods are those that have been shown by mathematical proof to converge to the exact result under the appropriate conditions. However, in practice, there is always some small error present in the computed data due to the numerical evaluation of integrals, computer roundoff, and so on. Examples of rigorous methods are the finite-difference time domain (FDTD) technique and the MM.

Approximate formulations are based on assumptions and therefore are subject to limitations in their application and accuracy. Unlike the rigorous methods, even if there is no computational error, the approximate result

will not necessarily converge to the true result. If the approximation is a good one, then the error will not be significant for the problem under consideration. Examples of approximate methods are PO and microwave optics.

8.1. Phasors

Phasor notation is commonly used when working with time-harmonic fields. *Time-harmonic fields* are those that have a sinusoidal time variation of the form $\cos \omega t$, where $\omega = 2\pi f$. Since the sources and fields have the same time dependence, it can be factored out of all electromagnetic quantities and suppressed (i.e., dropped). When the calculations are completed, the time variation is reintroduced. Thus a time-varying quantity $\mathcal{E}(x, y, z, t)$ can be obtained from the phasor $\mathbf{E}(x, y, z)$ by multiplying the phasor by $e^{j\omega t}$ and taking the real part

$$\mathcal{E}(x, y, z, t) = \text{Re}[\mathbf{E}(x, y, z)e^{j\omega t}]$$

All quantities appearing throughout this article are phasors unless otherwise indicated.

8.2. Spherical and Plane Waves

Ideal spherical waves (i.e., waves for which the planes of constant phase are spheres) originate from point sources, which do not actually exist. However, for practical purposes, spherical wave behavior results if the observer is located "far enough" from an extended source as depicted in Fig. 1. Spherical waves have the phasor form

$$\mathbf{E}(r) = \mathbf{E}_0 \frac{e^{-j\beta r}}{r} \quad (13)$$

where r is the distance from the source. The vector constant \mathbf{E}_0 (which may have complex components) is determined by the amplitude, phase, and polarization of the extended source.

At great distances from the source ($r \rightarrow \infty$) the target only intercepts a small section of the spherical wavefront with a very large radius of curvature. Thus it appears that planes of constant phase exist over the extent of the target, and the electric field can be approximated by

$$\mathbf{E}(r) = \mathbf{E}_0 e^{-j\beta r}$$

where r is now the distance from the phase reference and \mathbf{E}_0 is determined from the intensity of the spherical wave at the target. If the source is at the origin of a spherical coordinate system, then \mathbf{E}_0 can only have $\hat{\theta}$ and $\hat{\phi}$ components in the far zone. (This would be the case for a radar antenna located at the origin.)

Both spherical and plane waves have the characteristics of a transverse electromagnetic (TEM) wave:

1. The electric and magnetic field vectors are perpendicular to each other and the direction of propagation.
2. The magnitudes of the electric and magnetic fields are related by the intrinsic impedance of free space.

Thus, if $\hat{\beta}$ is a unit vector in the direction of propagation, then

$$\mathbf{H} = \frac{\hat{\beta} \times \mathbf{E}}{\eta_0} \tag{14}$$

A plane wave of arbitrary polarization is given by the formula

$$\mathbf{E} = (E_{0\theta}\hat{\theta} + E_{0\phi}\hat{\phi})e^{-j\beta \cdot \mathbf{r}} \tag{15}$$

where \mathbf{r} is a position vector to the point x,y,z at which the field is to be evaluated:

$$\mathbf{r} = \hat{x}x + \hat{y}y + \hat{z}z$$

The corresponding magnetic field intensity for a plane wave propagating inward toward the origin ($\hat{\beta} = -\hat{\mathbf{r}}$) is

$$\mathbf{H} = -\frac{1}{\eta_0}(E_{0\theta}\hat{\phi} - E_{0\phi}\hat{\theta})e^{-j\beta \cdot \mathbf{r}} \tag{16}$$

The $\hat{\theta}$ component of the electric field is called *transverse magnetic to z* (TM_z) because the magnetic field vector associated with this component [$E_{0\theta}\hat{\phi}$ term in Eq. (16)] lies entirely in a plane transverse to the z axis. Similarly, the $\hat{\phi}$ component of the electric field is referred to as *transverse electric to z* (TE_z) because this component of the electric field [$E_{0\phi}\hat{\theta}$ term in Eq. (15)] lies entirely in a plane transverse to the z axis. Thus, for a TM_z-polarized plane wave $E_{0\phi} = 0$; for a TE_z-polarized plane wave $E_{0\theta} = 0$. Any arbitrary polarization can be expressed as a linear combination of the two. In a similar manner one could define TE_x, TM_y, and so on.

8.3. Radiation Integrals

Scattered fields are set up by a combination of electric and (in general) magnetic currents. Currents are induced such that the total fields satisfy the boundary conditions and Maxwell's equations. The radiation integrals provide a means of calculating the fields due to a prescribed set of currents. The radiation integrals, or Stratton–Chu integrals, are integral solutions to Maxwell's equations. They can be derived directly by taking the curl of Maxwell's first two equations, using the vector Green's theorem, and then integrating [23].

For RCS calculations, according to Eq. (1), only the scattered field far from the target is of interest, because $R \rightarrow \infty$. Consider a scattering body of volume V that is enclosed by a surface S as shown in Fig. 9. The standard convention is to denote observation point quantities by unprimed symbols, and source point quantities by primed symbols.

In the far zone, the following approximations are employed:

1. The vector from the origin to the observation point and the vector from any source point on S to the observation point are approximately parallel (\mathbf{R} parallel to \mathbf{r}).

Figure 9. Current flows on the surface of a PEC. The total scattered field at the observation point is obtained by an integration of the current over the entire surface.

2. For large distances the difference in amplitude between a spherical wave emanating from the origin and one emanating from any point on the surface S is negligible ($1/R \approx 1/r$).

With these assumptions, the radiation integral for the electric field components tangential to a sphere of radius r centered at the origin can be expressed as

$$\begin{aligned} \mathbf{E}_{s\theta}(x,y,z) &= -\frac{j\beta\eta_0}{4\pi r} e^{-j\beta r} \iiint_V \left(\mathbf{J} \cdot \hat{\theta} + \frac{1}{\eta_0} \mathbf{M} \cdot \hat{\phi} \right) e^{-j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} \end{aligned} \tag{17a}$$

$$\begin{aligned} \mathbf{E}_{s\phi}(x,y,z) &= -\frac{j\beta\eta_0}{4\pi r} e^{-j\beta r} \iiint_V \left(\mathbf{J} \cdot \hat{\phi} - \frac{1}{\eta_0} \mathbf{M} \cdot \hat{\theta} \right) e^{-j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} \end{aligned} \tag{17b}$$

where \mathbf{J} (A/m²) and \mathbf{M} (V/m²) are the volume electric and magnetic currents, respectively. (Magnetic current is a fictitious quantity because isolated magnetic charge does not exist, but under some circumstances it is used as a matter of mathematical convenience.)

The use of volume current is advantageous for computing the scattered fields from highly inhomogeneous bodies. However, for most targets, it is more efficient to use a surface current formulation. As shown in Fig. 10, current flows on all interfaces between materials, as well as the external surface of the target. For surface currents, the

Figure 10. If a target is not a PEC, then volume currents may exist inside the target. The volume currents can be replaced by surface currents using the surface equivalence principle.

far-field form of the radiation integral becomes

$$\begin{aligned} \mathbf{E}_{s\theta}(x, y, z) &= -\frac{j\beta\eta_0}{4\pi r} e^{-j\beta r} \iint_S \left(\mathbf{J}_s \cdot \hat{\theta} + \frac{1}{\eta_0} \mathbf{M}_s \cdot \hat{\phi} \right) e^{-j\beta \hat{r} \cdot \mathbf{r}'} \quad (18a) \end{aligned}$$

$$\begin{aligned} \mathbf{E}_{s\phi}(x, y, z) &= -\frac{j\beta\eta_0}{4\pi r} e^{-j\beta r} \iint_S \left(\mathbf{J}_s \cdot \hat{\phi} - \frac{1}{\eta_0} \mathbf{M}_s \cdot \hat{\theta} \right) e^{-j\beta \hat{r} \cdot \mathbf{r}'} \quad (18b) \end{aligned}$$

where S includes all of the surfaces over which nonzero current exists. If the current is known, then the integrals in Eqs. (17) or (18) can be evaluated numerically.

If the scattering body is a perfect electrical conductor (PEC), then only electric current exists, and the surface of integration corresponds to a real physical surface. However, S in Eq. (18) need not exist; it can be a fictitious surface defined for convenience. The currents on the fictitious surface can be determined from the actual tangential electric and magnetic fields at every point on S . Thus

$$\mathbf{J}_S = \hat{\mathbf{n}} \times \mathbf{H} \quad (19a)$$

$$\mathbf{M}_S = \hat{\mathbf{n}} \times \mathbf{E} \quad (19b)$$

where $\hat{\mathbf{n}}$ is the unit vector normal to the surface. This is a consequence of the *equivalence principle* of electromagnetics [4].

8.4. Approximate Prediction Methods

Approximate prediction methods are used for a variety of reasons, but primarily because they are computationally less demanding, thereby allowing data to be generated more rapidly. This is an advantage in the early stages of design, when major tradeoff studies are being performed. Coarse approximations can be applied in the beginning, and then refined as the design progresses. Eventually it may be necessary to verify the performance of a specific design by a rigorous calculation.

At microwave frequencies, useful approximations should include scattering contributions from large surface areas, edges, surface waves, and interactions between and among surfaces and edges. There are two approaches to computing the RCS. One is based on estimating the induced currents and is referred to as a current-based approach: the PO approximation. The second is based on postulating relationships between the incident and scattered waves, or rays: GO. This is a ray-based approach.

PO and GO are used to calculate the scattered field from surfaces; the effects of the edges of surfaces are not

properly modeled or not included. Supplemental theories have been developed to allow for edge scattering. The PTD is the current-based method used in conjunction with PO. The GTD is a ray-based method for calculating diffracted fields. Both the current and ray approaches can be shown to yield identical results under the same conditions. Table 3 summarizes the two methods.

8.4.1. Physical Optics. A rigorous calculation of the currents \mathbf{J}_s and \mathbf{M}_s typically requires a great amount computational effort. The PO approximation is an estimate of the electric current that is accurate for a large, smooth PEC. The current is approximated by [9]

$$\mathbf{J}_s(x, y, z) = \begin{cases} 2\hat{\mathbf{n}}(x, y, z) \\ \quad \times \mathbf{H}_i(x, y, z) & \text{on the illuminated part of } S \\ 0 & \text{on the shadowed part of } S \end{cases} \quad (20)$$

where \mathbf{H}_i is the incident magnetic field intensity.

Equation (20) is explained by approximating the target surface in the vicinity of the point (x, y, z) by an infinite, flat surface. Assume that the incident wave is due to a source at a distance R and the electric field vector is parallel to the surface. By the method of images, the target can be removed and replaced by an equivalent scattering source at a distance R below the surface. To satisfy the boundary conditions (i.e., the tangential component of the total electric field must be zero) the electric field of the equivalent scattering source must be equal and opposite to that of the incident field. Because the two waves are propagating in opposite directions toward the surface, from Eq. (14) the magnetic field vectors will be oriented in the same direction; thus the factor of 2 in Eq. (20).

Perhaps the simplest application of the PO approximation is for a flat plate [6]. Let the plate be centered at the origin in the $z = 0$ plane and have dimensions of a in the x direction and b in the y direction. A plane wave of arbitrary polarization is incident at an angle θ_i . The PO approximation for the current is

$$\mathbf{J}_S \approx 2(\mathbf{J}_{0x}\hat{\mathbf{x}} + \mathbf{J}_{0y}\hat{\mathbf{y}}) \frac{e^{-j\beta \hat{\mathbf{r}}_i \cdot \mathbf{r}'}}{\eta_0} \quad (21)$$

where

$$J_{0x} = E_{0\theta} \cos \phi - E_{0\phi} \cos \theta \sin \phi$$

$$J_{0y} = E_{0\theta} \sin \phi + E_{0\phi} \cos \theta \cos \phi$$

and

$$-\hat{\mathbf{r}}_i \cdot \mathbf{r}' = u_i x + v_i y + w_i z$$

Table 3. Summary of Approximate Methods For RCS Prediction

Mechanism	Current-Based	Ray Optics-Based
Surface scattering	GO surface current—physical optics (PO)	Specular rays—geometric optics (GO)
Edge scattering	Fringe currents—physical theory of diffraction (PTD)	Diffracted rays—geometric theory of diffraction (GTD)
Surface waves	Interaction between fringe currents	Multiple diffractions between edges

The subscript “i” denotes incident wave quantities. The x , y , and direction cosines are defined by

$$u_i = \sin \theta_i \cos \phi_i \quad (22a)$$

$$v_i = \sin \theta_i \sin \phi_i \quad (22b)$$

$$w_i = \cos \theta_i \quad (22c)$$

Using Eq. (21) in (18a) and the fact that $z' = 0$ gives

$$\mathbf{E}_{s\theta} = \frac{-j\beta}{2\pi r} e^{-j\beta r} \hat{\boldsymbol{\theta}} \cdot (\mathbf{J}_{0x} \hat{\mathbf{x}} + \mathbf{J}_{0y} \hat{\mathbf{y}}) \int_{-a/2}^{a/2} \int_{-b/2}^{b/2} e^{j\beta(x'u_i + y'v_i)} e^{j\beta(x'u + y'v)} dx' dy' \quad (23)$$

For the monostatic RCS $u_i = u$ and $v_i = v$; therefore the exponents in the integrand can be combined. Furthermore, the x and y integrals can be separated, and both are of the form

$$\int_{-a/2}^{a/2} e^{j2\beta x'u} dx' = a \frac{\sin(\beta ua)}{\beta ua} \equiv a \operatorname{sinc}(\beta ua) \quad (24)$$

Now assume that a TM_z -polarized plane wave is incident ($E_{0\phi} = 0$) and the radar receive antenna is sensitive to the same polarization. Thus we use the notation $\sigma_{\theta\theta}$, where the first subscript denotes the polarization of the receiver and the second the polarization of the incident wave. Using Eqs. (23) and (24) in the definition of RCS yields

$$\sigma_{\theta\theta} = \frac{4\pi A^2}{\lambda^2} \operatorname{sinc}^2(\beta ua) \operatorname{sinc}^2(\beta vb) \cos^2 \theta \quad (25)$$

where $A = ab$ is the area of the plate.

The monostatic RCS of a square plate with $a = 5\lambda$ and $b = 2.5\lambda$ is shown in Fig. 11 for $\phi = 0^\circ$. The xz and yz planes are referred to as *principal planes*, because they are transverse to the plate edges. For comparison, the RCS obtained by a rigorous calculation of the current (MM) is also shown. (The MM result is converged and can therefore be considered exact.) The maxima of the $\operatorname{sinc}(\cdot)$

Figure 11. A comparison of the RCS of a plate with dimensions $a = 5\lambda$ and $b = 2.5\lambda$ in the plane $\phi = 0^\circ$. The approximate (PO) and rigorous (MM) methods are in close agreement in the region of the main lobe but disagree at wide angles.

functions in Eq. (25) occur at $\theta = \phi = 0^\circ$ and have values of 1. Thus the maximum value of the RCS is given by Eq. (6). As the dimensions of the plate in wavelengths increase, the width of the central lobe narrows. Note that the major difference between the two methods occurs at wide angles (near $\pm 90^\circ$). In this region the RCS is primarily determined by the current distribution near the plate edges, which is where the PO approximation fails.

8.4.2. Physical Theory of Diffraction. The PTD, also known as the method of edge waves (MEW), is a current-based approach to obtaining the edge scattered field [24]. The total current on a conductor with an edge can be decomposed into a PO component and a nonuniform (edge or fringe) component. If the fringe current is known, then the edge-scattered field can be computed by using this current in the radiation integral. The total field at an observation point is the sum of the PO and edge-scattered fields.

For a surface that is very large relative to the wavelength of the incident wave, the current distribution at a point near the edge is primarily determined by the local features of the geometry. If the edge is very long and the point under consideration is not close to the end of the edge, then the current is approximately the same as that for an infinitely long edge. Thus edge scattering can be considered a local phenomenon, and the current approximated by the current of the corresponding canonical scattering problem. (A canonical problem is one that has fundamentally the same geometry as the one under consideration, but whose solution is known.) If the total current can be determined for a canonical problem, in this case an infinite knife edge, then the PO component can be subtracted out and the result used as an estimate for the fringe current on a finite edge. The fringe currents are then used in the radiation integrals to obtain an edge-scattered field.

This approach has the advantage that the edge-scattered fields remain finite at shadow and reflection boundaries. However, the fringe currents extend a significant distance from the edge (a minimum of about 0.5λ), so that two-dimensional integrals must be evaluated. Michaeli has reduced the PTD fringe currents to filaments that flow along the body edge, thus reducing the integration to one dimension [25].

The electric and magnetic current filaments for a knife edge are given by

$$\begin{aligned} \mathbf{I}_e = & \frac{-2j}{\eta_0 \beta \sin^2 \gamma'} \frac{\sqrt{2} \sin(\phi'/2)}{\cos \phi' + \delta} [\sqrt{1 - \delta} - \sqrt{2} \cos(\phi'/2)] (\mathbf{E}_i)_{\tan} \\ & + \frac{2j}{\beta \sin \gamma' (\cos \phi' + \delta)} (\cot \gamma' \cos \phi' + \cos \phi \cot \gamma) \\ & + \sqrt{2} \cos(\phi'/2) \frac{\delta \cot \gamma' - \cot \gamma \cos \phi}{\sqrt{1 - \delta}} (\mathbf{H}_i)_{\tan} \end{aligned} \quad (26)$$

$$\mathbf{I}_m = \frac{2j\eta_0}{\beta \sin \gamma' \sin \gamma \cos \phi' + \delta} \left(1 - \frac{\sqrt{2} \cos(\phi'/2)}{\sqrt{1 - \delta}} \right) (\mathbf{H}_i)_{\tan} \quad (27)$$

where

$$\delta = \frac{\cos \gamma' \cos \gamma + \sin \gamma' \sin \gamma - \cos^2 \gamma'}{\sin^2 \gamma'}$$

The PTD is simple in principle, but can be inconvenient in practice. The currents in Eqs. (26) and (27) are a function of incidence angle, so for monostatic calculations the integrations must be performed again after each angle change. Another disadvantage is that modeling the fringe current interaction is difficult. On the plus side is that the edge-scattered field is simply added to the PO field. This is the major attraction of the PTD, since PO is so convenient and widely used.

8.4.3. Geometric Optics. GO is the theory of ray tracing that has been used for centuries to design systems of lenses such as telescopes. It works well at optical frequencies because the lens and mirror dimensions are much larger than a wavelength and thus the interaction of the wave with the lens becomes a localized phenomenon. The reflected ray appears to originate from a single point on the surface, called a specular or reflection point.

GO is the most basic theory that describes wave behavior on reflection or refraction at an interface between two materials [10]. GO is based on seven assumptions or postulates:

1. Waves are everywhere locally plane and TEM.
2. The wave direction is specified by the normal to the equiphase surfaces, that is, a ray. (Equiphase surfaces are also referred to as eikonal surfaces.)
3. Rays travel in straight lines in a homogeneous medium (Fermat's principle).
4. Polarization is constant along a ray.
5. At the reflection point, the reflected fields are linearly related to the incident fields by reflection coefficients.
6. Reflected rays satisfy the law of reflection.
7. Power in a tube of rays is conserved. The field strength is inversely proportional to the square root of the cross-sectional area of the flux tube.

Ray tubes are also called ray bundles or flux tubes. For a plane wave, all of the rays are parallel and therefore a bundle of rays has a constant cross section. However, for a spherical wave, a bundle of rays expands as the distance from the source increases. The power flowing through a slice of the bundle must be constant if the medium is lossless and power is conserved.

For the general scattering problem the incident wave front and scattering surface may have some curvature, as illustrated in Fig. 12. The local curvature at a point on a doubly curved surface, whether it is a wave front or target surface, can be expressed in terms of two principal radii of curvature. Let the incident wave front be characterized by the principal radii of curvature R_1^i and R_2^i . Similarly, let the scattering surface be characterized by the principal radii of curvature R_1^s and R_2^s . If these two sets of radii are

Figure 12. GO can be used to predict the reflected field from a doubly curved surface. The curvatures of the incident wave front and surface affect the curvature of the reflected wavefront.

known, then the radii of curvature of the reflected wavefront can be computed using the following equation

$$\frac{1}{R_{1,2}^r} = \frac{1}{2} \left(\frac{1}{R_1^i} + \frac{1}{R_2^i} \right) + \frac{1}{f_{1,2}} \quad (28)$$

where $f_{1,2}$ are the focal lengths in the two principal planes. (The focal length is another measure of curvature.) The focal lengths can be computed by [4]

$$\begin{aligned} \frac{1}{f_{1,2}} = \frac{1}{\cos \theta_i} & \left(\frac{\sin^2 \theta_2}{R_1^s} + \frac{\sin^2 \theta_1}{R_2^s} \right) \\ & \pm \left[\frac{1}{\cos^2 \theta_i} \left(\frac{\sin^2 \theta_2}{R_1^s} + \frac{\sin^2 \theta_1}{R_2^s} \right)^2 - \frac{4}{R_1^s R_2^s} \right]^{1/2} \end{aligned} \quad (29)$$

where the angles are given by

$$\theta_1 = \cos^{-1}(\hat{\mathbf{t}}_1 \cdot \hat{\boldsymbol{\beta}}_i) \quad (30a)$$

$$\theta_2 = \cos^{-1}(\hat{\mathbf{t}}_2 \cdot \hat{\boldsymbol{\beta}}_i) \quad (30b)$$

$$\theta_i = \cos^{-1}(\hat{\mathbf{n}} \cdot \hat{\boldsymbol{\beta}}_i) \quad (30c)$$

The vectors $\hat{\mathbf{t}}_1$ and $\hat{\mathbf{t}}_2$ are tangent to the surface at the reflection point and lie in principal planes 1 and 2, respectively.

The postulates allow the reflected field to be computed from the incident field at the reflection point by multiplying by a reflection coefficient. In matrix form

$$\mathbf{E}_r(s) = \mathbf{R} \cdot \mathbf{E}_i(s') \mathbf{A}(s) e^{-j\beta s} e^{j\phi_c} \quad (31)$$

where

$$\mathbf{E}_r(s) = \begin{bmatrix} E_{r\perp}(s) \\ E_{r\parallel}(s) \end{bmatrix} \quad (32)$$

$$\mathbf{E}_i(s') = \begin{bmatrix} E_{i\perp}(s') \\ E_{i\parallel}(s') \end{bmatrix} \quad (33)$$

and the reflection coefficient matrix is

$$\mathbf{R} = \begin{bmatrix} \Gamma_{\perp\perp} & \Gamma_{\perp\parallel} \\ \Gamma_{\parallel\perp} & \Gamma_{\parallel\parallel} \end{bmatrix} \quad (34)$$

The subscripts \parallel and \perp refer to a polarization where the electric field is parallel or perpendicular to the plane of incidence (the plane defined by the vectors $\hat{\mathbf{n}}$ and $\hat{\boldsymbol{\beta}}_i$).

The divergence and spreading factor for the reflected wave is

$$A(s) = \left(\frac{R_1^r R_2^r}{(R_1^r + s)(R_2^r + s)} \right)^{1/2} \quad (35)$$

The quantity s' is the distance from the source point S to the reflection point Q , and s is the distance along the reflected ray from the reflection point to the observation point P .

The last factor in Eq. (31) allows for phase transitions through caustics, which are points or lines at which the cross section of a ray tube is zero (and thus the power density is infinite); we have

$$\phi_c = \begin{cases} 0 & \text{if neither center of curvature lies between } Q \text{ and } P \\ \pi/2 & \text{if one center of curvature lies between } Q \text{ and } P \\ \pi & \text{if both centers of curvature lies between } Q \text{ and } P \end{cases} \quad (36)$$

A well-known formula for the RCS of a curved surface can be derived using the preceding formulas. The fact that for a plane wave $R_1^i = R_2^i = \infty$ and the observer is far from the target ($R_1^s, R_2^s \gg s$) yields the approximation

$$\sigma \approx \pi R_1^s R_2^s \quad (37)$$

Equation (37) has been widely applied to basic geometric shapes such as spheres and ellipsoids. Note that GO predicts zero field in shadow regions. That is, if the path between the source and observation points is blocked, then there is no received field.

8.4.4. Geometric Theory of Diffraction. GO provides a means of calculating the field reflected from a surface. The associated edge effects require a mathematical model for edge diffraction. The GTD is such a ray-based edge diffraction theory [26]. For the GTD, rays are hypothesized that obey diffraction laws similar to reflection laws. A diffraction coefficient is defined, which depends on the edge geometry and polarization of the incident wave. On diffraction, the scattered field is given by the incident field

times the diffraction coefficient. Furthermore, the diffracted wave follows prescribed straight-line paths in free space. The total field at an observation point is the vector sum of all the reflected and diffracted fields arriving at that point.

As first developed, the GTD had several shortcomings with regard to singularities in the field. Several modified versions of the GTD, such as the uniform theory of diffraction (UTD) [27] and the asymptotic theory of diffraction (ATD) [28], have eliminated the problems in many cases by introducing correction factors. In the following discussions GTD will refer to the collection of these diffraction theories.

The postulates of the GTD are similar to those of GO; only numbers 5 and 6 change:

5. At the diffraction point, the diffracted fields are linearly related to the incident fields by diffraction coefficients.
6. Diffracted rays emerge radially from the edge.

In addition, rays traversing a caustic encounter a phase advance of 90° ; an edge is always a caustic. At a focus there is a phase advance of 180° .

The behavior of diffracted rays from an infinite conducting wedge is illustrated in Fig. 13. The diffracted rays lie on the surface of a cone (referred to as the Keller cone) with its tip located at the diffraction point and axis along the edge. The cone half-angle γ is equal to the angle that the incident ray makes with the edge, γ' (a consequence of Fermat's principle). The coordinate variables (s, γ, ϕ) and (s', γ', ϕ') uniquely define the directions of diffraction (observation) and incidence (source), respectively.

In the light of postulate 5 the diffracted field from an edge can be written as

$$\mathbf{E}_d(s) = \mathbf{D} \cdot \mathbf{E}_i(s') A(s) e^{-j\beta s} \quad (38)$$

The vectors \mathbf{E}_d and \mathbf{E}_i have the same form as in Eqs. (32) and (33), except that parallel and perpendicular are defined relative to the edge rather than the plane of incidence. In Eq. (38) \mathbf{D} is a two-dimensional matrix of

Figure 13. The GTD is used to predict edge diffracted fields. As long as the diffraction point is not near the end of the edge, the diffracted field is similar to that of an infinitely long edge.

diffraction coefficients

$$\mathbf{D} = \begin{bmatrix} D_{\perp\perp} & D_{\perp\parallel} \\ D_{\parallel\perp} & D_{\parallel\parallel} \end{bmatrix} \quad (39)$$

and the divergence and spreading factor is

$$A(s) = \left(\frac{\rho_c}{s(\rho_c + s)} \right)^{1/2} = \begin{cases} \frac{1}{\sqrt{s}}, & \text{plane waves} \\ \sqrt{\frac{s'}{s(s+s')}}}, & \text{spherical waves} \end{cases} \quad (40)$$

where ρ_c is the distance from the caustic.

The diffraction coefficients are derived from the appropriate canonical problem. The GO field is subtracted from the total scattered field. The difference is the diffracted field, which can be used to determine the elements of \mathbf{D} , given the known form of Eq. (36). For a knife edge the diffraction coefficients are

$$D_{\parallel,\perp} = \frac{e^{-j\pi/4}}{2\sqrt{2\pi\beta} \sin \gamma} \left(\frac{F(\beta\ell a(\phi^-))}{\cos \phi^-} \pm \frac{F(\beta\ell a(\phi^+))}{\cos \phi^+} \right) \quad (41)$$

where the transition function is

$$F(\xi) = j2|\sqrt{\xi}|e^{j\xi} \int_{|\sqrt{\xi}|}^{\infty} e^{-t^2} dt \quad (42)$$

with

$$\begin{aligned} \phi^\pm &= \phi \pm \phi' \\ \alpha(\phi^\pm) &= 2 \cos(\phi^\pm/2) \\ \ell &= \begin{cases} \frac{ss'}{s+s'} \sin^2 \gamma, & \text{spherical waves} \\ s \sin^2 \gamma, & \text{plane waves} \end{cases} \end{aligned} \quad (43)$$

In special cases where \mathbf{E}_d is tangent to the surface of a PEC, the surface diffracted ray is zero. For a rectangular plate, there will not be an interaction (higher-order diffraction) between the two parallel edges. In fact, there is an interaction between two edges of a parallel plate even when the electric field is parallel to the edge, and it is included by adding a slope diffraction term to Eq. (38)

$$\mathbf{E}_d(s) = \left(\mathbf{D} \cdot \mathbf{E}_i(\mathbf{Q}) + \mathbf{D}' \cdot \frac{\partial \mathbf{E}_i}{\partial n} \Big|_{\mathbf{Q}} \right) A(s) e^{-j\beta s} \quad (44)$$

where \mathbf{D}' is a matrix of slope diffraction coefficients.

8.5. Rigorous Methods

8.5.1. Method of Moments. The radiation integrals provide a means of calculating the scattered field from a target once the induced current on the surface is known. Except for the most simple shapes, the current distribu-

tion on the target is not known accurately. For electrically large bodies that are smooth and sufficiently flat, the PO approximation provides a good estimate at points far from discontinuities and shadow boundaries. By a discontinuity is meant any abrupt change in the surface contour or composition. Examples are edges, steps, cracks, and material joints.

In order to compute the current rigorously, an integral equation (IE) for the current can be formulated from Maxwell's equations and the boundary conditions. IEs have the unknown quantity in the integrand and possibly in other terms outside of the integral. In most problems of practical interest, the IE must be solved numerically using a computer. The most popular solution technique, called the *method of moments* (MM), consists in expanding the current into a series with unknown coefficients [11]. The expansion is inserted into the integral equation and a weighting process applied. The properties of the expansion functions are used to reduce the integral equation to a set of simultaneous linear equations that can be solved for the coefficients.

The *E*-field integral equation (EFIE) is the most commonly used. It can be derived by using the general form of the radiation integrals and placing the observation point on the surface of the body. [The general form of the radiation integrals does not make the assumption of a far-field observation point as in Eqs. (17) and (18).] If the target is a PEC, then $(\mathbf{E}_i + \mathbf{E}_s)_{\text{tan}} = 0$ on the surface. The incident field is known, and the radiation integrals give the scattered field in terms of the unknown surface current. Thus the following form of the EFIE is obtained:

$$\begin{aligned} \mathbf{E}_i(\mathbf{r})|_{\text{tan}} &= \iint_S (j\omega\mu_0 \mathbf{J}_s(\mathbf{r}') G(\mathbf{r}, \mathbf{r}')) \\ &\quad - \frac{j}{\omega\epsilon} [\nabla' \cdot \mathbf{J}_s(\mathbf{r}')][\nabla' G(\mathbf{r}')] \Big|_{\text{tan}} ds' \end{aligned} \quad (45)$$

where, as usual, primes denote source point quantities associated with the current and unprimed denotes observation point quantities. The free-space Green function is defined by

$$G(\mathbf{r}, \mathbf{r}') = \frac{e^{-j\beta R(\mathbf{r}, \mathbf{r}')}}{4\pi R(\mathbf{r}, \mathbf{r}')} \quad (46)$$

with

$$R(\mathbf{r}, \mathbf{r}') = \sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}$$

Equation (45) is reduced to a matrix equation using the MM. First the current is expanded into a series of basis functions $\{\mathbf{J}_n\}$ with unknown current coefficients $\{I_n\}$:

$$\mathbf{J}_s(\mathbf{r}') = \sum_{n=1}^N I_n \mathbf{J}_n(\mathbf{r}') \quad (47)$$

The basis functions are chosen to be mathematically convenient and adequately represent the current over

the surface. They are of two general types: (1) subdomain or (2) entire domain. In the subdomain case, each function is nonzero over only a part of the surface. On the other hand, each entire domain basis function is nonzero over the entire surface. Using a function of time as an analogy, it can be expressed as a series of sinusoids (Fourier series), which are an example of entire-domain basis functions. The time function could also be expressed as a series of steps (a “stair step” approximation), which is an example of subdomain basis functions.

Once the basis functions are chosen, Eq. (47) is inserted into Eq. (45) and a test is performed that involves multiplying by a set of weighting functions \mathbf{W}_n and integrating. Generally the complex conjugates of the basis functions are selected as the weighting functions (Galerkin’s method): $\mathbf{W}_n = \mathbf{J}_n^*$. This leads to N equations

$$V_m = \sum_{n=1}^N \iint_{S_m} Z_{mn} I_n, \quad m = 1, 2, \dots, N$$

which can be cast into the matrix form

$$\mathbf{V} = \mathbf{Z}\mathbf{I} \quad (48)$$

where

$$Z_{mn} = \iint_{S_m} \iint_{S_n} \{j\omega\mu_0 \mathbf{W}_m(\mathbf{r}) \cdot \mathbf{J}_n(\mathbf{r}') - \frac{j}{\omega\epsilon} [\nabla' \cdot \mathbf{J}_n(\mathbf{r}')] [\nabla' \cdot \mathbf{W}_m(\mathbf{r})] \} \times G(\mathbf{r}, \mathbf{r}') ds ds' \quad (49)$$

which is an impedance, and

$$V_m = \iint_{S_m} \mathbf{W}_m(\mathbf{r}) \cdot \mathbf{E}_i ds \quad (50)$$

which is a voltage. Thus Eq. (48) can be solved for \mathbf{I} , then used in Eq. (47), which in turn is used in the radiation integrals to obtain the scattered field.

A commonly encountered basis function is the triangular subdomain [29]. The surface of a target is represented by a collection of triangular facets. This type of subdomain has the flexibility to model curved surfaces with arbitrary edge contours. Each basis function is associated with an edge as shown in Fig. 14:

$$\mathbf{J}_n(\mathbf{r}') = \begin{cases} \frac{L_n \rho_n^+}{2A_n^+}, & \mathbf{r}' \text{ in } T_n^+ \\ \frac{L_n \rho_n^-}{2A_n^-}, & \mathbf{r}' \text{ in } T_n^- \end{cases} \quad (51)$$

The current at a point in a subdomain is the vector sum of the currents crossing all edges, weighted by the distance from the edge.

Using Eq. (51) in Eq. (49) gives

$$Z_{mn} = L_m \left(\frac{j\omega}{2} (A_{mn}^+ \cdot \rho_m^{c+} + A_{mn}^- \cdot \rho_m^{c-}) + \Phi_{mn}^- - \Phi_{mn}^+ \right)$$

Figure 14. Any arbitrary-shaped surface can be represented by triangular facets. Triangular (rooftop) basis functions span each edge. The total current is a superposition of all of the basis functions at a point.

where

$$A_{mn}^\pm = \frac{\mu_0}{4\pi} \iint_{S_n} \mathbf{J}_n(\mathbf{r}') \frac{e^{-j\beta R_{mn}^\pm}}{R_{mn}^\pm} ds'$$

$$\Phi_{mn}^\pm = \frac{j}{4\pi\omega\epsilon_0} \iint_{S_n} \nabla' \cdot \mathbf{J}_n(\mathbf{r}') \frac{e^{-j\beta R_{mn}^\pm}}{R_{mn}^\pm} ds'$$

$$R_{mn}^\pm = |\mathbf{r}_{mn}^{c\pm} - \mathbf{r}'|$$

The excitation vector elements are

$$V_m = L_m (\mathbf{E}_m^+ \cdot \rho_m^{c+} + \mathbf{E}_m^- \cdot \rho_m^{c-})$$

where the electric field at the centroid of the facet is

$$\mathbf{E}_m^\pm = \mathbf{E}_i(\mathbf{r}_m^{c\pm})$$

These basis functions result in a linear approximation to the current over each facet. The rigorous result for the rectangular plate shown in Fig. 11 was computed using the method of moments.

There are a few instances when other basis functions may be more efficient than triangular subdomains. For example, consider a body of revolution (BoR), which is generated by rotating a plane curve around an axis. Included in this class are cylinders, cones, spheres, and ellipsoids. A hybrid basis function, that is, a combination of entire-domain and subdomain basis functions, is an efficient alternative to triangular facets [30]. In these cases overlapping triangular basis functions can be used to represent the current along the generating curve axis, while entire-domain complex exponentials are used in the azimuthal direction (around the circumference of the body). The result is a linear approximation to the current in the axial direction (from back to front) and a Fourier series representation for the current around the body. The major advantage of this approach is that each Fourier mode, which is actually a matrix whose size is determined by the number of subdomains along the axis, is independent of all other modes. Thus a large-matrix problem is decomposed into a series of smaller matrices, thereby

permitting larger bodies to be modeled for a given computer resource.

8.6. Hybrid Methods

Hybrid computation methods combine several prediction techniques in a single solution [31,32]. A hybrid solution decomposes a problem into subproblems, which are solved using different techniques. Generally the mutual effects (interaction between the subproblems) are included to some degree. For example, PO is known to give excellent results for large smooth surfaces away from edges and discontinuities. A hybrid approach might use PO on regions of the surface away from discontinuities and the MM near discontinuities. Larger problems can be modeled than with a pure MM approach, and more accuracy is achieved than using PO separately. The disadvantage is that each hybrid combination is tailored for a specific type of problem and therefore may not yield accurate results under all conditions.

One hybrid method that is used extensively in RCS calculation for large targets at high frequencies is the shooting and bouncing ray (SBR) technique [33]. It combines GO and PO, and can be supplemented by the PTD. Current distributions are determined from the trajectories of rays in a dense bundle. The current distributions can be used to:

1. Initiate secondary rays to evaluate multiple reflections
2. Compute PTD fringe currents for edge diffraction contributions
3. Compute the far scattered fields

Currently this technique is the most accurate and flexible for computing the RCSs of large complex targets such as aircraft with engine inlets and cockpits.

8.7. Surface Impedance Approximation

The *impedance boundary* is an approximate boundary condition that can be used to replace a surface composed of multiple materials and layers by a single surface. It was first proposed by Leontovich [34] and is frequently referred to as the Leontovich boundary condition. The concept is illustrated in Fig. 15, which shows the use of a surface current approach to calculate the scattered field from a target composed of several materials.

The possibility of surface currents flowing on all of the interfaces dramatically increases the mathematical and computational complexity of the problem over that of a single surface. In many cases it may be sufficient to replace the collection of surfaces with a single layer that has approximately the same external scattering properties as the combination of original surfaces. (For the RCS the fields inside the body are not of interest.) The same scattering properties for the original and equivalent problems are ensured if the boundary conditions on the tangential field components are the same. The required relationship between the electric and magnetic fields is referred to as a *surface impedance approximation*.

Figure 15. A complex multilayered target can be replaced by an equivalent target having the same surface contour but an equivalent surface impedance.

Mathematically it relates the tangential components of the electric and magnetic fields at every point on the surface:

$$\eta_s = \frac{|\mathbf{E}_{\text{tan}}|}{|\mathbf{H}_{\text{tan}}|} \quad (52)$$

where η_s is the surface impedance in ohms. In vector form

$$\eta_s \hat{\mathbf{n}} \times \mathbf{H} = \mathbf{E} - (\hat{\mathbf{n}} \cdot \mathbf{E}) \hat{\mathbf{n}} = \eta_s \mathbf{J}_s \quad (53)$$

There is a dual to this equation:

$$-\frac{1}{\eta_s} \hat{\mathbf{n}} \times \mathbf{E} = \mathbf{H} - (\hat{\mathbf{n}} \cdot \mathbf{H}) \hat{\mathbf{n}} = \frac{1}{\eta_s} \mathbf{M}_s \quad (54)$$

Comparing Eqs. (53) and (54) reveals that the surface impedance relates the electric and magnetic currents at every point on the surface:

$$\mathbf{M}_s = -\eta_s \hat{\mathbf{n}} \times \mathbf{J}_s \quad (55)$$

Note that $\eta_s = 0$ corresponds to a PEC, and the resulting reflection coefficient for a wave normally incident on the PEC is

$$\Gamma = \frac{\eta_s - \eta_0}{\eta_s + \eta_0} = -1 \quad (56)$$

The surface impedance approximation is most accurate when

1. The surface is electrically large and the incident wave is near normal incidence to the surface ($\theta_i \approx 0^\circ$).
2. The relative dielectric constant of the material is high ($\sqrt{\epsilon_r} \gg 1$).
3. The local radius of curvature of the surface is large compared to a wavelength.

Impedance boundary conditions can be used to derive integral equations (35) or to simplify an approximate solution. They are widely used in spite of the fact that they usually cannot be justified rigorously.

An estimate of the surface impedance can be obtained from the permittivities and permeabilities of the constituent materials. For layers, a transmission-line model can be used to compute the reflection coefficient at the outer surface, and then Eq. (56) solved for η_s . Using this approach, η_s is a function of the angle of incidence because the Fresnel reflection coefficients are angle-dependent. Generally an average value near normal incidence is used, because it is near the local normal that each region of the surface makes its greatest contribution to the RCS.

A second set of approximate boundary conditions are used to represent thin films [36]. They are the resistive sheet and conductive sheet boundary conditions, which provide a relationship between the currents on the surface and the tangential field components. A resistive sheet is an infinitely thin imperfect electric conductor (finite conductivity), and it does not support a magnetic current, namely

$$\mathbf{E}_{\text{tan}} = \mathbf{J}_s R_s \quad (57)$$

where R_s is the surface resistivity in ohms per square. The limiting cases are $R_s = 0$ for a PEC and $R_s = \infty$ for a perfectly transparent sheet. The reflection coefficient of the sheet is

$$\Gamma = \frac{-\eta_0}{2R_s + \eta_0} \quad (58)$$

Resistive films are an effective means of controlling the reflection coefficient of a surface. They consist of thin metallic deposits on low-dielectric films such as Mylar. A common example of a commercially available resistive film is window tinting of the type used for automobiles.

The dual of the resistive sheet is the *conductive sheet*, with the boundary condition

$$\mathbf{M}_s = -\frac{\mathbf{H}_{\text{tan}}}{G_s} \quad (59)$$

where G_s is the surface conductance. The conductive sheet does not support an electric current. A combination of resistive and conductive sheets can be viewed as an *impedance sheet*.

Figure 16 compares the RCSs of PEC and composite aircraft wings. The RCS of the composite wing is significantly reduced because more of the wave is transmitted and less reflected.

8.8. Rough Surfaces

Imperfections and errors in the assembly and manufacturing processes have a significant effect on the low-level RCS. The sources of errors are variations in the physical dimensions and electrical characteristics of the target materials. Most of the errors behave in a random fashion. Random deviations in the characteristics of a target result in an increase in diffuse scattering and a corresponding decrease in specular reflection.

Figure 16. The RCS of a metal skin aircraft is compared to that of a composite aircraft. The monostatic RCS is lower for the composite aircraft because more of the incident field is scattered in the forward direction. The surface impedance approximation has been used.

The Rayleigh condition is the traditional criterion for a rough surface

$$\bar{h} \leq \frac{\lambda}{8 \sin \psi}$$

where \bar{h} is the average height of the irregularities and ψ the grazing angle. The surface impedance boundary condition can also be used to simulate surface irregularities [37].

The calculation of the RCS for targets with random characteristics can be performed using a Monte Carlo simulation (method of repeated trials) or by applying probability theory to the governing equations of electromagnetics. Both approaches start by writing the RCS in terms of the random variables of interest (for example, target dimensions). In the Monte Carlo method, the equations are computer-programmed and repeatedly executed using a different random seed each time. The average RCS and its standard deviation can be computed from the output data.

Another approach is to take the expected value of the RCS expression. If the probability density functions of the random variables are known, then the expectation operation results in an expression for the average RCS. Using this approach, the RCS of a “lumpy” surface with a correlation interval \bar{c} (the distance beyond which on average the surface deviations become independent) is given approximately by [6]

$$\sigma = \frac{4\pi A^2}{\lambda^2} \cos^2 \theta e^{-4\beta^2 \bar{c}^2} \left[P_0 + \frac{4\pi \bar{c}^2 \beta^2 \bar{\delta}^2}{A} \exp\left(\frac{c^2 \pi^2 \sin^2 \theta}{\lambda^2}\right) \right] \quad (60)$$

where $\bar{\delta}^2$ is the variance of the surface deviations (assumed small). P_0 is the error-free power pattern

normalized to A^2 . [Using a flat plate as an example, $P_0 = [\text{sinc}(\beta ua) \text{sinc}(\beta vb) \cos \theta]^2$.] The second term in the brackets of Eq. (60) represents a random noise that increases with the level of the error. A small correlation interval yields lower, more uniformly dispersed scattering than a large correlation interval.

9. MEASUREMENT OF RADAR CROSS SECTION

Measurements are a crucial step in the design and verification of an LO platform. In general, measured RCS data can serve three purposes:

1. To establish a target's RCS for design verification
2. For comparison with calculated RCS to evaluate numerical methods or the validity of approximations
3. As a diagnostic tool

Measurements are performed throughout the design of a stealthy platform. During the conceptual stage, scale models of candidate designs may be built and tested to verify that the RCS levels are close to those expected. At various stages in the development of the full-scale components (such as wings and antennas), measurements can be used to verify assembly tolerances, RCS treatments, and other manufacturing processes. Problem areas can be reworked and then checked again. Finally, if the target is not too large, a measurement can be made on the completed product. This step may serve as part of the official fulfillment of a contract.

Measurement facilities can be categorized by a variety of attributes that include physical characteristics, instrumentation capabilities, and data analysis and presentation modes. Table 4 summarizes some commonly used descriptors.

Most systems measure monostatic RCSs by using a fixed transmit/receive antenna and rotating the target. The traditional continuous wave (CW) measurement involves two steps. First, a calibration target of known RCS (typically a sphere) is placed in the chamber, and the

Table 4. RCS Measurement Facility Descriptors

System Descriptor	Categories
Physical Configuration	Indoor/outdoor
	Near field
	Far field
	Compact
Instrumentation	Tapered
	Time domain
	Frequency domain
Data analysis and presentation	Continuous wave (CW)
	Pulsed CW
	Fixed frequency/variable aspect
	Fixed aspect/frequency sweep
	Two-dimensional frequency Aspect
	Time-domain trace
	Target imaging
	Polar or rectangular plots

received power is recorded for reference. Next, the calibration target is replaced by the object with unknown RCS, and the power measured as the target is rotated. By comparing the received and reference powers, the RCS of the unknown target is obtained. In an analog system, the power difference drives the vertical (RCS) axis of a plotter, and the horizontal (angle) axis is slewed to the target mount. The final result is a plot of RCS versus aspect angle. The data obtained using the classical far-field CW RCS measurement of a rectangular plate are illustrated in Fig. 17.

For a true far-field measurement the target must be illuminated by a plane wave. This condition is never rigorously satisfied in practice, because the need for a directive transmit antenna usually results in a nonuniform-amplitude illumination of the target. Furthermore, the wave incident on the target is always spherical, not planar. Finally, because the system components are near the floor, ceiling, and walls, reflections from these surfaces affect the measurement.

Figure 17 illustrates the types of inaccuracies that can occur, such as sidelobe asymmetry and the existence of a noise floor. The noise floor sets a lower limit on the RCS that can be reliably measured. Measures of chamber performance are

1. Pattern symmetry in angle
2. Noise floor (noise level)
3. Quiet zone (linear extent of the region where the amplitude and phase of the incident wave are approximately plane)

Figure 17. The measured RCS of a 16-in. square plate for a 2 GHz CW source. Errors in the measurement were more pronounced in older measurement systems. Background subtraction techniques can be used to reduce measurement errors.

4. Repeatability
5. Allowable target size and weight for the mount
6. Allowable range of target motion
7. Instrumentation capabilities
8. Data processing capabilities
9. Data presentation capabilities

The state-of-the-art instrumentation used in RCS measurement is essentially a programmable multimode radar. Data can be collected in either the time or the frequency domain and transformed back and forth between the two. In the time domain, gating can be employed to discard signals that do not correspond to the time delay of a scattered signal from the target's extent. Processing such as *windowing* can be performed on the raw data to enhance various characteristics and then see how they behave as a function of frequency or aspect. Data processing techniques can even generate high-resolution images that highlight scattering hot spots on the target.

9.1. Chamber Configurations

The majority of all RCS measurement facilities are completely enclosed (indoor ranges). This provides isolation from the external environment, which is desirable for both security and technical reasons. In an indoor chamber the interference from other RF sources is reduced or eliminated, and the temperature is controlled for increased instrumentation stability. The result is a more accurate and repeatable measurement than possible in an outdoor facility. The obvious limitation on an indoor chamber is the size of the building required for large targets.

Figure 18 shows two types of indoor chambers. The first is the standard far-field configuration. The separation of the antenna and target must be large enough so that the difference between an ideal plane wave and the actual spherical wave is negligible. The required distance is a function of target size and the frequency. If the distance is R and the target length L , as indicated in Fig. 19, the round-trip phase difference between rays to the edge and center is

$$2\beta\Delta_{\max} = 2\beta[\sqrt{R^2 + (L/2)^2} - R] \approx \frac{\pi L^2}{2R\lambda} \quad (61)$$

where the right-hand side holds for $R \gg L$. Based on the convention used for the definition of the far field of a radiating antenna, one may limit the round trip phase error to $\pi/8$, so that the minimum range becomes

$$R_{\min} = \frac{4L^2}{\lambda}$$

This limit turns out to be overly restrictive and is usually not adhered to in practice. Equation (61) assumes that all of the target surface contributes coherently to the total RCS, as will happen, for example, with a smooth plate. On the other hand, if the target is composed of many independent scatterers, the far-field distance is primarily determined by the distribution of dominant scatterers in space. Thus when the dominant scatterers are clustered, a much smaller range is acceptable [38].

Figure 18. Common indoor chamber configurations include the conventional far-field range, the tapered chamber, and the compact range. The compact range is capable of handling physically large targets over a wide frequency range.

In addition to a plane phase front at the target, the amplitude of the incident wave across the target must be constant. The amplitude distribution is controlled by the antenna beamwidth and the ratio L/R . An isotropic antenna provides the flattest phase front, but also results in stronger illumination of the chamber walls and other obstacles. The transmitted power must also be higher if the antenna gain is low. Thus there is a tradeoff involved in determining the optimum antenna configuration.

The demands on chamber size required for accurate low-level RCS measurements have resulted in the

Figure 19. The incident spherical wave from the transmitter deviates from a plane wave. The deviation leads to an error in the measured RCS. To reduce the error the transmitter to target distance must be increased.

Figure 20. A compact range provides a uniform field over the target with shorter antenna-to-target distances than a conventional far-field range. Some sources of measurement error are illustrated.

development of *compact ranges*. The layout of a typical compact range is shown in Fig. 20. The parent reflector configuration is a Cassegrain, and the reflector surfaces have been arranged so that no blockage occurs. The antenna is located at the focus, and a plane-wave field is excited a short distance in front of the paraboloid. The total volume of a compact range is much less than that of a far-field configuration.

The compact range is not without its own problems, though. To obtain uniform amplitude over the target requires a shaped feed pattern or some subreflector shaping. Cross-polarization and edge diffraction can be significant. Since the target is close to the reflector edges, the effects of edge scattering are especially important at low RCS levels. Much effort has gone into the design of rolled or serrated edges that control the level and direction of edge diffraction.

9.2. Sources of Measurement Error

The received signal in a measurement is not entirely due to scattering from the target. It also includes noise introduced by the receiving system and extraneous scattered signals originating from the chamber walls and other obstacles. Furthermore, some of the transmit signal couples directly to the receive antenna. This leakage is strongest when a common antenna is used for both transmit and receive.

Chambers that are used to measure low-level RCSs must be carefully designed, maintained, and calibrated. Great care is taken to reduce the error signals in the vicinity of the target. The cross-sectional dimension of the chamber that is essentially free of extraneous signals and maintains the plane-wave phase and amplitude is called the *quiet zone*. It is usually specified in feet or meters. The quiet zone, frequency range of operation, and noise floor effectively characterize the chamber performance.

Measurement errors are mitigated using background subtraction. First a measurement is taken with the target absent. Ideally the received signal should be zero if the chamber walls are perfect absorbers and there is no leakage. In practice a nonzero signal is present due to the sources indicated in Fig. 20, and this value is stored as

a reference. Next, the measurement is repeated with the target present. The measured value includes the target's RCS as well as the error signals. If the interaction between the target and chamber is negligible, vector subtraction of the background signal should yield a close approximation to the isolated target's RCS.

The subtraction method requires that the characteristics of the measurement equipment remain stable during the calibration and measurement runs. If the power level or frequency drifts, the background reference is no longer valid and the difference is attributed to the target. Even small changes in phase caused by cable movement can affect low RCS measurements.

9.3. Target Mounts

A potential source of large measurement error is the target mount. If at all possible, the pedestal should be made of low-density material that does not scatter. Frequently the target is suspended and held in tension using thin polyester filaments similar to fishing line. For large, heavy targets that must be tilted and rotated there is no alternative but to use metal mounts. In this case special-shaped fixtures are used to shield the pedestal. Absorbing material can also be used in conjunction with shaping to reduce mount scattering.

9.4. Resolved RCS and Target Imaging

Returns from individual scattering elements on a complex target can be isolated or resolved. The strength of the return is plotted as a function of down range (y) and cross-range (x) in Fig. 21. If the cell size becomes small enough, a high-resolution two-dimensional image of the target can be constructed. As shown in Fig. 22, imaging clearly identifies the strongest scattering sources on a target.

Resolving the individual scattering sources on a target requires that accurate angle and range information be available as the returns are received. Range resolution is achieved by using a short pulse that only illuminates a small slice of the target. Knowledge of the time elapsed after the leading edge of the pulse hits the target is equivalent to knowledge of the downrange coordinate y .

One method of obtaining the crossrange value is by accurately pointing a narrow antenna beam. The beam is scanned over the entire solid angle of the target, thereby

Figure 21. Radar images can be generated by plotting the intensity of the scattered field as a function of the target surface coordinates. The downrange size of the resolution cell is determined by the radar pulsewidth; the crossrange resolution is determined by the Doppler measurement capability of the radar.

Figure 22. The radar image of the target can be used to determine where RCS treatments should be applied, as well as evaluate the effectiveness of RCS reduction methods.

providing angle data that can be processed along with the range data to construct an image. This approach is not efficient at microwave frequencies, however, because of the large antenna size needed for fine angle resolution. It is more practical at millimeter wavelengths and smaller, and is highly successful at laser wavelengths. A more practical method for obtaining crossrange exploits the Doppler shift [39]. The target is rotated at an angular velocity ω_r as shown in Fig. 23. Target surface points rotate with a linear velocity that depends on their distance from the center of rotation. The radial component of relative velocity (component along R) gives rise to a Doppler shift.

Referring to the coordinate system shown in Fig. 23, let R_0 be the range to the target's center of rotation along the y coordinate, and r the distance to a scattering point at a distance d from the center. Using the law of cosines, we obtain

$$r^2 = R_0^2 + d^2 - 2dR_0 \cos \phi$$

which simplifies to

$$r = R_0 \sqrt{1 - \frac{2d \sin \phi}{R_0}}$$

when $R_0 \gg d$. The first term under the square root is associated with the round-trip time delay to and from

Figure 23. A point rotating on the surface of the target has a Doppler frequency shift. The frequency shift can be used to determine the cross-range coordinate.

the target center, and the second is the Doppler shift due to rotation. Since $\phi = \omega_r t$ (where ω_r is the rotation rate of the target), the Doppler frequency in hertz is

$$f_d = \frac{1}{2\pi} \frac{d}{dt} (-2\beta R_0 + 2\beta d \sin \omega t) = \frac{2\omega_r}{\lambda} x \quad (62)$$

This method of rotating the target to obtain crossrange information is the same principle used in inverse synthetic aperture radar (ISAR) method.

RADAR EQUIPMENT

MARC RESSLER
 MATTHEW BENNETT
 TUAN TON
 LAM NGUYEN
 Army Research Laboratory

Modern radars operate at frequencies from megahertz to hundreds of gigahertz and at power levels from milliwatts to megawatts. This means that many RF hardware

components will vary greatly, whereas control and display systems will be functionally and physically similar. In recent years, the improvements in solid-state devices and the explosive growth in the capabilities of digital circuits and digital processors have provided new approaches to radar designs. Analog circuits, which tend to be smaller and have lower power consumption, are being replaced with digital circuits, which are more stable in the presence of varying temperature, vibration, and power supply voltages, while providing flexibility often unavailable in the analog domain.

1. RADAR FREQUENCIES

To provide some measure of security during World War II (WWII), letters were used to designate frequency bands instead of specifying frequencies. Although the electronic warfare community has adopted a sequentially lettered set of frequency bands, the original radar band designations were so commonly used that eventually a standard for letter designated radar bands (IEEE Std 521-1984) was developed. Table 1 [1] shows these bands and the actual frequency assignments designated for radar operation by the International Telecommunications Union (ITU) for North and South America (region 2). Note that no specifically assigned HF radar band exists and that the UHF radar band extends only to 1000 MHz, whereas the more common definition of UHF extends to 3000 MHz. The use of the millimeter designation is often applied to the frequencies above 40 GHz, thus including both the V and W bands.

The radar bands are grouped together with similar performance characteristics. The high-frequency (HF)

Table 1. Standard Radar-Frequency Letter Band Nomenclature

Band Designation	Nominal Frequency Range	Radar Frequency Ranges Based on ITU Assignments for Region 2
HF	3–30 MHz	None
VHF	30–300 MHz	138–144 MHz 216–225 MHz
UHF	300–1000 MHz	420–450 MHz 890–942 MHz
L	1000–2000 MHz	1215–1400 MHz
S	2000–4000 MHz	2300–2500 MHz 2700–3700 MHz
C	4000–8000 MHz	5250–5925 MHz
X	8000–12,000 MHz	8500–10,680 MHz
K _u	12–18 GHz	13.4–14.0 GHz 15.7–17.7 GHz
K	18–27 GHz	24.05–24.25 GHz
K _a	27–40 GHz	33.4–36.0 GHz
V	40–75 GHz	59–64 GHz
W	75–110 GHz	76–81 GHz 92–100 GHz
mm	110–300 GHz	126–142 GHz 144–149 GHz 231–235 GHz 238–248 GHz

band requires physically large antennas but has negligible propagation losses and can take advantage of ionospheric bending at HF to support extended range, over-the-horizon (OTH) radars. The frequency of operation is usually adjusted to find the optimal propagation path to the desired target region of the globe as ionospheric conditions change. Very high frequency (VHF) and ultrahigh frequency (UHF) radars require parabolic reflectors that are too large to be practical and even Yagi antenna arrays are a few meters long, but propagation losses because of atmospheric and weather effects are still negligible, making VHF and UHF radars suitable for long-range surveillance. Two-way losses through 10–20 m of foliage (typical of what might be seen from an aircraft) are about 3–6 dB [2–4], making VHF and UHF bands suitable for finding targets masked by trees. Two-way losses in these bands for sandy soils may run as low as 1 dB/m in dry soils to over 30 dB/m in damp soils, and above 100 dB/m in soils with high clay content, making it possible to detect subterranean targets at shallow depths depending on soil type [5–7].

L band offers higher resolution with antenna reflectors approximately 10 m across, while propagation losses remain low [8]. S band and more notably C band are suitable for medium-range operations as atmospheric and weather losses climb, but this also means they are useful for weather measurements [9,10]. X band and K_u band can provide high resolution with meter-sized antennas but have noticeably more propagation losses, limiting their use to shorter ranges or clear-weather operation. K_a -band and higher suffer high atmospheric losses and extreme rain losses and backscatter but provide very high resolution with physically small antennas that may be used in short range applications such as radar fuzing and fire control systems. The water absorption lines at 22.2 and 185 GHz and the oxygen resonance lines at 60 and 120 GHz produce such high losses as to limit operations near these frequencies. Lower-loss “windows” in the atmospheric attenuation near 35 and 95 GHz provide the possibility of short-range operations but still at higher losses than K_u band.

To meet system requirements, the radar designer must pick a range of components and frequency band that will support the desired performance. The basic radar range equation is

$$R^4 = \frac{P_t G_t L_t}{4\pi} \times \frac{A_e L_r \sigma}{4\pi k T_0 B F_n \text{SNR}} \times L_p L_a \quad (1)$$

The first group of terms is related to the transmitter, the second to the receiver, and the third to other propagation effects, where

- R = maximum radar range
- P_t = average transmit power
- G_t = gain of transmit antenna
- L_t = losses from transmitter to antenna (e.g., circulators, duplexers, transmission lines)
- A_e = effective antenna aperture of receive antenna (aperture area times efficiency)
- L_r = losses in receive path, similar to those for the transmit chain

- σ = radar cross section of target
- k = Boltzmann’s constant
- T_0 = system reference temperature (typically 290 K)
- B = receiver bandwidth
- F_n = receiver noise figure
- SNR = signal-to-noise ratio required to meet detectability requirements (typically 12–15 dB)
- L_p = two-way antenna pattern losses
- L_a = two-way propagation losses (atmospheric, weather)

Note that there is no frequency-related term in Eq. (1). However, the effective aperture is related to the gain of the receive antenna by

$$G_r = \frac{4\pi A_e}{\lambda^2}$$

where λ is the wavelength. Thus, for a fixed aperture size, the gain increases with frequency. The choice of frequency is typically application-driven, but since the size of many RF components scale inversely with frequency (see Fig. 1), the radar designer may choose a particular frequency band based on size and weight constraints if radar performance will not be adversely affected. Atmospheric and transmission line losses generally increase with frequency, and receiver noise figures degrade. The designer can improve transmit and receive gain by using a higher-gain antenna, at the cost of a loss in area coverage and can increase signal-to-noise performance by using a narrower system bandwidth, or by effecting an equivalent bandwidth reduction with signal processing. Often the only choice left to the designer, to meet target detectability requirements, is to increase average power.

2. TYPES OF RADAR

There are a number of basic variations in radar system designs. We will examine the operation of different types and some of the hardware specific to particular types.

Figure 1. A 15-dB-gain L-band horn that contains the other items dwarfs the W-band waveguide and 25 dB gain horn sitting in front of an S-band coupler and 15 dB gain horn. (U.S. Army photo.)

2.1. Continuous-Wave Doppler Radar

The simplest of all radars, and by far the most common, is the continuous-wave (CW) Doppler radar. Its biggest advantage is also its biggest disadvantage [11]. By operating at a 100% duty cycle, it maximizes the use of the transmit power and eliminates issues of Doppler ambiguity, but the receiver is forced to operate while the transmitter is on and no range information is available (although modulating the carrier frequency can provide range information). For a medium-power, sensitive radar, two antennas are usually required to isolate the receiver from the large transmit signal and from the noise sidebands of the transmitter. Nearby fixed targets (clutter) can also have an impact on performance because they will also cause a large signal return that might overload the receiver. Most CW radars have homodyne (direct-conversion) receivers; that is, the local oscillator for the mixer is at the same frequency of the transmitter. Figure 2 shows a simplified block diagram of a CW radar. The return signal from the target is shifted in frequency because of the radial component of the velocity of the target with respect to the radar (i.e., that portion of the motion that is toward or away from the radar v_r). A sample of the transmit signal f_0 is used as the local oscillator signal. This signal is mixed with the return signal from the target and the difference between these signals is the Doppler shift f_d , which is fed to a frequency meter. The sum frequency out of the mixer is usually so far beyond the response of such a meter that filtering is not necessary, although it can be easily provided with a simple lowpass filter. The Doppler shift is

$$f_d = f_0 \frac{2v_r}{c} = \frac{2v_r}{\lambda} \quad (\text{for } v_r \ll c)$$

where the frequency is shifted up for approaching velocities and down for receding velocities. The factor of 2 is a result of the signal traveling both ways and can perhaps be more easily understood as a change in signal phase. If the target moves a half wavelength closer to the radar, the pathlength to the target and back changes by one wavelength.

The Doppler shift is in the human audible range for typical ground target speeds and operating frequencies in X band and K_u band, and a number of radars have been built. The basic output device of these radars is a set of headphones the operator wears. This is not as strange as it sounds because a trained operator can estimate velocity of the target. Other moving parts of the target (e.g., wheels, treads, propellers) provide secondary audible signatures so that the operator also can determine to what class the

Figure 2. Block diagram for a simplified CW Doppler radar.

Figure 3. An X-band Doppler transceiver and mating horn antenna. Mechanical tuning coarsely sets frequency, whereas fine tuning and AFC can be provided by modulating the operating voltage. (U.S. Army photo.)

target belongs (such as wheeled vs. tracked vehicles or fixed wing vs. rotary wing aircraft) [12].

Small, low-power versions of CW Doppler radars are used as speed sensors (mostly well known in police radar applications), automatic door openers in warehouses and retail stores, intrusion detectors, vehicle detectors for traffic control, and proximity fuzes in rockets, bombs, and projectiles. In these applications, the range to the target is usually small, and the loss in sensitivity because of the use of a single antenna is acceptable. One of the parts that made designs of such radars simpler was the Microwave Associates (now M/A-COM) Gunnplexer Doppler transceiver (Fig. 3), which packs a transmitter, ferrite circulator, and mixer into a single module. A Gunn oscillator is the basic transmitter, which is coupled to a single antenna through the circulator. Transmitter power reflected back from the antenna port acts as the local oscillator into the single balanced mixer (an adjustable screw allows intentional standing-wave ratio (SWR) mismatch to force an adequate level of return signal). The addition of an antenna, frequency meter, and a direct-current (DC) power source completes the radar (Fig. 4).

2.2. Pulse Radar

The pulse radar is what most people think of when they think of radar, which is the acronym for radio detection and ranging. A short burst of microwave energy is transmitted toward the target, and the time t for the echo to return in microseconds is measured to determine the

Figure 4. Block diagram for a simple single-antenna CW Doppler radar based on a Doppler transceiver.

range r to the target in meters where

$$r = c \frac{t}{2}$$

with the factor of 2 representing the path the signal takes to the target and back. The length of the pulse determines the capability of the radar to resolve two closely spaced targets, the basic limitation being that the echoes from the two targets will merge into a single return. At a pulsewidth of $t_w \mu s$, this merging occurs when the two targets are separated by approximately a distance r using the preceding formula. Decreasing the pulsewidth improves resolution capability at a cost of reduced average power levels.

The development in Britain of the magnetron (a pulsed power oscillator) during WWII made microwave pulse radar practical, and the magnetron [13] is still the most commonly used transmitter in pulse radars. It is capable of producing peak power levels of kilowatts through megawatts in compact packages (Figs. 5 and 6). A simplified block diagram of a magnetron-based pulse radar is shown in Fig. 7. The power supply/modulator provides the high-voltage pulse at the desired pulse repetition frequency (PRF) to drive the magnetron. The PRF is usually set to guarantee that there is enough time between pulses to receive a return from the farthest expected target range. The transmit/receive (T/R) switch, or duplexer, automatically connects the transmitter to the antenna, while effectively disconnecting the receiver from the antenna. The T/R switch in high-powered radars is often based on a gas-filled tube that conducts in the presence of the RF field [14], but in lower-powered sets, these functions may be assumed with circulators or positive-intrinsic-negative (pin) diode switches [15]. The receiver protector is typically a diode limiter that further restricts the voltage developed across the receiver input, whereas the transmitter is operating to protect sensitive low-noise preamplifiers in the receiver.

Referring again to the radar range equation, we note that the return signal for a fixed-size target varies as the fourth power of the range to the target. This means that a target at 1 km will be 80 dB stronger than that target at a range of 100 km. The sensitivity-time-control (STC) increases the gain of the receiver versus the time elapsed from when the pulse was transmitted (this is effectively

Figure 5. An X-band weather radar designed for aircraft use. The transmitter and receiver are located in the assembly behind the reflector, and the control electronics are located in the display unit. The transmitter is a 3 kW magnetron that is approximately 60 cm^3 . (U.S. Army photo.)

Figure 6. A 1 MW X-band magnetron transmitter. The power supply/modulator is in the upper left with its $20 \times 40\text{-cm}$ cover removed. The large rectangular device to the right of the water-cooled heat exchanger is the pulse-forming network. (U.S. Army photo.)

the range to a target) so that there is less change in signal dynamic range as the range to target varies [16], and allows choosing an analog-to-digital converter (ADC) with fewer bits to support the receiver output. R^4 correction will produce a constant radar cross-sectional output but will usually require controlling the gain of multiple stages of the receiver. However, the targets are often not the limiting factor in setting dynamic range limits. In ground-based radars, clutter (undesired wide area returns from natural or cultural objects) is usually larger than the desired targets, and the amount of clutter region illuminated by a radar beam increases as range increases; so in this case, an r^3 gain correction is a better choice. Weather radars, on the other hand, respond to the backscatter return from a volume of space, so a constant target return is best obtained with an r^2 correction. Figure 8 shows a combined receiver protector/STC module attached to the duplexer of a lowpower radar.

2.3. Moving-Target Detecting Radars

As mentioned in the previous paragraph, in a ground-based radar, a large region of high-strength undesired

Figure 7. Block diagram of a magnetron-based pulse radar.

Figure 8. A 500-W K_u -band duplexer with a combined receiver protector/STC module attached. Antenna connection is made to the open waveguide connection on the left, and the transmitter is connected to the RF connector on the top. The receiver protector can be run in a self-rectifying mode or can be driven by an external DC signal. STC control range is about 30 to 40 dB. (U.S. Army photo.)

radar signals from fixed targets (clutter) masks the moving targets the radar is typically designed to detect. A moving-target indication (MTI) radar attempts to minimize the response from the clutter to enhance the signal-to-clutter ratio and improve target detectability. A simple block diagram of how this can be accomplished is shown in Fig. 9. A sample of the received signal is delayed by one pulse repetition interval (PRI—the inverse of PRF) and subtracted from the current input signal. This can be a rather long delay and was often provided by multiple reflections within a multifaceted bulk quartz delay line. Such long delays can also be provided by digital shift registers or memory circuits, in which the subtraction is provided after the ADC stage. The digital approach has the advantages of stability in time and temperature, whereas the analog approach reduces the dynamic range into the ADCs, relaxing the requirements for the number of bits required. Proper cancellation of the clutter requires being able to compensate for the delays and losses through the delayed path, and in this case the digital approach also has an advantage, as the analog approach typically requires constructing a circuit path that duplicates the attenuation of the delay line and the gain, delay, and nonlinearities of the delay-line amplifier chain to provide proper cancellation. As long as the radar has adequate stability, the fixed targets will maintain the same phase from pulse to pulse and will be canceled, whereas the moving targets will vary in phase, thus producing a time-varying output. However, realize that the moving targets must have a radial component of motion with respect to the radar location for this phase difference to occur.

Figure 9. Block diagram of a simple one-pulse canceler.

Targets that move tangentially to the radar will be canceled, as if they were not moving, because no phase change is observed. Note also that a pulsed radar is basically a sampled data system, which leads to a similar problem if the target is moving at a rate such that its Doppler frequency is equivalent to the PRF, or a multiple thereof, because this is equivalent to sampling a signal a number of complete cycles later, and no phase difference will be observed from sample to sample. These target velocities are referred to as “blind speeds” because targets moving at these speeds will not be detected by an MTI radar [17].

Although magnetrons do not have pulse-to-pulse phase stability, they have reasonable short-term stability in frequency, and it is possible to synchronize the final receiver local oscillator (the coherent oscillator, or COHO) phase to that of the transmitter on each pulse (known as a coherent-on-receive system) and thus provide magnetron-based radars with an MTI mode of operation. Area MTI is another approach to clutter reduction, and one that does not require a coherent radar system in which a complete scan of the radar video is stored in memory and subtracted from the next scan. In a digital image, this operation is equivalent to a pixel-by-pixel subtraction and will mask small targets located over large areas of clutter (cities, forests) as the larger signal returns from the two samples of the clutter regions are subtracted from each other, leaving a small residue. Area MTI does have the advantage that tangentially moving targets are highlighted because they will have moved far enough between scans to appear in a different position on the screen.

Another approach to detecting moving targets is the pulse-Doppler radar: a coherent transmitter–receiver (Figs. 10 and 11) processes the received signals, not only into range bins but also into multiple Doppler bins. This processing is done most easily with a digital signal processor [18], providing the temporary storage for a group of pulse returns and typically a Fourier transform to provide the bank of filters. The quadrature mixer of Fig. 10 provides both in-phase (I) and quadrature (Q) outputs to a pair of ADCs to support complex fast Fourier transforms (FFTs). There are now purely digital approaches [19,20] that can provide I and Q outputs from a single, higher sample-rate ADC. The advantage of the digital approach is that there are no problems in balancing gain and phase in the two channels. Having both I and Q outputs allows

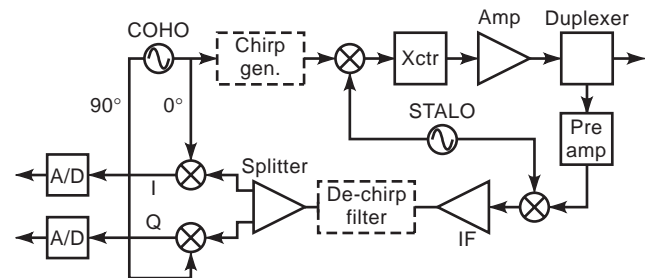

Figure 10. Block diagram of a coherent transceiver for use in pulse Doppler radar. The stable local oscillator (STALO) provides the translation frequency from RF to IF. Optional chirp modules are denoted by the dashed boxes.

Figure 11. The Eaton/AIL G-199 K_u -band transceiver for the AN/TPS-74(V) modular radar. Various modules could be substituted to provide options for ground or airborne applications. This specific assembly contains modules for power supply, exciter, STALO, receiver, and antenna pedestal control.

sorting the Doppler bins into incoming (Doppler above the carrier frequency) and outgoing (Doppler below the carrier frequency) velocities. The zero frequency (DC) filter output is where the bulk of the clutter lies, and it is discarded. Motion of the clutter or the radar may spread the clutter energy into adjacent frequency bins, and they may be discarded as well, either automatically or under operator control. If the radar is on an airborne platform (Fig. 12), then returns from large clutter patches on the ground can be used to select the Doppler bin or bins that represent the clutter velocity in the direction of look [21]. As mentioned previously, the Doppler frequencies depend on the radial component of the target velocity. Dopplers that exceed the Nyquist criteria will be interpreted as having a direction opposite to their actual direction of travel, and blind

Figure 12. The electrically driven antenna of an F-16 equipped with one of Northrop Grumman's APG-66/68(V) family of coherent radars. The radar supports 25 air-to-air, air-to-ground, and mapping modes that provide target detection, acquisition, and tracking in both benign and hostile electromagnetic emissions environments. (Photo courtesy of Northrop Grumman Corporation.)

Figure 13. The Northrop Grumman ASR-12 is a modular, fully solid-state, S-band airport surveillance radar. It uses a moving-target detection scheme that combines adaptive Doppler filter and fine-scale clutter mapping to enhance the returns from tangential targets. (Photo courtesy of Northrop Grumman Corporation.)

speeds will again occur at multiples of the PRF. Increasing the PRF can eliminate this ambiguity in Doppler determination, at the cost of creating an ambiguity in range. Range ambiguity can occur when the PRF is high enough that a target return from a far-range target generated by an earlier pulse appears in the range processing time of the current pulse [22]. Dithering the PRF or switching between multiple PRFs can allow Doppler and range ambiguities to be resolved [17,23], but such an approach will not work with the simple fixed-delay MTI of Fig. 9. Modern air-traffic control radars (Fig. 13) use a combination of MTI techniques to improve detection of targets because aircraft often circle the airport as well as make direct approaches and departures.

Because we already have a coherent transceiver that allows us to recover the phase of the received signal, a number of improvements to the radar system performance are possible by modulating the transmitted waveform. This modulation increases the bandwidth of the transmitted signal, which, when processed in the receiver, provides improved resolution, while maintaining a longer pulsewidth to improve the average signal power. The disadvantage is that a long pulse limits the ability to detect targets close to the radar, in what is called the eclipsing zone, because returns from these targets will arrive at the receiver while the transmitter is still on. The most common modulation approach is to use linear FM, or chirp, modulation [24]. This can be provided simply with a surface acoustic wave (SAW) device in the transmit chain (Fig. 14) and a complementary compressive SAW device in the receiver intermediate frequency (IF), returning a signal with a pulsewidth equivalent to that of the modulation bandwidth. Alternately, high-speed synthesizers can provide the transmit modulation [25], while digital signal processors can provide the compressive function.

Figure 14. An exciter module from the AN/TPS-74(V) showing in the upper right the 60-MHz impulse generator and mating SAW chirp unit. For this unit, the 10 μ s transmit pulse was compressed to a 0.5 μ s pulse in the receiver for a 20:1 compression ratio. (U.S. Army photo.)

2.4. Synthetic Aperture Radar

Although we have now seen a way to improve the resolution in range, it would seem that the only way to improve the resolution in cross-range is to increase the size of the antenna system, narrowing the beamwidth of the radar. In synthetic aperture radar (SAR), cross-range resolution improvement is accomplished by moving an antenna in space [26], creating an effective aperture that is much larger than the physical antenna (Fig. 15). Returns from targets in the direction of motion of the radar are shifted up in frequency, whereas those behind the radar are shifted down in frequency, allowing the contributions from various points in the range swath to be separated. Typically, an SAR will also have a high resolution in range, requiring a large amount of frequency content in the transmitted waveform and thus a wide IF bandwidth and a high-speed ADC. If chirp modulation is used to generate the bandwidth, then by reproducing the slope of the modulating waveform in the receiver mixer (an approach called stretch processing), these bandwidths can be reduced [27]. Modern direct digital synthesizers (DDS) (Fig. 16) allow such flexibility in frequency control. In addition, they are able to compensate for distortions in amplitude and phase response because of the transmit-

Figure 15. Synthetic aperture radar. As the antenna is moved, radar returns from all the surveillance areas are collected and stored to be later processed as if there was a single antenna the size of the aperture flown.

Figure 16. An experimental direct digital synthesizer. DDS technology has an advantage over other traditional waveform-generation techniques—it can arbitrarily create different waveforms in a small, lightweight, cost-effective package. The Sciteq DDS architecture is a double-accumulator GaAs linear frequency modulation synthesizer that allows input of the starting frequency and chirp rate and has a separate phase modulation port. Maximum output bandwidth is 230 MHz, with 24-bit frequency resolution, updated at a 2 ns rate, and spurious responses below -50 dBc. (U.S. Army photo.)

receive chain [28]. Combining the return signals from all the aperture positions usually requires a high-speed processor (Fig. 17) capable of processing a large number of two-dimensional FFTs, but the resulting imagery (Fig. 18) is almost photographic in clarity.

In SAR, there is the need to have relative motion between the radar and the target, but the motion does not need to be along straight line, nor does the antenna need to be oriented normal to the flight path. Some of the more

Figure 17. A large number of calculations are necessary to process SAR data. This radar signal processor, used in a Northrop Grumman SAR, consists of nine 9U VME cards, each containing 16 Intel i860 array processors. Each processor card has an aggregate rating of 1.28 Gflops. Figure 18. A NASA SAR image of Yellowstone National Park, Wyoming. The image was obtained using the L-band radar channel, with vertical transmit polarization and horizontal receive, on the shuttle's 39th orbit on October 2, 1994. The large dark feature at the right is Yellowstone Lake, which appears this way because the bulk of the transmit energy is forward-scattered off the relatively smooth lake surface.

common variations of SAR include spotlight SAR and inverse SAR (ISAR). In spotlight SAR [29] the antenna is continually pointed toward the area of interest, by rotating the antenna as the aperture is flown, or by flying an aperture in the shape of an arc [30]. This allows larger than normal apertures to be flown (thus improving resolution) as well as allowing use of higher-gain, narrower-beamwidth antennas. ISAR is typically viewed as having the radar fixed and the target moving; more generally, however, both can move as in the cases of airborne radars imaging ships. In ISAR, the motion of the maneuvering target is used to provide additional detail of the target for target recognition [31] and possibly allowing 3D reconstruction of the target. This implies that existing radars could gain from added signal processing capabilities, but the processing burden is high, as the path and maneuvering nature of the target is unknown and must also be extracted from the data to correctly focus the target [32].

2.5. Impulse Radar

An impulse radar is perhaps the simplest form of pulse radar. An extremely short pulse, or a single cycle of a sine wave, which has a very wide bandwidth, is radiated from an antenna that typically sets the useful radar bandwidth of the system [33,34]. The short pulsewidth provides an inherent high-range resolution capability. Most of these systems are denoted ultra wideband (UWB) radars because their bandwidth is greater than half their center frequency, and many of them operate in the VHF and/or UHF region to provide foliage or ground penetration capability. Because the frequency coverage and bandwidth can be provided by other means (such as chirp), the advantages that the impulse radar offer are the capability to detect close-in targets (as in ground contact radars) because of the small eclipsing zone and simple and highly efficient transmitters that are low in size and weight (Fig. 19).

Figure 19. The PowerSpectra BASS-02X is a bulk avalanche semiconductor switch activated by a semiconductor laser. Rise-times are about 150 ps with a falltime of approximately 2 ns. Peak output power is approximately 2 MW, and average power is approximately 1.5 W. Prime power is 28 VDC, and the unit weighs approximately 2 kg. (U.S. Army photo.)

2.6. Bistatic Radar

Some of the problems with radars are that they are active devices, and therefore susceptible to detection; they can have large, high-power transmitters that reduce their mobility; and they detect Doppler shifts only from the radial component of target velocities. One way to improve the situation is to separate the transmitter and to provide remote, receive-only radar systems (Fig. 20). Such systems are called bistatic radars, or more appropriately multi-static radars when multiple transmitters and receivers are used [35]. Forward-scattered energy from large regions is often much stronger than the backscattered energy and may give clues as to the texture or construction of the region. Existing radars (designed for other purposes) are often used as the transmit source, whereas smaller, cheaper receivers take advantage of the existing signals to provide simple low-cost radars at multiple sites, all serviced by the existing emitter. Bistatic radars have been used for semiautomatic missile guidance (the missile carries only the receiver, while the launching platform usually supports the transmitter), low-cost passive cueing of target angle of approach, examining heavenly bodies (from separate Earth locations or with an Earth receiver and a satellite transmitter) and providing simultaneous reception from multiple sites to develop three-dimensional models of ionospheric or atmospheric events [36].

Figure 20. In a bistatic radar, the transmitter and receivers are physically separated, and multiple receivers are serviced by the same transmitter.

3. RADAR NOMENCLATURE

No standards exist for the identification of commercial radar systems, although many manufactures will number a series of products with a common name or common acronym descriptive of their purpose. The most common nomenclature system is the Joint Electronics Type Designation System (JTEDS, MIL-STD-196D, 1985), which is an outgrowth of the Joint Army-Navy Nomenclature System (AN System) and the Joint Communications-Electronics Nomenclature System developed during WWII in the United States. Although the JTEDS nomenclature scheme also covers units and subgroups of systems, it is best known for its distinctive sequence of the letters AN followed by a forward slash, followed by a three-letter indicator series, followed by a dash, and then followed by a sequence number and possibly suffixes designating variations in the design. The three indicator letters (Table 2) describe the type of installations, type of equipment, and purpose of the system. Radar systems will always have a middle letter P, although some systems with a P may not be radars because this equipment type also covers radar detectors, electronic recognition and identification (IFF) equipment, radar beacons, and pulse-type navigational aids. The system has been extended to include other English-speaking countries with blocks of sequence numbers being assigned to various countries. Canada is assigned sequence numbers 500–599 and 2500–2599, Australia has the block 2000–2099, New Zealand has 2100–2199, and the United Kingdom has 2200–2299. Thus the designator AN/APS-506 identifies a Canadian airborne search radar, whereas AN/PPS-15A is the first upgrade to a U.S. man-portable search radar.

The U.S. National Weather Service designates its radars as WSR (originally for Weather Service Radar, now

more commonly Weather Surveillance Radar) followed by a number, which is the last two digits of the year the radar was put into service. Thus the WSR-57 is a unit that was first placed into service in 1957. Later units had alphabetic suffixes designating the radar band in which they operated, such as WSR 74C and the WSR-74S. Most recently, the letter designator has been used for other purposes as well, as in the WSR-88D (the NEXRAD system radar) where the D designation stands for Doppler. The Federal Aviation Administration (FAA) has a series of radars for air-traffic control, which typically are designated by their task name acronyms and a sequence number. Examples of current equipment include the long range air route surveillance radars (ARSR-4) (Fig. 21), the terminal surface monitoring airport surveillance radars (ASR-9 and 11) and airport surface detection equipment (ASDE-3); the windshear products, which include the shared NEXRAD system and the terminal Doppler weather radar (TDWR); and the secondary surveillance radar designated as the precision runway monitor (PRM).

4. RADAR TARGETS

It is useful to have a set of standard radar targets that can be used to test, evaluate, or measure the performance of radar systems [37]. The most common of these are simple geometric shapes; their radar cross section (RCS) is easily calculable and have been extensively studied in the literature. The sphere is the best known of these targets, re-radiating uniformly in all directions, but it does not present a very large RCS for its physical size. A specular reflector, like the flat plate, presents a much larger cross section, especially at higher frequencies, but this larger return happens only over a small angular region, near the

Table 2. Equipment Indicators

Installation	Type of Equipment	Purpose
A—Piloted aircraft	A—Invisible light, heat radiation	A—Auxiliary assembly
B—Underwater mobile, submarine	C—Carrier	B—Bombing
D—Pilotless aircraft	D—Radiac	C—Communications
F—Ground, fixed	E—Laser	D—Direction finder
G—Ground, general	G—Telegraph/teletype	E—Ejection/release
K—Amphibious	I—Interphone/public address	G—Fire control/searchlight directing
M—Ground, mobile	K—Electromechanical/inertial wire	H—Recording/reproducing
P—Portable	L—Countermeasures	K—Computing
S—Water	M—Meteorological	M—Maintenance/test
T—Ground, transportable	N—Sound in air	N—Navigational
U—General utility	P—Radar	Q—Special/combined purposes
V—Ground, vehicular	Q—Sonar/underwater sound	R—Receiving/passive detecting
W—Surface and underwater combination	R—Radio	S—Detecting/range/bearing/search
Z—Airborne vehicle combination	S—Special/combinations of types	T—Transmitting
	T—Telephone (wire)	W—Automatic or remote control
	V—Visual/visible light	X—Identification and recognition
	W—Armament	Y—Surveillance and control
	X—Facsimile/television	
	Y—Data processing	

Note: Special suffix T is reserved for training, and suffixes X, Y, and Z are reserved for changes in voltage, phase, or frequency. (V) designates variable groupings of equipment and (P) designates units accepting plugins. (Xnn) designates developmental units with the second (and third) letter used to designate the developmental agency. Open () (called “bowlegs”) designate developmental equipment or generically indicate equipment families.

normal to the surface. Corner reflectors have a wider angle of acceptance, in at least one dimension, as does a cylinder. Figure 22 shows a number of radar targets and their approximate RCS, based on geometric optics. For these RCS values to be realistic, target dimensions need to be about 10λ . As target dimensions approach 1λ , or less, diffraction effects must be considered, and the target cross sections should be calculated using physical optics, uniform theory of diffraction, or computational electromagnetics [38].

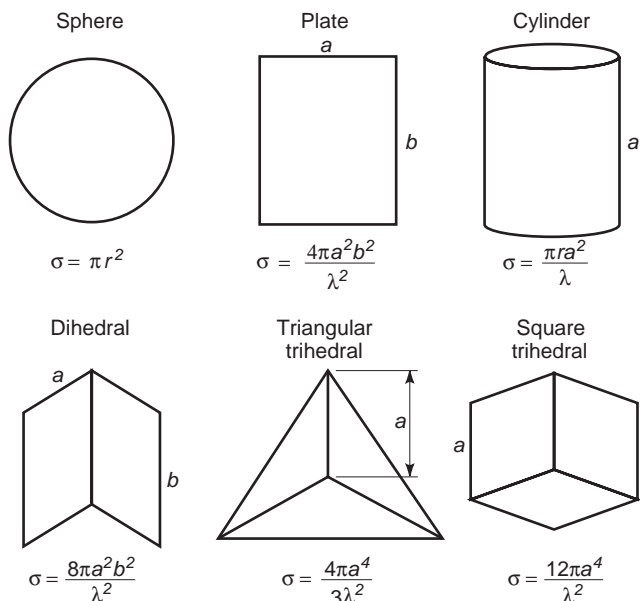

Figure 22. Common radar targets and their equivalent radar cross section σ , where r is the radius of the circular objects.

Figure 23. A motorized set of trihedrals provides a moving target for W band. Note the angle offset between the support arm and the trihedrals. This offset was designed so that the “flash” from the arm, as it becomes normal to the radar wave, will not occur at the same time as the peak of the trihedral response.

Although it is not the optimal solution [39], the triangular plate trihedral is the most commonly used specular target, having a reasonably wide angle of operation in both elevation and azimuth and having simple assembly requirements. The RCS of a 30-cm-radius sphere is 0.28 m^2 , whereas a triangular trihedral with sides 30 cm long has a maximum RCS 37.7 m^2 , at 10 GHz. These targets are usually placed a number of wavelengths above the ground to help reduce multipath interference and oriented to maximize target return in the expected direction of the radar.

These targets are useful for evaluating pulse radars, but for evaluating MTI and pulse Doppler radars, a moving target is needed. Figure 23 shows a simple approach to the problem, but one in which the radial velocity of the target varies over the angle swept by the motorized arm. Electronic simulators have the advantage that RCS and Doppler can be varied by simple choice of circuit parameters, and with the addition of a delay line, even the range to the target can appear to vary. This delay can allow the

Figure 24. A K_u -band electronic moving-target simulator. One horn receives the transmitted signal, which is mixed down with one STALO and mixed back up with another matched STALO. A discriminator circuit provides a visual indication of target Doppler frequency and direction. An attenuator provides control over the radar cross section of the return signal.

Figure 25. The slip ring assembly for the AN/TPS-74(V) showing the fiberoptic transceivers. Only DC power and digital signals pass through the slip rings.

target return to be placed in a range cell that differs from the one the simulator occupies, thus eliminating possible corruption of the signal because of the clutter return from the simulator itself. The target simulator is often a simple superhetrodyne receiver that uses a single sideband modulator to add the desired Doppler signal to the IF output, which is then upconverted back to the initial radar band with the same local oscillator chain. The choice of upper or lower sideband will, respectively, make the target appear

as either incoming or outgoing. The addition of an extremely long delay line can allow such an electronic simulator to be used in a laboratory setting while making targets appear as if they are kilometers away. A simpler, although less time and temperature stable, approach to designing a target simulator is shown in Fig. 24, in which the return frequency is simply shifted.

5. SCANNING THE SCENE

The typical surveillance radar antenna (Fig. 13) rotates through 360° of azimuth and possibly some amount of elevation. RF is usually supplied through a rotary joint for azimuth and through another rotary joint for elevation, or for limited angles, through flexible waveguide. For lower radar frequencies, the losses may be low enough, and for fixed installations, usually an abundance of transmitter power is available. But at higher frequencies, the losses and noise because of these feed mechanisms may be objectionable. One approach to avoid these losses, for lower-power mobile systems, is to mount the radar transceiver at the antenna (Fig. 25), or at least part of the RF assembly at the antenna. Figure 26 shows the large rotating antenna radomes of the E-2C. The larger, and perhaps more well-known, E-3 Sentry airborne warning and control system (AWACS) sports a similar 9.1-m-diameter rotodome, which rotates at 6rpm over a Boeing 707. However, vertical scanning and height finding are performed by electronic scanning techniques using ferrite phase-shifters. The phase shifters, phase control electronics, receiver protectors, and receiver preamplifiers are mounted on back of the antenna. A better view of an electronic elevation scan can be seen in the picture of the ARSR-4 antenna in Fig. 27. Many applications require much less than 360° coverage, and with the radar transceiver mounted at the

Figure 26. A pair of Northrop Grumman E-2C Hawkeyes are easily identified by their distinctive 7.3-m (24-ft)-diameter rotodomes, which contain both the low-side lobe radar antenna and the IFF antenna. A Lockheed Martin An/APS-145 radar system automatically detects, identifies, and tracks targets at ranges exceeding 300 mi. (U.S. Naval Institute collection.)

Figure 27. The view inside the radome of the ARSR-4, long-range L-band radar, exposes the phased array feed that supports up to nine simultaneous elevation beams that can be steered up to 30°. Figure 28. The Arleigh Burke (DDG-51) Aegis system is based on the AN/SPY-1D multifunction phased-array S-band radar. The SPY-1 antennas are the octagonal panels on the corners of the deckhouse. The inset in the upper left shows an antenna being installed in a deckhouse. (U.S. Naval Institute collection.)

Figure 29. The Lockheed Sanders Mark IV microwave module is a two-channel MMIC T/R module that covers 6–18 GHz in a package of which its volume is less than 16 cm^3 (cubic centimeters). The module is 2.1 cm wide \times 11.9 cm long. (© Lockheed Martin Corporation 1991.)

antenna, often flexible cables can supply power and control signals. Another approach is shown in Fig. 5, in which azimuth scanning is provided by tilting the reflector left and right, while elevation is accomplished by moving the feed horn.

It is possible to provide 360° coverage and elevation control in a phased-array-based antenna system. The Aegis weapons system (Fig. 28) is based on the AN/SPY-ID multifunction phased-array S-band radar, which is able to perform search, track, and missile guidance functions simultaneously with a track capacity of over 100 targets. Four antenna panels, situated around the deckhouse, provide full 360° coverage. Each array has 4100 discrete elements and measures $3.65 \times 3.65 \text{ m}$. Output power is approximately 4 MW and is provided by a four-stage amplifier employing traveling-wave tubes (TWT) and cross-field amplifiers (CFAs). It is possible to build high-power solid-state radars while avoiding the need for high-power phase shifters to provide beamsteering. T/R modules allow the construction of large phased arrays in which the output of literally hundreds of low-power solid-state amplifiers are spatially combined. Common phase shifters and builtin RF switching in such modules means that beamsteering works the same on both transmit and receive. Figure 29 shows a 6–18 GHz dual-channel T/R module that uses a single vector modulator in each channel to provide phase and amplitude control for both the receive and transmit paths. Each channel also supports a vertical and horizontal antenna channel so that multiple polarizations can be used, including, with the addition of a 90° phase-shifter, circular polarization. A common serial digital control circuit runs both channels to minimize control lines and provides control over the T/R switches,

Figure 30. An A-scope display from a high-resolution impulse radar. The large spikes are the result of trihedral targets in the scene. The slower variations in the baseline value are due to the clutter return from the surrounding terrain.

the 5-bit phase shifters, and the 4-bit attenuators. The preamplifiers and output amplifiers both have nominal gains of 20 dB with typical noise figures of less than 8 dB and output powers of 26 dBm [40].

6. RADAR DISPLAYS

The original radar displays, developed during WWII, were assigned alphabetic designators (A, B, etc.) and were based on oscilloscope technology. Many of the display types were developed to satisfy special needs, typically to present additional information on the screen [41]. Displays can be broken into three general types: one-axis, two-axis, and plan view. In the A-scope (Fig. 30), the most common one-axis display, the amplitude of the radar return is plotted against radar range, which is usually derived from a linear time-based sweep circuit. The sweep circuit allows the operator to change the sweep speed to change the range coverage being displayed. Two-axis displays are based on an x - y oscilloscope and use intensity modulation to indicate the amplitude of the return signal. The most common two-axis display is the B-scope, in which azimuth position is plotted on the horizontal axis and range is plotted on the vertical axis. Elevation is the next most commonly used variable in a two-axis display. The problem with two-axis displays is the geometric distortion that results from plotting angular displacements on a linear axis. Plan displays solve this distortion problem by plotting in cylindrical coordinates, or sectors of cylindrical coordinates. The most common of these displays is the plan position indicator (PPI) or type P display. Early PPI displays rotated the deflection assembly of the CRT in synchronism with rotation of the radar antenna so that the range sweep started at the center of the CRT and moved out radially in the direction the antenna was currently pointing.

More recently, the large use of computers in radar processing has resulted in the use of computer-driven displays to generate synthetically plan view plots of radar data while adding both coordinate and cultural features on the same display (Fig. 31), virtually eliminating the need for plastic plotting boards for keeping track of targets. The explosive growth of the personal computer has led to a large number of computer-driven raster display systems. Monochrome, color, and LCD displays are typically available for small shipboard radar systems, whereas high-resolution color graphic displays are now being used in military and air traffic control radar systems. These displays (Fig. 32) allow the radar operator to overlay map information, weather data, satellite photos, target

Figure 31. A computer-driven vector scope displays a plan view of an area registered to UTM map coordinates and includes digitized road networks over which radar targets can be plotted. Moving targets that are being automatically tracked are plotted as numbered symbols with “tails” that show a recent history of past locations.

1. INTRODUCTION

Radar is an electromagnetic instrument used for the detection and location of targets, such as aircraft, ships, and ground vehicles. Radar transmits electromagnetic energy to a target and receives the reflected signal. From the received radar signal, target-related information such as location and velocity can be accurately measured. Compared to optical and infrared sensors, radar as a radiofrequency (RF) sensor can perform with high accuracy, at long distances, and under all weather conditions. Therefore, it has been widely used for civilian and military purposes. Radar is capable of detecting and imaging moving targets for wide-area surveillance, targeting information, and other military purposes. It is also capable of generating high-resolution maps for earth-resource mapping, terrain structure information, environment monitoring, and other civilian applications.

Radar imaging is an imaging method obtained by processing radar signals reflected from objects. The radar image of an object is the distribution of its reflectivity in the range and cross-range domain. The range is the dimension

along the radar line of sight (LoS) to the object, and the cross-range is the dimension transverse to the radar LoS. An important factor of the image quality is its resolution: the ability to separate closely spaced scatterers in range or in cross-range. The resolution along the radar LoS to the object is called *slant range* or *range resolution*. The resolution transverse to the radar LoS is called the *cross-range resolution*. The range resolution is inversely proportional to the bandwidth of the transmitted signal. High range resolution is obtained by using wide-bandwidth radar signal waveforms. High cross-range resolution requires a large aperture for the radar antenna.

A large aperture can be synthesized by using a small real antenna aperture mounted on a moving platform. The synthetic aperture technique was initially developed in the 1950s [1–3]. Such a radar system with a synthetic aperture is called the *synthetic aperture radar* (SAR). The first SAR was an airborne system. Later, in 1978 a spaceborne SAR system was built.

The most common modes in SAR are stripmap mode and spotlight mode. In stripmap mode, the antenna beam bears on a fixed direction relative to the moving direction of the platform as illustrated in Fig. 1a. When the platform moves, a strip of area is swept over. If the antenna direction is off the perpendicular of the flight path, it is referred to as *squinted stripmap SAR*. The stripmap mode can generate a wide-area map of the terrain. The length of the imaged area is determined by the length of the data collection; and the azimuth resolution in along-track direction is determined by its antenna beamwidth. It should be noted that after correction of range migrations, the “azimuth” is actually the “cross-range,” and the azimuth resolution becomes the cross-range resolution. The concept of spotlight synthetic aperture was proposed in 1980 [4]. In the spotlight mode, the antenna has narrower beamwidth and steers to the same small patch of an area as the physical aperture moves through the length of the synthetic aperture as shown in Fig. 1b. Spotlight SAR generates images of smaller scenes at finer resolution. The azimuth resolution is determined by the length of the data collection, and the size of the imaged area is determined by the antenna beamwidth. Another mode, called *inverse synthetic aperture radar* (ISAR), is similar

to spotlight SAR, but its data collection is different. In ISAR, the radar can be stationary and the target being imaged is moving. The relative motion between the radar and the target is the key to creating an image of the target. Unlike spotlight SAR, which moves around the target area in order to acquire the necessary angular data, ISAR collects multiple aspect data through the target’s movement.

In SAR and ISAR, a common approach for generating an image from collected data is a range–Doppler processor, which takes the Fourier transform along the azimuth direction in the range-compressed data. With the spotlight SAR and ISAR configuration, data are inherently distributed in a polar grid. To use the Fourier transform for generating a focused image, the processor must remap the polar formatted data onto a rectangular grid, called *polar formatting*. Other approaches of generating a focused image, such as the wavenumber approach [5,6], were also developed.

2. RADAR IMAGING GEOMETRY AND SYNTHETIC APERTURE

To produce a focused radar image, the processor in radar imaging systems should include motion compensation, interpolation, data formatting, Fourier transform, autofocus, and distortion correction. The focused image produced may be further used for feature extraction, image registration, image exploitation, and automatic target recognition.

2.1. Geometry

The geometry of airborne radar is shown in Fig. 2, where an aircraft is moving with a constant velocity V at height H and along a flight track parallel to the x axis. Assume that the origin of a coordinate system (x, y, z) is located at the center of the scene. The range between the flight path and the center of the scene is $R_s = (H^2 + y_0^2)^{1/2}$, where y_0 is the ground range to the center of the scene. Assume that the length of the synthetic aperture is L and that the azimuth resolution of the radar image is determined by the length of the synthetic aperture. When the platform

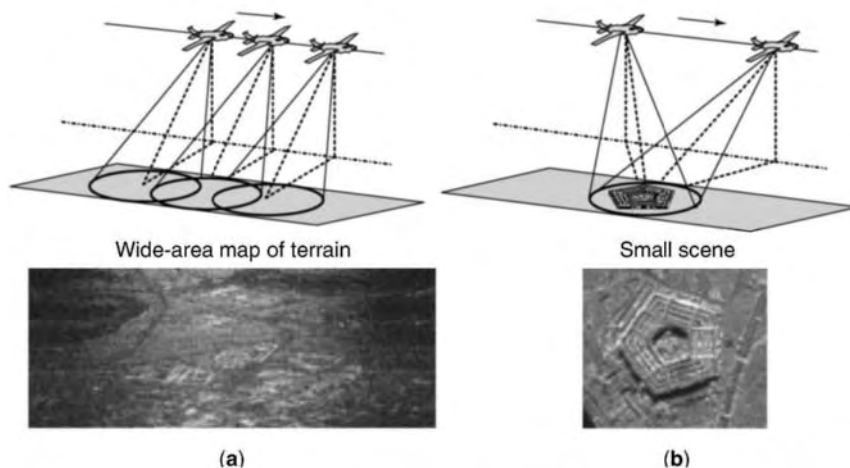

Figure 1. (a) Stripmap SAR; (b) spotlight SAR.

Figure 2. Geometry of airborne SAR.

moves, the radar antenna position x_a along the flight path varies. Thus, the distance from the antenna to the center of the scene R_a also varies. Assume a point target is located at $(x_t, y_t, z_t = 0)$ and the distance between the radar antenna and the point target is $R_t = [(x_a - x_t)^2 + y_t^2 + H^2]^{1/2}$, which also varies with x_a . In Fig. 2, the area being imaged is assumed to be two-dimensional. The limits on y are the inner and outer edges of the swath, and the limit on x is determined by the length of data collection.

2.2. Synthetic Aperture

Radar with a real aperture transmits signals and receives signals reflected from an object. The 3-dB-beamwidth β is determined by the length of the real aperture (D_{RA}) and the wavelength (λ): $\beta = \lambda/D_{RA}$. Assume a point scatterer at range R . For a small β , the azimuth resolution along the track is

$$\Delta A = 2R \tan \frac{\beta}{2} \cong R\beta = R \frac{\lambda}{D_{RA}}$$

To achieve a high azimuth resolution, it is necessary to either increase the physical aperture size or reduce the wavelength. For example, to achieve a desired along-track azimuth resolution of 1 m at a range of 50,000 m, a radar operating at 0.03 m of wavelength (X band) needs a physical aperture length

$$D_{RA} = \frac{\lambda}{\Delta A} R = \frac{0.03}{1} 50,000 = 1500 \text{ (m)}$$

which is too long to realize. Therefore, to achieve the same azimuth resolution without using an extremely large physical aperture, a synthetic aperture technique must be used. The synthetic technique moves a real aperture along a track to transmit and receive signals at each sample location and, then, coherently processes the received signals at all the sample locations to synthesize a large aperture.

For the stripmap mode, x indicates the position of the radar platform along the line of the track. The sampling interval Δx is determined by the platform velocity V and the pulse repetition frequency (PRF): $\Delta x = V/\text{PRF}$. The

maximum length of the synthetic aperture is determined by the length that the scatterer remains in the beamwidth of the real aperture. The effective length of the synthetic aperture D_{SA} is twice that of the physical aperture length $2D_{RA}$. Thus, the azimuth resolution of the synthetic aperture becomes

$$\Delta A_{SA} = R\beta_{SA} = R \frac{\lambda}{2D_{RA}} = R \frac{\lambda}{2R\lambda/D_{RA}} = \frac{D_{RA}}{2}$$

Thus, for the stripmap SAR, the azimuth resolution of the synthetic aperture is not dependent on the range and the wavelength. It is determined only by the physical aperture length D_{RA} . A smaller aperture offers better along-track resolution.

However, in the spotlight SAR, the radar antenna is steered to a small patch area when the radar platform is moving. Thus, longer real apertures can be used, and smaller beamwidth steers to a small area of interest. The azimuth resolution is proportional to the total slew angle covered, but not half of the physical extent of the real aperture used.

As mentioned earlier, the ‘‘azimuth resolution’’ used here is not quite exact because after correcting range migration, the ‘‘azimuth’’ is actually the ‘‘cross-range’’ [7].

3. STRIPMAP-MODE SAR IMAGING

In the stripmap-mode SAR, the radar antenna steering angle is at a fixed angle and the range to the center of the swath is kept constant. The most important aspect of the stripmap SAR is that the azimuth resolution is dependent only on the physical length of the real aperture and independent of the range and the frequency or wavelength. Thus, smaller physical aperture offers better azimuth resolution.

The imaging geometry of the stripmap SAR mode is shown in Fig. 2. The waveform usually used in high-resolution stripmap SAR is a linear FM chirp. Dechirp processing is performed on the radar receiver side. Some image formation algorithms, such as the range migration algorithm, do not require a chirp waveform and dechirp on

the receiver side. The received signal returned from a point scatterer can be expressed as a 2D convolution of the radar cross-section (RCS) with an impulse response function h . This impulse response function can be expressed as a 2D convolution of two impulse response functions: $h = h_1 \otimes h_2$, where h_1 is the impulse response function for azimuth compression and h_2 is the impulse response function for range compression [8]. To compensate for range migration, interpolation in the range–Doppler domain is used to straighten the curved point scatterer locus. Therefore, the RCS of the target can be reconstructed by two step correlations of the returned signal with two impulse response functions h_2 and h_1 .

Usually, SAR data $s(t,x)$ are arranged in a 2D matrix in the slant-range/along-track domain, called the (t,x) domain. Focusing of SAR data requires a 2D space-variant correlation algorithm. One method is 2D time-domain correlation, but its computational load is high. Other algorithms take advantage of the frequency-domain correlation. They are the range–Doppler algorithm, range migration algorithm, chirp-scale algorithm, and other variations of wavenumber-domain algorithms.

3.1. Range–Doppler Algorithm

The change of the time delay (slant range) from pulse to pulse is referred to as the “range migration.” To solve the problem of range migration in satellite SAR, a range–Doppler algorithm that processes SAR data into complex images was introduced by Wu in 1976 [9]. Since then, the range–Doppler algorithm has become a standard algorithm for satellite SAR. To handle satellite SAR geometries with squint, a secondary range compression algorithm was also proposed [8].

SAR data are usually arranged in the delay time t (or slant-range) and the along-track x (or azimuth), that is, (t,x) domain. However, the range–Doppler algorithm works in the slant range and the spatial azimuth frequency or Doppler domain, called the (t,k_x) domain, where k_x is the spatial frequency of the along-track x . To transform into the Doppler domain, the Fourier transform is taken in the along-track domain x . Then, in the (t,k_x) domain, the correction of the range migration is performed by using interpolation.

The spatial frequency k is also called the *wavenumber* and is equivalent to the number of times a wave has the same phase over the spatial domain. The wavenumber is defined by $k = \omega/c = 2\pi/\lambda$, where ω is the angular frequency and c is the speed of the wave propagation. If the radar radiation wave has an incident angle θ , the wavelength and wavenumbers k_x and k_y are related by [5]

$$\lambda = \frac{2\pi c}{\omega}; \quad k_x = \frac{2\pi}{\lambda} \sin \theta; \quad k_y = \frac{2\pi}{\lambda} \cos \theta; \quad \omega = \frac{c}{2} \sqrt{k_x^2 + k_y^2}$$

The range–Doppler algorithm can be summarized as follows:

1. *Range Migration Correction.* By taking a 1D Fourier transform of the range-compressed baseband data $s(t,x)$ in the along-track or x direction, the range–

Doppler data in the delay time t (or slant range) and spatial wavenumber k_x (or Doppler) can be obtained: $S(t, k_x) = FT_{1D}\{s(t, x)\}$. Range migration correction is performed by a k_x -dependent timeshift that requires a time-domain interpolation. Thus, the range migration correction function is a k_x -dependent linear phase function in the 2D Fourier domain (ω, k_x)

$$\exp\left\{j \frac{cR}{4} \cdot \frac{k_x^2}{\omega_0^2} \omega\right\}$$

where ω is the temporal frequency of the delay time t , R is the slant or across-track range, and ω_0 is the carrier angular frequency.

2. *Azimuth Compression.* Azimuth compression is performed by multiplying a phase compensation function

$$\exp\left\{jR \cdot \left(\sqrt{4 \frac{\omega_0^2}{c^2} - k_x^2} - 2 \frac{\omega_0}{c}\right)\right\} \\ \approx \exp\left\{-j \frac{cR}{4} \cdot \frac{k_x^2}{\omega_0}\right\}$$

to correct the spreading of the range-dependent loci.

The combined 2D range and azimuth correction function can be expressed by

$$\exp\left\{-j \frac{cR}{4} \cdot \frac{k_x^2}{\omega_0^2} (\omega_0 - \omega)\right\}$$

Compared with the optimal 2D correction function, the range–Doppler algorithm has a 2D phase aberration that causes defocusing when the squint angle or spatial Doppler wavenumber is large.

3.2. Range Migration Algorithm

The range migration algorithm (RMA) was originally from seismic signal processing [10,11] and is an important image formation method for stripmap SAR. It is also an important algorithm for spotlight SAR image formation [12,13].

The RMA works in the temporal frequency and spatial wavenumber (ω, k_x) domain by taking a 2D Fourier transform of the range-compressed data. Thus, the time delay becomes a phase shift, which is a linear function of ω and can be easily compensated by a phase operation. Therefore, range migration is no longer a problem in the (ω, k_x) domain. The algorithm uses a matched filter and a coordinate remapping called the *Stolt interpolation* to transform from coordinates (ω, k_x) into (k_r, k_x) , where

$$k_r = \sqrt{4k^2 - k_x^2}$$

is the spatial wavenumber in the slant range.

The RMA can be summarized as follows:

1. Transform the collected data $s(t, x)$ into the frequency domain by taking the 2D Fourier transform:

$$S(\omega, k_x) = \text{FT}_{2\text{D}}\{s(t, x)\}$$

2. Map the 2D transformed data from the (ω, k_x) domain to the (k_r, k_x) domain by Stolt interpolation. The Stolt interpolation is a k_x -dependent point-to-point mapping from ω to k_r :

$$k_r(\omega, k_x) = \sqrt{4\left(\frac{\omega + \omega_0}{c}\right)^2 - k_x^2} - 2\frac{\omega_0}{c}$$

3. Perform the 2D phase compression in the (k_r, k_x) domain: using $\exp[jR_S(\sqrt{k_r^2 - k_x^2} - k_r)]$ to compensate the range migration, where R_S is a fixed slant-range distance between the flight path and the center of the scene as shown in Fig. 2.
4. Take a 2D inverse Fourier transform to reconstruct the image.

The RMA can be used with waveforms other than chirp waveforms. It is also not necessary to dechirp on the receiver side. The RMA does not have the space-variant defocus and geometric distortion that other algorithms usually suffer from (such as the polar format algorithm). Thus, it can be used to form a fine-resolution image of a large terrain area and to image large scenes at short range. However, because scatterers located at different positions have different migration loci, the Stolt interpolation requires a long computation time.

3.3. Chirp-Scale Algorithm

The range–Doppler algorithm and wavenumber-domain algorithms need interpolation that makes the SAR image formation processing more complicated in design and becomes a large source of aliasing effects.

An algorithm called the *chirp-scale algorithm* (CSA), sometime called the *differential range deramp algorithm* [14–16], is an efficient image formation algorithm that eliminates interpolation procedure and still preserves phase information. It works in both the range–Doppler domain and the 2D spatial frequency domain. It can be used in the stripmap mode as well as the spotlight mode. This algorithm can handle large apertures and large squints, and has better phase and geometry accuracy than other algorithms.

The key to this algorithm is to use the linear FM property of the range chirp to differentially shift the range energy as a function of spatial azimuth frequency, and then to do the range cell migration correction (RCMC) in the 2D spatial frequency domain.

The CSA begins with data chirped in the range. First, it processes the collected data in order to compensate its phase to a line that is parallel to the flight path and crossing through the center of the scene. Then, the processed data are chirped in both azimuth and range. The CSA

transforms data to the two-dimensional spatial frequency domain. All the range cell migration trajectories are adjusted to match the reference trajectory of a scatterer at the selected reference range R_{ref}

$$\tau_{\text{ref}}(k_x) = \frac{2}{c} R_{\text{ref}} [1 + C(k_x)]$$

where

$$C(k_x) = \frac{1}{\sqrt{1 - [\lambda k_x / (2v)]^2}} - 1$$

is the curvature factor and v is the relative velocity between the reference scatterer and the radar. This procedure requires a linear scaling with a scale factor $[1 + C(k_x)]^{-1}$. Then, RCMC is performed by multiplying a phase function to each point. However, because only the shift and linear components are compensated, RCMC does not completely compensate for motion through resolution cells. However, the result is still satisfactory.

The CSA algorithm can be summarized as follows:

1. *Azimuth FFT*. Take FFT in the azimuth direction and transform the data from the (t, x) domain to the range–Doppler (t, k_x) domain, where the linear FM signal structure prior to range compression can be exploited.
2. *Chirp Scaling Operation*. Multiply by a function whose phase is chosen so that the range migration phase term of every scatterer is equalized to that of the reference range. After range focusing, the spatial loci of the resulting range curvatures are equalized.
3. *Range FFT*. The data are transformed to the 2D wavenumber (k_r, k_x) domain.
4. *2D Phase Compensation*. This procedure includes RCMC, range compression, and secondary range compression (SRC). The RCMC corrects the dominant range curvature effects, known as the “bulk RCMC”.
5. *Range Inverse FFT*. Transform the data back to the range–Doppler (t, k_x) domain.
6. *Azimuth Filter and Phase Residual*. In the range–Doppler domain, an azimuth frequency (k_x) -dependent bandpass filter is selected for weighting and look processing, and the Doppler centroid is adjusted over the range.
7. *Azimuth Inverse FFT*. Take inverse FFT in the azimuth direction. The focused complex image is obtained.

4. SPOTLIGHT MODE SAR IMAGING

Spotlight SAR [17,18] images objects in a small area or a target of interest as illustrated in Fig. 1b. In the spotlight SAR, the radar antenna is steered to the same small patch of area when the radar platform is moving; thus, its

footprint always stays over the same area of terrain. Since much longer real apertures are used, a smaller beamwidth and consequently a smaller footprint stays over a small area of interest. In spotlight SAR, the azimuth resolution is proportional to the total slew angle covered, and not half of the physical extent of the real aperture.

4.1. Image Formation in Spotlight SAR

The azimuth resolution in the spotlight SAR is proportional to the total effective rotation angle of the antenna

$$\Delta A = \frac{\lambda}{2\Delta\theta}$$

where $\Delta\theta$ is the total integrated angle.

The returned baseband signal from the scene center has zero Doppler frequency shift because there is no relative radial motion between the radar and the scene center after motion compensation to the scene center. While the translation is compensated, rotational motions between the radar and the scene center still remain. First, the signal is dechirped in both range and azimuth. Then, the data are transformed into the 2D wavenumber (k_r, k_x) domain.

However, in the (k_r, k_x) domain the data samples are not on a rectangular grid. They are on a ribbon-type polar grid. Because the Fourier transform is performed in a rectangular format, a 2D interpolation must be applied to remap the data from a polar grid to a rectangular grid. This is called *polar formatting*. After interpolation, the 2D sampling points are lined up on a uniform grid in both range and cross-range. Then, a matched filter can be applied to compensate for nonlinear phase shift and, therefore, a 2D Fourier transform can be used for both range and azimuth compression simultaneously. By taking a 2D inverse Fourier transform, the final image can be formed. If the scene of a target of interest is small, the small ribbon-type polar data are approximately rectangular. Thus, a 2D inverse Fourier transform can be directly applied without image defocus.

For spotlight SAR, either RMA or CSA can be directly applied without requiring motion compensation to the center of the scene.

4.2. Polar Formatting Algorithm

The polar formatting algorithm (PFA) is an image formation technique based on tomography. It was originally developed for spotlight SAR imaging [19,20], and has been

adapted for use in ISAR imaging [21]. In spotlight SAR and ISAR, the relative rotation between the radar and the object causes the collected data to be distributed in polar format. To obtain fine-resolution imagery using Fourier-based image formation, polar-to-rectangular remapping is required. PFA compensates the phase of the collected radar data to a fixed point at the center of the scene and, thus, the preprocessed data become dechirped in azimuth as well as in range.

The PFA involves reconstructing the spatial distribution of an object by applying the Fourier transform to a set of observations, where each is a projection of the object onto a line, taken over a series of aspect angles. A Fourier transform produces a line segment in the 3D Fourier space offset from the origin by the carrier frequency and at an angle determined by the angle of the radar LoS. As successive pulses are received and the aspect between the radar and the object changes, the line segment sweeps out a data surface in 3D Fourier space. Once the data surface is formed, an image of the object can be reconstructed by transforming the surface into the spatial domain using the inverse Fourier transform.

The implementation of the PFA involves measuring the target motion dynamics, estimating parameters for the data surface model, projecting the data surface onto a planar surface, interpolating the data into equally spaced samples, and performing the inverse Fourier transform. The image formed by the PFA is illustrated in Fig. 3. The comparison of imagery produced by the conventional method shown on the left side of the figure and the polar reformatting method shown on the right side of the figure and the improvement in the image quality can be seen. Polar reformatting can produce high-quality imagery even in conditions with significantly complex target motion.

4.3. Autofocus

If the relative motion between the radar and the target cannot be accurately estimated and compensated, the residual relative motion will induce phase errors. The phase error is the cause of image defocusing. *Autofocus* is a technique that estimates and compensates the phase errors in the range-compressed phase history data in order to achieve a well-focused image of the target. Most autofocus algorithms are space-invariant compensations that apply the same phase correction function to the whole data.

There are many autofocus algorithms available; two important ones are the phase gradient algorithm (PGA) and the prominent point processing (PPP) algorithm.

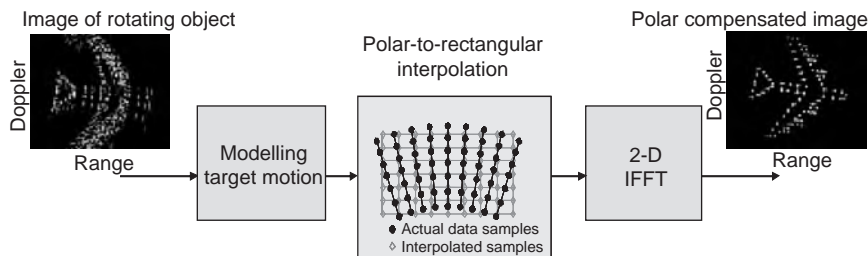

Figure 3. Radar image formed by polar formatting algorithm.

4.3.1. Phase Gradient Algorithm. The phase gradient autofocus (PGA) proposed by Wahl et al. [22] has been widely used in SAR systems. It was developed to make a robust estimation of the gradient of the phase error using the defocused SAR image data. The PGA is an iterative algorithm that allows robust and nonparametric estimation and exploits the redundancy of the phase error information contained in the degraded image. Because the performance of the PGA is independent of the content in a SAR scene, there is no need to require isolated pointlike reflections in the SAR scene as in other algorithms.

The PGA can be applied to a phase-degraded complex SAR image no matter how the image was formed. Because the complex image and phase history are a Fourier transform pair, the range-compressed phase-history-domain data can be obtained by taking a 1D Fourier transform in the azimuth direction.

To allow robust phase error estimation and image restoration, there are four critical processing steps in the PGA:

1. *Center (Circular) Shifting.* This procedure performs a circular shift on each row of the image in order to place the strongest scatterer of the row in the middle of the image.
2. *Windowing.* This consists of weighted windowing of each row of the image previously shifted. This operation allows one to preserve the width of the central image points and discard the others that do not contribute to the phase error estimation. Shifting and windowing together may achieve the highest signal-to-noise ratio in order to maximize the accuracy of the phase error estimation.
3. *Phase Gradient Estimation.* This is a linear, unbiased minimum variance estimate. The phase error estimate is obtained by integrating the estimated phase gradient. Before operating the phase correction on each row, it is necessary to remove the linear phase component from the estimated phase error to prevent any image shifting due to the phase correction.
4. *Iterative Phase Correction.* This procedure is applied iteratively to the image until the root-mean-square phase error becomes small enough or convergence is reached. Finally, all the estimated phase errors are summed together to give a total phase error, which is removed from the original image.

4.3.2. Prominent Point Processing. Prominent point processing (PPP), initially used in resolving moving target imaging in SAR [23], utilizes information from several prominent points to correct phase errors and convert non-uniform rotation into a uniform rotation.

In spotlight SAR, any motion compensation method must remove space-variant errors as well as space-invariant errors. Multiple PPP is the procedure that can remove both space-invariant and space-variant errors. In the multiple PPP, the first prominent point is used to remove translational motions and adjust frequency and phase of the returned signal so as to form a new image center. The

second prominent point corrects the phase error induced by nonuniform rotations. The third prominent point is used to measure the rotation rate and estimate the azimuth scale factor of the resulting image to achieve complete focusing.

Figure 4 is a block diagram of multiple PPP embedded in a spotlight SAR image formation. Instead of using sensors to measure motion dynamics, the first point corrects the space-invariant phase error induced by translation motion and, thus, a new image center is formed. The second point makes uniform rotation, and equalizes the gain of the sampling position in azimuth. The third point estimates the azimuth scale factor corresponding to the new sampling position in azimuth. Then, the PFA utilizes this information on accurate angular position to interpolate and generates fine-resolution and well-focused SAR images.

5. INVERSE SYNTHETIC APERTURE RADAR (ISAR) IMAGING

In spotlight SAR, the radar platform moves around the object being imaged to acquire the necessary angular data, while in ISAR, a stationary radar collects the angular data through the object's movement. Therefore, ISAR can be seen as a variation of SAR that images objects by coherently processing the returned radar data collected at different aspect angles.

The challenges in ISAR image formation stem from the unknown nature of the object's motion. An object being imaged is often engaged in complicated motions that combine translation and rotational motions. Thus, motion compensation must be applied to form a focused image of the object. Because the only available information is the radar-collected data themselves, the ISAR motion compensation is a data-driven process.

5.1. ISAR Motion Compensation

An ISAR image is formed by the Doppler shift at each range cell, obtained by taking the Fourier transform over the observation time interval. To use the Fourier transform properly, it is assumed that the frequency content of the analyzed signal is time-invariant. With this assumption, a long observation time provides high Doppler resolution. However, when the target moves, Doppler shifts are time-varying and the assumption of time-invariant Doppler frequency shifts is no longer valid. Thus, the Doppler spectrum becomes smeared, degrading the cross-range (formally called the *azimuth resolution*), and the radar image becomes blurred.

There are many motion compensation algorithms for solving the problem of Doppler smearing and image blurring [24,25]. Most methods are Fourier-based approaches. In order to apply the Fourier transform properly, during the imaging time scatterers must remain in their range cells and their Doppler frequency shifts must be constant.

Motion compensation algorithms typically consist of range alignment and Doppler tracking. The standard range alignment is accomplished by tracking the movement of a reference point in the range profile (such as a

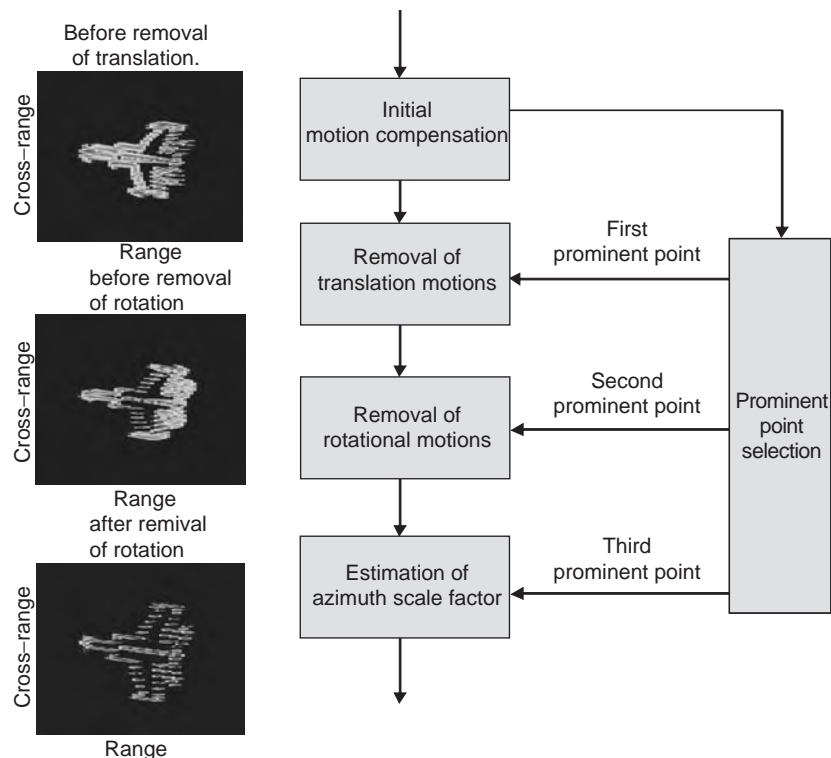

Figure 4. Block diagram of the multiple prominent point processing.

prominent peak or the centroid) across pulses and fitting it to a low-order polynomial [26]. This coarse range alignment allows a point scatterer to be sorted into the same range bin across all the pulses. However, the accuracy of the alignment is limited by the range resolution. The range alignment may not be sufficient to overcome the phase errors measured in terms of the radar wavelength. Consequently, Doppler tracking must be carried out in order to align the phase. There are many different schemes that perform Doppler tracking, including the subaperture approach [27,28], the cross-range centroid tracking approach [29], and PGA. These methods consider the Doppler shifts of the target as a whole, and apply the same correction vector to all the scatterers in the image. This is effective when translation motion is dominant.

From the radar received signal, if the target's range as a function of time is known exactly over the imaging time duration, then the extraneous range-dependent phase term can be removed by multiplying its conjugate with the received signal. This is referred to as *gross focusing* or *motion compensation*. Then, the image of the target can be formed simply by taking the inverse Fourier transform of the motion-compensated signal.

When the coherent processing interval is long or when the target exhibits fast maneuvers, the phase error due to the nonuniform rotational motion is seldom negligible and must also be properly compensated. One useful scheme to carry out this operation is to utilize the multiple PPP algorithm to track one or more point scatterers in the image in order to extract the motion parameters. Once the motion parameters are known, compensation of both translation and rotational motions can be achieved. The main

challenge in applying the multiple PPP algorithm is the selection of the prominent point scatterers. However, in practice, prominent point scatterers may be difficult to pinpoint or not available at all.

Time-frequency analysis is another attractive way to address the Doppler tracking issue in motion compensation [30,31]. Specifically, in Ref. 30 it was shown that by applying the time-frequency transform in place of the Fourier transform, the ISAR image can be effectively examined at each dwell-time instance, thus eliminating range drift and Doppler smearing. A time-frequency-based procedure for achieving both translation and rotational motion compensation can be found in Ref. 32, where an adaptive procedure extended from the adaptive spectrogram [33] is used to select and extract the phase of multiple prominent point scatterers on the target. The extracted phase is then coupled with the multiple PPP model to eliminate the undesirable motion errors in the original radar data. In this manner, the phase of the focused image is preserved and the Doppler resolution offered by the full coherent processing interval can be achieved.

5.2. ISAR Polar Formatting

The PFA for ISAR imaging is similar to that for spotlight SAR imaging. The main difference is that in ISAR processing the motion of the target provides the change in aspect necessary for Doppler processing, whereas in spotlight SAR the change in aspect comes from the motion of the radar. As a consequence of this difference, the aspect change between the radar and the target is both unknown and uncontrollable in ISAR imaging. Because the aspect

change defines the shape of the data surface, the rotation of the target must be determined before PFA can be used to process the data into imagery. Instead of modeling the target motion, ISAR PFA models the data surface directly and uses measurable scatterer motion quantities, such as range, Doppler, and translation acceleration, to estimate the data surface model parameters [21]. A quadratic data surface model may be used that requires few parameters but still allows compensation for the majority of the non-linear rotational motion in the target.

5.3. Time–Frequency-Based ISAR Image Formation

Conventional ISAR image formation is based on the Fourier transform and assumes that Doppler frequency shifts of scatterers are constant. However, when the Doppler spectrum is time-varying, Fourier-based images become blurred and, thus, time–frequency-based image formation should be used to generate clearer images of moving targets [30].

Figure 5a illustrates time–frequency-based image formation. Standard motion compensation is used prior to image formation. The Fourier-based image formation generates only one image frame from an $M \times N$ complex (in-phase and quadrature phase) dataset. The data consist of M time-series histories, each having length N . However, time–frequency-based image formation takes the time–frequency transform for each time series and generates an

$N \times N$ time–Doppler distribution. By combining the M time–Doppler distributions at M range cells, the $N \times M \times N$ time–range–Doppler cube $Q(r_m, f_n, t_n)$ can be formed as

$$Q(r_m, f_n, t_n) = \text{TF}\{G(r_m(n))\}$$

where TF denotes the time–frequency operation with respect to the variable n . At a particular time instant t_i , only one range–Doppler image frame $Q(r_m, f_n, t_n = t_i)$ can be extracted from the cube. There are a total of N image frames available, and every one represents a full range–Doppler image at a particular time instant. Therefore, by replacing the Fourier transform with the time–frequency transform, a 2D range–Doppler Fourier image frame becomes a 3D time–range–Doppler image cube. The integration of the N timeframes is equivalent to the Fourier image. By sampling the image cube in time, a time sequence of 2D range–Doppler images can be viewed. Each individual time-sampled frame from the cube provides not only a clear image with superior resolution but also temporal change properties from one time to another.

Figure 5b shows the conventional ISAR Fourier image of an aircraft using an X-band radar operating at 9000 MHz [31]. Because the target is maneuvering, the Fourier image of the target is still blurred even after applying the standard procedure for focusing. By using time–frequency-based image formation, because each scatterer has its own range and Doppler shift at each time instant,

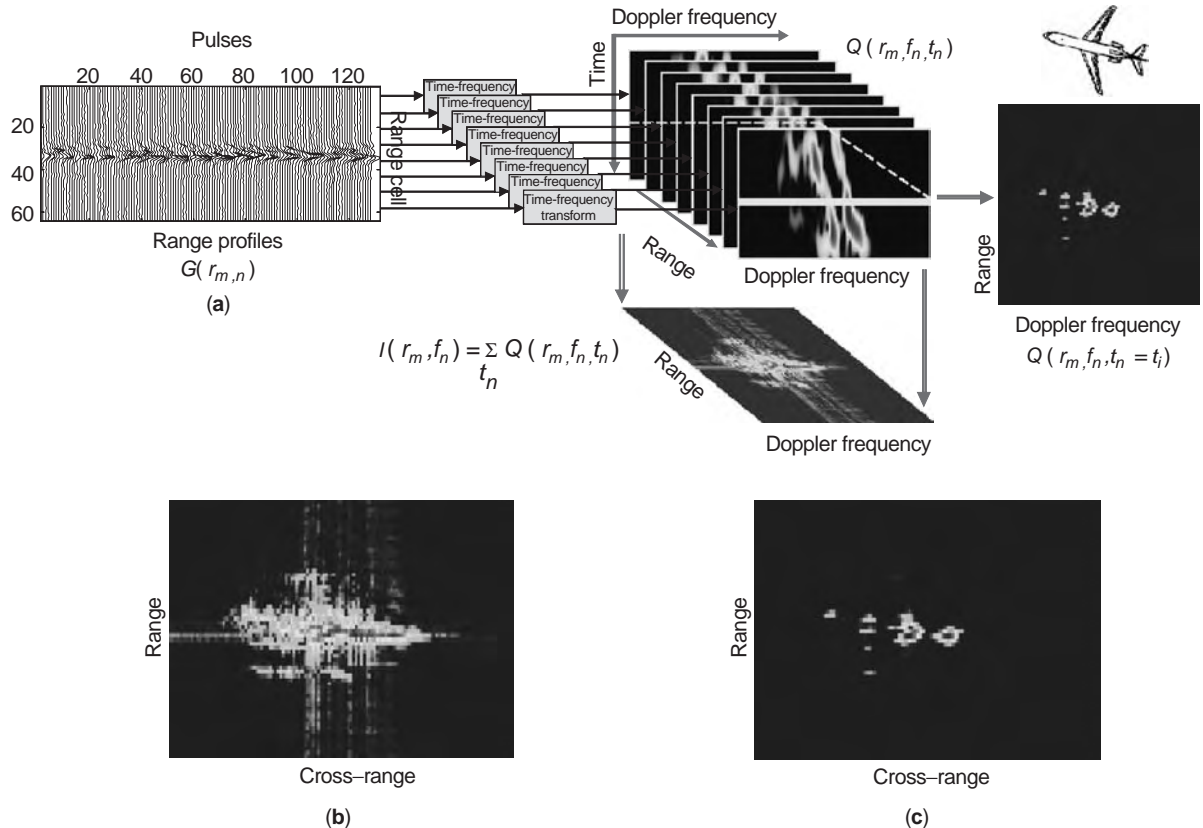

Figure 5. (a) Time–frequency-based image formation; (b) Fourier image; (c) time–frequency image.

without knowing any of the target's kinematic parameters and after resampling the data, a blurred Fourier image becomes a sequence of clear time–frequency images. Figure 5c shows one of these time–frequency images in which the nose, wingtips, fuselage, and engines of the aircraft can be seen very clearly. The blurred image due to target maneuvering can be refocused without applying sophisticated autofocus or motion compensation algorithms.

6. SAR IMAGING OF MOVING TARGETS

A SAR image is a high-resolution map of surface target areas and terrain in the range and cross-range domains. If there are moving targets in the scene, SAR cannot simultaneously produce clear images of both the stationary targets and moving targets. Usually, moving targets appear as defocused and spatially displaced objects superimposed on the SAR map. Therefore, how to detect and clearly image moving targets becomes an important issue.

Moving-target indication (MTI) is a function in SAR. With the MTI function, radar returns from terrain and stationary objects can be suppressed; only the returns from moving targets are used to reconstruct radar images. For focusing the image of detected moving targets, many algorithms that compensate the target's motion and perform phase correction can be used. Because of the additional Doppler shift caused by target motion, the detected and focused target is not necessarily located in its true location in the SAR scene. To relocate it, a multiple-aperture antenna array may be used in the SAR system.

When targets are moving, the motion-induced phase errors cause these images to be mislocated in the cross-range dimension and smeared in both the cross-range and the range domains.

Raney in [34] first discussed the issue of SAR imaging of moving targets. He proposed a simple frequency-domain technique for detecting moving targets in a single-aperture channel SAR. Because the detection requires clutter suppression, clutter cancellation approaches using multiple-antenna channels, such as the space-time adaptive processing, can also be used.

6.1. Multiple-Antenna SAR

Raney discussed the effect of motion parameters on the image of a moving target, specifically, the problem of image smearing and mislocating [34]. If we know the Doppler centroid and the Doppler rate exactly, then the velocity of the moving target can be calculated. However, the Doppler centroid and the Doppler rate of the moving target are determined not only by its velocity but also by its initial location, which we may not know. Therefore, the velocity of a moving target cannot be obtained, and the mislocating problem cannot be solved.

To estimate the target's velocities and reposition mislocated moving targets to their true locations, multiple-antenna systems, such as the interferometry, planar apertures, and antenna arrays, are required. Using multiple antennas with their independent receive channels, the so-called displaced phase center antenna technique or the

spacetime adaptive processing technique can be applied to suppress clutter.

The displaced phase center antenna (DPCA) technique was motivated by the two-pulse cancellation technique in moving-target indication [35]. Two side-looking antenna apertures are aligned along the flight track and normal to the radar LoS. The PRF of the transmitted signals is adjusted such that if a pulse is transmitted at the first aperture, the second aperture will transmit a pulse when it moves to the position where the first aperture was located and transmitted the previous pulse. With DPCA, targets that are buried in the clutter and cannot be detected using single-channel methods may be detectable.

DPCA uses only two antenna apertures. If multiple apertures are used, the radar receives a set of returns, each stamped by its time of arrival and its spatial location at the apertures. The multiaperture processing is referred to as a *space-time processing*. Space-time adaptive processing (STAP) is the one with adaptive spatial and temporal weights [36,37].

With multiple-antenna and space-time adaptive processing, SAR is able to detect moving targets and produce range and cross-range image of both stationary targets and moving targets.

6.2. Ground Moving-Target Indicator

The ground moving-target indicator (GMTI) is designed to reject radar returns from clutter, such as buildings and trees, and detect moving targets, such as tanks, trucks, and aircraft, that could otherwise be obscured. The difference in Doppler frequency shifts between moving targets and the clutter is used to suppress the clutter and detect moving targets. With the GMTI, slow moving targets can also be detected even if their Doppler shifts are very small.

Several multiple-antenna techniques are used to perform GMTI. The basic idea behind using multiple antennas is to have multiple phase centers. The radar compares the received data at the same place in space but at different times. When the radar platform moves, the phase center of each antenna passes through the same place but at a different time. This is called a *displaced phase center*. With displaced phase centers, the clutter will remain the same, but moving targets will change their locations.

In the GMTI radar system, instead of a single-antenna aperture, an antenna array is used. The antenna array may be either along the flight track such as the Joint Strategic Target Attack Radar System (Joint STARS) [38], which is an electronically scanned side-looking airborne radar, or a scanned planar array mounted on the nose of an airplane such as the AN/APY-6 radar [39]. Both the Joint STARS and the AN/APY-6 is a three-port interferometric radar. Compared with the conventional monopulse radar, the interferometric radar provides a low-sidelobe radiation pattern.

7. CONCLUDING REMARKS

After more than 20 years' accomplishments in theories, algorithms, and experiments, radar imaging becomes a well-developed technique and is widely used for civilian

and military purposes. However, many conventional synthetic aperture radar systems operate with a single antenna and a fixed polarization mode for both transmission and reception, and generate two-dimensional images.

Polarimetric SAR that utilizes combinations of antenna polarization for transmission and reception has been developed [40]. Polarimetry provides valuable information on identifying different scattering properties in SAR scenes. Polarimetric data are usually represented by a complex scattering matrix or covariance matrix. Combinations of the antenna polarization include horizontal transmit/horizontal receive (HH), horizontal transmit/vertical receive (HV), vertical transmit/horizontal receive (VH), and vertical transmit/vertical receive (VV). Any polarization can be obtained by a linear combination of a set of orthogonal polarizations.

The conventional SAR image is a two-dimensional depth (range) and width (cross-range) image without height. If height information can be obtained for each cell in the SAR image, then a three-dimensional image of the SAR scene can be generated. Similar to the optical stereo technique, a three-dimensional SAR image may be obtained by using two SAR images of the same scene recorded at different antenna locations, called the *interferometric* SAR. The interferometric SAR utilizes two receiving antenna apertures to record radar returns from scatterers at slightly different altitudes and generates topographic maps. The phase difference between the two receiving apertures is related to the height of a scatterer [41,42]. Height information can also be obtained in a single-antenna SAR flying along a curved flight path or by making two passes of a straight-line flight path at different altitudes. Polarimetric interferometry SAR proposed in Ref. 43 combines the polarimetric and the interferometric SAR that improves the signal-to-noise ratio in SAR image.

For imaging objects under tree canopy or buried in the ground, ultrawideband (UWB) foliage penetration (FOPEN) SAR and ground penetration radar (GPR) have been developed. UWB SAR operates at a low radiofrequency (20–1100 MHz) such that it can penetrate foliage for counter camouflage, concealment, and deception (CCD) and penetrate ground for the detection of buried objects [44,45].

Another advanced development in radar imaging is the bistatic SAR. “Bistatic” means that the transmitter and receiver of the radar are located in two different sites, which have the potential of countering vulnerability from electronic countermeasures. To form an image from a bistatic radar, image formation algorithms derived from the monostatic SAR must be modified to include the effects of motion in both the transmitter and the receiver. More sophisticated high-resolution bistatic image formation algorithms are under development [46,47].

RADAR POLARIMETRY

MARK A. SLETTEN
 Naval Research Laboratory
 Washington, DC
 DAVID J. McLAUGHLIN
 University of Massachusetts
 Amherst, Massachusetts

Radar polarimetry is the study of the vector nature of radar signals and how the relationships between the vector field components can be used to infer the geometry and composition of the illuminated surfaces and targets. In much the same way that a color photograph contains more information than a black-and-white image, polarimetric radar systems, those that measure the vector properties of the scattered radiation, provide much more information on the illuminated scene than do single polarization systems. The polarimetric properties of a radar target are intimately connected to the target's geometry. Spherically shaped targets, such as raindrops, respond to polarized electromagnetic radiation very differently than do the pointed corners of a building, the filamentary branches of a tree, or the waves on the ocean surface. Polarimetric radar systems quantify these differences and exploit them. For instance, polarimetry can be used to better discriminate between bursts of wind-blown rain and aircraft, between breaking water waves and submarine periscopes, and between forested and urban areas.

Polarization is a characteristic of all electromagnetic (EM) radiation. Any EM wave, regardless of which part of the spectrum it occupies, propagates through free space as a transverse wave. The electric and magnetic fields of the wave are directed perpendicular to one another and lie in a plane perpendicular to the direction of propagation. It is the direction of these fields and how they vary with time and space that define the *polarization state* of the wave. The phenomenon of polarization can be illustrated easily with polarized sunglasses. Polarized sunglasses are designed to preferentially attenuate light whose electric field is oriented horizontally, since this is the predominant polarization state of the reflected light that constitutes glare. When the glasses are oriented horizontally (as they are when they are worn), the light that passes through the lenses is essentially vertically polarized. If a second pair of glasses is placed in line with the first, little change in the transmitted light will occur until the second pair is rotated by 90°. The lenses then become cross-polarized, and the

view through the cascaded lenses goes dark as the second lens blocks the polarized light passed by the first.

Most common radar systems, such as those found on ships for navigation or those used by police to monitor automobile speeds, use a single antenna and thus a single polarization. These systems transmit a pulse with a polarization state determined by the antenna design. The pulse propagates out from the antenna, reflects off the target, and then propagates back to the antenna, where it is detected by the radar receiver. Although the target echo and the transmitted pulse may have different polarization states, due to changes incurred by the target's geometry or composition, only the component of the reflected echo that matches the antenna polarization will be collected. Were the target to alter the polarization state sufficiently, such that the reflected echo was orthogonal to the transmitted pulse, no echo would be detected by the radar. As in the case of the cross-polarized sunglasses, the target would be essentially invisible to this single-polarization radar. In contrast, polarimetric radar systems use multiple antennas and switches that allow a complete characterization of the reflected echo while allowing variation in the transmitted polarization as well. In fact, a fully polarimetric system can determine the echo for *any* combination of transmit and receive polarizations using only a small number (at most four) of judiciously chosen measurements.

Radar systems require more than multiple antennas and switches to operate polarimetrically. Another important aspect of a polarimetric radar system is *coherence*. Determination of the polarization state of an EM wave requires specification of both the relative magnitudes of the EM field components as well as their relative phases. A radar is coherent if it can measure the relative phase, as well as magnitude, of received echoes, and thus polarimetric radars must be coherent. (An exception to this rule is discussed in the last section of this article.) *Relative phase* indicates the timing of one EM wave component relative to another, specifying whether the vertically polarized component reaches its peak when the horizontal is near its minimum, for instance. This timing difference contains information on the structure and composition of the target.

Relative phase is also crucial if the response of a target to an arbitrary combination of transmit and receive polarizations is to be mathematically synthesized, rather than directly measured. This process is called *polarization synthesis*. From a small set of coherent measurements utilizing orthogonal polarizations (e.g., vertical and horizontal), polarization synthesis computes the radar cross section (RCS) of a given target for *any* desired combination of transmit and receive polarizations. No additional measurements of the target are needed. The results of polarization synthesis indicate which polarization combinations enhance the visibility of the target and which combinations reduce the backscatter from other, undesired objects (often referred to as *clutter*). In addition, a plot of the RCS as a function of the receive and transmit polarizations forms a *polarization signature*, which may indicate the basic geometry of the target.

Just how much can be learned about an object or a surface from its polarimetric properties is still an area of

active research, particularly in the remote sensing community. Airborne polarimetric radars are being investigated as tools for monitoring land use, classifying terrain, topographic mapping, and imaging of the ocean surface. The mathematical tools that aid in the analysis and interpretation of polarimetric data are under development as well. These tools allow decomposition of a complicated scene into simpler, canonical structures that indicate the nature of the predominant scattering centers.

The following sections describe radar polarimetry in more detail. In the next section, the basic mathematical framework of polarimetry is presented, including the representation of polarized EM fields and of the polarimetric response. Important aspects of polarimetric system design are then discussed, and the article concludes with a summary of current research topics.

1. MATHEMATICAL FOUNDATION

1.1. Representation of Polarized Electromagnetic Waves

1.1.1. Completely Polarized Waves. The polarization state of an EM wave is determined by the relative magnitudes and phases of its electric field components. Assume a plane EM wave is propagating along the z -axis of a right-handed coordinate system. The electric field lies in the x - y plane and can be expressed as

$$\mathbf{E} = E_x^\circ \cos(\omega t - kz + \alpha_x) \hat{\mathbf{x}} + E_y^\circ \cos(\omega t - kz + \alpha_y) \hat{\mathbf{y}} \quad (1)$$

where $\omega = 2\pi f$ is the radian frequency, $k = 2\pi/\lambda$ is the wave-number, λ is the wavelength, t is time, and $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ are unit vectors in the x and y directions, respectively. α_x and α_y are the phases of the x and y components, and the corresponding magnitudes are E_x° and E_y° .

The wave is said to be *linearly polarized* if $\alpha_x = \alpha_y = \alpha$. In this case, the two components are in phase with one another and Eq. (1) can be simplified to

$$\begin{aligned} \mathbf{E} &= \cos(\omega t - kz + \alpha) \cdot (E_x^\circ \hat{\mathbf{x}} + E_y^\circ \hat{\mathbf{y}}) \\ &= E^\circ \cos(\omega t - kz + \alpha) \cdot \hat{\mathbf{e}} \end{aligned} \quad (2)$$

where

$$E^\circ = \sqrt{(E_x^\circ)^2 + (E_y^\circ)^2} \quad (3)$$

$$\hat{\mathbf{e}} = \frac{E_x^\circ \hat{\mathbf{x}} + E_y^\circ \hat{\mathbf{y}}}{E^\circ} \quad (4)$$

In this case, the field is always parallel to the unit vector $\hat{\mathbf{e}}$, as illustrated in Fig. 1. As the magnitude and sign of the field vary with time and/or position, the tip of the field vector traces out a straight line parallel to $\hat{\mathbf{e}}$.

Elliptical polarization results when $\alpha_x \neq \alpha_y$. In this more general case, the two components are no longer in phase and the direction of the electric field is no longer constant. The tip of the electric field vector at any point in space (value of z) traces out an ellipse as time progresses. This can be illustrated by evaluating Eq. (1) at a

Figure 1. Electric field at three instants in time for a linearly polarized EM wave. The electric field vector is always parallel to a line defined by the vector $\hat{\mathbf{e}}$. The direction of $\hat{\mathbf{e}}$ depends on the relative magnitudes of the x and y components of the field.

particular value of z , for example, $z = 0$:

$$\mathbf{E}(z = 0) = E_x^{\circ} \cos(\omega t + \alpha_x) \hat{\mathbf{x}} + E_y^{\circ} \cos(\omega t + \alpha_y) \hat{\mathbf{y}} \quad (5)$$

This ellipse is illustrated in Fig. 2. The ellipse is characterized by its *orientation angle* ψ and *ellipticity angle* χ . In terms of the original x and y amplitudes and phases, ψ and χ are given by

$$\begin{aligned} \tan(2\psi) &= \tan(2\xi) \cdot \cos(\delta) \\ \sin(2\chi) &= \sin(2\xi) \cdot \sin(\delta) \end{aligned} \quad (6)$$

Figure 2. Electric field at three instants in time for an elliptically polarized EM wave. The tip of the electric field vector traces out an ellipse as time progresses. The ellipse is characterized by its orientation angle ψ and its ellipticity angle χ .

where

$$\tan(\xi) = \frac{E_y^{\circ}}{E_x^{\circ}} \quad (7)$$

and

$$\delta = \alpha_y - \alpha_x \quad (8)$$

Note that ψ is defined as the smallest angle between the x axis and the major axis of the ellipse. The ellipticity angle can be related to the major and minor axes of the ellipse, $2E_x^{\circ}$ and $2E_y^{\circ}$, respectively, through the expression

$$\tan(\chi) = \mp E_y^{\circ} / E_x^{\circ} \quad (9)$$

With these definitions, the limits of χ are $-45^{\circ} \leq \chi \leq 45^{\circ}$ while ψ spans the range $-90^{\circ} \leq \psi \leq 90^{\circ}$. The direction of rotation of the electric field vector about the ellipse is specified by the sign of χ . By IEEE convention, left-hand elliptical polarization is specified by $\chi > 0$, while right-hand rotation is denoted by $\chi < 0$. Note that if $|\chi| = 45^{\circ}$, the ellipse degenerates to a circle. This special case is referred to as *circular polarization*.

Vector notation is a convenient way to denote polarized fields. In vector exponential form, Eq. (1) can be written as

$$\mathbf{E} = \text{Re} \left\{ e^{-j(\omega t - kz + \alpha_y)} \begin{bmatrix} E_x^{\circ} e^{j\delta} \\ E_y^{\circ} \end{bmatrix} \right\} = \text{Re} \{ e^{-j(\omega t - kz + \alpha_y)} \mathbf{E} \} \quad (10)$$

where

$$\mathbf{E} = \begin{bmatrix} E_x^{\circ} e^{j\delta} \\ E_y^{\circ} \end{bmatrix} \equiv \begin{bmatrix} E_x \\ E_y \end{bmatrix} \quad (11)$$

completely defines the polarization state of the wave. When a polarized electromagnetic wave is expressed in the vector form of Eq. (11), the time harmonic factor $e^{-j(\omega t - kz)}$ is assumed. The phase factor $e^{-j\alpha_y}$ in Eq. (10) can be dropped, since the value of α_y depends on the arbitrary choice of a phase reference. The polarization state can be defined even more compactly by the complex polarization ratio, $P = E_y/E_x$. All aspects of a polarized wave (except for field strength) can be expressed in terms of this single, complex number [1a].

The *Stokes vector* is an alternative representation of polarized fields, defined in the following manner:

$$\mathbf{F} = \begin{bmatrix} |E_x|^2 + |E_y|^2 \\ |E_x|^2 - |E_y|^2 \\ 2 \text{Re}(E_x E_y^*) \\ 2 \text{Im}(E_x E_y^*) \end{bmatrix} = \begin{bmatrix} I_0 \\ Q \\ U \\ V \end{bmatrix} \quad (12)$$

[The Stokes vector is sometimes defined with the element V in the second position within the vector:

$$\mathbf{F} = \begin{bmatrix} |E_x|^2 + |E_y|^2 \\ 2 \operatorname{Im}(E_x E_y^*) \\ |E_x|^2 - |E_y|^2 \\ 2 \operatorname{Re}(E_x E_y^*) \end{bmatrix}$$

In addition, some authors define $V = 2 \operatorname{Im}(E_x^* E_y) = (-1) \cdot 2 \operatorname{Im}(E_x E_y^*)$.] While the representations in Eqs. (11) and (12) contain the same information about wave polarization in the case of a completely polarized wave, the Stokes vector has the advantage that all the vector elements are real-valued, and, as discussed in the following section, it can accommodate fields that are not completely polarized.

For completely polarized waves, it can be shown that $I_0^2 = Q^2 + U^2 + V^2$. This is the equation of a sphere of radius I_0 . Each polarization state can thus be mapped uniquely onto a point of a sphere, using the parameters Q, U, V as Cartesian coordinates. This graphical representation of wave polarization is referred to as the *Poincaré sphere* [1b].

1.1.2. Partial Polarization. Not all polarized EM waves can be adequately described using the representation of Eq. (11). The polarization state of natural EM waves, such as sunlight, is unpolarized, meaning that the polarization state varies randomly from one time instant to the next. Similarly, the polarization state of the radar backscatter from some surfaces, such as the sea surface or a wind-blown canopy of trees, may vary rapidly with time. The total radar backscatter in these cases is the vector sum of many individual echoes produced by many discrete scattering centers located within the radar footprint, each of which is moving and evolving. The net polarization state may be nearly linear at one instant, but elliptical only a few milliseconds later. Even if these surfaces could be frozen in time, the polarization state would still vary appreciably as the radar beam was moved about in space, since new scattering centers would enter the spot illuminated by the beam as others would exit. What is needed in these situations is a *statistical* measure of the polarization state of the wave. The Stokes vector can be adapted to these situations, in which the time and/or spatially varying fields are termed *partially polarized*.

For partially polarized waves, the ensemble averages of the Stokes vector elements, indicated by angular brackets $\langle \rangle$, are used. The Stokes vector becomes

$$\mathbf{F} = \begin{bmatrix} \langle |E_x|^2 + |E_y|^2 \rangle \\ \langle |E_x|^2 - |E_y|^2 \rangle \\ \langle 2 \operatorname{Re}(E_x E_y^*) \rangle \\ \langle 2 \operatorname{Im}(E_x E_y^*) \rangle \end{bmatrix} \quad (13)$$

The average may be over time with the radar directed at a single spot, over space if the surface is stationary, or over a mixture of time and space. The last two elements, U and V ,

indicate the degree of correlation between the x and y components. For a completely unpolarized wave, E_x and E_y are uncorrelated and thus $U = V = 0$.

1.1.3. Vertical and Horizontal Polarization. In most radar applications, it is more convenient to represent polarized waves in a spherical, rather than rectangular, coordinate system. Since the electric and magnetic fields that propagate in free space are transverse to the direction of propagation, and thus do not always lie in a convenient, fixed plane (such as the x - y plane assumed thus far), a spherical coordinate system is a more natural choice. This is illustrated in Fig. 3. The direction of propagation of the wave (formerly the \hat{z} direction) is denoted by the unit vector $\hat{\mathbf{k}}$, while the transverse coordinate unit vectors (formerly $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$) are $\hat{\mathbf{v}}$ and $\hat{\mathbf{h}}$. The coordinate system $(\hat{\mathbf{k}}, \hat{\mathbf{v}}, \hat{\mathbf{h}})$ is defined such that it coincides with the standard spherical system $(\hat{\mathbf{r}}, \theta, \phi)$. The letters \mathbf{v} and \mathbf{h} refer to *vertical* and *horizontal* polarization, respectively, a reference to the fact that if the $\theta = 90^\circ$ plane is assumed to be Earth's surface (as it usually is), $\hat{\mathbf{v}}$ contains a vertically oriented component while $\hat{\mathbf{h}}$ lies in a horizontal plane. In this coordinate system, a spherical wave can be expressed as

$$\mathbf{E} = (E_v \hat{\mathbf{v}} + E_h \hat{\mathbf{h}}) \frac{e^{jk \cdot \mathbf{r}}}{r} \quad (14)$$

where $\mathbf{r} = r\hat{\mathbf{r}}$, and r is the distance from the coordinate system origin. Sufficiently far from the origin and over a small enough range of angles about the direction $\hat{\mathbf{k}}$, this

Figure 3. Diagram indicating the decomposition of the electric field $\mathbf{E}(t, z)$ into vertically and horizontally polarized components. The direction of propagation, denoted by the unit vector $\hat{\mathbf{k}}$, and the vertically and horizontally polarized unit vectors, $\hat{\mathbf{v}}$ and $\hat{\mathbf{h}}$, respectively, form a right-handed coordinate system coincident with the standard spherical coordinate system $(\hat{\mathbf{r}}, \theta, \phi)$. The terms “vertical” and “horizontal” arise from the fact that $\hat{\mathbf{h}}$ is always parallel to the horizontal ($\theta = 90^\circ$) plane while $\hat{\mathbf{v}}$ has a component in the vertical (\hat{z}) direction.

spherical wave can be considered to be a plane wave. All the expressions derived above for a plane wave propagating in the z direction are then still valid with the x and y subscripts interchanged with “ v ” and “ h ”, respectively. Note that with this transformation, the orientation angle, ψ , is defined relative to the vertical axis. Other authors use alternative conventions, however, that define ψ relative to the horizontal.

1.2. Representation of the Polarimetric Response

The previous section describes how the polarization state of an EM wave can be described mathematically. In this section, two formalisms are presented that describe how the polarization state of a wave is *altered* when it reflects off a target. The first, which applies to completely polarized waves, utilizes the *scattering matrix* to describe the target’s polarimetric properties. The second, which can be applied to completely or partially polarized targets, uses the *Mueller matrix* to describe the target. Both matrices describe the target’s polarimetric properties by quantifying how the polarization of the reflected wave is related to the polarization of the incident wave, and both are *complete* descriptions of the scattering properties of the illuminated scene or target. As shown in what follows, the response of the scene to any combination of transmit and receive polarizations can be computed from these matrices, without the need for additional measurements.

When using any representation of the polarimetric response, care must be taken that consistent source, target, and receiver coordinate systems are used. This article assumes the backscatter alignment (BSA) convention in which the incident and scattered wave unit vectors are identical. For a description of other conventions, see Refs. 1a, 1b, and 2. The notation used in this section closely matches that of Ref. 2.

1.2.1. Polarization Scattering Matrix. The scattering matrix is a 2×2 matrix relating the transmitted wave incident on a target \mathbf{E}^t to the reflected wave at the receiver \mathbf{E}^r :

$$\mathbf{E}^r = \frac{e^{jkr}}{r} \bar{\mathbf{S}} \mathbf{E}^t \quad (15)$$

where

$$\mathbf{E}^r = \begin{bmatrix} E_v^r \\ E_h^r \end{bmatrix}, \quad \mathbf{E}^t = \begin{bmatrix} E_v^t \\ E_h^t \end{bmatrix} \quad (16)$$

and

$$\bar{\mathbf{S}} = \begin{bmatrix} \bar{S}_{vv} & \bar{S}_{vh} \\ \bar{S}_{hv} & \bar{S}_{hh} \end{bmatrix} \quad (17)$$

is the scattering matrix. The elements of $\bar{\mathbf{S}}$ are complex, containing both magnitude and phase information, but in most cases the four magnitudes and phases are not independent. In the case of a monostatic radar in the absence of any nonreciprocal materials (e.g., ferromagnetics or

plasmas in a magnetic field), the reciprocity theorem forces $\bar{S}_{vh} = \bar{S}_{hv}$, and thus there are three independent magnitudes and two independent (relative) phases. Although not explicitly shown in Eq. (17), the elements of $\bar{\mathbf{S}}$ are in general functions of the radar frequency as well as the orientation of the target relative to the radar system.

The variation of the scattering matrix elements with target orientation is undesirable in terms of target recognition. The task of identifying an unknown target at an unknown aspect would be much simpler if the form of its scattering matrix were essentially independent of orientation. An eigenvalue analysis of the scattering matrix can partially achieve this goal while also providing physical insight into the scattering process. Through an eigenvalue analysis (e.g., see Ref. 1b), it can be shown that the scattering matrix can be diagonalized and represented by the following five independent parameters; m^2 , the maximum RCS of the target; ψ_t , the orientation angle; τ , the symmetry angle; ν , the bounce angle; and γ , the polarizability angle. With the exception of ψ_t , which is a direct measure of the target’s rotation angle, these parameters are independent of target rotations about the radar line of sight and are thus relatively invariant indicators of a target’s identity. (The parameter values will change, however, if the radar views the target from a different line of sight.) τ is a measure of the symmetry of the target, having a value of 0° for targets with a plane of symmetry and a value of $\pm 45^\circ$ for nonsymmetric objects, and is also the ellipticity angle of the eigenvectors. The bounce angle ν indicates the number of bounces involved in the target scattering, with a value of 0° corresponding to an odd number of bounces and a value of $\pm 90^\circ$ indicating an even number. Examples of odd bounce targets are spheres (one bounce) and trihedral corner reflectors (three bounces; see Example 1 below here), while the dihedral corner reflector is an even bounce scatterer (two bounces; see Example 2 here). The polarizability γ indicates the ability of the target to polarize incident radiation that is unpolarized, with 0° and 45° corresponding to complete and no polarizability, respectively. An example of a target with a high degree of polarizability is a long, thin wire, which tends to reflect only radiation polarized parallel to its axis. In contrast, a sphere exhibits $\gamma = 45^\circ$, since it has no preferred axis of symmetry. These five parameters are sometimes referred to as the Huynen parameters, in reference to their introduction by J. R. Huynen [3]. These parameters also describe the *null* and *maximum polarizations* for the target, those polarization states for which the RCS is zero and m^2 , respectively. When plotted on the Poincaré sphere, these polarization states define a characteristic structure called the *polarization fork* (see, e.g., Refs. 2 and 4).

In practice, the elements of the scattering matrix are generally obtained by recording the radar echoes from two pulses. First, the radar system transmits a pure vertically polarized wave

$$\mathbf{E}^t = E_v^t \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

and the receiver detects and records both the vertically and horizontally polarized echoes, E_{vv} and E_{hv} . From

Eqs. (15)–(17), \bar{S}_{vv} and \bar{S}_{hv} can then be calculated from

$$\bar{S}_{vv} = \frac{r}{e^{jkr}} \cdot \frac{E_{vv}}{E_v^t}, \quad \bar{S}_{hv} = \frac{r}{e^{jkr}} \cdot \frac{E_{hv}}{E_v^t} \quad (18)$$

Similarly, \bar{S}_{hh} and \bar{S}_{vh} are determined by transmitting a pure horizontally polarized pulse,

$$\mathbf{E}^t = E_h^t \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

and recording the vertically and horizontally polarized echoes E_{hh} and E_{vh} from which the remaining scattering matrix elements

$$\bar{S}_{hh} = \frac{r}{e^{jkr}} \cdot \frac{E_{hh}}{E_h^t}, \quad \bar{S}_{vh} = \frac{r}{e^{jkr}} \cdot \frac{E_{vh}}{E_h^t} \quad (19)$$

are obtained. Of course, two pulses of any two linearly independent polarization states could be used to determine the scattering matrix elements, since Eq. (15) defines four equations in four unknowns. But in general practice, pure vertically and horizontally polarized pulses are used.

Example 1 (Sphere). The simplest scattering matrix is that of sphere, given by

$$\bar{S}_{\text{sphere}} = A \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad (20)$$

where the constant A depends on the sphere’s size. This target does not alter the polarization state of the incident radiation, since $\bar{S}_{hv} = \bar{S}_{vh} = 0$, and responds identically to horizontally and vertically polarized radiation. Other objects with scattering matrices of the same form are large, flat surfaces at normal incidence and trihedral corner reflectors. The latter is a type of radar calibration target resembling the inside corner of a box. For these targets, the Huynen parameters τ , ν , and γ are equal to 0° , 0° , and 45° , respectively, while the orientation angle ψ_t is arbitrary.

Example 2 (Rotated Dihedral Corner Reflector). A dihedral corner reflector is a radar calibration target formed from two intersecting, perpendicular plates. The scattering matrix of this target with the seam rotated at an angle θ relative to the horizontal plane is

$$\bar{S}_{\text{dihedral}} = A \begin{bmatrix} \cos(2\theta) & \sin(2\theta) \\ \sin(2\theta) & -\cos(2\theta) \end{bmatrix} \quad (21)$$

where A depends on the size of the plates. The tendency of this target to depolarize (change the polarization state of) the incident radiation is strongly dependent on its orientation. At $\theta = 22.5^\circ$, vertically or horizontally polarized incident radiation will be rotated 45° after reflection, whereas at $\theta = 45^\circ$, the rotation is 90° . The Huynen parameters for the dihedral are $\psi_t = \theta$, $\tau = 0^\circ$, $\nu = 45^\circ$, and $\gamma = 45^\circ$.

Example 3 (Helix). The scattering matrix for a simple helix is

$$\bar{S}_{\text{helix}} = \frac{1}{2} \begin{bmatrix} -1 & \pm j \\ \pm j & 1 \end{bmatrix} \quad (22)$$

where the $+$ and $-$ signs refer to left- and right-handed helices, respectively. The factor $j = \sqrt{-1} = e^{j\pi/2}$ arises from the natural mode of oscillation for the helix, circular polarization, in which the relative phase between the vertical and horizontal components is $\pi/2$ radians (90°). The Huynen parameters τ and γ are $\pm 45^\circ$ and 0° , respectively, while ψ_t and ν are arbitrary.

1.2.2. Mueller Matrix. In the same way that the scattering matrix relates the EM fields incident on and reflected from a target, the Mueller matrix relates the incident and scattered Stokes vectors

$$\mathbf{F}^r = \frac{1}{r^2} \bar{\mathbf{L}} \mathbf{F}^t \quad (23)$$

where

$$\mathbf{F}^r = \begin{bmatrix} I_0^r \\ Q^r \\ U^r \\ V^r \end{bmatrix}, \quad \mathbf{F}^t = \begin{bmatrix} I_0^t \\ Q^t \\ U^t \\ V^t \end{bmatrix} \quad (24)$$

and $\bar{\mathbf{L}}$ is the 4×4 Mueller matrix. Unlike in the case of the scattering matrix, the Mueller matrix elements are real. (Note that a factor of $1/r^2$ is required, rather than $1/r$ as for the scattering matrix expression, since the Stokes vector elements are proportional to products of the field components.) As shown in Ref. 2, the Mueller matrix elements can be expressed in terms of the scattering matrix elements through

$$\bar{\mathbf{L}} = \mathbf{R} \bar{\mathbf{W}} \mathbf{R}^{-1} \quad (25)$$

where

$$\mathbf{R} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & -i & i \end{bmatrix} \quad (26)$$

and

$$\bar{\mathbf{W}} = \begin{bmatrix} \bar{S}_{vv}^* \bar{S}_{vv} & \bar{S}_{vh}^* \bar{S}_{vh} & \bar{S}_{vh}^* \bar{S}_{vv} & \bar{S}_{vv}^* \bar{S}_{vh} \\ \bar{S}_{hv}^* \bar{S}_{hv} & \bar{S}_{hh}^* \bar{S}_{hh} & \bar{S}_{hh}^* \bar{S}_{hv} & \bar{S}_{hv}^* \bar{S}_{hh} \\ \bar{S}_{hv}^* \bar{S}_{vv} & \bar{S}_{hh}^* \bar{S}_{vh} & \bar{S}_{hh}^* \bar{S}_{vv} & \bar{S}_{hv}^* \bar{S}_{vh} \\ \bar{S}_{vv}^* \bar{S}_{hv} & \bar{S}_{vh}^* \bar{S}_{hh} & \bar{S}_{vh}^* \bar{S}_{hv} & \bar{S}_{vv}^* \bar{S}_{hh} \end{bmatrix} \quad (27)$$

This relationship between $\bar{\mathbf{L}}$ and $\bar{\mathbf{S}}$ is strictly valid only for completely polarized targets, since $\bar{\mathbf{S}}$ does not exist otherwise. Complex radar targets, such as wind-blown trees, exhibit time-varying polarization matrix elements, and no single scattering matrix can describe their polarization transformation properties. The elements of $\bar{\mathbf{S}}$ tend to be zero-mean quantities, and so averaging these terms is not an effective way to describe the average polarization scattering behavior of a target. This average behavior can be described by computing a time-averaged Mueller matrix, however. In practice, the average Mueller matrix is sometimes calculated by first computing the scattering matrix elements from each pair of a large number of alternating vertically and horizontally polarized transmit pulses, using Eqs. (18) and (19). Equations (26) and (27) are then used to compute individual Mueller matrices for each measurement. The final, averaged Mueller matrix is then calculated by averaging the individual matrix elements. This procedure is valid if the target or scene of interest can be considered to be stationary, and thus completely polarized, over the time period required to transmit a single pair of vertically and horizontally polarized pulses. As this interval can be as short as a fraction of a millisecond, this is a very reasonable assumption in many cases. A direct technique for computing the time-averaged Mueller matrix, without calculating a sequence of polarization scattering matrices, is described in Ref. 5.

Some authors use different names for the matrix $\bar{\mathbf{L}}$ defined using the BSA convention and that defined using the forwardscatter alignment (FSA) convention, referring to the former as the *Kennaugh matrix* and the latter as the *Mueller matrix* [1a]. While making this distinction avoids potential confusion, both are commonly referred to as the Mueller matrix.

1.2.3. Other Representations of the Polarimetric Response. In addition to the scattering and Mueller matrix formalisms, the polarimetric scattering properties of the target can also be expressed by the covariance matrix \mathbf{C} and the coherency (or density) matrix ρ . In terms of the scattering matrix elements, these matrices are given by

$$\mathbf{C} = \begin{bmatrix} S_{vv}S_{vv}^* & \sqrt{2}S_{vv}S_{vh}^* & S_{vv}S_{hh}^* \\ \sqrt{2}S_{vh}S_{vv}^* & 2S_{vh}S_{vh}^* & \sqrt{2}S_{vh}S_{hh}^* \\ S_{hh}S_{vv}^* & \sqrt{2}S_{hh}S_{vh}^* & S_{hh}S_{hh}^* \end{bmatrix} \quad (28)$$

$$\rho = \begin{bmatrix} aa^* & ab^* & ac^* \\ ba^* & bb^* & bc^* \\ ca^* & cb^* & cc^* \end{bmatrix} \quad (29)$$

where

$$a = \frac{S_{vv} + S_{hh}}{2}, \quad b = \frac{S_{vv} - S_{hh}}{2}, \quad c = S_{vh} = S_{hv} \quad (30)$$

(These expressions apply to the backscattering, reciprocal case. In the general bistatic case, both \mathbf{C} and ρ are 4×4 matrices.) As in the case of the Mueller matrix, these

matrices can be applied to the partially polarized case through averaging of the elements, and they contain the same information as do the scattering or Mueller matrices. Different aspects of polarimetry are expressed more compactly with one representation or the other, however. (See, e.g., Refs. 2 and 4.)

1.2.4. Polarization Synthesis. The scattering and Mueller matrices are complete representations of the polarimetric scattering properties of a target or surface in that the target response to any combination of transmit and receive polarizations can be computed from them. *Polarization synthesis* refers to the process of determining a target's response to an arbitrary combination of transmit and receive polarizations by way of the target's scattering or Mueller matrix, without actually transmitting and receiving these polarization states.

The equation describing polarization synthesis can be derived by starting with the definition of the (monostatic) RCS of a target

$$\sigma = 4\pi \lim_{r \rightarrow \infty} r^2 \left(\frac{\mathbf{E}^s \cdot \mathbf{E}^{s*}}{\mathbf{E}^t \cdot \mathbf{E}^{t*}} \right) = 4\pi \lim_{r \rightarrow \infty} r^2 \left(\frac{|\mathbf{E}^s|^2}{|\mathbf{E}^t|^2} \right) \quad (31)$$

where $|\mathbf{E}^s|^2$ is the electric field intensity scattered by the target, measured at the receiver, and $|\mathbf{E}^t|^2$ is the incident electric field intensity, measured at the target, and r is the distance between the radar antenna and the target. This expression states that the RCS is given by the power per unit solid angle incident on the antenna divided by the power per unit area incident on the target.

As it stands, this expression does not account for the polarization of the receive antenna. A system will measure this value of the RCS only if the receive antenna is designed to receive the polarization state of \mathbf{E}^s . Otherwise, only a fraction of the power incident on the antenna will be actually absorbed, and the measured RCS will be lower than that given by Eq. (31). This effect can be accounted for in the following way. The polarization of an antenna is defined by the unit vector \mathbf{p} , the polarization vector, given by

$$\mathbf{p} = \frac{\mathbf{E}}{|\mathbf{E}|} \quad (32)$$

where, by IEEE convention, \mathbf{E} is the far field radiated by the antenna when it is used to transmit. If a field \mathbf{E}^s impinges on a receive antenna having polarization \mathbf{p}^r , the effective field incident on the antenna is the projection of \mathbf{E}^s on \mathbf{p}^r , $\mathbf{p}^r \cdot \mathbf{E}^s$, and the effective field intensity is then $|\mathbf{p}^r \cdot \mathbf{E}^s|^2$. The expression for the cross section in this case is

$$\sigma_{rt} = 4\pi \lim_{r \rightarrow \infty} r^2 \left(\frac{|\mathbf{p}^r \cdot \mathbf{E}^s|^2}{|\mathbf{E}^t|^2} \right) \quad (33)$$

Noting that $\mathbf{E}^s = (e^{jkr}/r)\bar{\mathbf{S}}\mathbf{E}^t$ and making the substitution $\mathbf{p}^t = (\mathbf{E}^t/|\mathbf{E}^t|)$ produces the polarization synthesis equation:

$$\sigma_{rt} = (\mathbf{p}^r \cdot \bar{\mathbf{S}}\mathbf{p}^t)^2 \quad (34)$$

Once $\bar{\mathbf{S}}$ has been determined, the target RCS for *any* combination of transmit and receive polarizations can be computed from this expression. The unit vectors \mathbf{p}^r and \mathbf{p}^t corresponding to the desired transmit and receive polarizations are simply inserted. A similar expression using the Stokes vector and Mueller matrix representation can also be derived [2].

1.2.5. Polarization Response. The RCS values computed by Eq. (34) can be represented graphically by a surface termed the *polarization signature* or *polarization response* [6]. The term *signature* refers to the fact that these surfaces are distinctive and can be used to broadly classify targets. Two types of signatures are used: the co-polarized signature, in which the incident and scattered polarization states are assumed to be identical; and the cross-polarized signature, in which the incident and scattered states are assumed to be orthogonal. The signatures of some common targets are shown in Figs. 4–6.

Example 4 (Sphere). The co- and cross-polarized signatures of a sphere are shown in Figs. 4a and 4b, respectively. The signature consists of a plot of the target RCS versus the ellipticity and orientation angles χ and ψ of the incident and scattered radiation. Linearly polarized states lie along the $\chi = 0^\circ$ line, with vertical located at ($\chi = 0^\circ$, $\psi = \pm 90^\circ$) and horizontal located at ($\chi = 0^\circ$, $\psi = 0^\circ$). Left- and right-handed circular polarizations are located along the $\chi = \pm 45^\circ$ lines. The ridge in the copolarized surface along the $\chi = 0^\circ$ line indicates that the copolarized RCS of the sphere is maximized when the polarization is linear. The response vanishes when circular polarization is used. (For this reason, some operational radar systems use circular polarization when monitoring targets through rain. This choice of polarization reduces the clutter signal produced by raindrops, which are roughly spherical in shape.) In

contrast, the cross-polarized response is minimized by linear polarization and maximized when circular polarization is used. The surfaces in Fig. 4 are also the polarization signatures of a trihedral corner reflector and a flat plate at normal incidence, since these targets have the same normalized scattering matrices as the sphere [Eq. (20)].

Example 5 (Dihedral Corner Reflector). Figures 5a and 5b show the co- and cross-polarized responses, respectively, of a dihedral corner reflector with its seam oriented parallel to the horizontal plane. The copolarized RCS is maximum for vertical, horizontal, and circular polarizations, but vanishes for linear polarized radiation with an orientation angle $\psi = \pm 45^\circ$. Examination of the dihedral scattering matrix [Eq. (21)], shows that when the incident polarization state is linear with $\psi = \pm 45^\circ$, the scattered and incident polarization states are orthogonal. The copolarized response consequently vanishes, while the cross-polarized response (Fig. 5b), exhibits maxima at these points.

Example 6 (Helix). The co- and cross-polarized signatures of a left-handed helix are shown in Figs. 6a and 6b, respectively. The co-polarized RCS is maximized when left-hand circular polarization is used and vanishes for right-hand circular polarization. Unlike for the sphere or the dihedral corner reflector, the cross-polarized response of the helix never achieves a value of 1.

2. POLARIMETRIC RADAR DESIGN

A polarimetric radar, or polarimeter, measures the scattering matrix of a target by sequentially transmitting a pair of orthogonally polarized pulses toward the target and simultaneously measuring the co- and cross-polarized

Figure 4. (a) Copolarized signature for a sphere. The surface is a plot of the normalized RCS of the sphere versus the orientation and ellipticity angles of the transmit and receive polarizations. The cross section is maximum for linearly polarized radiation, as indicated by the ridge in the surface for $\chi = 0$, and vanishes for left- and right-handed circular polarization ($\chi = \pm 45^\circ$). (b) Cross-polarized signature for the sphere. The cross-polarized signature is a plot of the normalized RCS of the sphere versus the orientation and ellipticity angles of the transmit polarization, assuming that the transmit and receive antennas are orthogonally polarized. The cross-polarized RCS vanishes for linear polarization and is maximized for left- and right-handed circular polarization.

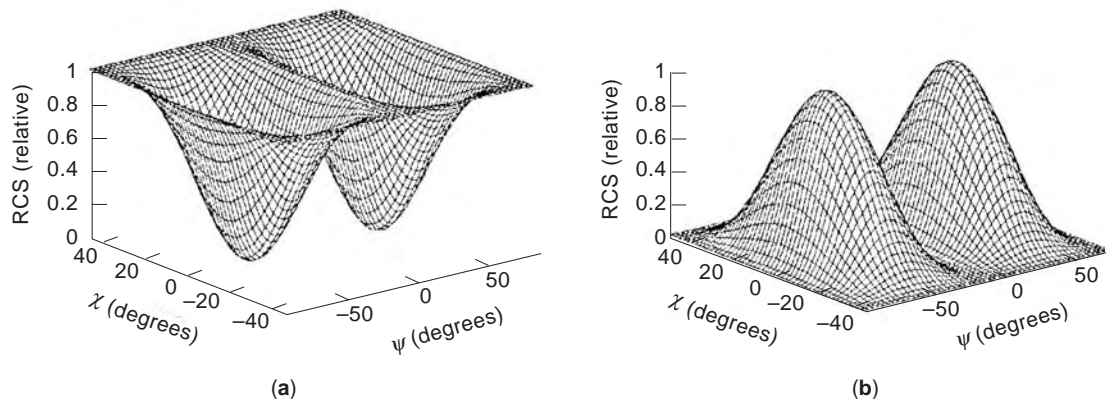

Figure 5. (a) Copolarized signature for a dihedral corner reflector with its seam oriented horizontally. The RCS is maximum for vertical, horizontal, and circular polarizations and vanishes for linear polarizations with $\psi = \pm 45^\circ$. (b) Cross-polarized signature for the dihedral corner reflector. The cross-polarized RCS is maximum for linear polarizations with $\psi = \pm 45^\circ$ and vanishes for vertical, horizontal, and circular polarizations.

components of the scattered wave. The need to transmit and receive multiple polarizations makes the design of a polarimetric radar more complicated than the design of a conventional, single polarization, radar system. A basic polarimeter is composed of a transmitter that generates microwave pulses at a specified carrier frequency, an antenna capable of transmitting and receiving two orthogonally polarized wave components and focusing these waves into a narrow angular beamwidth in space, switching circuitry that alternately routes the transmitted pulses between the two orthogonal ports of the antenna feed, a pair of receivers for detecting the signals received from the antenna, and a multichannel data acquisition system for recording the signals backscattered from the target.

As in conventional radar design, the most important design equation for radar polarimetry is the radar range equation

$$SNR = \frac{P_t G_t \sigma A}{(4\pi)^2 R^4 k T B F_n} \tag{35}$$

which gives the receiver signal-to-noise ratio (SNR) in terms of the peak transmitted power level P_t ; the antenna gain, $G_t = 4\pi/\theta^2$, where θ is the antenna's focusing beamwidth (assumed here to be equal in azimuth and elevation planes, as is the case for a pencil-beam antenna); the antenna's collecting area A , which typically ranges between 60% and 95% of its physical area, depending on the aperture illumination efficiency; the polarization-dependent radar cross section of the target σ ; the range between the radar antenna and the target R ; the bandwidth B and noise figure F_n of the receiver; Boltzmann's constant, $k = 1.38 \times 10^{-23}$ J/K; and the physical temperature of the receiver T , usually taken to be 290 K. Whereas reliable radar target detection can often be accomplished with a receiver SNR of 15 dB using a conventional radar [7], measuring the polarimetric response of a target typically requires SNR levels of 20 dB or higher [8]. A large part of polarimeter system design involves trading off the various parameters of Eq. (35) to achieve a specified level of SNR performance. Reference 2 describes some of the tradeoffs

Figure 6. (a) Copolarized signature for a left-handed helix. The copolarized RCS is maximized by left-handed circular polarization and vanishes for right-handed circular polarization. (b) Cross-polarized signature of a left-handed helix. The cross-polarized response is maximized with linear polarizations, but the peak response is weaker than the maximum exhibited in the copolarized case.

involved in the design of a spaceborne imaging radar polarimeter having transmitted power level $P_t = 5$ kW, antenna gain $G_t = 10,000$ (40 dB), and surface area $A = 32$ m² (15 dB) that achieves an SNR level of 24 dB when viewing Earth's surface at 400 km range. Another example of a spaceborne imaging polarimeter is given in Ref. 9.

The operating wavelength of a polarimetric radar system is chosen as the result of a tradeoff among considerations such as the physical size of the antenna, peak transmitted power level, availability of components, cost, and for most remote sensing applications, the sensitivity of the surface backscatter coefficient [or normalized radar cross section (NRCS)] to environmental parameters. In general, radar systems operating at higher microwave frequencies have smaller antennas and larger peak transmitted power levels than do radars operating at lower microwave frequencies. The focusing gain and physical size of an antenna are related by the equation $A = \lambda^2 G_t / 4\pi$ (assuming 100% aperture efficiency), where wavelength λ is inversely related to the operating frequency f by the equation $\lambda = c/f$, where c is the speed of light. These equations reveal that larger antenna gains can be obtained for a given antenna size at higher frequencies than at lower frequencies. Conversely, a specified amount of focusing gain can be achieved with a smaller physical antenna size at a higher frequency than at a lower frequency. However, receiver SNR is proportional to the product of the focusing gain and the physical collecting area of the antenna. Therefore, increasing the operating frequency to reduce the physical size of an antenna while achieving a specified level of antenna gain results in reduced receiver SNR. This loss must be compensated by increasing the peak transmitted power level of the radar system. This tradeoff is particularly important in airborne and spaceborne radar system deployments where it is desirable to utilize small antennas.

At millimeter-wave frequencies and higher microwave frequencies (typically above X band), atmospheric attenuation becomes an important consideration, and the SNR in Eq. (35) must be multiplied by the term $\exp(-2\alpha R)$, where α , having units of nepers (napiers) per meter (Np/m), is the attenuation coefficient. Attenuation coefficients for propagation through the clear atmosphere and through rain are given in Ref. 10 for different frequencies. When scattering targets are small compared with the operating wavelength, such as raindrops observed with a millimeter-wave radar system, σ is a strong function of frequency and is given by the Rayleigh expression $\sigma = a/\lambda^4$, where the constant a depends on the shape of the target. The SNR in this case is given by the equation

$$\text{SNR} = \frac{P_t G_t^2 a \exp(-2\alpha R)}{(4\pi)^3 R^4 k T B F_n \lambda^2} \quad (36)$$

which reveals that increases in the operating frequency (decreases in wavelength) result in higher SNR levels relative to operating at a lower operating frequency. Reference 11 describes a dual-frequency polarimetric radar system developed for cloud profiling studies. The radar contains transmitters operating at 33 and 95 GHz that

share a common 1-m-diameter dielectric lens antenna. Because of the strong wavelength dependence in the backscatter coefficient from the raindrops, the 33-GHz channel of this radar requires 120 kW peak power level, whereas the 95-GHz channel requires only 1.5 kW peak power level to achieve the same SNR.

2.1. Transmitter Design Considerations

Polarimetric processing of radar data involves the coherent combination of scattered wave measurements corresponding to a pair of consecutive transmitted pulses. Phase-coherent transmitters are therefore used in most polarimetric radar designs. (A technique for measuring the time-averaged Mueller matrix directly that does not require a coherent transmitter is described in Ref. 5.) The master oscillator power amplifier (MOPA) transmitter configuration is commonly used in coherent transmitter design. In this configuration, a low-power (typically in the tens of milliwatts) microwave signal, derived from a microwave oscillator that is phase-locked to a stable crystal oscillator, is pulse-modulated using a pin diode switch and then amplified to achieve the required peak power level using a power amplifier. Solid-state field-effect transistor (FET) amplifiers are often used in lower frequency (X-band and below) microwave systems having power levels of several watts. Microwave power tube amplifiers [TWTs (traveling-wave tubes) and klystrons] are often used in higher-power and microwave frequency radar transmitters. Examples of polarimeter systems utilizing klystron amplifiers with peak power levels of 200 kW at S band and 1.5 kW at 95 GHz are described in Refs. 11 and 12, respectively. MOPA transmitters tend to be expensive, typically costing several tens to hundreds of thousands of dollars. These systems provide for highly flexible transmitted waveforms, however, and a variety of waveforms (pulsed, chirped, phase-coded) can be generated using a MOPA design.

Self-excited power oscillator tubes, such as the magnetron oscillator and the extended interaction oscillator (EIO), are also used in polarimeter transmitter designs. These devices often cost considerably less than MOPA transmitters, but they are typically limited to pulsed applications. These incoherent power oscillators typically exhibit frequency drift and pulse-to-pulse phase modulations, and frequency stabilization and coherent-on-receive circuits are required when these devices are used in polarimetric radar designs. Reference 11 gives an example of a high-power magnetron transmitter for a millimeter-wave polarimeter system.

2.2. Polarimeter Antennas

Polarimetric radar antennas must be capable of transmitting and receiving two orthogonally polarized waves. Any pair of orthogonal polarizations can be used, but vertical/horizontal linear and right/left circular are the most common. As in a conventional radar, the physical size of the antenna must be large enough to achieve the focusing beamwidth and directive gain specified by the system design and SNR budget, and the antenna sidelobes must be below some specified value. The antenna designs used in

radar polarimeters must also achieve high polarization purity. A typical specification requires the cross-polarized radiation, integrated across the antenna pattern, to be 30 dB below the copolarized signal level [8].

Many of the antennas used for conventional radar design can be used in polarimeter systems by adapting them for dual-polarization operation. A corrugated horn antenna equipped with an orthomode transducer (OMT) can be used for dual-linear polarization operation in applications requiring modest directive gain (up to 20 dB). Higher levels of directive gain can be achieved by using the corrugated horn to illuminate a parabolic reflector in either a prime-focus or Cassegrain configuration [13,14]. References 11 and 15 describe millimeter-wave polarimeter systems that use dielectric lens antennas. The antenna for the polarimetric radar flown on the space shuttle, the *Spaceborne Imaging Radar—C* (SIR-C), is a microstrip patch array with transmit/receive (T/R) modules distributed across the array surface [9]. The system operates simultaneously at L and C bands.

2.3. Polarization Switches

Single-pole double-throw (SPDT) switches are needed in the transmitter of a polarimetric radar to alternately route the transmitted signal between the two ports of the antenna. The switching is performed on a pulse-to-pulse basis, so the switches must be capable of toggling the high-power microwave-transmitted pulse between the two antenna ports at switching speeds of 0.1–1 ms or faster. For low-power (less than 10 W), short-range polarimeter designs, pin diode switches are often used. Higher-power applications (up to tens or hundreds of watts of peak transmitted power level) typically use ferrite switching circulators. Three circulators are typically used in the design, as described in Ref. 14. Off-the-shelf ferrite switching circulators capable of handling several tens of kilowatts are commonly available at L- through Ku-band microwave frequencies at a cost of several thousand dollars per circulator.

Many polarimeter designs require peak transmitter power levels that are too high for off-the-shelf ferrite switches. Reference 14 describes a high-power, 1-MW S-band polarimeter design that uses a ferrite switching circulator custom-made at a cost of \$75,000. Reference 11 describes a 33-GHz, 125-kW polarimeter that uses two separate transmitters to feed the antenna ports, rather than a single transmitter with a polarization switch.

2.4. Receiver and Data Acquisition

Two superheterodyne receiving channels are used in a polarimeter to detect the co- and cross-polarized components of the scattered wave. Current designs achieve dynamic ranges of up to 100 dB by using low-noise front-end amplifiers, matched filters, and wide-dynamic-range coherent detectors. Standard in-phase/quadrature demodulator circuits operate over a limited dynamic range, typically on the order of 30 dB. The wide-dynamic-range circuits used in many polarimeter receivers use logarithmic detectors for measuring signal amplitude and constant-phase limiters followed by in-phase/quadrature demodulators for

measuring signal phase. Examples of these detector circuits are given in Refs. 11 and 14. Data acquisition systems with six channels are required in polarimeters that utilize these wide-dynamic-range detectors.

2.5. Polarimeter Calibration

Calibration is an important aspect of polarimetric radar design that has received considerable attention in recent years. In order to determine the scattering or Mueller matrix of a target, accurate measurements of the relative magnitudes and phases of the EM fields constituting the target echo are needed. However, the estimates of these quantities that the radar system produces are inevitably contaminated by the system itself, due to component mismatch and/or a lack of polarization isolation. Without a proper calibration, the fixed biases (errors) in the measured magnitudes and phases introduced by the system cannot be differentiated from the true radar response of target. The objective of calibration is thus to determine the gain (magnitude and phase) of the four different measurement paths (vertical transmitter–vertical receiver; vertical transmitter–horizontal receiver; horizontal transmitter–horizontal receiver; and horizontal transmitter–vertical receiver) followed by the radar pulse during measurement of a target's scattering matrix, as well as to estimate the degree of cross-polarization distortion caused by the transmitting and receiving antennas. Once these calibration measurements are made, the contribution of the system to any target measurement can be determined and removed. One technique that is commonly used is to measure the polarimetric scattering behavior of three reference targets having known scattering matrices. The measurements so obtained provide enough information to uniquely determine the set of seven complex unknowns in the polarimeter distortion matrices required for polarimetrically calibrating the radar system [16]. Other calibration techniques have been developed that invoke assumptions about the observed targets, such as reciprocity and uncorrelated co- and cross-polarized scattering, to estimate the system distortion matrices directly, without relying on reference scattering targets [17]. A procedure for field calibration of bistatic polarimeter systems without using reference scattering targets has also been developed [18]. For a summary of polarimetric calibration procedures, see Ref. 19.

3. CURRENT RESEARCH

3.1. Radar Scattering Studies

Polarimetric radar measurements can often be used to determine the physical scattering mechanisms responsible for a radar echo. As discussed in a previous section, a sphere and a trihedral corner reflector are examples of “odd-bounce scatterers” that exhibit scattering matrices having elements S_{vv} and S_{hh} in phase with each other. A dihedral corner reflector, in contrast, is an example of an “even-bounce scatterer”, in which the S_{vv} and S_{hh} elements exhibit a 180° phase difference. In the case of the Mueller matrix, the elements L_{33} and L_{44} convey similar

information. A complex radar target dominated by a single-bounce scattering mechanism exhibits large positive values for elements L_{33} and L_{44} , whereas these elements are negative when the target is dominated by a double-bounce scattering mechanism. In contrast, the Mueller matrix of a target composed of a combination of even- and odd-bounce scatterers exhibits near-zero values for L_{33} and L_{44} [20].

The mechanisms responsible for radar backscatter from the sea surface are a topic of current investigations. McLaughlin et al. [13] describe measurements of ocean waves in the Chesapeake Bay performed at a 3° grazing angle using a high-range-resolution (1.5-m) X-band polarimetric radar. These measurements were conducted to determine the physical scattering mechanisms responsible for *sea spikes*, which are strong radar echoes with anomalous polarization characteristics that occur in low-grazing-angle radar backscatter from the ocean surface. Figure 7 shows a typical copolarization signature of the ocean surface echo in the absence of a sea spike. The plot exhibits maximum RCS at VV polarization, minimum RCS at HH polarization, and intermediate cross sections of approximately 0.25, corresponding to a level 6 dB below the VV peak, at right-hand and left-hand circular polarizations. The *coefficient of variation*, a measure of the polarization sensitivity of a scatterer, is defined as the ratio of minimum to maximum RCS in a polarization signature plot [6]. The coefficient of variation of this plot is 0.01 (-20 dB), indicating that the radar echo is highly polarized. The Mueller matrix (not shown) exhibited large values for L_{33} and L_{44} , meaning that a single-scattering mechanism, such as distributed *Bragg scattering*, dominates the radar echo from the ocean surface. Figure 8 shows a copolarization signature for a sea spike radar echo that occurred during the passage of a long ocean wave crest through the radar resolution cell. The sea spike echo exhibits polarimetric scattering characteristics that are substantially different from the ocean surface echo in the absence of sea spikes. Figure 8 exhibits RCS maxima at VV and HH polarizations as well as a large “pedestal”

Figure 7. Copolarized signature of the sea surface in the absence of sea spikes. The high RCS at vertical polarization, the minimum at horizontal polarization, and the high degree of polarization (low pedestal) indicate a single, Bragg-like scattering mechanism.

Figure 8. Copolarized signature of the sea surface in the presence of a sea spike. Peaks in the response at both vertical and horizontal polarizations and the low degree of polarization (high pedestal) indicate a mixture of scattering mechanisms.

corresponding to relatively high cross-section values at other copolarization states. The coefficient of variation for this plot is 0.3 (-5.2 dB), a relatively large value, meaning that the echo is weakly polarization-sensitive. The L_{33} and L_{44} Mueller matrix elements for this echo had small values indicating that no single scattering mechanism dominates the backscatter signal. One possible explanation for this observation is that a combination of Bragg resonant waves and non-Bragg scatterers, such as plumes generated at breaking wavecrests, combine to form the sea spike echo from the ocean surface.

Sletten et al. [21a,b] have also utilized a polarimetric radar to investigate sea spikes. In their experiments, an *ultrawideband*, polarimetric radar system was used to investigate the backscatter from breaking water waves generated in a laboratory wavetank. (The term *ultrawideband* refers to the ability of a radar to measure the backscatter from a target over a wide band of radar frequencies simultaneously.) Observed differences in the VV and HH responses as a function of radar frequency indicate that the strongest echoes (sea spikes) produced by the breakers are the result of a double-bounce scattering mechanism, arising from multiple scatter between the front face of the wave and a plume near its crest. In particular, the VV and HH frequency responses were found to be roughly complementary (i.e., HH high when VV is low, and vice versa), a result related to the 180° phase shift observed between S_{hh} and S_{vv} for double-bounce scatterers.

3.2. Image Classification

Another active area of research is image classification. In remote sensing, the objective of this research is to automatically separate different regions of an image into different classes, dependent on the type of terrain or land usage. For instance, classification schemes are under development to separate forested, urban, agricultural, and water-covered regions in remotely sensed imagery. In an ideal classification scheme, the signal characteristics that define each class can be uniquely associated with physical attributes of the scatterers in that class. Polarimetric

images are the best candidates for this type of processing, given the amount of information they provide on the scatterers in the scene. Signal polarization constitutes another dimension in which distinctions can be drawn between regions in an image. The same principle can be applied to the problem of detecting and classifying targets (as opposed to regions within an image) with a nonimaging radar. This is the situation encountered in some military applications.

Polarimetric target decomposition is one approach to classification. In this approach, the scattering, Mueller, or coherency matrix is considered to be a linear combination of several basis matrices, each of which represents a canonical target or a departure of the original matrix from the canonical target. In any radar image of a real surface, the signal for a given pixel is produced by several (perhaps many) scattering centers or objects within the illuminated scene. The total signal is a mixture of the echoes produced by each scattering center, and thus the polarimetric properties of that pixel are a mixture as well. In addition, motion of the scatterers (due to surface winds, e.g.) may cause variation in their scattering properties, resulting in partial polarization. Target decomposition techniques attempt to break the measured matrices down into their fundamental constituents or to extract the characteristics of the primary scattering centers from the background.

The application of polarimetric decomposition theories to radar problems began with the pioneering work of Huynen [22]. Huynen decomposed the coherency matrix into two components: a pure (i.e., completely polarized) target, and a mixed (partially polarized) state that was invariant to rotations of the radar system about the line of sight. The pure target is intended to represent the average, or dominant, target, and the mixed state is the residue or remainder. Enforcing rotational invariance on the residue ensures, at least to some degree, that the mixed state has no preferred axis of symmetry and is thus produced by the unpolarized noise in the measurement. Holm and Barnes [23] later determined that there are actually two other Huynen-like decompositions of the coherency matrix, which makes interpretation of the results somewhat ambiguous. Holm and Barnes also developed another decomposition method, referred to as the “natural” or “characteristic” decomposition, which breaks the coherency matrix into three components: a matrix representing a pure state that provides a measure of the average target; a mixed-state matrix, which indicates the variance of the target about its average; and an unpolarized component. This decomposition is based on an eigenvalue analysis of the coherency matrix and can thus be expected to produce statistically independent components. In a simulation, this method was successfully used to extract a rotating dihedral corner reflector embedded in polarization noise. Krogager and Czyz [24] have taken a different approach to the decomposition problem, concentrating instead on decomposition of the scattering matrix. In this technique, the scattering matrix is decomposed into three coherent (nonaveraged) components that can be physically interpreted as representing a sphere, a rotated dihedral corner reflector, and a helix. While these three matrices are not orthogonal (the dihedral component can also be attributed

to a pair of helices), the technique has physical appeal and may be a natural scheme for some applications. Freeman and Durden [25] have developed a three-component model comprising three mechanisms: volume scatter from a cloud of dipoles with random orientations, double-bounce scatter from two orthogonal surfaces with different dielectric constants, and a moderately rough surface modeled by Bragg scatter. A fit of this three-component model to imagery containing backscatter from a variety of vegetation and open water indicates that the model describes the actual scattering mechanisms well. Cloude and Pottier have summarized these and other decomposition techniques [26] and have introduced their own classification scheme based on an eigenvector decomposition of the coherency matrix [27]. The technique classifies pixels within an image through two parameters: the polarimetric entropy H , which is derived from the eigenvalues of the coherency matrix and that indicates the degree of polarization; and an angle α , which indicates the dominant scattering mechanism. α ranges from 0° to 90° , with low values indicating geometric optics and higher values indicating Bragg scattering and double-bounce mechanisms. The authors divide the H - α plane into different zones, each of which indicates a different class of scattering behavior. The scheme is unsupervised (i.e., does not require training data), and the results of its application to imagery containing a mixture of vegetation, urban buildings, and open water are promising.

Other approaches to polarimetric image classification exist as well. For instance, Lee et al. [28] have applied a Bayes maximum-likelihood classifier to the problem, including the effects of multiple-look averaging, while Yueh [30] conducted a similar investigation assuming single-look statistics. Lee et al. [29] have also combined the unsupervised decomposition scheme of Cloude and Pottier with a maximum-likelihood classifier based on the complex Wishart distribution for the polarimetric covariance matrix. Ferrazzoli et al. [31] have used a simplified scheme that considers the normalized RCS values for five polarization combinations (HH, VV, HV, circular copolarized, and circular cross-polarized) and three radar frequency bands (P, L, and C) to distinguish between forest, urban areas, and agricultural areas and to classify several types of crops. Fully polarimetric synthetic aperture radar (SAR) imagery has also been classified using algorithms based on neural nets (see, for instance, Ref. 32).

3.3. Contrast Enhancement

The scattering environment observed by a radar system is composed of many different targets that scatter incident electromagnetic energy. To the extent that the different scatterers or classes of scatterers have different polarization signatures, the echoes from one type of scatterer may be enhanced relative to the echoes from other scatterers by using a polarimetric radar. As discussed earlier in this article, knowledge of the polarization scattering matrix or Mueller matrix of a target allows one to calculate the transmitting and receiving polarizations that would result in maximum or minimum radar cross-section level [33]. It is also possible to simulate (synthesize) any desired

receive polarization in the signal processor of a polarimetric radar by forming a weighted linear combination of the signals received by the two receiving channels [34]. Similarly, it is possible to synthesize any arbitrary transmitting antenna polarization by forming a weighted linear combination of the received signals corresponding to two consecutive transmitted pulses. Therefore, the processor can synthesize the appropriate combination of transmitting and receiving antenna polarization states that maximize (or minimize) the echo from a given scatterer having a known polarization scattering matrix or Mueller matrix.

Figure 9 illustrates the concept of image contrast enhancement. Figures 9a, 9b, and 9c show SAR images of San Francisco, California processed using HH, VV, and VH=HV polarizations, respectively. The Golden Gate Bridge appears as a bright, vertical line in the middle third of the images, and Golden Gate Park is the wide, horizontal band that appears in the lower quadrant. A comparison of the three images shows that HH polarization maximizes the contrast between the developed, urban areas (recognized by a grid pattern formed by perpendicular streets) and Golden Gate Park, which contains mixed vegetation. VV polarization increases the relative RCS of the waves present on the surface of the Pacific Ocean, as seen by a comparison of Figs. 9a and 9b, while the image in Fig. 9c shows that maximum contrast between the land and water occurs for the HV(=VH) polarization combination. [The imaging polarimeter used to collect the data presented in Fig. 9, the NASA/JPL AIRSAR, was developed by the Jet Propulsion Laboratory (JPL). For more information on the system and its successors, see Refs. 2, 6, and 35].

For target detecting radars, it is desirable to enhance the radar echo from wanted targets, such as aircraft, while suppressing the echo from unwanted targets, such as terrain clutter. In certain imaging radar applications, it is desirable to enhance the echo from one type of terrain while suppressing the echo from other types of terrain. The limitations to contrast enhancement are (1) lack of a priori knowledge of the scattering matrix of the desired target and (2) similarity of polarimetric responses of the desired and undesired scattering targets. Research performed on the target detection problem, including techniques to adaptively estimate the scattering matrices of targets and clutter, is described in Refs. 36–38. Work in polarization-based suppression of bistatic clutter is described in Ref. 39. Several papers dealing with polarimetric contrast enhancement in imaging radars for terrain mapping are summarized in Ref. 2.

3.4. Meteorology

While Doppler (coherent) radar has become an indispensable tool for meteorologists, the current fleet of operational weather radars utilize a single polarization. Research has shown, however, that polarization-diverse radars can provide weather forecasters with additional information. For example, polarimetric radar systems can discriminate ice particles from water droplets, and can detect hail. Radar echoes from precipitation are complex and depend on the shape, size distribution, water-phase state, and type of hydrometeor responsible for scattering the incident energy [40]. Large raindrops assume a flat pancake shape as they achieve terminal falling velocity, and thus scatter horizontally polarized energy more effectively than vertically polarized energy. Hailstones, in contrast, have irregular shapes but tumble as they fall, and thus exhibit equal scattering cross sections at vertical and horizontal polarizations. Exploiting this observation, Aydin et al. [41] developed a technique for discriminating rain from hail echoes by computing the ratio of horizontal to vertical power levels received when a dual-polarization radar transmits pulses into storms. Accurate measurement of rainfall rate is another important and evolving issue in the meteorological community. The relationship between the radar reflectivity coefficient of rain and the rain rate is different for different types of rain. Seliga and Bringi [42] have shown that independent measurement of rain reflectivity at vertical and horizontal polarizations provides more accurate rainfall estimates than do single-polarization radar estimates. Polarization diverse radars can also provide information on clouds. Mead [5] has developed a lightweight 94-GHz radar for airborne cloud profiling studies, and has used this system to determine the height of the melting layer. The technique involves calculation of the ratio of cross-polarized to copolarized scattering when looking vertically into a layer of developing clouds.

3.5. Topographic Mapping

Schuler et al. [43,44] have developed a technique to extract topographic information from fully polarimetric radar imagery. The method extracts the azimuthal slope of the imaged terrain by determining the shift that this slope induces in the polarimetric response. Integration of the inferred slopes across the image, in conjunction with suitable tie points (integration constants), then yields the elevation profile. To illustrate the basic principle behind

Figure 9. Synthetic aperture radar image of San Francisco, near Golden Gate Park, processed with three different polarization combinations: (a) HH polarization, showing the strongest contrast between urban and mixed vegetation areas; (b) VV polarization, which exhibits stronger backscatter from the areas covered by open water; and (c) HV = VH polarization, which maximizes the contrast between open water and land.

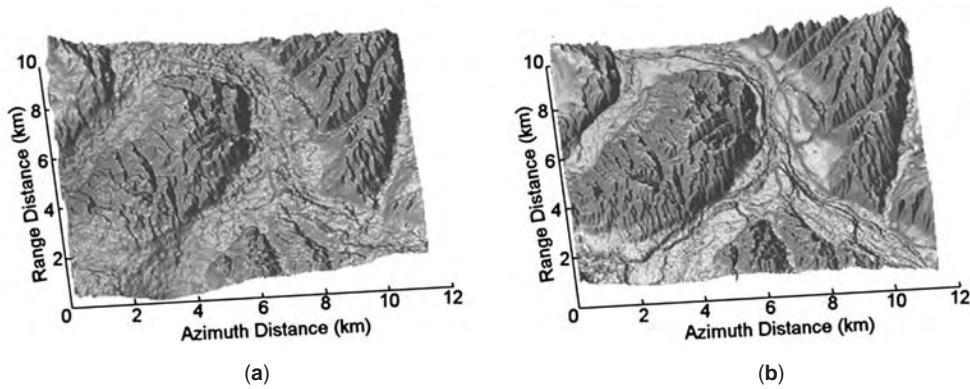

Figure 10. (a) Topographic map of Camp Roberts, CA produced from polarimetric SAR data collected by the JPL AIRSAR. The surface elevation is computed by integrating surface slopes derived from the polarimetric signature. Data from two orthogonal aircraft passes are used to reduce the number of required tie points to one. (b) Topographic map of the area in Fig. 10a produced using the JPL TOPSAR system. The RMS difference between the maps is 28 m.

the technique, assume that the scattering from the surface can be described by Bragg scatter, and thus has a scattering matrix (in the absence of any azimuthal tilts) of the form

$$\mathbf{S} = \begin{bmatrix} a & 0 \\ 0 & b \end{bmatrix} \quad (37)$$

where a and b are real and $b > a$. If the surface is tilted in the azimuthal plane by an angle δ , the scattering matrix becomes

$$\mathbf{S} = \begin{bmatrix} \cos \delta & -\sin \delta \\ \sin \delta & \cos \delta \end{bmatrix} \cdot \begin{bmatrix} a & 0 \\ 0 & b \end{bmatrix} \cdot \begin{bmatrix} \cos \delta & \sin \delta \\ -\sin \delta & \cos \delta \end{bmatrix} \quad (38)$$

which, after carrying out the matrix multiplication, can be expressed as

$$\mathbf{S} = \begin{bmatrix} a \cos^2 \delta + b \sin^2 \delta & (a - b) \cos \delta \sin \delta \\ (a - b) \cos \delta \sin \delta & a \sin^2 \delta + b \cos^2 \delta \end{bmatrix} \quad (39)$$

$$= \begin{bmatrix} S_{\delta(hh)} & S_{\delta(hv)} \\ S_{\delta(vh)} & S_{\delta(vv)} \end{bmatrix}$$

Tilting the surface introduces the off-diagonal terms $S_{\delta(hv)}$ and $S_{\delta(vh)}$ with $S_{\delta(hv)} = S_{\delta(vh)}$ from reciprocity. Solving this system of equations for δ produces the following expression:

$$\delta = \frac{1}{2} \tan^{-1} \left(\frac{2S_{\delta(vh)}}{S_{\delta(hh)} - S_{\delta(vv)}} \right) \quad (40)$$

Thus, the azimuthal slope of the surface can be derived from the elements of the measured scattering matrix. While Eq. (40) applies only to the case of Bragg scattering and cannot be applied in general, it illustrates the basic principle behind the method. A more general technique

for determining the shift in the polarimetric response, and thus the azimuthal slope, is discussed in Ref. 43.

Figure 10a shows an elevation map of the terrain near Camp Roberts, CA, derived from JPL AIRSAR data using this method [44]. For comparison, a digital elevation map (DEM) of the same area derived from data collected with the JPL TOPSAR system, an interferometric SAR designed to measure terrain topography, is displayed in Fig. 10b. The overall form of the two maps agrees very well, as do many of the details. The RMS elevation difference between the maps over the entire region is 28 m, while the maximum and minimum elevations in the scene are 300 and 180 m, respectively. The errors in the polarimetrically derived map are greatest in the river valleys, where more complex, manmade structures are present. In order to reduce the required number of tie points to one, data from two orthogonal aircraft passes have been used. The final elevation map is obtained as an iterative solution to the Poisson equation using curvature data derived from the two passes as inputs [43].

RADAR REMOTE SENSING

JAKOB J. VAN ZYL
YUNJIN KIM
California Institute of
Technology
Pasadena, California

Radar remote sensing instruments acquire data useful for geophysical investigations by measuring electromagnetic interactions with natural objects. Examples of radar remote sensing instruments include synthetic aperture radars (SAR), scatterometers, altimeters, radar sounders, and meteorological radars such as cloud and rain radars. The main advantage of radar instruments is their ability to penetrate clouds, rain, tree canopies, and even dry soil surfaces depending on the operating frequencies. In addition, since a remote sensing radar is an active instrument, it can operate during day and night by providing its own illumination.

Imaging remote sensing radars such as SAR produce high-resolution (from submeter to few tens of meters) images of surfaces. The geophysical information can be derived from these high-resolution images by using proper postprocessing techniques. Scatterometers measure the backscattering cross section accurately in order to characterize surface properties such as roughness. Altimeters are used to obtain accurate surface height maps by measuring the round-trip time delay from a radar sensor to the surface. Radar sounders can image underground material variations by penetrating deeply into the ground. Unlike surveillance radars, remote sensing radars require accurate calibration in order for the data to be useful for scientific applications.

In this article, we start with the basic principles of remote sensing radars. Then, we discuss the details of imaging radars and their applications. We complete the remote sensing radar discussion by briefly examining nonimaging radars such as scatterometers, altimeters, radar sounders, and meteorological radars. We also provide extensive references for each type of radar for readers who need an in-depth description of a particular type.

1. RADAR PRINCIPLES

We start our discussion with the principles necessary to understand the radar remote sensing instruments that will be described in later in this article. For more detailed discussions, readers are referred to Refs. 1–3.

1.1. Radar Operation

A radar transmits an electromagnetic signal and receives and records the echo reflected from the illuminated terrain. Hence, a radar is an active remote sensing instrument since it provides its own illumination. The basic radar operation is illustrated by Fig. 1. A desired signal waveform, commonly a modulated pulse, is generated by a waveform generator. After proper frequency upconversion and high-power amplification, the radar signal is transmitted from an antenna. The reflected echo is received by

the antenna and is amplified and downconverted to video frequencies for digitization. The digitized data are either stored in a data recorder for later ground data processing or processed by an onboard data processor. Since remote sensing radars usually image large areas, they are commonly operated from either an airborne or a spaceborne platform.

1.2. Basic Principles of Radar Imaging

Imaging radars generate surface images very similar to visible and infrared images. However, the principle behind the image generation fundamentally varies between the two cases. Visible and infrared sensors use a lens or mirror system to project the radiation from the scene on a “two-dimensional array of detectors,” which could be an electronic array or a film using chemical processes. The two-dimensionality can also be achieved by using scanning systems. This imaging approach conserves the angular relationships between two targets and their images as shown in Fig. 2.

Imaging radars use the time delay between the echoes that are backscattered from different surface elements to separate them in the *range* (cross-track) dimension, the angular size (in the case of the real aperture radar), or the Doppler history (in the case of the synthetic aperture radar) to separate surface pixels in the *azimuth* (along-track) dimension. The imaging radar sensor uses an antenna that illuminates the surface to one side of the flight track. Usually, the antenna has a fan beam that illuminates a highly elongated elliptical shaped area on the surface as shown in Fig. 3. The illuminated area across the track defines the image *swath*. Within the illumination beam, the radar sensor transmits a very short effective pulse of electromagnetic energy. Echoes from surface points farther away along the cross-track coordinate will be received at proportionally later time (Fig. 3). Thus, by dividing the receive time in increments of equal time bins, one can subdivide the surface into a series of *range bins*. The width in the along-track direction of each range bin is equal to the antenna footprint along the track x_a . As the platform moves, the sets of range bins are covered sequentially, thus allowing strip mapping of the surface line by line. This is comparable to strip mapping with a push-broom imaging system using a line array in the visible and infrared part of the electromagnetic spectrum. The brightness associated with each image pixel in the radar image is proportional to the echo power contained within the corresponding time bin. As we will see later, the different types of imaging radars really differ in the way in which the azimuth resolution is achieved.

The *look angle* is defined as the angle between the vertical direction and the radar beam at the radar platform, while the *incidence angle* is defined as the angle between the vertical direction and the illuminating radar beam at the surface. When Earth surface curvature effects are neglected, the look angle is equal to the incidence angle at the surface when the surface is flat. In the case of spaceborne systems, surface curvature must be taken into account, which leads to an incidence angle that is always larger than the look angle [3] for flat surfaces. If

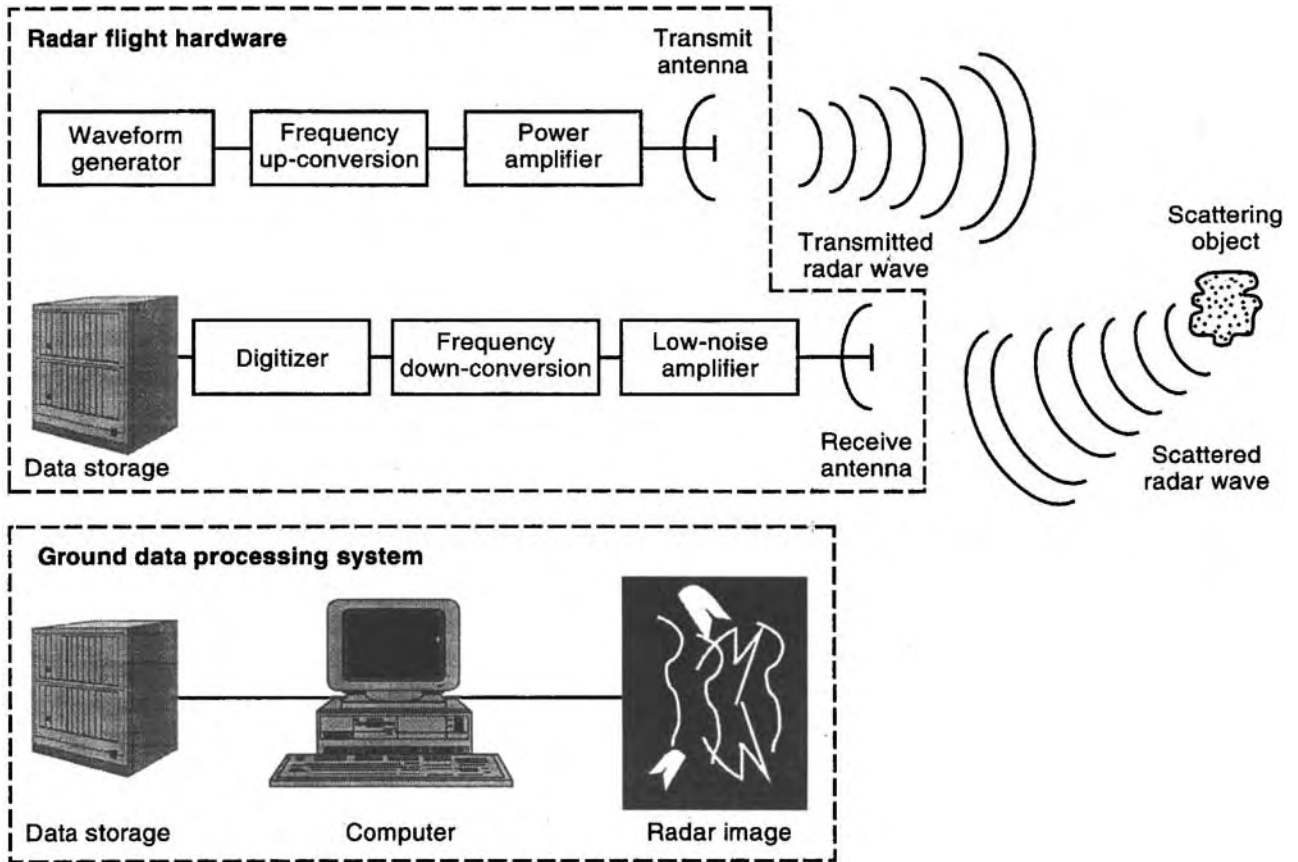

Figure 1. The basic components of a radar system. A pulse of energy is transmitted from the radar system antenna, and after a time delay an echo is received and recorded. The recorded radar echoes are later processed into images. The flight electronics are carried on the radar platform, either an aircraft or a spacecraft. Image processing is usually done in a ground facility.

Figure 2. Optical imaging systems preserve the angular relationship between objects in the image.

Figure 3. Radar imaging geometry and definition of terms.

topography is present, that is, if the surface is not flat, the local incidence angle may vary from radar image pixel to pixel.

1.3. Resolution

The *resolution* is defined as the surface separation between the two closest features that can still be resolved in the final image. First, consider two point targets that are separated in the range direction by x_r . The corresponding echoes will be separated by a time difference Δt equal to

$$\Delta t = 2x_r \frac{\sin \theta}{c} \tag{1}$$

where c is the speed of light and the factor 2 is included to account for the signal round-trip propagation. The angle θ in Eq. (1) is the incidence angle. The two features can be differentiated if the leading edge of the pulse returned from the second object is received later than the trailing edge of the pulse received from the first feature. Therefore, the smallest discriminable time difference in the radar receiver is equal to the pulse effective time length τ :

$$2x_r \frac{\sin \theta}{c} = \tau \Rightarrow x_r = \frac{c\tau}{2 \sin \theta} \tag{2}$$

In other words, the range resolution is equal to half the footprint of the radar pulse on the surface. Sometimes the effective pulse length is described in terms of the system bandwidth B . To a good approximation

$$\tau = \frac{1}{B} \tag{3}$$

The $\sin \theta$ term in the denominator of Eq. (2) means that the range resolution of an imaging radar will be a strong function of the look angle at which the radar is operated. To illustrate, a signal with a bandwidth $B = 20$ MHz (i.e., effective pulse length $\tau = 50$ ns) provides a range resolution of 22 m for $\theta = 20^\circ$, while a signal bandwidth $B = 50$ MHz ($\tau = 20$ ns) provides a range resolution of 4.3 m at $\theta = 45^\circ$.

In the azimuth direction, without further data processing, the resolution x_a is equal to the beam footprint on the surface that is defined by the azimuth beamwidth of the radar antenna θ_a given by

$$\theta_a = \frac{\lambda}{L} \tag{4}$$

from which it follows that

$$x_a = \frac{h\theta_a}{\cos \theta} = \frac{\lambda h}{L \cos \theta} \tag{5}$$

where L is the antenna length and h is the altitude of the radar above the surface being imaged. To illustrate, for $h = 800$ km, $\lambda = 23$ cm, $L = 12$ m, and $\theta = 20^\circ$, then $x_a = 16$ km. Even if λ is as short as 2 cm and h as low as 200 km, x_a will still be equal to about 360 m, which is considered to be a relatively low resolution, even for remote sensing. This has led to very limited use of the real

aperture technique for surface imaging, especially from space. Equation (5) is also directly applicable to optical imagers. However, because of the small value of λ (about $1 \mu\text{m}$), resolutions of a few meters can be achieved from orbital altitudes with an aperture only a few tens of centimeters in size.

When the radar antenna travels along the line of flight, two point targets, at different angles from the flight track, have different Doppler frequencies. Using this Doppler frequency spread, one can obtain a higher resolution in the along-track direction. As shown in the synthetic aperture radar section, the along-track resolution can be as small as the half of the antenna length in the along-track direction. This method is often called *Doppler beam sharpening*.

1.4. Radar Equation

One of the key factors that determine the quality of the radar imagery is the corresponding *signal-to-noise* ratio, commonly abbreviated SNR. This is the equivalent of the brightness of a scene being photographed with a camera versus the sensitivity of the film or detector. Here, we consider the effect of thermal noise on the sensitivity of radar imaging systems.

Let P_t be the sensor generated peak power transmitted out of the antenna. One function of the antenna is to focus the radiated energy into a small solid angle directed toward the area being imaged. This focusing effect is described by the antenna gain G , which is equal to the ratio of the total solid angle over the solid angle formed by the antenna beam

$$G = \frac{4\pi}{\theta_r \theta_a} = \frac{4\pi LW}{\lambda^2} = \frac{4\pi A}{\lambda^2} \tag{6}$$

where L is the antenna length in the flight track direction, W is the antenna length in the cross-track direction, and A is the antenna area. The radiated wave propagates spherically away from the antenna toward the surface. Thus the power density P_i per unit area incident on the illuminated surface is

$$P_i = \frac{P_t G}{4\pi R^2} \tag{7}$$

The backscattered power P_s from an illuminated surface area s is given by

$$P_s = P_i s \sigma_0 \tag{8}$$

where σ_0 is the surface *backscattering cross section*, which represents the efficiency of the surface in reemitting back toward the sensor some of the energy incident on it. It is similar to the surface albedo at visible wavelengths. The backscattered energy propagates spherically back toward the sensor. The power density P_c at the antenna is then

$$P_c = \frac{P_s}{4\pi R^2} \tag{9}$$

and the total received power is equal to the power intercepted by the antenna

$$P_r = P_c A \quad (10)$$

or

$$P_r = \frac{P_t G_t}{4\pi R^2} s \sigma_0 \frac{\lambda^2 G_r}{(4\pi R)^2} \quad (11)$$

In Eq. (11) we explicitly show that the transmit and receive antennas may have different gains. This is important for the more advanced SAR techniques such as polarimetry, where antennas with different polarizations may be used during transmission and reception.

In addition to the target echo, the received signal also contains noise that results from the fact that all objects at temperatures higher than absolute zero emit radiation across the whole electromagnetic spectrum. The noise component that is within the spectral bandwidth B of the sensor is passed through with the signal. The thermal noise power is given by

$$P_N = kTB \quad (12)$$

where k is Boltzmann's constant ($k = 1.38 \times 10^{-23} \text{ W}^{-1} \text{ Hz}^{-1} \text{ K}^{-1}$) and T is the total equivalent noise temperature. The resulting *signal to noise ratio* is then

$$\text{SNR} = \frac{P_r}{P_N} \quad (13)$$

One common way of characterizing an imaging radar sensor is to determine the surface backscatter cross section σ_N , which gives an $\text{SNR} = 1$. This is called the *noise equivalent backscatter cross section*. It defines the weakest surface return that can be detected, and therefore the range of surface units that can be imaged.

1.5. Backscattering Cross Section and Calibration Devices

The *normalized backscattering cross section* represents the reflectivity of an illuminated area in the backscattering direction. A higher backscattering cross section means that the area more strongly reflects the incidence radar signal. It is mathematically defined as

$$\sigma_0 = \lim_{R, A_i \rightarrow \infty} \left\{ \frac{4\pi R^2}{A_i} \frac{\langle E_s E_s^* \rangle}{E_i E_i^*} \right\} \quad (14)$$

where A_i is the illuminated area and E_s and E_i are the scattered and incident electric fields, respectively. In order to calibrate the radar data, active and/or passive calibration devices are commonly used.

By far the most commonly used passive calibration device is a trihedral corner reflector, which consists of three triangular panels bolted together to form right angles with respect to each other. The maximum radar cross section (RCS) of a trihedral corner reflector is given by

$$\text{RCS} = \frac{4\pi a^4}{3\lambda^2} \quad (15)$$

where a is the long-side triangle length of a trihedral corner reflector. This reflector has about 40° half-power beamwidth, which vendors the corner reflector response relatively insensitive to the position errors. In addition, these devices are easily deployed in the field, and since they require no power to operate, they can be used unattended in remote locations under most weather conditions.

1.6. Signal Modulation

A pulsed radar determines the range by measuring the round-trip time by transmitting a pulse signal. In designing the signal pattern for a radar sensor, there is usually a strong requirement to have as much energy as possible in each pulse in order to enhance the signal-to-noise ratio. This can be done by increasing the peak power or by using a longer pulse. However, particularly in the case of spaceborne sensors, the peak power is usually strongly limited by the available power devices. On the other hand, an increased pulse length (i.e., smaller bandwidth) leads to a lower range resolution [see Eq. (2)]. This dilemma is usually resolved by using *modulated* pulses that have the property of a wide bandwidth even when the pulse is very long. One such modulation scheme is the linear frequency modulation or chirp.

In a "chirp", the signal frequency within the pulse is linearly changed as a function of time. If the frequency were linearly changed from f_0 to $f_0 + \Delta f$, the effective bandwidth would be equal to

$$B = |(f_0 + \Delta f) - f_0| = |\Delta f| \quad (16)$$

which is independent of the pulse length. Thus a pulse with long duration (i.e., high energy) and wide bandwidth (i.e., high range resolution) can be constructed. The instantaneous frequency for such a signal is given by

$$f(t) = f_0 + \frac{B}{\tau'} t \quad \text{for} \quad -\frac{\tau'}{2} \leq t \leq \frac{\tau'}{2} \quad (17)$$

and the corresponding signal amplitude is

$$A(t) \sim \cos \left[\int f(t) dt \right] = \cos \left[f_0 t + \frac{B}{2\tau'} t^2 \right] \quad (18)$$

Note that the instantaneous frequency is the derivative of the instantaneous phase. A pulse signal such as Eq. (18) has a physical pulse length τ' and a bandwidth B . The product $\tau' B$ is known as the *time-bandwidth product* (TBP) of the radar system. In typical radar systems, TBPs of several hundred are used.

At first glance it may seem that using a pulse of the form of Eq. (18) cannot be used to separate targets that are closer than the projected physical length of the pulse. It is indeed true that the echoes from two neighboring targets that are separated in the range direction by much less than the physical length of the signal pulse will overlap in time. If the modulated pulse, and therefore the echoes, have a constant frequency, it will not be possible to resolve the two targets. However, if the frequency is modulated as described in Eq. (18), the echoes from the two targets will

have different frequencies at any instance of time and therefore can be separated by frequency filtering. In actual radar systems, a matched filter is used to *compress* the returns from the different targets. It can be shown [3] that the effective pulselength of the compressed pulse is as given by Eq. (3). Therefore, the achievable range resolution using a modulated pulse of the kind given by Eq. (18) is a function of the chirp bandwidth, and not the physical pulselength. In typical spaceborne and airborne SAR systems, physical pulselengths of several tens of microseconds are used, while bandwidths of several tens of megahertz are no longer uncommon for spaceborne systems, and several hundreds of megahertz are common in airborne systems.

2. REAL APERTURE RADAR

The real aperture imaging radar sensor uses an antenna that illuminates the surface to one side of the flight track. Usually, the antenna has a fan beam that illuminates a highly elongated elliptical shaped area on the surface as shown in Fig. 3. As mentioned before, the illuminated area across the track defines the image swath. For an antenna of width W operating at a wavelength λ , the beam angular width in the range plane is given by

$$\theta_r \approx \frac{\lambda}{W} \quad (19)$$

and the resulting surface footprint or swath S is given by

$$S \approx \frac{h\theta_r}{\cos^2 \theta} = \frac{\lambda h}{W \cos^2 \theta} \quad (20)$$

where h is the sensor height above the surface, θ is the angle from the center of the illumination beam to the vertical (known as the *look angle* at the center of the swath), and θ_r is assumed to be very small. To illustrate, for $\lambda = 27$ cm, $h = 800$ km, $\theta = 20^\circ$, and $W = 2.1$ m, the resulting swath width is 100 km.

As shown before, the main disadvantage of the real aperture radar technique is the relatively poor azimuth resolution that could be achieved from space. From aircraft altitudes, however, reasonable azimuth resolutions can be achieved if higher frequencies (typically at X band or higher) are used. For this reason, real aperture radars are not commonly used any more.

3. SYNTHETIC APERTURE RADAR

Synthetic aperture radar refers to a particular implementation of an imaging radar system that utilizes the movement of the radar platform and specialized signal processing to generate high-resolution images. Prior to the discovery of synthetic aperture radar principle imaging radars operated using the real aperture principle, and were known as *side-looking aperture radars* (SLARs).

Carl Wiley of the Goodyear Aircraft Corp, is generally credited as the first person to describe the use of Doppler frequency analysis of signals from a moving coherent

radar to improve along-track resolution. He noted that two targets at different along-track positions will be at different angles relative to the aircraft velocity vector, resulting in different Doppler frequencies. Therefore, targets can be separated in the along-track direction on the basis of their different Doppler frequencies. This technique was originally known as *Doppler beam sharpening*, but later became known as *synthetic aperture radar* (SAR). The reader interested in a discussion of the history of SAR, both airborne and spaceborne, is referred to an excellent discussion in Chap. 1 of Ref. 3.

In this section, we discuss the principles of radar imaging using synthetic aperture techniques, the resulting image projections, distortions, tonal properties, and environmental effects on the images. We have attempted to give simple explanations of the different imaging radar concepts. For more detailed mathematical analysis, the reader is referred to specialized texts such as Refs. 1–3.

3.1. Synthetic Aperture Radar Principle

As discussed in the previous section, a real aperture radar cannot achieve high azimuth resolution from an orbital platform. In order to achieve a high resolution from any altitude, the synthetic aperture technique is used. This technique uses successive radar echoes acquired at neighboring locations along the flight line to synthesize an equivalent very long antenna that provides a very narrow beamwidth and thus a high image resolution. In this section, we explain the synthetic aperture radar (SAR) using two different approaches, the synthetic array approach and the Doppler synthesis approach, which lead to the same results. We will also discuss uses of linear frequency modulation (chirp) as well as some limitations and degradation that are inherent to the SAR technique. Our discussion closely follows that of Ref. 1.

The range resolution and radar equation derived previously for a real aperture radar are still valid here. The main difference between real and synthetic aperture radars is in the way in which the azimuth resolution is achieved.

3.1.1. Synthetic Array Approach. The synthetic array approach explains the SAR technique by comparing it to a long array of antennas and the resulting increase in the resolution relative to the resolution achieved with one of the array elements. Let us consider a linear array of antennas consisting of N elements (Fig. 4). The contribution on the n th element to the total far-field electric field E in the direction β is proportional to

$$E_r \sim a_n e^{i\phi_n} e^{-ikd_n \sin \beta} \quad (21)$$

where a_n and ϕ_n are the amplitude and phase of the signal radiated from the n th element, d_n is the distance of the n th element to the array center, and $k = 2\pi/\lambda$. The total electric field is given by

$$E(\beta) \sim \sum_n a_n e^{i\phi_n} e^{-ikd_n \sin \beta} \quad (22)$$

Figure 4. Geometry of a linear array of antenna elements.

If all the radiators are identical in amplitude and phase and are equally spaced with a separation d , then

$$E(\beta) \sim ae^{i\phi} \sum_n e^{-inkd \sin \beta} \quad (23)$$

This is the vector sum of N equal vectors separated by a phase $\Psi = kd \sin \beta$. The resulting vector shown in Eq. (23) has the following properties:

- For $\beta = 0 \Rightarrow \Psi = 0 \Rightarrow$ all vectors add together leading to a maximum for E .
- As β increases, the elementary vectors will spread and lead to a decrease in the magnitude of E .
- For β such that $N\Psi = 2\pi$, the vectors are spread all around a circle leading to a sum equal to zero.

Thus, the radiation pattern has a null for

$$Nkd \sin \beta = 2\pi \Rightarrow \beta = \sin^{-1} \frac{2\pi}{Nkd} = \sin^{-1} \frac{\lambda}{D} \quad (24)$$

where $D = Nd$ is the total physical length of the array.

From the discussion and equations above it is seen that an array of total length $D = Nd$ has a beamwidth equal to the one for a continuous antenna of physical size D . This is achieved by adding the signals from each element in the array coherently, namely, amplitude *and* phase. The fine structure of the antenna pattern depends on the exact spacing of the array. Close spacing of the array elements is required to avoid grating effects.

In a conventional array, the signals from the different elements are combined together with a network of waveguides or cables leading to a single transmitter and receiver. Another approach is to connect each element to its own transmitter and receiver. The signals are coherently recorded and added later using a separate processor. A third approach could be used if the scene is quasistatic. A single transmitter/receiver/antenna element can be moved from one array position to the next. At each location a signal is transmitted and the echo recorded coherently. The echoes are then added in a separate processor or computer. A stable oscillator is used as a reference to assure coherency as the single element moves along the array line. This last configuration is used in a SAR where a

Figure 5. The width of the antenna beam in the azimuth direction defines the length of the synthetic aperture.

single antenna element serves to synthesize a large aperture.

Referring to Fig. 5, it is clear that if the antenna beam is equal to $\theta_a = \lambda/L$, the maximum possible synthetic aperture length that would allow us to observe a point is given by

$$L' = R\theta_a \quad (25)$$

This synthetic array will have a beamwidth θ_s equal to

$$\theta_s = \frac{\lambda}{2L'} = \frac{\lambda}{2R\theta_a} = \frac{L}{2R} \quad (26)$$

The factor 2 is included to account for the fact that the 3 dB (half-power) beamwidth is narrower in a radar configuration where the antenna pattern is involved twice, once each at transmission and reception. The corresponding surface along-track resolution of the synthetic array is

$$x_a = R\theta_s = \frac{L}{2} \quad (27)$$

This result shows that the azimuth (or along-track) surface resolution is equal to half the size of the physical antenna and is independent of the distance between the sensor and the surface. At first glance this result seems most unusual. It shows that a smaller antenna gives better resolution. This can be explained in the following way. The smaller the physical antenna is, the larger its footprint. This allows a longer observation time for each point on the surface; thus a longer array can be synthesized. This longer synthetic array allows for a finer synthetic beam and surface resolution. Similarly, if the range between the sensor and surface increases, the physical footprint increases, leading to a longer synthetic array and finer angular resolution that counterbalances the increase in the range.

As the synthetic array gets larger, it becomes necessary to compensate for the slight changes in geometry when a point is observed (Fig. 6). It should also be taken into account that the distance between the sensor and the target is variable depending on the position in the array. Thus, an additional phase shift needs to be added in the processor to the echo received at location x_i equal to

$$\phi_i = 2k(R_0 - R_i) = \frac{4\pi}{\lambda}(R_0 - R_i) \quad (28)$$

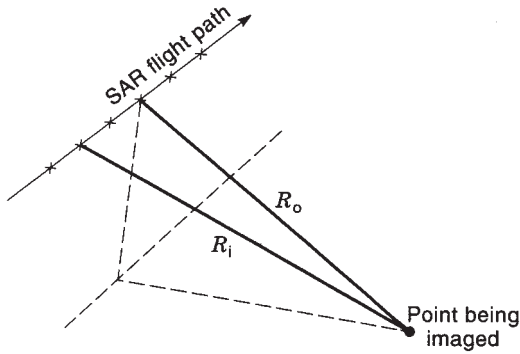

Figure 6. For large synthetic arrays, one has to compensate during ground processing for the change in geometry between the antenna elements and the point being imaged.

where R_0 is the range at closest approach to the point being imaged. In order to focus at a different point, a different set of phase shift corrections needs to be used. However, because this is done at a later time in the processor, optimum focusing can be achieved for each and every point in the scene. SAR imaging systems that fully apply these corrections are called *focused*.

In order to keep the processing simple, one can shorten the synthetic array length and use only a fraction of the maximum possible length. In addition, the same phase shift correction can be applied to all the echoes. This would lead to constructive addition if the partial array length is such that

$$\phi_i \leq \frac{\pi}{4}$$

or

$$2k \left\{ \sqrt{R^2 + \left(\frac{L'}{2}\right)^2} - R \right\} \leq \frac{\pi}{4} \tag{29}$$

For large ranges, this reduces to

$$L' \leq \sqrt{\frac{\lambda R}{2}} \tag{30}$$

and the achievable azimuth resolution is

$$x_a \geq \sqrt{2\lambda R} \tag{31}$$

This is called an *unfocused* SAR configuration where the azimuth resolution is somewhat degraded relative to the fully focused one, but still better than that of a real aperture radar. The advantage of the unfocused SAR is that the processing is fairly simple compared to that of a fully focused SAR.

To illustrate, for a 12-m antenna, with a wavelength of 3 cm, and a platform altitude of 800 km, the azimuth resolutions will be 6, 220, and 2000 m for the cases of a fully focused SAR, an unfocused SAR, or a real aperture radar, respectively.

3.1.2. Doppler Synthesis Approach. Another way to explain the synthetic aperture technique is to examine the

Doppler shifts of the radar signals. As the radar sensor moves relative to the target being illuminated, the back-scattered echo is shifted in frequency due to the Doppler effect. This Doppler frequency is equal to

$$f_d = 2 \frac{v}{c} f_0 \cos \Psi = 2 \frac{v}{\lambda} \sin \theta_t \tag{32}$$

where f_0 is the transmitted signal frequency, Ψ is the angle between the velocity vector $\vec{v} = v\hat{v}$ and the sensor-target line, and $\theta_t = \pi/2 - \Psi$. As the target moves through the beam, the angle θ_t varies from $+\theta_a/2$ to $-\theta_a/2$, where θ_a is the antenna azimuth beamwidth. Thus, a well-defined Doppler history is associated with every target. Figure 7 shows such a history for two neighboring targets P and P' located at the same range but at different azimuth positions. The Doppler shift varies from $+f_D$ to $-f_D$ where

$$f_D = 2 \frac{v}{\lambda} \sin \frac{\theta_a}{2} \tag{33}$$

When $\theta_a \ll 1$, Eq. (28) can be written as

$$f_D = 2 \frac{v}{\lambda} \frac{\theta_a}{2} = 2 \frac{v}{\lambda} \frac{\lambda}{2L} = \frac{v}{L} \tag{34}$$

The instantaneous Doppler shift is given by

$$f_D(t) = 2 \frac{v}{\lambda} \theta_t \approx 2 \frac{v^2 t}{\lambda h} \cos \theta \tag{35}$$

where $t = 0$ corresponds to the time when the target is exactly at 90° to the flight track. Thus, the Doppler histories for the two points P and P' will be identical except for a time displacement equal to

$$\Delta t = \frac{PP'}{v} \tag{36}$$

Figure 7. Doppler history for two targets separated in the azimuth direction.

It is this time displacement that allows the separation of the echoes from each of the targets.

The resolution along-track (azimuth resolution) x_a is equal to the smallest separation PP' that leads to a time separation Δt that is measurable with the imaging sensor. It can be shown that this time separation is equal to the inverse of the total Doppler bandwidth $B_D = 2f_D$. In a qualitative way, it can be stated that a large B_D gives a longer Doppler history that can be better matched to a template. This would allow a better determination of the zero Doppler crossing time. Thus, the azimuth resolution is given by

$$x_a = (PP')_{\min} = v\Delta t_{\min} = v\left(\frac{1}{2f_D}\right) = v\left(\frac{L}{2v}\right) = \frac{L}{2} \quad (37)$$

which is the same as the result derived using the synthetic array approach [see Eq. (27)].

As mentioned earlier, the imaging radar transmits a series of pulsed electromagnetic waves. Thus, the Doppler history from a point P is not measured continuously but is sampled on a repetitive basis. In order to get an accurate record of the Doppler history, the Nyquist sampling criterion requires that sampling occurs at least at twice the highest frequency in the Doppler shift. Thus, the pulse repetition frequency, usually abbreviated PRF, must be larger than

$$\text{PRF} \geq 2f_D = \frac{2v}{L} \quad (38)$$

In other terms, this equation means that at least one sample (i.e., one pulse) should be taken every time the sensor moves by half an antenna length. The corresponding aspect in the synthetic array approach is that the array elements should be close enough to each other to have a reasonably “filled” total aperture in order to avoid significant grating effects. To illustrate, for a spaceborne imaging system moving at a speed of 7 km/s and using an antenna 10 m in length, the corresponding minimum PRF is 1.4 kHz.

3.2. Signal Fading and Speckle

A close examination of a synthetic aperture radar image shows that the brightness variation is not smooth but has a granular texture called “speckle” (Fig. 8). Even for an imaged scene that has a constant backscatter property, the image will have statistical variations of the brightness on a pixel-by-pixel basis but with a constant mean over many pixels. This effect is identical to when a scene is observed optically under laser illumination. This is a result of the coherent nature (or very narrow spectral width) of the illuminating signal.

To explain this effect in a simple way, let us consider a scene that is completely “black” except for two identical bright targets separated by a distance d . The received signal V at the radar is given by

$$V = V_0 e^{-i2kr_1} + V_0 e^{-i2kr_2} \quad (39)$$

and assuming that $d \ll r_0$ (for spaceborne radars, the pixel size is typically on the order of tens of meters, while the

Figure 8. The granular texture shown in this image acquired by the NASA/JPL AIRSAR system is known as “speckle”. Speckle is a consequence of the coherent nature in which a synthetic aperture radar acquires images.

range is typically several hundred kilometers), then

$$\begin{aligned} V &= V_0 e^{-i2kr_0} (e^{-i2kd \sin \theta} + e^{+i2kd \sin \theta}) \\ \Rightarrow |V| &= 2|V_0 \cos(kd \sin \theta)| \end{aligned} \quad (40)$$

which shows that, depending on the exact location of the sensor, a significantly different signal value would be measured. If we now consider an image pixel that consists of a very large number of point targets, the resulting coherent superposition of all the patterns will lead to a “noiselike” signal. Rigorous mathematical analysis shows that the resulting signal has well-defined statistical properties [1–3]. The measured signal amplitude has a Rayleigh distribution, and the signal power has an exponential distribution. In order to narrow the width of these distributions (i.e., reduce the brightness fluctuations), successive signals or neighboring pixels can be averaged incoherently. This would lead to a more accurate radiometric measurement (and a more pleasing image) at the expense of degradation in the image resolution.

Another approach to reduce speckle is to combine images acquired at neighboring frequencies. In this case the exact interference patterns lead to independent signals but with the same statistical properties. Incoherent averaging would then result in a smoothing effect. In fact, this is the reason why a scene illuminated with white light does not show speckled image behavior.

In most imaging SARs, the smoothing is done by averaging the brightness of neighboring pixels in azimuth, or range, or both. The number of pixels averaged is called the number of *looks* N . It can be shown [1] that the signal standard deviation S_N is related to the mean

signal power \bar{P} by

$$S_N = \frac{1}{\sqrt{N}} \bar{P} \quad (41)$$

The larger the number of looks N , the better the quality of the image from the radiometric point of view. However, this degrades the spatial resolution of the image. It should be noted that for N larger than about 25, a large increase in N leads to only a small decrease in the signal fluctuation. This small improvement in the radiometric resolution should be traded off against the large increase in the spatial resolution. For example, if one were to average 10 resolution cells in a 4-look image, the speckle noise would be reduced to about 0.5 dB. At the same time, however, the image resolution would be reduced by an order of magnitude. Whether this loss in resolution is worth the reduction in speckle noise depends on both the aim of the investigation and the kind of scene imaged.

Figure 9 shows the effect of multilook averaging. The same image as Fig. 8, acquired by the NASA/JPL AIRSAR system is shown displayed at 1, 4, 16, and 32 looks, respectively. This figure clearly illustrates the smoothing effect, as well as the decrease in resolution resulting from the multilook process. In one early survey of geologists done by Ford [4], the results showed that even though the optimum number of looks depended on the scene type and resolution, the majority of the responses preferred 2-look images. However, this survey dealt with images that had rather poor resolution to begin with, and one may well find that with today's higher-resolution systems, analysts may be asking for a larger number of looks.

3.3. Ambiguities and Anomalies

Radar images could contain a number of anomalies that result from the way imaging radars generate the image. Some of these are similar to what is encountered in optical systems, such as blurring due to defocusing or scene motion, and some such as range and azimuth ambiguities are unique to radar systems. This section addresses the anomalies most commonly encountered in radar images.

As mentioned earlier (see Fig. 3), a radar images a surface by recording the echoes line by line with successive pulses. The leading edge of each echo corresponds to the near edge of the image scene, and the tail end of the echo corresponds to the far edge of the scene. The length of the echo (i.e., swath width of the scene covered) is determined by the antenna beamwidth and the size of the data window. The exact timing of the echo reception depends on the range between the sensor and the surface being imaged. If the timing of the pulses or the extent of the echo are such that the leading edge of one echo overlaps with the tail end of the previous one, then the far edge of the scene is folded over the near edge of the scene. This is called *range ambiguity*. Referring to Fig. 10, the temporal extent of the echo is equal to

$$T_e \approx 2 \frac{R}{c} \theta_r \tan \theta = 2 \frac{h\lambda}{cW} \frac{\sin \theta}{\cos^2 \theta} \quad (42)$$

Figure 9. The effects of speckle can be reduced by incoherently averaging pixels in a radar image, a process known as *multilooking*. Shown in this figure is the same image, processed as a single look (the basic radar image), 4 looks, 16 looks, and 32 looks. Note the reduction in granular texture as the number of looks increase. Also note that as the number of looks increase, the resolution of the images decreases. Some features, such as those in the largest dark patch, may be completely masked by the speckle noise.

This time extent should be shorter than the time separating two pulses (i.e., $1/\text{PRF}$). Thus we must have

$$\text{PRF} < \frac{cW \cos^2 \theta}{2h\lambda \sin \theta} \quad (43)$$

In addition, the sensor parameters, specifically the PRF, should be selected such that the echo is completely within an interpulse period; that is, no echoes should be received during the time that a pulse is being transmitted.

Equation (43) gives an upper limit for the PRF. Another kind of ambiguity present in SAR imagery also results

Figure 10. Temporal extent of radar echoes. If the timing of the pulses or the temporal extent of the echoes is such that the leading edge of one echo overlaps the trailing edge of the previous one, the far edge of the scene will be folded over the near edge, a phenomenon known as *range ambiguities*.

from the fact that the target’s return in the azimuth direction is sampled at the PRF. This means that the azimuth spectrum of the target return repeats itself in the frequency domain at multiples of the PRF. In general, the azimuth spectrum is not a bandlimited signal; instead, the spectrum is weighted by the antenna pattern in the azimuth direction. This means that parts of the azimuth spectrum may be aliased, and high-frequency data will actually appear in the low-frequency part of the spectrum. In actual images, these *azimuth ambiguities* appear as ghost images of a target repeated at some distance in the azimuth direction as shown in Fig. 11. To reduce the azimuth ambiguities, the PRF of a SAR has to exceed the lower limit given by Eq. (33).

In order to reduce both range and azimuth ambiguities, the PRF must therefore satisfy the conditions expressed by both Eq. (33) and Eq. (43). Therefore, we must insist that

$$\frac{cW \cos^2 \theta}{2h\lambda \sin \theta} > \frac{2v}{L} \tag{44}$$

from which we derive a lower limit for the antenna size as

$$LW > \frac{4vh\lambda \sin \theta}{c \cos^2 \theta} \tag{45}$$

Another type of artifact in radar images results when a very bright surface target is surrounded by a dark area. As the image is being formed, some spillover from the bright target, called sidelobes, although weak, could exceed the background and become visible as shown in Fig. 12. It should be pointed out that this type of artifact

Figure 11. Azimuth ambiguities result when the radar pulse repetition frequency is too low to sample the azimuth spectrum of the data adequately. In that case, the edges of the azimuth spectrum fold over themselves, creating ghost images as shown in this figure. The top image was adequately sampled and processed, while the bottom one clearly shows the ghost images due to the azimuth ambiguities. The data were acquired with the NASA/JPL AIRSAR systems, and a portion of Death Valley in California is shown.

is not unique to radar systems. They are common in optical systems, where they are known as the *sidelobes* of the point spread function. The difference is that in optical systems, the sidelobe characteristics are determined by the characteristics of the imaging optics, namely, the hardware, whereas in the case of a SAR, the sidelobe characteristics are determined by the characteristics of the processing filters. In the radar case, the sidelobes may therefore be reduced by suitable weighting of the signal spectra during matched filter compression. The equivalent procedure in optical systems is through apodization of the telescope aperture.

The vast majority of these artifacts and ambiguities can be avoided with proper selection of the sensor’s and processor’s parameters. However, the interpreter should be aware of their occurrence because in some situations they might be difficult, if not impossible, to suppress.

3.4. Geometric Effects and Projections

The time delay/Doppler history basis of SAR image generation leads to an image projection different from that in the case of optical sensors. Even though at first look radar images seem very similar to optical images,

Figure 12. Sidelobes from the bright target, indicated by arrows in this image, mask out the return from the dark area surrounding the target. The characteristics of the sidelobes are determined mainly by the characteristics of the radar processing filters.

close examination quickly shows that geometric shapes and patterns are projected differently by the two sensors. This difference is particularly acute in rugged terrain. If the topography is known, a radar image can be reprojected into a format identical to an optical image, thus allowing image pixel registration. In extremely rugged terrain, however, the nature of the radar image projection leads to distortions that sometimes cannot be corrected.

In the radar image, two neighboring pixels in the range dimension correspond to two areas in the scene with slightly different range with respect to the sensor. This has the effect of projecting the scene in a cylindrical geometry on the image plane, which leads to distortions as shown in Fig. 13. Areas that slope toward the sensor appear shorter in the image, while areas that slope away from the sensor seem longer in the image than do horizontal areas. This effect is called *foreshortening*. In the extreme case where the slope is larger than the incidence angle, *layover* occurs. In this case, a hill would appear to be projected over the region in front of it. Layover cannot

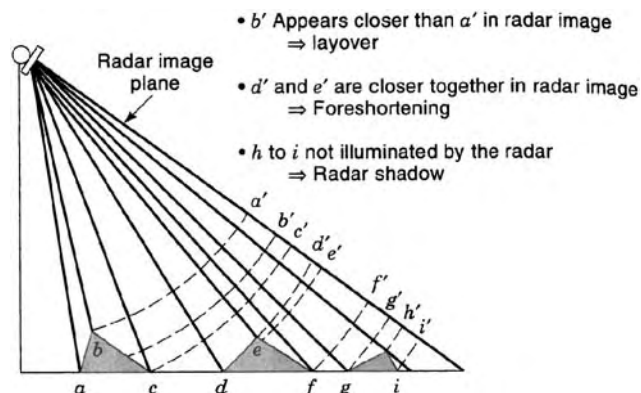

Figure 13. Radar images are cylindrical projections of the scene onto the image plane, leading to characteristic distortions. Refer to the text for more detailed discussions.

Figure 14. This NASA/JPL AIRSAR image shows examples of foreshortening and shadowing. Note that since the radar provides its own illumination, radar shadowing is a function of the radar look direction and does not depend on the sun angle. This image was illuminated from the left.

be corrected and can be avoided only by having an incidence angle at the surface larger than any expected surface slopes. When the slope facing away from the radar is steep enough such that the radar waves do not illuminate it, *shadowing* occurs and the area on that slope is not imaged. Note that in the radar images, shadowing is always away from the sensor flight line and is not dependent on the time of data acquisition or the sun angle in the sky. Shadowing can be beneficial for highlighting surface morphologic patterns. Figure 14 contains some examples of foreshortening and shadowing.

4. ADVANCED SAR TECHNIQUES

The field of synthetic aperture radar changed dramatically over the years, and especially since the early 1990s with the operational introduction of advanced radar techniques such as polarimetry and interferometry. While both of these techniques have been demonstrated much earlier, radar polarimetry became an operational research tool only with the introduction of the NASA/JPL AIRSAR system in the early 1980s, and reached a climax with the two SIR-C/X-SAR flights on board the space shuttle *Endeavour* in April and October 1994. Radar interferometry received a tremendous boost when the airborne TOPSAR system was introduced in 1991 by NASA/JPL, and further when data from the European Space Agency ERS-1 radar satellite became routinely available in 1991.

4.1. SAR Polarimetry

Electromagnetic wave propagation is a vector phenomenon; that is, all electromagnetic waves can be expressed as complex vectors. Plane electromagnetic waves can be represented by two-dimensional complex vectors. This is also the case for spherical waves when the observation point is sufficiently far removed from the source of the spherical wave. Therefore, if one observes a wave transmitted by a radar antenna when the wave is at a large distance from the antenna (in the far field of the antenna), the radiated electromagnetic wave can be adequately described by a

two-dimensional complex vector. If this radiated wave is now scattered by an object, and one observes this wave in the far field of the scatterer, the scattered wave can again be adequately described by a two-dimensional (2D) vector. In this abstract way, one can consider the scatterer as a mathematical operator that takes one 2D complex vector (the wave impinging on the object) and changes that into another 2D vector (the scattered wave). Mathematically, therefore, a scatterer can be characterized by a complex 2×2 scattering matrix

$$\mathbf{E}^{\text{sc}} = [\mathbf{S}]\mathbf{E}^{\text{tr}} \quad (46)$$

where \mathbf{E}^{tr} is the electric field vector that was transmitted by the radar antenna, $[\mathbf{S}]$ is the 2×2 complex scattering matrix that describes how the scatterer modified the incident electric field vector, and \mathbf{E}^{sc} is the electric field vector

that is incident on the radar receiving antenna. This scattering matrix is a function of the radar frequency and the viewing geometry. Once the complete scattering matrix is known and calibrated, one can synthesize the radar cross section for any arbitrary combination of transmit and receive polarizations. Figure 15 shows a number of such synthesized images for the San Francisco Bay area in California. The data were acquired with the NASA/JPL AIRSAR system.

The voltage measured by the radar system is the scalar product of the radar antenna polarization and the incident wave electric field:

$$V = \mathbf{p}^{\text{rec}} \cdot [\mathbf{S}]\mathbf{p}^{\text{tr}} \quad (47)$$

Here, \mathbf{p}^{tr} and \mathbf{p}^{rec} are the normalized polarization vectors describing the transmitting and receiving radar

Figure 15. Radar polarimetry allows one to synthesize images at any polarization combination. This set of images of San Francisco, California, was synthesized from a single set of measurements acquired by the NASA/JPL AIRSAR system. Note the differential change in brightness between the city (the bright area) and Golden Gate Park, the dark rectangular area in the middle of the images. This differential change is due to difference in scattering mechanism. The city area is dominated by a double reflection from the streets to the buildings and back to the radar, while the park area exhibits much more diffuse scattering.

antennas. The power received by the radar is the magnitude of the voltage squared

$$P = VV^* = |\mathbf{p}^{\text{rec}} \cdot [\mathbf{S}]\mathbf{p}^{\text{rad}}|^2 \quad (48)$$

Expanding the expression inside the magnitude sign, it can be shown that the received power can also be written in terms of the scatterer covariance matrix as follows

$$P = VV^* = (\tilde{\mathbf{A}}\mathbf{T})(\tilde{\mathbf{T}}\mathbf{A})^* = \tilde{\mathbf{A}}\mathbf{T}\mathbf{T}^*\mathbf{A}^* = \mathbf{A} \cdot [\mathbf{C}]\mathbf{A}^*; [\mathbf{C}] = \tilde{\mathbf{T}}\tilde{\mathbf{T}}^* \quad (49)$$

where $\tilde{\mathbf{A}} = (p_h^{\text{rec}} p_h^{\text{rad}} p_v^{\text{rec}} p_v^{\text{rad}} p_h^{\text{rec}} p_h^{\text{rad}} p_v^{\text{rec}} p_v^{\text{rad}})$ represents the antenna polarization vector elements and $\tilde{\mathbf{T}} = (S_{hh} S_{hv} S_{vh} S_{vv})$ represents only the scatterer. The superscript * denotes complex conjugation. The covariance matrix characterization is particularly useful when analyzing multilook radar images, since the covariance matrix of a multilook pixel is simply the average covariance matrix of all the individual measurements contained in the multilook pixel. Equation (49) shows the covariance matrix to be a 4×4 complex matrix. In the case of radar backscatter, reciprocity dictates that $S_{hv} = S_{vh}$ and the covariance matrix can in general be written as a 3×3 complex matrix.

The typical implementation of a radar polarimeter involves transmitting a wave of one polarization and receiving echoes in two orthogonal polarizations simultaneously. This is followed by transmitting a wave with a second polarization, and again receiving echoes with both polarizations simultaneously. In this way, all four elements of the scattering matrix are measured. This implementation means that the transmitter is in slightly different positions when measuring the two columns of the scattering matrix, but this distance is typically small compared to a synthetic aperture, and therefore does not lead to a significant decorrelation of the signals. The NASA/JPL AIRSAR system pioneered this implementation for SAR systems [5], and the same implementation was used in the SIR-C part of the SIR-C/X-SAR radars [6].

The past few years (as of 2004) have seen relatively few advances in the development of hardware for polarimetric SAR systems; newer implementations are simply using more advanced technology to implement the same basic hardware configurations as in the initial systems. Significant advances were made, however, in the field of analysis and application of polarimetric SAR data.

4.1.1. Polarimetric SAR Calibration. Many of the advances made in analyzing polarimetric SAR data result directly from the greater availability of calibrated data. Unlike the case of single-channel radars, where only the radar cross section needs to be calibrated, polarimetric calibration usually involves four steps: crosstalk removal, phase calibration, channel imbalance compensation, and absolute radiometric calibration [7]. *Crosstalk removal* refers to correcting mostly the cross-polarized elements of the scattering matrix for the effects of system crosstalk that couples part of the copolarized returns into the cross-polarized channel. *Phase calibration* refers to correcting

the copolarized phase difference for uncompensated path-length differences in the transmit and receive chains, while *channel imbalance* refers to balancing the copolarized and cross-polarized returns for uncompensated gain differences in the two transmit and receive chains. Finally, absolute radiometric calibration involves using some kind of a reference calibration source to determine the overall system gain to relate received power levels to normalized radar cross section.

While most of the polarimetric calibration algorithms currently in use were published in 1990 and 1991 [7–11], several groups are still actively pursuing the study of improved calibration techniques and algorithms. The earlier algorithms are reviewed in Refs. 12 and 13, while Ref. 14 provides a comprehensive review of SAR calibration in general. Some of these earlier algorithms are now routinely used to calibrate polarimetric SAR data operationally, as, for example, in the NASA/JPL AIRSAR and SIR-C processors [15].

4.1.2. Example Applications of Polarimetric SAR Data.

The availability of calibrated polarimetric SAR data allowed research to move from the qualitative interpretation of SAR images to quantitative analysis of the data. This sparked significant progress in classification of polarimetric SAR images, lead to improved models of scattering by different types of terrain, and allowed the development of some algorithms to invert polarimetric SAR data for geophysical parameters, such as forest biomass, surface roughness, and soil moisture.

4.1.3. Classification of Earth Terrain. Many Earth science studies require information about the spatial distribution of landcover types, as well as the change in landcover and land use with time. In addition, it is increasingly recognized that the inversion of SAR data for geophysical parameters involves an initial step of segmenting the image into different terrain classes, followed by inversion using the algorithm appropriate for the particular terrain class. Polarimetric SAR systems, capable of providing high-resolution images under all weather conditions as well as during day or night, provide a valuable data source for classification of Earth terrain into different landcover types.

Two main approaches are used to classify images into landcover types: (1) maximum-likelihood classifiers based on Bayesian statistical analysis and (2) knowledge-based techniques designed to identify dominant scattering.

Some of the earlier studies in Bayesian classification focused on quantifying the increased accuracy gained from using all the polarimetric information. References 16 and 17 showed that the classification accuracy is significantly increased when the complete polarimetric information is used compared to that achieved with single-channel SAR data. These earlier classifiers assumed equal a priori probabilities for all classes, and modeled the SAR amplitudes as circular Gaussian distributions, which means that the textural variations in radar backscatter are not considered to be significant enough to be included in the classification scheme. Reference 18 extended the Bayesian classification to allow different a priori probabilities for different classes.

The method in that study [18] first classifies the image into classes assuming equal a priori probabilities, and then iteratively changes the a priori probabilities for subsequent classifications on the basis of the local results of previous classification runs. Significant improvement in classification accuracy is obtained with only a few iterations. More accurate results are obtained using a more rigorous maximum a posteriori (MAP) classifier where the a priori distribution of image classes is modeled as a Markov random field and the optimization of the image classes is done over the whole image instead of on a pixel-by-pixel basis [19]. In a subsequent work, the MAP classifier is extended to include the case of multifrequency polarimetric radar data [20]. The MAP classifier was used in Ref. 21 to map forest types in the Alaskan boreal forest. In this study, five vegetation types (white spruce, balsam poplar, black spruce, alder/willow shrubs, and bog/fen/nonforest) were separated with accuracies ranging from 62 to 90%, depending on which frequencies and polarizations are used.

Knowledge-based classifiers are implemented according to determination of dominant scattering mechanisms through an understanding of the physics of the scattering process as well as experience gained from extensive experimental measurements [22]. One of the earliest examples of such a knowledge-based classifier was published in 1989 [23]. In this unsupervised classification, knowledge of the physics of the scattering process was used to classify images into three classes: odd numbers of reflections, even numbers of reflections, and diffuse scattering. The odd and even numbers of reflection classes are separated on the basis of the copolarized phase difference, while the diffuse scattering class is identified according to high cross-polarized return and low correlation between the copolarized channels. While no direct attempt was made to identify each class with a particular terrain type, it was noted that in most cases the odd numbers of reflection class corresponded to bare surfaces or open water; even numbers of reflections usually indicated urban areas or sparse forests, sometimes with understory flooding present; while diffuse scattering is usually identified with vegetated areas. As such, all vegetated areas are lumped into one class, restricting the application of the results. Pierce et al. [22] extended this idea and developed a level 1 classifier that segments images into four classes: tall vegetation (trees), short vegetation, and urban and bare surfaces. First the urban areas are separated from the rest by using the L-band copolarized phase difference and the image texture at C band. Then areas containing tall vegetation are identified using the L-band cross-polarized return. Finally, the C-band cross-polarized return and the L-band texture are used to separate the areas containing short vegetation from those with bare surfaces. Accuracies better than 90% are reported for this classification scheme when applied to two different images acquired in Michigan. Another example of a knowledge-based classification is reported in by Hess et al. [24]. In this study, a decision-tree classifier is used to classify images of the Amazonian floodplain near Manaus, Brazil into five classes: water, clearing, macrophyte, nonflooded forest, and flooded forest based on polarimetric scattering properties. Accuracies better than 90% are reported.

4.1.4. Geophysical Parameter Estimation. One of the most active areas of research in polarimetric SAR involves estimating geophysical parameters directly from the radar data through model inversion. Space does not permit a full discussion of the most recent work here. Therefore, in this section only a brief summary of recent work will be provided, with emphasis on vegetated areas.

Many electromagnetic models exist to predict scattering from vegetated areas [25–34], and this remains an area of active research. Much of the work is aimed at estimating forest biomass [35–39]. Earlier works correlated polarimetric SAR backscatter with total aboveground biomass [35,36] and suggested that the backscatter saturates at a biomass level that scales with frequency, a result also predicted by theoretic models. This led some investigators to conclude that these saturation levels define the upper limits for accurate estimation of biomass [40], arguing for the use of low-frequency radars to monitor forest biomass [41].

More recent work suggests that some spectral gradients and polarization ratios do not saturate as quickly and may therefore be used to extend the range of biomass levels for which accurate inversions could be obtained [37]. Reference 41 showed that inversion results are most accurate for monospecies forests, and that accuracies decrease for less homogeneous forests. Those authors conclude that the accuracies of the radar estimates of biomass are likely to increase if structural differences between forest types are accounted for during the inversion of the radar data.

Such an integrated approach to retrieval of forest biophysical characteristics has been reported [42,43]. These studies first segment images into different forest structural types, and then use algorithms appropriate for each structural type in the inversion.

Furthermore, Dobson et al. [43] estimate the total biomass by first using the radar data to estimate tree basal area and height and crown biomass. The tree basal area and height are then used in allometric equations to estimate the trunk biomass. The total biomass, which is the sum of the trunk and crown biomass values, is shown to be accurately related to allometric total biomass levels up to 25 kg/m², while Kasischke et al. [44] estimate that biomass levels as high as 34–40 kg/m² could be estimated with an accuracy of 15–25% using multipolarization C-, L-, and P-band SAR data.

Research in retrieving geophysical parameters from nonvegetated areas is also an active research area, although not as many groups are involved. One of the earliest algorithms to infer soil moisture and surface roughness for bare surfaces was published in 1992 [45]. This algorithm uses polarization ratios to separate the effects of surface roughness and soil moisture on the radar backscatter, and an accuracy of 4% for soil moisture is reported. More recently, Dubois et al. [46] reported a slightly different algorithm, based only on the copolarized backscatters measured at L band. Their results, using data from scatterometers, airborne SARs, and spaceborne SARs (SIR-C), show an accuracy of 4.2% when inferring soil moisture over bare surfaces. Shi and Dozier [47] reported an algorithm to measure snow wetness and demonstrated accuracies of 2.5%.

4.2. SAR Interferometry

SAR interferometry refers to a class of techniques where additional information is extracted from SAR images that are acquired from different vantage points, or at different times. Various implementations allow different types of information to be extracted. For example, if two SAR images are acquired from slightly different viewing geometries, information about the topography of the surface can be inferred. On the other hand, if images are taken at slightly different times, a map of surface velocities can be produced. Finally, if sets of interferometric images are combined, subtle changes in the scene can be measured with extremely high accuracy.

In this section, we shall first discuss so-called cross-track interferometers used for the measurement of surface topography. This will be followed by a discussion of along-track interferometers used to measure surface velocity. The section ends with a discussion of differential interferometry used to measure surface changes and deformation.

4.2.1. Radar Interferometry for Measuring Topography.

SAR interferometry was first demonstrated by Graham [48], who demonstrated a pattern of nulls or interference fringes by vectorally adding the signals received from two SAR antennas: one physically situated above the other. Later, Zebker and Goldstein [49] demonstrated that these interference fringes can be formed after SAR processing of the individual images if both the amplitude and the phase of the radar images are preserved during the processing.

The basic principles of interferometry can be explained using the geometry shown in Fig. 16. Using the law of cosines on the triangle formed by the two antennas and the point being imaged, it follows that

$$(R + \delta R)^2 = R^2 + B^2 - 2BR \cos\left(\frac{\pi}{2} - \theta + \alpha\right) \quad (50)$$

where R is the slant range to the point being imaged from the reference antenna, δR is the pathlength difference

Figure 16. Basic interferometric radar geometry. The pathlength difference between the signals measured at each of the two antennas is a function of the elevation of the scatterer.

between the two antennas, B is the physical interferometric baseline length, θ is the look angle to the point being imaged, and α is the baseline tilt angle with respect to the horizontal.

From Eq. (50) it follows that we can solve for the pathlength difference δR . If we assume that $R \gg B$ (a very good assumption for most interferometers), one finds that

$$\delta R \approx -B \sin(\theta - \alpha) \quad (51)$$

The radar system does not measure the pathlength difference explicitly, however. Instead, what is measured is an interferometric phase difference that is related to the pathlength difference through

$$\phi = \frac{a2\pi}{\lambda} \quad \delta R = -\frac{a2\pi}{\lambda} B \sin(\theta - \alpha) \quad (52)$$

where $a = 1$ for the case where signals are transmitted out of one antenna and received through both at the same time, and $a = 2$ for the case where the signal is alternately transmitted and received through one of the two antennas only. The radar wavelength is denoted by λ .

From Fig. 16, it also follows that the elevation of the point being imaged is given by

$$z(y) = h - R \cos \theta \quad (53)$$

where h denotes the height of the imaging reference antenna above the reference plane with respect to which elevations are quoted. From Eq. (52) one can infer the actual radar look angle from the measured interferometric phase as

$$\theta = \alpha - \sin^{-1}\left(\frac{\lambda\phi}{a2\pi B}\right) \quad (54)$$

Using Eqs. (54) and (53), one can now express the inferred elevation in terms of system parameters and measurables as follows:

$$z(y) = h - R \cos\left(\alpha - \sin^{-1}\left(\frac{\lambda\phi}{a2\pi B}\right)\right) \quad (55)$$

This expression is the fundamental interferometric SAR equation for broadside imaging geometry.

SAR interferometers for the measurement of topography can be implemented in one of two ways. In the case of single-pass interferometry, the system is configured to measure the two images at the same time through two different antennas usually arranged one above the other. The physical separation of the antennas is referred to as the *baseline* of the interferometer. In the case of repeat-track interferometry, the two images are acquired by physically imaging the scene at two different times using two different viewing geometries.

So far most single-pass interferometers have been implemented using airborne SARs [49–51]. The Shuttle Radar Topography Mission (SRTM), a joint project between the United States National Imagery and Mapping Agency (NIMA) and the National Aeronautics and Space Administration (NASA), was the first spaceborne implementation of a single-pass interferometer [52]. Launched

in February 2000 from Cape Canaveral in Florida on the space shuttle *Endeavour*, SRTM used modified hardware from the C-band radar of the SIR-C system, with a 62-m-long boom and a second antenna to form a single-pass interferometer. The SRTM mission acquired digital topographic data of the globe between 60° north and south latitudes during one 11-day shuttle mission. The SRTM mission also acquired interferometric data using modified hardware from the X-band part of the SIR-C/X-SAR system in a collaboration between NASA and the Deutsches Zentrum für Luft und Raumfahrt (DLR) in Germany. The swaths of the X-band system, however, were not wide enough to provide global coverage during the mission.

The SRTM payload used the maximum resources that the space shuttle could offer with respect to energy use, flight duration, and payload mass, with the result that the mapping phase of the flight operations was limited to 159 orbits. With the 62-m-long mast, and the more than 13 tons of payload, SRTM was the largest structure ever flown in space. The C-band radar was operated in the SCANSAR mode, which allowed complete global coverage between 54° south latitude and 60° north latitude. All the SRTM data have been processed into digital elevation maps. Figure 17 shows a shaded relief map of the state of California derived from the SRTM data. Processed data and general information about the SRTM mission can be

found on the Web at <http://www.jpl.nasa.gov/srtm/> and at <http://srtm.usgs.gov/>. The vertical accuracy (90%) of the SRTM data is estimated to be about 7 m.

Most of the SAR interferometry research has gone into understanding the various error sources and how to correct their effects during and after processing. As a first step, careful motion compensation must be performed during processing to correct for the actual deviation of the aircraft platform from a straight trajectory [53]. As mentioned before, the single-look SAR processor must preserve both the amplitude and the phase of the images. After single-look processing, the images are carefully coregistered to maximize the correlation between the images. The so-called interferogram is formed by subtracting the phase in one image from that in the other on a pixel-by-pixel basis.

The interferometric SAR technique is better understood by briefly reviewing the difference between traditional and interferometric SAR processing. In traditional (noninterferometric) SAR processing, it is assumed that the imaged pixel is located at the intersection of the Doppler cone (centered on the velocity vector), the range sphere (centered at the antenna), and an assumed reference plane, as shown in Fig. 18. Since the Doppler cone has its apex at the center of the range sphere, and its axis of symmetry is aligned with the velocity vector, it follows

Figure 17. Shaded relief map of California derived from SRTM C-band radar interferometry measurements.

Figure 18. In traditional (noninterferometric) SAR processing, the scatterer is assumed to be located at the intersection of the Doppler cone, the range sphere, and some assumed reference plane.

that all points on the intersection of the Doppler cone and the range sphere lie in a plane orthogonal to the velocity vector.

The additional information provided by cross-track interferometry is that the imaged point also has to lie on the cone described by a constant phase, which means that one no longer has to assume an arbitrary reference plane. This cone of equal phase has its axis of symmetry aligned with the interferometer baseline and also has its apex at the center of the range sphere. It then follows that the imaged point lies at the intersection of the Doppler cone, the range sphere, and the equal phase cone, as shown in Fig. 19. It should be pointed out that in actual interferometric SAR processors, the two images acquired by the two interferometric antennas are actually processed individually using the traditional SAR processing assumptions. The resulting interferometric phase then represents the elevation with respect to the reference plane assumed during the SAR processing. This phase is then used to find the actual intersection of the range sphere, the Doppler cone, and the phase cone in three dimensions.

Once the images are processed and combined, the measure phase must be *unwrapped*. During this procedure, the measured phase, which varies only between 0° and 360° , must be unwrapped to retrieve the original phase by adding or subtracting multiples of 360° . The earliest phase unwrapping routine was published by Goldstein et al. [54]. In this algorithm, areas where the phase will be discontinuous as a result of layover or poor signal-to-noise ratios are identified by branchcuts, and the phase unwrapping routine is implemented such that branchcuts are not crossed when unwrapping the phases. Phase unwrapping remains one of the most active areas of research, and many algorithms remain under development.

Figure 19. Interferometric radars acquire all the information required to reconstruct the position of a scatterer in three dimensions. The scatterer is located at the intersection of the Doppler cone, the range sphere, and the interferometric phase cone.

Even after the phases have been unwrapped, the absolute phase is still not known. This absolute phase is required to produce a height map that is calibrated in the absolute sense. One way to estimate this absolute phase is to use ground control points with known elevations in the scene. However, this human intervention severely limits the ease with which interferometry can be used operationally. Madsen et al. [53] reported a method by which the radar data themselves are used to estimate this absolute phase. The method breaks the radar bandwidth up into an upper and lower halves, and then uses the differential interferogram formed by subtracting the upper-half spectrum interferogram from the lower-half spectrum interferogram to form an equivalent low-frequency interferometer to estimate the absolute phase. Unfortunately, this algorithm is not robust enough in practice to fully automate interferometric processing. This is one area where significant research is needed if the full potential of automated SAR interferometry is to be realized.

Absolute phase determination is followed by height reconstruction. Once the elevations in the scene are known, the entire digital elevation map can be geometrically rectified. Madsen et al. [53] reported accuracies ranging between 2.2 m RMS for flat terrain and 5.5 m RMS for terrain with significant relief for the NASA/JPL TOPSAR interferometer.

An alternative way to form the interferometric baseline is to use a single-channel radar to image the same scene from slightly different viewing geometries. This technique, known as *repeat-track interferometry*, has been applied mostly to spaceborne data starting with data collected with the L-band SEASAT SAR [54–59]. Other investigators used data from the L-band SIR-B [60] the C-band ERS-1 radar [61,62], and more recently the L-band SIR-C

[63] and the X-band X-SAR [64]. Repeat-track interferometry has also been demonstrated using airborne SAR systems [65].

Two main problems limit the usefulness of repeat-track interferometry. The first is due to the fact that, unlike the case of single-pass interferometry, the baseline of the repeat-track interferometer is not known accurately enough to infer accurate elevation information from the interferogram. Zebker et al. [62] show how the baseline can be estimated using ground control points in the image. The second problem is due to differences in scattering and propagation that results from the fact that the two images forming the interferogram are acquired at different times. One result is temporal decorrelation, which is worst at the higher frequencies [58]. For example, C-band images of most vegetated areas decorrelate significantly over as short a time as one day. This problem more than any other limits the use of the current operational spaceborne single-channel SARs for topographic mapping, and led to proposals for dedicated interferometric SAR missions to map the entire globe [66,67].

4.2.2. Along-Track Interferometry. In some cases, the temporal change between interferometric images contains much information. One such case is the mapping of ocean surface movement. In this case, the interferometer is implemented in such a way that one antenna images the scene a short time before the second antenna does, preferably using the same viewing geometry. Goldstein and Zebker [68] described such an implementation in which one antenna is mounted forward of the other on the body of the NASA DC-8 aircraft. In a later work, Goldstein et al. [69] measured ocean currents with a velocity resolution of 5–10 m/s. Marom et al. [70,71] along-track interferometry used to estimate ocean surface current velocity and wavenumber spectra. This technique was also applied to the measurement of ship-generated internal wave velocities [72].

In addition to measuring ocean surface velocities, Carande [73] reports a dual-baseline implementation, implemented by alternately transmitting out of the front and aft antennas, to measure ocean coherence time. He estimated typical ocean coherence times for L band to be about 0.1 s. Shemer and Marom [74] proposed a method to measure ocean coherence time using only a model for the coherence time and one interferometric SAR observation.

4.2.3. Differential Interferometry. One of the most exciting applications of radar interferometry is implemented by subtracting two interferometric pairs separated in time from each other to form a so-called differential interferogram. In this way surface deformation can be measured with unprecedented accuracy. This technique was first demonstrated by Gabriel et al. [75] using SeaSat data to measure millimeter-scale ground motion in agricultural fields. Since then this technique has been applied to measure centimeter-meter-scale coseismic displacements [76–81] and measure centimeter-scale volcanic deflation [82]. The added information provided by high-spatial-resolution coseismic deformation maps was shown to provide

insight into the slip mechanism that would not be attainable from the seismic record [79,80].

Differential SAR interferometry has also led to spectacular applications in polar ice sheet research by providing information on ice deformation and surface topography at an unprecedented level of spatial details. Goldstein et al. [83] observed icestream motion and tidal flexure of the Rutford Glacier in Antarctica with a precision of 1 mm per day and summarized the key advantages of using SAR interferometry for glacier studies. Joughin [84] studied the separability of ice motion and surface topography in Greenland and compared the results with those from both radar and laser altimetry. Rignot et al. [85] estimated the precision of the SAR-derived velocities using a network of in situ velocities, and demonstrated, along with Joughin et al. [86], the practicality of using SAR interferometry across all the different melting regimes of the Greenland ice sheet. Large-scale applications of these techniques is expected to yield significant improvements in our knowledge of the dynamics, mass balance, and stability of the world's major ice masses.

One confusing factor in the identification of surface deformation in differential interferograms is due to changing atmospheric conditions. In observing Earth, radar signals propagate through the atmosphere, which introduces additional phase shifts that are not accounted for in the standard geometric equations describing radar interferometry. Spatially varying patterns of atmospheric water vapor change the local index of refraction, which, in turn, introduces spatially varying phase shifts to the individual interferograms. Since the two (or more) interferograms are acquired at different times, the temporal change in water vapor introduces a signal that could be on the same order of magnitude as that expected from surface deformation, as discussed by Goldstein [87]. Another limitation of the technique is temporal decorrelation. Changes in the surface properties may lead to complete decorrelation of the images and no detectable deformation signature [78].

4.2.4. Polarimetric Interferometry. In the preceding discussion on radar interferometry, it was assumed that only one polarization was transmitted, and only one polarization measured on reception of the radar waves. However, as mentioned before, electromagnetic wave propagation is by nature a vector phenomenon. Therefore, in order to capture the complete information about the scattering process, interferometric measurements should really be made in the full polarimetric implementation of a radar system. In this case, there are really three different measurements being made at the same time. First, there are the two polarimetric radar measurements at each end of the baseline, represented below by the two covariance matrices $[C_{11}]$ and $[C_{22}]$. Since the baseline is generally short compared to the distance to the scene, these two measurements can be expected to be nearly identical, except for the very small change in the angle of incidence from one end of the baseline to the other. (The exception, of course, is if the two measurements are made in the repeat-track implementation. In that case, temporal changes could cause the two covariance matrices to be quite different.) The third

measurement, of course, is the full vector interferogram as opposed to the scalar implementation described earlier.

The vector interferogram, which is the complex cross-correlation of the signal from one end of the baseline with that from the other end of the baseline, can be described as

$$V_1 V_2^* = \tilde{\mathbf{A}}_1 \mathbf{T}_1 \tilde{\mathbf{T}}_2^* \mathbf{A}_2^* = \mathbf{A}_1 \cdot [\mathbf{C}_{12}] \mathbf{A}_2^* \quad (56)$$

The correlation of the two signals after averaging is

$$\begin{aligned} \mu &= \frac{\langle V_1 V_2^* \rangle}{\sqrt{\langle V_1 V_1^* \rangle \langle V_2 V_2^* \rangle}} \\ &= \frac{\mathbf{A}_1 \cdot \langle [\mathbf{C}_{12}] \rangle \mathbf{A}_2^*}{\sqrt{(\mathbf{A}_1 \cdot \langle [\mathbf{C}_{11}] \rangle \mathbf{A}_1^*) (\mathbf{A}_2 \cdot \langle [\mathbf{C}_{22}] \rangle \mathbf{A}_2^*)}} \end{aligned} \quad (57)$$

where the angular brackets $\langle \rangle$ denote averaging. The interferometric phase is the phase angle of the numerator of [57]

$$\phi_{\text{int}} = \arg(\mathbf{A}_1 \cdot \langle [\mathbf{C}_{12}] \rangle \mathbf{A}_2^*) \quad (58)$$

Using this formulation, Cloude and Papathanassiou [88] showed, using repeat-track SIR-C interferometric data, that polarization diversity can be used successfully to optimize the correlation between images. They also showed significant differences in the measured elevation in forested areas when using polarization optimization. At present, polarimetric interferometry is a very active research area. Unfortunately, progress is hampered severely by lack of availability of well-calibrated data, as only a handful of radar systems have been upgraded to full polarimetric interferometry capability.

Current research is still only beginning to realize the full potential of radar interferometry. Because of the success of the SRTM mission, and some excellent fundamental research in the application of interferometric and differential interferometric radar data, the next few years will undoubtedly see an explosion in the interest and use of this type of remote sensing data.

5. NONIMAGING RADARS

5.1. Ocean Scatterometer

Scatterometers measure the surface backscattering cross section precisely in order to relate the measurement to geophysical quantities such as the ocean wind vector (both speed and direction) [89]. Spaceborne ocean scatterometers are capable of measuring global wind vectors over oceans for use in studies of upper ocean circulation, tropospheric dynamics, and air-sea interaction. Typical resolution of an ocean scatterometer is several tens of kilometers even though a higher-resolution scatterometer can provide useful information such as the coastal ocean wind vector. Since the backscattering cross section depends strongly on the surface roughness and the dielectric constant, a scatterometer can detect the electrical and geometric properties of a surface. As wind blows over the ocean surface, wind stress generates surface waves that

roughen the ocean surface. Since the dielectric constant of an ocean surface is very large at the microwave spectrum, the backscattering is related mainly to the surface roughness. Therefore, the backscattering cross section measured by an ocean scatterometer is sensitive to the windspeed via the surface roughness [90]. Since the surface roughness scale at the size of the radar wavelength strongly influences the backscattering cross section, the scatterometer wavelength should be at the centimeter scale in order to derive the surface windspeed. Specifically, the surface roughness size (Λ) responsible for backscattering is related to the radar wavelength λ as

$$\Lambda = \frac{\lambda}{2 \sin \theta} \quad (59)$$

where θ is the incidence angle. This wavelength Λ is also known as the *Bragg wavelength*, which represents a resonance scale presented in the scattering surface.

The received power must be calibrated to produce the accurate backscattering cross section using the radar equation. The noise power must be estimated and subtracted from the receive power during the calibration process. As discussed in Section 3.2, radar return measurements are contaminated by the speckle noise. In order to measure the backscattering cross section accurately, a large number of independent observations must be averaged [91]. This can be done in either the frequency or time domain. In scatterometry, a commonly adopted parameter for the backscattering cross section measurement accuracy is K_p defined as

$$K_p = \frac{\sqrt{\text{var}\{\sigma_0\}}}{\sigma_0} \quad (60)$$

which is the normalized standard deviation of the measured backscattering cross section [92]. To obtain an accurate measurement, K_p must be minimized.

Using the calibrated backscattering cross section, a geophysical model function must be developed to relate the backscattering cross section to the wind vector [93]. In general, a model function can be written as

$$\sigma_0 = F(\vec{U}) \quad (61)$$

for the given frequency, incidence angle, and polarization of a scatterometer. Here, \vec{U} denotes the wind vector (speed and direction). Because of the difficulty in deriving rigorous theoretical models, empirical models have been used for scatterometry applications. Figure 20 shows schematic model functions. As an example of a model function, Wentz and coworkers [94,95] have used SeaSat data to derive a Ku-band geophysical model function known as SASS-2.

It can be observed that σ_0 is a function of the radar azimuth angle (α) relative to the wind direction. A single σ_0 measurement is not sufficient to solve for both windspeed and direction. Figure 21 shows the double-sinusoidal relationship [93]. Thus, σ_0 is maximum at upwind ($\alpha=0$) and downwind ($\alpha=180$) directions while it is minimum near the crosswind direction ($\alpha=90$ and 270). As can be

Figure 20. Schematic scatterometer model function. Using this geophysical model function, backscattering measurements are related to windspeed.

seen from Fig. 21, σ_0 in the upwind direction is slightly higher than one in the downwind direction. In principle, a unique wind vector can be determined as a result of this small asymmetry. However, extremely accurate measurements are required to detect this small difference. It is clear that more than one σ_0 measurement must be made at different azimuth angles to determine the wind direction. In order to explain the wind direction determination technique, we use a simple model given by

$$\sigma_0 = AU^\gamma(1 + a \cos \alpha + b \cos 2\alpha) \quad (62)$$

where A , a , b , and γ are empirically determined for the windspeed U measured at a reference altitude (usually at 19.5 m above the ocean surface). As can be seen from Eq. (62), two measurements provide the windspeed U and the wind direction with a fourfold ambiguity.

Figure 21. Backscattering cross section in terms of the radar azimuth angle relative to the wind direction. Note that σ_0 in the upwind direction is slightly higher than in the downwind direction.

Additional measurements must be used to remove the ambiguity. Otherwise, auxiliary meteorological information is required to select the correct wind direction from ambiguous vectors [96].

An ocean scatterometer must be designed to provide multiple azimuth measurements and wide-swath coverage. Two antenna types have been used for this purpose: multiple-fan beam and conically scanning spot beam [97]. For example, a multiple-fan beam with three antennas can measure backscattering cross sections at three different azimuth angles as shown in Fig. 22a. As a satellite moves, an ocean surface is observed by the forward-looking antenna, the center antenna, and the aft antenna. The narrow antenna pattern provides resolution in one dimension, and the Doppler and range filtering provides resolution in the wide antenna pattern direction. The advantage of the multiple-fan beam is that the multiple azimuth measurements are made at fixed optimal azimuth angles. The disadvantages are that the nadir gap and the measurements must be made at a wide range of incidence angles. A conically scanning antenna system with two beams can make maximum four azimuth measurements at fixed two incidence angles as shown in Fig. 22b. The advantages of the scanning antenna are that the geophysical model function should be limited to a narrow range of incidence angles and there is no nadir gap. The obvious disadvantage is that the antenna system must rotate continuously.

The hardware of a scatterometer is composed of three major components: RF, digital, and antenna subsystems. The functions of both RF and digital subsystems are similar to the imaging radar case. Typically, a scatterometer signal is amplified by TWTA (traveling-wave tube amplifier) consisting of a TWT (traveling wave tube) and the associated high-voltage power supply. A stable calibration noise source is used to calibrate the receiver gain. The digital subsystem accumulates many independent measurements in both frequency and time domains to minimize K_p and to reduce the data volume. The ground processing system should produce global ocean wind vectors in a timely manner for natural-hazard applications such as hurricane tracking. In addition, it is important to identify the data contaminated by ice, land, and rain.

Examples of a spaceborne scatterometer are SASS (Seasat-A Scatterometer System), ERS-1 [98,99], NSCAT, and SeaWinds. Their radar parameters are shown in Table 1.

Figure 22. Two scatterometer antenna implementations: (a) multiple-fan beam; (b) conically scanning spot beam.

Table 1. Spaceborne Scatterometer Parameters

	SASS	ERS-1	NSCAT	SeaWinds
Frequency (GHz)	14.6	5.3	14	13.4
Spatial resolution (km)	50	50	25, 50	25
Swath width (km)	500	500	600	1800
Antenna type	Fan beam	Fan beam	Fan beam	Scanning spot beam
Number of antennas	4	3	6	1
Polarization	VV,HH	VV	VV,HH	VV,HH
Orbit altitude (km)	800	785	820	803

5.2. Ocean Altimeter

A radar altimeter [89] measures the distance between the sensor and the surface at the nadir direction to derive a topographic map of the surface. The primary application of a spaceborne ocean altimeter is to measure the sea surface elevation resulting from geostrophic ocean currents, which requires an accuracy of several centimeters. Long-term measurements of an ocean topography will contribute to the determination of the general circulation of the ocean and its variability. This allows us to study the role of oceans in the Earth climate system.

A radar altimeter transmits a short pulse to the nadir direction and measures the round-trip time (T) accurately. Hence, the distance (H) from the sensor to the surface can be calculated from

$$H = \frac{vT}{2} \tag{63}$$

where v is the speed of a radar wave in the propagating medium. The height error (δH) can be written in terms of the velocity error (δv) and the timing error (δT) as

$$\delta H = \frac{T\delta v}{2} + \frac{v\delta T}{2}. \tag{64}$$

The velocity error results from the refractive index variation due to ionosphere and atmosphere. A dual-frequency altimeter can be used to estimate the ionospheric effect, and a multiple-frequency radiometer may be used to estimate the atmospheric range delay. The timing error is related mainly to the finite signal bandwidth and the clock accuracy on the spacecraft. In addition, the small-scale roughness variation over the surface elevation causes an electromagnetic bias [100]. This bias is about 1% of the significant wave height (SWH). These errors must be estimated and corrected to achieve the required height accuracy. The location of a satellite must be known accurately since the distance is measured from an altimeter. Global positioning system (GPS) data and other satellite tracking techniques can be used for precision orbit determination.

The altimeter spatial resolution can be determined by either the radar beamwidth or the pulselength. If the beam footprint is smaller than the pulse footprint, the altimeter is called *beam-limited*. Otherwise, it is pulse-limited (see Fig. 23). The beam-limited footprint is given by

Figure 23. Beam-limited and pulse-limited altimeter footprints.

$\lambda h/L$, while the pulse-limited footprint is $2\sqrt{c\tau h}$. Here, h is the altitude, L is the antenna length, and τ is the pulselength. For a typical ocean altimeter, a long physical pulse is used to increase the signal-to-noise ratio. Then, a pulse compression technique is used to increase the range resolution. A “deramping” chirp technique is used for pulse compression. The deramping chirp is identical to the transmit chirp with a given time lag. The return signal and the deramping chirp are mixed together, and the difference frequency is processed to determine the range precisely.

The altimeter mean return waveform $W(t)$ [101,102] can be written as

$$W(t) = F(t)*q(t)*p(t) \tag{65}$$

where $F(t)$ is the flat surface impulse response, including radar antenna beamwidth and pointing angle effects, $q(t)$ is the surface height probability density function, and $p(t)$ is the radar system impulse response. Here, the symbol $*$ denotes the convolution operator. As illustrated in Fig. 24, the return pulseshape changes for different surface roughness. The antenna pointing angle is also important for waveform fitting. The half-power point on the waveform corresponds to the nadir mean sea level if the sea surface height distribution is Gaussian. In order to operate the altimeter electronics within the linear region of all receivers, an automatic gain control is implemented. An adaptive tracking unit attempts to track nadir mean sea level by keeping the half-power point in the tracking gate.

Figure 24. Altimeter return pulseshape for different surface roughnesses.

As an example of radar altimeters, we briefly describe the TOPEX radar altimeter [103]. The resulting RMS height accuracy of a single-pass TOPEX measurement is 4.7 cm [104]. This information is used to study the circulation of the world's oceans. The TOPEX altimeter is a dual-frequency (5.3- and 13.6-GHz) radar in order to retrieve the ionospheric delay of the radar signal. The TOPEX microwave radiometer measures sea surface emissivity at three frequencies (18, 21, and 37 GHz) to estimate the total water vapor content. The bandwidth and the pulsewidth of the TOPEX altimeter are 320 MHz and 102.4 μ s, respectively. The peak transmit power is 20 W. The antenna is a 1.5-m parabola with the 1.1° beamwidth at Ku band. In addition, the satellite carries a GPS receiver for precise satellite tracking. All these measurements are used to produce high-accuracy altimeter data. More recent research topics related to radar altimetry can be found in Ref. 104.

Conventional altimetry observations produced by the TOPEX altimeter provide high-precision ocean topography in the along-track direction. This allows the calculation of one geostrophic velocity component. However, knowledge of the two-dimensional velocity vector is required for an accurate estimate of important ocean characteristics such as the transport of mass, heat, freshwater, and chemicals. A new instrument using radar interferometry has been proposed to measure two-dimensional ocean topography. This instrument is known as the *wide-swath ocean altimeter* [105]. A three-satellite radar altimeter concept also has been proposed to observe the two-dimensional ocean surface gradient [106].

5.3. Radar Sounder

Radar sounders are used to image subsurface features by measuring reflections from dielectric constant discontinuities. For example, an ice sounding radar can measure the ice thickness by detecting the ice-ocean boundary [107]. In order to penetrate into subsurface, a long-wavelength radar is desired. Various radar sounding techniques are comprehensively summarized by Daniels et al. [108]. In order to image subsurface features, a radar signal must penetrate to the target depth with the satisfactory SNR. Like other radars, subsurface sounding radars should have an adequate bandwidth for sufficient resolution to detect buried objects or other dielectric discontinuity.

For a ground-penetrating radar [109], a probing antenna must be design for efficient coupling of electromagnetic radiation into the ground. The depth resolution can be obtained by using similar techniques described in the previous sections. However, the physical distance must be estimated from the slant range information and the real part of the medium refractive index. In order to enhance horizontal resolution, one can use the synthetic aperture technique. However, the matched filter construction is very difficult since the medium dielectric constant is usually inhomogeneous and unknown. The most important quantity to design a subsurface radar is the medium loss that determines the penetration depth. For a ground subsurface radar, it is advantageous to average many samples or increase effective pulselength to enhance

SNR. Polarimetric information is also important when buried objects are long and thin since strong backscattering is produced by a linearly polarized signal parallel to the long axis.

For an airborne [110] or a spaceborne radar sounder [111], subsurface returns must be separated from unwanted surface returns. Since a surface return is usually much stronger than a subsurface return, the radar must be designed for an extremely low sidelobe. A surface return can be an ambiguous signal if it is at the same range as a subsurface return (surface ambiguity). This problem becomes more serious as the altitude of a radar becomes higher or the antenna gain becomes lower. In addition, when the medium loss is large, radar must have a large dynamic range to detect a small subsurface return.

As an example of orbiting radar sounders, we will briefly describe the Apollo 17 lunar sounder radar [111]. The objectives of the sounder experiment were to detect subsurface geologic structures and to generate a lunar surface profile. Since lunar soil and rock exhibit less attenuation due to the absence of free water, one may expect deeper subsurface penetration compared with the observations on Earth. This sounder was operating at three frequencies (5, 15, and 150 MHz). This instrument was also used to generate a lunar surface profile using the strong surface return. In addition, galactic noise in the lunar environment was measured at the HF band.

5.4. Cloud Radar

Spaceborne cloud measurements to be accomplished by NASA's CloudSat mission [112,113] will answer a number of outstanding cloud-climate problems. The CloudSat measurements will evaluate quantitatively the representation of clouds and cloud processes in global atmospheric circulation models. The cloud profiling radar of the CloudSat will provide the global survey of the vertical structure of cloud systems at 500 m vertical resolution and 1.4 km horizontal resolution. Most meteorological radars [114] operate at centimeter wavelengths in order to avoid the significant attenuation by precipitation. However, cloud radars operate at millimeter wavelength since clouds cannot be observed easily by using conventional centimeter wavelength radars [115]. In order to minimize absorption, the radar frequency must be in the spectral windows whose center frequencies are 35, 100, and 150 GHz. The first millimeter-wave radar observations of clouds were done in the 35-GHz window [116]. Using the technology development at 94 GHz, the CloudSat radar operates at 94 GHz since higher radar reflectivity is expected at shorter wavelengths.

The cloud profiling radar of the CloudSat measures the power reflected from clouds as a function of distance from the radar. A minimum detectable cloud reflectivity is -26 dBZ. The radar is composed of RF electronics, digital electronics, high-power amplifier, and antenna subsystems. The CloudSat antenna diameter is a fixed 1.85-m-diameter reflector made from space-qualified composite graphite material to reduce mass. The antenna gain is higher than 63 dBi, and the sidelobes are less than -50 dB for angles larger than 7° from the boresight.

The low sidelobe level is important to eliminate the contamination from the surface reflection that is much stronger than the reflection from clouds. In order to minimize the loss, the quasioptical transmission line is used to feed the antenna instead of waveguides. The peak transmit power is 1.7 kW produced by EIK (extended-interaction klystron) and a high-voltage power supply. The thermal noise is reduced by averaging many samples of measured power and subtracting the estimated noise power. A higher PRF provides more samples to average; however, it increases the range ambiguity.

For a pulsed radar, the received power (P_r) can be written as

$$P_r = \frac{P_t G^2 \lambda^2 V}{(4\pi)^3 r^4} \eta e^{-2\alpha} \quad (66)$$

where P_t is the peak transmit power, G is the antenna gain, λ is the wavelength, V is the resolution volume, η is the volumetric radar cross section, and α is the one-way loss [117]. If the cloud particles are much smaller than the radar wavelength, using the Rayleigh scattering method, the radar reflectivity (Z) can be written as

$$Z = \frac{\eta \lambda^4}{\pi^5 |K|^2} \quad (67)$$

where $K = (n^2 - 1)/(n^2 + 2)$ and n is the complex refractive index of a particle. If cloud returns are measured coherently, the radial velocity (v_r) can be measured by using the Doppler frequency (f_d) as

$$v_r = \frac{f_d \lambda}{2} \quad (68)$$

Coherent radar measurements provide simultaneous radar reflectivity and radial velocity profiles in terms of altitude. More recent airborne cloud radars [118,119] can measure polarimetric reflectivity that can provide the additional information such as the linear depolarization ratio (LDR). Using these parameters, a cloud region classification (ice, cloud droplets, mixed-phase hydrometeors, rain, and insects) can be achieved [117]. If multi-wavelength measurements are made, it may be possible to estimate the drop size distribution.

5.5. Rain Radar

The accurate measurement of rainfall is an important factor in understanding the global water–energy cycle. Rain radars measure the rain reflectivity that can be used to estimate the parameters related to rainfall using inversion algorithms [120]. As an example of rain radars, one of the tropical rainfall measuring mission (TRMM) [121] instruments is a single-frequency (13.8-GHz), cross-track scanning radar for precipitation measurement. The satellite altitude is 350 km, and the scanning swath is 220 km. The range and surface horizontal resolutions are 250 m and 4 km, respectively. Using TRMM data, the rain profile can be estimated [120].

The operation frequency (13.8 GHz) is selected by considering both antenna size and attenuation. At this frequency, the antenna size does not have to be too large and the attenuation is small enough to measure rainfall near the surface. As an airborne rain radar, the National Aeronautics and Space Administration and the Jet Propulsion Laboratory developed an airborne rain-mapping radar (ARMAR) that flies on the NASA DC-8 aircraft [122]. The ARMAR operates with the TRMM frequency and geometry to understand the issues related to the TRMM rain radar.

Due to the downward-looking geometry, it is possible that surface clutter return may obscure return from precipitation. Even for an antenna looking off-nadir, the nadir return can be at the same range as precipitation. In order to overcome these difficulties, both antenna sidelobes and pulse compression sidelobes must be low (~ -60 dB relative to the peak return) enough to detect precipitation. In order to measure rain reflectivity accurately, it is necessary to calibrate the radar precisely. Radar measurements such as the reflectivity, the fall velocity, the horizontal–vertical polarization phase difference, and the differential reflectivity can be used to estimate rain rate and rain profile.

RADAR REMOTE SENSING OF IRREGULAR STRATIFIED LAYERS

EZEKIEL BAHAR
University of Nebraska—
Lincoln
Lincoln, Nebraska

1. INTRODUCTION

A unified full-wave solution to scattering from irregular stratified media is adapted to sensing surface features with multiple scales of fluctuations. An overview of the full-wave approach with extensive reference to articles in the technical literature have been published in Volume 17 of the Wiley *Encyclopedia of Electrical and Electronics Engineering* [1]. The full-wave analysis leads to a set of generalized telegraphists' equations, which account for scattering due to fluctuations in the medium parameters (complex permittivity and permeability) as well as surface roughness. These medium and surface-height fluctuations are assumed to consist of a continuum of very-large-scale (compared to wavelength) to very-small-scale features. For purposes of illustration, only random rough-surface height fluctuations are considered here. Thus the composite rough surfaces are characterized by their surface height probability density functions, including their surface height spectral density functions. The surface height spectral density functions, which are the Fourier transforms of the surface height autocorrelation functions, are assumed to consist of a very broad spectrum of spatial components, corresponding to a wide range of correlation lengths. It is shown that the high- and low-frequency limiting forms of the original full-wave solutions [2] reduce to the physical optics solutions [3] and the small perturbation solution [4], respectively [5].

In general however, unlike the physical optics solutions for highly conducting surfaces, the full-wave solutions are polarization-dependent and, unlike the small-perturbation solution, the original full-wave solutions are not restricted by specific values of the mean-square heights of the rough surfaces. However, the original full-wave expressions, based on an iterative solution of the generalized telegraphists' equations, are restricted to rough surfaces with small to moderate mean-square slopes [2]. In order to apply rough-surface scattering theories to surfaces with multiple scales of roughness, two scale theories based on perturbation–physical optics hybrid approaches were introduced [6–8]. Thus patches of small-scale surfaces are assumed to ride on the large-scale surfaces, and the total cross section is expressed as a sum of a large-scale physical optics cross section and a slope-modulated small-scale surface cross section. Since the expressions for the small-scale surface cross sections are based on the small-perturbation solution, the Rayleigh parameters associated with the small-scale surface ($\beta = 4k_0^2 \langle h_s^2 \rangle$, where k_0 is the free-space wavenumber and $\langle h_s^2 \rangle$ is the mean-square height of the small-scale surface), are assumed to be significantly smaller than unity. Moreover, the results were shown to be

critically dependent on the choice of the Rayleigh parameters associated with the small-scale surface [8]. Since the superposition of a small-scale surface on a large-scale physical optics surface does not increase the power scattered by the rough surface, the results based on the summation of the two cross sections are restricted to very small fluctuations from the physical optics surface.

In this work the full-wave solutions are expressed in variational forms as a weighted sum of two cross sections [9]. Consistent with energy conservation, the contribution to the total cross section due to the surface with the larger-scale spectral components of the rough surface is reduced by a factor related to the characteristic function for the surface with the smaller-scale spectral components. The contributions to the total cross section due to the surface with the smaller-scale spectral components of the rough surface are modulated by the slopes of the surface with the larger-scale spectral components.

To avoid problems associated with ideal (step-type) filters, a smooth filtering scheme is introduced in order to separate the larger-scale (spatial) spectral components from the smaller-scale spectral components [10,11]. The variational parameter used to separate the larger-scale surface from the smaller-scale surface is associated with the mean-square height or slope of the larger- or smaller-scale surface. It may also be associated with the patch or pixel size associated with the smaller-scale surface [12].

Using the unified full-wave approach, this variational parameter associated with spectral splitting of the composite rough surface can be varied in a continuous manner. In one limit the entire rough-surface scatter cross section is given by the small-slope, original full-wave solution [2]. In the other limit the entire rough-surface cross section is given by the high-frequency limit of the full-wave solution (related to the physical optics solution). In these two limits no spectral decomposition of the rough surface is assumed. For the intermediate cases the variational parameter (related to the fraction of the mean-square heights or slopes of the larger-scale surface) is varied in a continuous manner. Thus, for example, $\langle h_1^2 \rangle / \langle h^2 \rangle$ or $\langle \sigma_1^2 \rangle / \langle \sigma^2 \rangle$ (where $\langle h_1^2 \rangle$ and $\langle \sigma_1^2 \rangle$ are the mean-square heights and slopes of the larger-scale surface while $\langle h^2 \rangle$ and $\langle \sigma^2 \rangle$ are the mean-square heights and slopes of the total rough surface) is varied continuously between zero and unity. It is shown that the total scatter cross section for the composite rough surface is stationary over a very broad range of the variational parameter. The criteria used to determine the stationarity of the results for the backscatter cross sections is related to the norm of the error over the full range of incident angles. The norm is related to the variational parameter [associated with the mean-square heights, slopes, or patch (pixel) size [12]]. Since the original full-wave solution is restricted by a specific value of the mean-square height and the mean-square slope of the rough surface, the results associated with the variational parameter [related to the fractional mean-square slope (σ_1^2 / σ^2)] are most revealing.

Since the slopes of the very-small-scale rough surface do not contribute to the cross section, the unified full-wave solutions can be applied without spectral truncation to Pearson–Moskovitz surfaces [8] or fractural surfaces.

Application of this work to remote sensing of soil moisture content is also of special interest. It is readily shown that for the physical optics limit or the small perturbation limit, the ratio of the backscatter cross sections for the vertically to horizontally polarized waves is independent of the surface roughness. Therefore, the extraction of information on moisture content from the measured data is relatively straightforward. However, in general this ratio cannot be assumed to be independent of surface roughness. In these cases it is necessary to determine the impact of surface slopes on the scatter cross sections in order to extract the data on moisture content. The full-wave approach can be applied to the remote sensing of manmade rough surfaces as well as naturally occurring surfaces. Contrary to results based on the small-perturbation approach, the unified full-wave solutions for the ratio of the backscatter cross section for vertically to horizontally polarized waves can be near unity, in agreement with experimental results.

2. FORMULATION OF THE PROBLEM

The rough interface that separates free space (with permittivity ϵ_0 and permeability μ_0) from a half-space characterized by its complex permittivity ϵ_1 and permeability μ_1 is given by

$$f(x_s, y_s, z_s) = y_s - h(x_s, z_s) = 0 \quad (1)$$

where $-L < x_s < L$ and $-l < z_s < l$ and $h(x_s, z_s) = h_0 = \text{const}$ for $|x| > L$ and $|z| > l$.

The electric field of the vertically or horizontally polarized plane wave incident in free space is given by

$$\vec{E}_i^P(x, y, z) = \vec{a}^P E_{i0}^P \exp(-i\vec{k}^i \cdot \vec{r}) \quad (2)$$

in which the superscript P, V (vertical) or H (horizontal) denotes the polarization of the wave. The unit vector \vec{a}^V is parallel to the plane of incidence and \vec{a}^H is perpendicular to the plane of incidence. The magnitude of the incident wave is E_{i0}^P , the wavevector \vec{k}_0^i for the incident wave in free space is parallel to the unit vector $\vec{a}^V x \vec{a}^H$, and \vec{r} is the position vector to the observation point. The unit vector normal to the mean plane of the rough surface $y = h_0$ is \vec{a}_y . Assuming $\exp(i\omega t)$ time excitations, the free-space wave-number is $k_0 = \omega \sqrt{\mu_0 \epsilon_0}$. The incident wavevector is in the direction of the unit vector \vec{n}^i .

$$\begin{aligned} \vec{k}_0^i = \vec{k}_0 \vec{n}^i = k_0 (\sin \theta_0^i \cos \phi^i \vec{a}_x \\ - \cos \theta_0^i \vec{a}_y + \sin \theta_0^i \sin \phi^i \vec{a}_z) \end{aligned} \quad (3)$$

in which θ_0^i is the elevation angle of incidence measured from the y axis and ϕ^i is the azimuth angle. The full-wave solution for the electromagnetic radiation fields diffusely scattered from the two-dimensionally rough surface is

given by

$$\begin{aligned} G_s^f = \left(\frac{k_0}{2\pi i} \right)^2 \int_{-L}^L \int_{-l}^l \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} S(\vec{k}', \vec{k}^i) \exp(-i\vec{k}'_0 \cdot \vec{r}) \\ \times \exp(i\vec{v} \cdot \vec{r}_t) \frac{[\exp(iv'_y h) - \exp(iv'_y h_0)]}{v'_y} \\ \times dx_s dz_s \frac{dk'_{0y} dk'_{0z}}{k'_{0x}} G^i = G^f - G_D^f \end{aligned} \quad (4)$$

in which G_s^f and G^i are 2×1 column matrices whose elements are the vertically and horizontally polarized components of the diffusely scattered electric fields and the incident electric fields E_s^{Pf} and E_1^P ($P = V, H$), respectively. The integrations are over the surface variables x_s, z_s and the wavevector variables k'_{0y}, k'_{0z} for the radiation fields. The 2×2 scattering matrix $S(\vec{k}', \vec{k}^i)$ is given by

$$S(\vec{k}', \vec{k}^i) = 2 \cos \theta'_0 \cos \theta_0^i R(\vec{k}', \vec{k}^i) \quad (5)$$

in which the elements of the 2×2 matrix $R(\vec{k}', \vec{k}^i)$ are

$$\begin{aligned} R^{\text{HH}} = \\ \frac{[\mu_r C_1^i \cos(\phi' - \phi^i) - S_0' S_0^i] (1 - 1/\epsilon_r) + (1 - \mu_r) \cos(\phi' - \phi^i)}{(C_0' + \eta_r C_1^i)(C_0^i + \eta_r C_1^i)} \end{aligned} \quad (6)$$

$$\begin{aligned} R^{\text{VV}} = \\ \frac{[\epsilon_r C_1^i \cos(\phi' - \phi^i) - S_0' S_0^i] (1 - 1/\mu_r) + (1 - \epsilon_r) \cos(\phi' - \phi^i)}{(C_0' + C_1^i/\eta_r)(C_0^i + C_1^i/\eta_r)} \end{aligned} \quad (7)$$

$$R^{\text{HV}} = \frac{-n_r [(1 - 1/\mu_r) C_1^i - (1 - 1/\epsilon_r) C_1^i] \sin(\phi' - \phi^i)}{(C_0' + C_1^i/\eta_r)(C_0^i + \eta_r C_1^i)} \quad (8)$$

$$R^{\text{VH}} = \frac{n_r [(1 - 1/\epsilon_r) C_1^i - (1 - 1/\mu_r) C_1^i] \sin(\phi' - \phi^i)}{(C_0' + \eta_r C_1^i)(C_0^i + C_1^i/\eta_r)} \quad (9)$$

The scatter wavevector in the direction of the unit vector \vec{n}^i is

$$\vec{k}'_0 = \vec{k}_0 \vec{n}^i = k_0 (\sin \theta'_0 \cos \phi' \vec{a}_x + \cos \theta'_0 \vec{a}_y + \sin \phi' \vec{a}_z) \quad (10)$$

where θ'_0 and ϕ' are respectively the elevation angle and azimuth angle for the scattered wave. The relative complex permittivity and permeability are $\epsilon_r = \epsilon_1/\epsilon_0$, $\mu_r = \mu_1/\mu_0$, respectively. The relative refractive index and intrinsic impedance of medium 1 below the interface are $n_r = (\mu_r \epsilon_r)^{1/2}$ and $\eta_r = (\mu_r/\epsilon_r)^{1/2}$, respectively. The sines and cosines of the angles θ_0 and θ_1 above and below the rough interface (denoted by S_0, S_1 and C_0, C_1) are related through Snell's law.

The position vector to a point on the rough surface is

$$\begin{aligned} \vec{r}_s = x_s \vec{a}_x + h(x_s, z_s) \vec{a}_y + z_s \vec{a}_z \\ = \vec{r}_t + h(x_s, z_s) \vec{a}_y \end{aligned} \quad (11)$$

and \bar{r}_t is its projection of \bar{r}_s on the x, z plane. The vector \bar{v}' is given by

$$\bar{v}' = \bar{k}'_0 - \bar{k}^i_0 \quad (12)$$

For L and $l \rightarrow \infty$, G_D^f , the second term in Eq. (4) reduces to the specularly reflected plane wave from an infinite flat surface. For observation points in the far field $k_0 r \gg 1$, the wavevector variables in Eq. (4) can be integrated using the steepest-descent method, and the diffusely scattered fields reduce to

$$G_s^f = G_0 \int_{-l}^l \int_{-L}^L S(\bar{k}^f, \bar{k}^i) \exp(-i\bar{v} \cdot \bar{r}_t) \frac{[\exp(i\bar{v}_y h) - \exp(i\bar{v}_y h_0)]}{v_y} dx_s dz_s = G^f - G_D^f \quad (13)$$

in which

$$\begin{aligned} \bar{k}_0^f &= k_0 (\sin \theta_0^f \cos \phi^f \bar{a}_x + \cos \theta_0^f \bar{a}_y) \\ &+ \sin \theta_0^f \sin \phi^f \bar{a}_z = k_0 \bar{n}^f \end{aligned} \quad (14)$$

and

$$\bar{v} = \bar{k}_0^f - \bar{k}^i_0 \quad (15)$$

The coefficient G_0 in Eq. (13) is

$$G_0 = \frac{k_0^2 \exp(-ik_0 r)}{2\pi i r} \quad (16)$$

In Eq. (13), the elements of the scattering matrix $S(\bar{k}^f, \bar{k}^i)$ can be obtained from Eqs. (5)–(9) on replacing the angles in \bar{k}' by the corresponding angles in \bar{k}^f .

If the mean surface is normal to the unit vector \bar{n} as shown in Fig. 1, the solutions for the diffusely scattered fields are given by Eq. (13) or (4) except that the scattering matrices $S(\bar{k}^f, \bar{k}^i)$ or $S(\bar{k}', \bar{k}^i)$ are replaced by

$$D(\bar{k}^f, \bar{k}^i) = T^f S_n(\bar{k}^f, \bar{k}^i) T^i \quad (17)$$

in which S_n^{PQ} , the elements of the scattering matrix S_n , are obtained from S^{PQ} on replacing the cosines of the incident and scatter angles in the reference coordinate system with the cosines of the incident and scatter angles in the tilted coordinate system, $(-\bar{n}^i \cdot \bar{n})$ and $(\bar{n}^f \cdot \bar{n})$, respectively. Furthermore, $\cos(\phi^f - \phi^i)$ is replaced by the cosine of the angle between the planes of incidence and scatter in the tilted coordinate system:

$$\cos(\phi^{fn} - \phi^{in}) = \frac{(\bar{n}^i \times \bar{n}) \cdot (\bar{n}^f \times \bar{n})}{|\bar{n}^i \times \bar{n}| |\bar{n}^f \times \bar{n}|}$$

The sines of the angles are transformed in a similar manner. The 2×2 matrices T^i and T^f respectively relate the vertically and horizontally polarized incident and scattered fields in the reference coordinate system to the incident and scattered fields in the tilted coordinate system [13]. In addition, the differential surface element $dx_s dz_s$ is replaced by $dx_s dz_s / \bar{n} \cdot \bar{a}_y$, and $h(x_s, z_s)$ is measured normal to the mean surface. Thus the full-wave solutions are invariant to coordinate translations and rotations. They

Figure 1. Arbitrarily oriented pixel on a rough surface.

intrinsically satisfy the reciprocity and duality relationships in electromagnetic theory.

3. FULL-WAVE SCATTER CROSS SECTIONS

Starting with the original full-wave solutions for the far fields in Eq. (13), the radar cross sections per unit area are expressed as follows

$$\langle \sigma_0^{PQ} \rangle = |S^{PQ}(\bar{k}^f, \bar{k}^i)|^2 Q(\bar{k}^f, \bar{k}^i) \quad (18)$$

in which $S^{PQ}(\bar{k}^f, \bar{k}^i)$ is the surface element scattering coefficient for incident waves in the direction \bar{n}^i and polarization $Q = V$ (vertical) or H (horizontal) and scatter waves in the direction \bar{n}^f and polarization $P = V$ or H and

$$Q(\bar{k}^f, \bar{k}^i) = \frac{k_0^4}{\pi \bar{v}_y^2} \int_{-2L}^{2L} \left(1 - \frac{|x_d|}{2L}\right) \left(1 - \frac{|z_d|}{2L}\right) \times [\chi_2(\bar{v}_y, -\bar{v}_y) - |\chi(\bar{v}_y)|^2] \exp(i\bar{v} \cdot \bar{r}_{dt}) d\bar{r}_{dt} \quad (19)$$

in which

$$\bar{r}_{dt} = (x_{s1} - x_{s2})\bar{a}_x + (z_{s1} - z_{s2})\bar{a}_z = x_d\bar{a}_x + z_d\bar{a}_z \quad (20)$$

and $d\bar{r}_{dt} = dx_d dz_d$.

For homogeneous isotropic random rough surfaces with Gaussian height probability density functions, the characteristic function $\chi(v_y)$ and the joint characteristic functions $\chi_2(v_y, -v_y)$ are given by

$$|\chi(v_y)|^2 = \exp[-v_y^2 \langle h^2 \rangle] \quad (21a)$$

and

$$\chi_2(v_y, -v_y) = \exp[-v_y^2 \langle h^2 \rangle (1 - R(r_d))] \quad (21b)$$

in which $v_y = \bar{v} \cdot \bar{a}_y$, $\langle h^2 \rangle$ is the mean-square height of the rough surface and $R(r_d)$ is the normalized surface height autocorrelation function, the Fourier transform of the surface height spectral density function $W(k)$. For homogeneous isotropic random rough surface the surface height autocorrelation function is a function of distance $r_d = (x_d^2 + z_d^2)^{1/2}$ only and $Q(\bar{k}^f, \bar{k}^i)$ can be expressed as follows for L and l much larger than the correlation lengths l_c :

$$Q(\bar{k}^f, \bar{k}^i) = \frac{2k_0^2}{v_y^2} \int_0^\infty (\chi_2(v_y, -v_y) - |\chi(v_y)|^2) \quad (22)$$

$$J_0(v_{xz} r_d) r_d dr_d$$

where J_0 is the Bessel function of order zero and

$$v_{xz} = (v_x^2 + v_z^2)^{1/2} = (v^2 - v_y^2)^{1/2} \quad (23)$$

It should be noted that $Q(\bar{k}^f, \bar{k}^i)$ remains finite as $v_y \rightarrow 0$ (backscatter at grazing angles).

4. DECOMPOSITION OF RANDOM ROUGH SURFACES INTO TWO SURFACES

Since the original full-wave solutions were derived iteratively for rough surfaces with small to moderate slopes, the corresponding expressions for the radar cross sections [Eq. (18)] are restricted to random rough surfaces with moderate to small slopes. In order to apply the full-wave solutions to rough surfaces with larger slopes, the surface is regarded as a superposition of a larger-scale surface consisting primarily of the larger-scale spatial components of the surface height spectral density function and a smaller-scale surface consisting primarily of the smaller-scale spatial components of the surface height spectral density function $W(k)$. To avoid problems associated with ideal (step-type) filters, a smooth decomposition procedure into larger and smaller scale surfaces is adopted [10,11]. To illustrate the smooth decomposition procedure, two cases are considered here. Assume first that the surface height autocorrelation function $\langle h^2 \rangle R(r_d)$ and its Fourier transform, the surface height spectral density function $W(k)$ are Gaussian:

$$\begin{aligned} W(k) &= \frac{\langle h^2 \rangle}{4\pi^2} \int_{-\infty}^{\infty} R(r_d) \exp(-i\bar{k} \cdot \bar{r}_d) d\bar{r}_d \\ &= \frac{\langle h^2 \rangle l_c^2}{4\pi} \exp\left(-\frac{k^2 l_c^2}{4}\right) \end{aligned} \quad (24)$$

where $\bar{r}_d = x_d \bar{a}_x + z_d \bar{a}_z$, $r_d = (x_d^2 + z_d^2)^{1/2}$, $\bar{k} = k_x \bar{a}_x + k_z \bar{a}_z$, and $k = (k_x^2 + k_z^2)^{1/2}$. The corresponding expression for the larger-scale surface is

$$\begin{aligned} W_1(k) &= \frac{\langle h_1^2 \rangle}{4\pi^2} \int_{-\infty}^{\infty} R_1(r_d) \exp(-i\bar{k} \cdot \bar{r}_d) d\bar{r}_d \\ &= \frac{\langle h_1^2 \rangle l_{cl}^2}{4\pi} \exp\left(-\frac{k^2 l_{cl}^2}{4}\right) \end{aligned} \quad (25)$$

Thus the surface height spectral density function for the smaller scale surface is

$$W_s(k) = W(k) - W_1(k) \quad (26)$$

Since $W_s(k=0) = 0$, the autocorrelation length l_{cl} and the mean-space height $\langle h_1^2 \rangle$ of the larger-scale surface are related to the autocorrelation length l_c and mean-square height $\langle h^2 \rangle$ of the total surface as follows:

$$\langle h_1^2 \rangle l_{cl}^2 = \langle h^2 \rangle l_c^2 \quad (27)$$

As a result, $l_{cl}^2 = \langle h^2 \rangle l_c^2 / \langle h_1^2 \rangle \geq l_c^2$, since $\langle h_1^2 \rangle \leq \langle h^2 \rangle$. Thus $W_s(k)$ is positive for all values of k and it peaks at k_m , where

$$k_m^2 = \frac{8 \ln(l_{cl}/l_c)}{l_{cl}^2 - l_c^2} \quad (28)$$

The corresponding surface height autocorrelation function for the smaller-scale surface is

$$\begin{aligned} \langle h_s^2 \rangle R_s(x_d) &= \langle h^2 \rangle \exp\left[-\left(\frac{r_d}{l_c}\right)^2\right] \\ &\quad - \langle h_1^2 \rangle \exp\left[-\left(\frac{r_d}{l_{cl}}\right)^2\right] \end{aligned} \quad (29)$$

where $\langle h_s^2 \rangle = \langle h^2 \rangle - \langle h_1^2 \rangle$ and $R_s(0) = 1$. The normalized autocorrelation function $R_s(r_0) = 0$ for

$$\begin{aligned} r_0^2 &= \ln\left[\frac{\langle h^2 \rangle}{\langle h_1^2 \rangle}\right] \frac{l_c^2 l_{cl}^2}{(l_{cl}^2 - l_c^2)} \\ &= \ln\left(\frac{l_{cl}}{l_c}\right)^2 \left(\frac{l_c^2 l_{cl}^2}{(l_{cl}^2 - l_c^2)}\right) \end{aligned} \quad (30)$$

Thus for $r_d < r_0$, $R(r_d) > 0$ and for $r_d > r_0$, $R(r_d) < 0$. The mean-square slope for Gaussian random rough surfaces is

$$\sigma^2 = \frac{4\langle h^2 \rangle}{l_c^2} \quad (31a)$$

The mean-square slope of the large-scale surface is

$$\sigma_1^2 = \frac{4\langle h_1^2 \rangle}{l_{cl}^2} \quad (31b)$$

and

$$\frac{\sigma_1^2}{\sigma^2} = \frac{\langle h_1^2 \rangle l_c^2}{\langle h^2 \rangle l_{cl}^2} = \left(\frac{\langle h_1^2 \rangle}{\langle h^2 \rangle}\right)^2 = \left(\frac{l_c}{l_{cl}}\right)^4 \quad (32)$$

The ratio of the mean-square height of the larger- or smaller-scale surface to the mean-square height of the total surface can be varied in a continuous manner between

zero and one, and the spectral decomposition between the two surfaces is smooth.

A more complex illustration of a composite rough surface that is considered here is a superposition of Pearson–Moskowitz-type sea surfaces. The spectral density function for such a rough surface is given by

$$W(k) = W_1(k) + W_2(k) = \frac{2}{\pi} \left[\frac{B_1 k^4}{(k^2 + \kappa_1^2)^4} + \frac{B_2 k^4}{(k^2 + \kappa_2^2)^4} \right] \quad (33)$$

in which the parameters $\kappa_i = 1/(335.2V_i^4)^{1/2} \text{cm}^{-1}$ and V is the windspeed in meters per second. For $k = \kappa_i$, $W_i(k) = (B_i/8\pi\kappa_i^4)$ is maximum. It is assumed here that $\kappa_2 > \kappa_1$. In this case the smooth decomposition is achieved by choosing the spectral density function for the smaller-scale surface as follows

$$W_s(k) = \frac{2}{\pi} \frac{(B_1 + B_2)k^4}{(k^2 + \kappa_s^2)^4} \quad (34)$$

where $\kappa_s \geq \kappa_2$. Thus, for $k \gg \kappa_s$

$$W(k) \approx W_s(k) \rightarrow \frac{2(B_1 + B_2)}{\pi k^4} \quad (35)$$

The corresponding expression for the larger-scale surface height spectral density function is

$$W_1(k) = W(k) - W_s(k) \quad (36)$$

and $W_1(k) > 0$ for all values of k . Furthermore, for $k \gg \kappa_s$

$$W_1(k) \rightarrow \frac{8[B_1(\kappa_s^2 - \kappa_1^2) + B_2(\kappa_s^2 - \kappa_2^2)]}{\pi k^6} \quad (37)$$

The corresponding surface height autocorrelation functions are Fourier transforms of $W(k)$, $W_s(k)$, and $W_1(k)$:

$$\langle h_i^2 \rangle R_i(r_d) = \frac{\pi}{2} \int_{-\infty}^{\infty} W_i(k) e^{i\vec{k} \cdot \vec{r}_d} k dk$$

They can be expressed in terms of modified Bessel functions [12,14]. The mean-square height of the total surface is

$$\langle h^2 \rangle = \frac{B_1}{6\kappa_1^2} + \frac{B_2}{6\kappa_2^2} = \langle h_1^2 \rangle + \langle h_2^2 \rangle \quad (38)$$

The mean-square height of the smaller-scale surface is

$$\langle h_s^2 \rangle = \frac{B_1 + B_2}{6\kappa_s^2} \quad (39)$$

and the mean-square slope of the larger scale surface is

$$\sigma_1^2 = \frac{\pi}{2} \int_{-\infty}^{\infty} W_1(k) k^3 dk = B_1 \ln \left(\frac{\kappa_s}{\kappa_1} \right) + B_2 \ln \left(\frac{\kappa_s}{\kappa_2} \right) \quad (40)$$

To evaluate the mean-square slope of Pearson–Moskowitz-type random rough surfaces, it is necessary to truncate the upper limit of the surface height spectral density function [8]. However, no such truncation is needed here to evaluate the mean-square slope of the larger-scale surface since $W_1(k)$ decreases as $1/k^6$ for $k \gg \kappa_s$. Evaluation of the full-wave solutions for the scatter cross sections does not involve the slopes of the smaller-scale (capillary) surface. This could also have a significant positive impact on the study of scattering from fracture-type random rough surfaces.

4.1. Application of the Unified Full-Wave Approach to Two-Scale Models

Using the decomposition scheme illustrated in Section 3, the composite random rough surface is expressed as

$$h(x_s, z_s) = h_1(x_s, z_s) + h_s(x_s, z_s) \quad (41)$$

in which the total h , larger-scale h_1 , and smaller-scale h_s , random rough surface heights are characterized statistically through their individual surface height spectral density functions. On applying the unified full-wave approach to two-scale models of composite random rough surfaces, it is shown that the total scatter cross sections (per unit area) $\langle \sigma^{\text{PQ}} \rangle$ can be expressed as follows in terms of a weighted sum of two cross sections [9]

$$\langle \sigma^{\text{PQ}} \rangle = \langle \sigma_s^{\text{PQ}} \rangle + |\chi_s| \langle \sigma_1^{\text{PQ}} \rangle \quad (42)$$

in which $\langle \sigma_s^{\text{PQ}} \rangle$ is the normalized scatter cross section associated with the small-scale surface (tilt-modulated by the slopes of the larger-scale surface). This cross section is given by the statistical average of $D^{\text{PQ}}(\vec{k}^f, \vec{k}^i) Q_s(\vec{k}^f, \vec{k}^i)$ over the slopes of the larger-scale surface, characterized by its probability diversity function

$$p(h_x, h_z) = p \left(\frac{\partial h_1}{\partial x}, \frac{\partial h_1}{\partial z} \right)$$

The unit vector normal to the tilted smaller scale surface is

$$\begin{aligned} \vec{n} &= \frac{-h_x \vec{a}'_x + \vec{a}'_y - h_z \vec{a}'_z}{(1 + h_x^2 + h_z^2)^{1/2}} \\ &= \sin \Omega \cos \tau \vec{a}'_x + \cos \Omega \cos \tau \vec{a}'_y + \sin \tau \vec{a}'_z \end{aligned}$$

in which Ω and τ are tilt angles in and perpendicular to the plane of incidence, thus

$$\langle \sigma_s^{\text{PQ}} \rangle = \langle D^{\text{PQ}}(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i) Q_s(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i) \rangle \quad (43)$$

in which D^{PQ} , (the slope-dependent surface element scattering coefficient) is the PQ ($P, Q = V, H$) element of the scattering matrix $D(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i)$ given by Eq. (17) and $Q(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i)$ is the slope-modulated version of Eq. (22)

$$Q_s(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i) = \frac{2k_0^2(1+h_x^2+h_z^2)}{v_y^2} \times \int_0^\infty [\chi_{2s}(v_y, v_y) - \chi_s(v_y)] \cdot J_0(v_{xy}r_d) r_d dr_d \quad (44)$$

where $v_y = \bar{\mathbf{v}} \cdot \bar{\mathbf{n}}$ and $v_{xz} = (v_x^2 + v_z^2)^{1/2} = (v^2 - v_y^2)^{1/2}$. Furthermore, $\chi_{2s}(v_y, -v_y)$ and $\chi_s(v_y)$ are the joint characteristic function and characteristic function for the smaller-scale surface. The second term in Eq. (42) is the contribution from the larger scatter scale surface. This contribution is equal to the physical optics scatter cross sections associated with the larger-scale surface $\langle \sigma_1^{\text{PQ}} \rangle$, weighted down by the magnitude squared of the smaller-scale surface characteristic function. It can be shown that

$$\langle \sigma_1^{\text{PQ}} \rangle = |D_s^{\text{PQ}}(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i)|^2 Q_1(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i) \quad (45)$$

where $D_s^{\text{PQ}}(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i)$ is the value of surface element scattering coefficient evaluated at the specular point where the unit vector normal to the surface is given by

$$\bar{\mathbf{n}}_s = \frac{\bar{\mathbf{v}}}{v} \quad (46)$$

Furthermore

$$Q_1(\bar{\mathbf{k}}^f, \bar{\mathbf{k}}^i) = \frac{2k_0}{\bar{v}_y} \int_0^\infty [\chi_{2l}(v'_{ys} - v'_y) - |\chi_1(v'_y)|^2] \times x J_0(v'_{xz}r_d) r_d dr_d \quad (47)$$

where $\chi_{2l}(v'_y, -v'_y)$ and $\chi_1(v'_y)$ are the joint characteristic function and the characteristic function for the larger-scale surface and $v'_y = \bar{\mathbf{v}} \cdot \bar{\mathbf{a}}'$, $v'_{xz} = (v'^2 - v_y'^2)^{1/2}$ and $\bar{\mathbf{a}}'$ is normal to the mean plane (see Fig. 1).

Since h_l and h_s can be chosen such that the variational parameters $\langle h_l^2 \rangle / \langle h^2 \rangle = 1 - \langle h_s^2 \rangle / \langle h^2 \rangle = n$ or $\sigma_l^2 / \sigma^2 = n$ can be varied between zero and one. The corresponding expressions for the total cross sections can be evaluated as functions of the variational parameters n . Denoting these quantities with the subscript n , the norm of the error over the range of backscatter angles θ_0^i is defined as follows

$$E_{n+\Delta n/2}^{\text{PQ}} = \sum_1 \frac{\langle \sigma_{n+\Delta n}^{\text{PQ}}(\theta_0^i) \rangle - \langle \sigma_n^{\text{PQ}}(\theta_0^i) \rangle}{\langle \sigma_{n+\Delta n}^{\text{PQ}}(\theta_0^i) \rangle + \langle \sigma_n^{\text{PQ}}(\theta_0^i) \rangle} \frac{2}{\Delta n}$$

in which

$$\Delta_n = \begin{cases} \frac{\langle h_l^2 \rangle_{n+\Delta n} - \langle h_l^2 \rangle_n}{\langle h_l^2 \rangle} \\ \text{or} \\ \frac{[\langle \sigma_l^2 \rangle_{n+\Delta n} - \langle \sigma_l^2 \rangle_n]}{\sigma_l^2} \end{cases}$$

The variational parameter could also be related to the smaller-scale surface patch size [12].

The cross sections $\sigma_n^{\text{PQ}}(\theta_0^i)$ are stationary over a wide range of the variational parameter (related to the mean-square heights or slopes of the larger-scale surface). The final cross sections are evaluated for n where the norm of the error is minimum.

5. CONCLUDING REMARKS

In this article a comprehensive procedure is presented for applying a unified full-wave approach to evaluate the radar cross sections of random rough surfaces, based on a variational two-scale model.

This variational approach is based on the intrinsic properties of the full-wave solution. In the low-frequency limit, when the wavelength of electromagnetic waves incident on the rough surfaces is very large compared to the scales of roughness of the surface, the full-wave solution reduces to the polarization-dependent small-perturbation solution. In the high-frequency limit, when the wavelength is much smaller than the scales of roughness of the surface, the full-wave solution reduces to the physical optics solution (associated with specular point scattering).

In the case of most natural land or sea surfaces, the scales of roughness consist of a continuum of very small to very larger scales of roughness. In these cases it becomes difficult to distinguish between surfaces with the larger scales and smaller scales of roughness. Furthermore, the hybrid perturbation-physical optics, two-scale approaches were restricted by the value of the Rayleigh parameter $\beta = 4k_0^2 \langle h_s^2 \rangle$ (associated with the small-scale surface) and the results were shown to be very sensitive to the selection of the spatial wavenumber k_d where spectral splitting is assumed to occur [8]. One reason for this is that the total cross section was assumed to be a simple sum of two cross sections instead of (42).

Several features distinguish the full-wave results (based on the two-scale model) from the familiar two-scale approach. A smooth decomposition of the surface height spectral density function is adopted rather than a step-type decomposition associated with the wavenumber k_d . The variational parameter associated with the fractional mean-square heights or slopes of the larger-scale surface, can be varied between one and zero in a continuous manner. In one limit, the full-wave solution reduces to the original full wave solution [2]. In the other limit, the full-wave solution reduces to the physical optics solution (associated with specular point scattering and the Fresnel reflection coefficients). For highly conducting surfaces, these physical optics solutions are polarization-independent. For the intermediate cases (associated with the

variational parameters between one and zero) the full-wave solutions for the total radar cross sections are expressed as weighted sums of two cross sections [9]. Thus, when the contributions from the smaller-scale rough surface increases, the corresponding contribution from the larger-scale spectral components of the surface decreases. The stationarity of the results (based on the unified full-wave approach) over a broad range of variational parameters corresponds to a broad minimum in the norm of the error (as defined in the previous section). The value of the total radar cross section obtained in this manner is relatively insensitive to changes in the variational parameter. The results obtained using the familiar hybrid perturbation–physical optics approach are very sensitive to changes in k_d (where spectral splitting occurs).

RADAR SIGNAL DETECTION

MINSHENG WANG
Texas Instruments Incorporated
ANDREW K. CHAN
Texas A & M University

Each day, we constantly make decisions. Given certain hypotheses, information is selected on which to base each decision, and under certain conditions, we may need to determine the reliability of the information. Such is the case in radar signal detection—a returned signal is received, and we have to decide whether a target is present or absent. If there were no noise or interference, the decision could be made with complete confidence. However, in reality, the received signal is usually heavily corrupted by environmental noise, interference, and noise from the radar system itself, and so on. In order to make a reliable decision, the noise and unwanted signals have to be suppressed with a so-called matched filter before a decision can be made.

Owing to the existence of noise and interference, radar signal detection has to be treated as a statistical problem, regardless of whether the signal under detection is deterministic. This statistical formalism of radar signal detection theory can be applied to all types of radar signals without restriction. To understand radar signal detection, noise has to be described quantitatively. A time-limited deterministic signal can be described as a time series, and a periodic deterministic signal can be represented as a Fourier series. In contrast, noise cannot be represented as a deterministic function in the time or frequency domains. In other words, we cannot predict a noise-contaminated radar signal with absolute certainty. However, with available noise information such as the expectation, the power, or even the probability distribution of noise, we can select a criterion on which to base our decision.

1. BASIC CONCEPTS AND CRITERIA

1.1. Concepts of Signal-to-Noise Ratio and Matched Filter

The signal-to-noise ratio (SNR) in radar and communication systems is defined as

$$\text{SNR} = \frac{(\text{signal power})}{(\text{noise variance})} \quad (1)$$

The maximum output SNR, the most frequently used criterion for radar detection, is defined as the ratio of the maximum instantaneous output signal power to the output noise power. The input SNR is a major limiting factor for radar detection performance.

For a fixed input SNR, a linear time-invariant filter whose frequency response function maximizes the output SNR is called a *matched filter*. Matched filtering transforms the raw radar data into a form that is suitable for (1) generating the optimal decision for detection, (2) estimating the target parameters with a minimal RMS error, or

Figure 1. (a) Signal $s(t)$ and (b) matched-filter $h(t)$ relations. Phase in units of degrees. The phase from $H(\omega)$ is the negative of that from $S(\omega)$, while $h(t)$ is the time reversal of $s(t)$.

(3) obtaining the maximum resolving power for a group of targets. The characteristics of matched filters can be described by either a frequency-domain transfer function or a time-domain impulse response function, each related to the other by the Fourier transform. In the frequency domain, the matched-filter transfer function $H(\omega)$ is the complex conjugate of the spectrum of the signal. Thus, in general terms

$$H(\omega) = kS^*(\omega)e^{-j\omega T} \tag{2}$$

where $S(\omega)$ is the spectrum of the input signal $s(t)$ and T is a delay constant required to make the filter physically realizable. The normalizing factor k and the delay constant are generally ignored in formulating the underlying significant relationship. This simplification yields

$$H(\omega) = S^*(\omega) \tag{3}$$

Equation (3) reveals that the bandwidth of the receiver must be the same as that of the signal. This is under-

standable, because if the bandwidth of the receiver is wide compared with that occupied by the signal energy, extraneous noise may be introduced into the excess bandwidth, which lowers the output signal-to-noise ratio. On the other hand, if the receiver bandwidth is narrower than the signal bandwidth, the noise energy is reduced along with part of the signal energy. The result is again a lowered SNR. When the receiver bandwidth is identical to the signal bandwidth as in the case of the matched filter, the output SNR is maximized. The conjugate in Eqs. (2) and (3) allows the phases of $S(\omega)$ and $H(\omega)$ to cancel each other out, and leaves the output signal spectrum a linear phase, $e^{-j\omega T}$, which results in a peak at the time instant T in the output.

The corresponding time-domain relationship between the signal to be detected and the matched filter is obtained from the inverse Fourier transform of $H(\omega)$. This leads to the result that the impulse response of a matched filter is a replica of the time inverse of the known signal function. Thus, if $h(t)$ represents the matched-filter impulse response, the relationship equivalent to Eq. (2) is given by

$$h(t) = ks(T - t) \tag{4}$$

As before, k and T can be ignored to yield the basic relationship

$$h(t) = s(-t) \tag{5}$$

Figure 1 illustrates the relationship given by Eqs. (3) and (5), where $s(t)$ is a pulsed linear frequency-modulated (LFM) signal with the form

$$s(t) = \begin{cases} \sin[2\pi(t - 1.2)^2], & t \in [1.2, 1.6] \\ 0, & \text{otherwise} \end{cases} \tag{6}$$

The phase from $H(\omega)$ is the negative of that from $S(\omega)$, while $h(t)$ is the time reversal of the $s(t)$.

Figure 2a shows a received signal, which is the signal $s(t)$ of Eq. (6) corrupted by a 6 dB Gaussian noise; that is, the input SNR is -6 dB. It is difficult to detect the

Figure 2. (a) Signal corrupted by noise by (b) the matched-filter output. The peak in the matched-filter output indicates the existence of the signal.

Figure 3. Block diagram of a matched filter.

existence of the signal $s(t)$ from this figure. However, after the received signal is processed by the matched filter, the detector output peak in Fig. 2b clearly indicates the existence of the signal.

The output from the matched filter, as shown in Fig. 3, is the convolution between the received signal and the matched filter impulse response:

$$\begin{aligned}
 y(t) &= \int_0^t [s(\tau) + n(\tau)]h(t - \tau) d\tau \\
 &= \int_0^t [s(\tau) + n(\tau)]s(T - t + \tau) d\tau
 \end{aligned}
 \tag{7}$$

Sampling $y(t)$ at $t = T$ yields the maximum output signal value, that is

$$\begin{aligned}
 y(t)_{\max} &= y(T) = \int_0^T [s(\tau) + n(\tau)]s(\tau) d\tau \\
 &= E_s + \int_0^T n(\tau)s(\tau) d\tau
 \end{aligned}
 \tag{8}$$

where E_s represents the signal energy. It can be easily verified that the expectation of $y(t)_{\max}$ is E_s , because the second term in Eq. (8) represents the noise whose mean is zero. This can be easily seen from Fig. 2b in which the maximum signal energy occurs at $t = T = 2$, and the maximum value is close to the expectation of $E_s = 0.18$ in this experiment. A detailed analysis of the matched filter will be given in Section 2.

Equation (7) describes the output of the matched filter as the cross-correlation between the received signal and a replica of the transmitted signal. This implies that the matched filter can be replaced by a cross-correlation that performs the same mathematical operation, as shown in Fig. 4. The received signal is multiplied by a delayed replica of the transmitted signal $s(t - t_1)$, and the product is passed through a lowpass filter. The cross-correlation

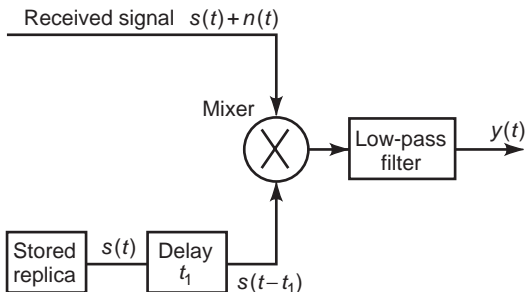

Figure 4. Block diagram of a cross-correlation, which is another implementation of the matched filter.

tests for the presence of a target at only one time: t_1 . Targets at other time delays, or ranges, may be found by varying t_1 . However, this requires a longer search time. The search time can be reduced by adding parallel channels, each containing a delay line corresponding to a particular value of t_1 , as well as a multiplier and a lowpass filter.

Since the cross-correlation and the matched filter are equivalent mathematically, the choice of which one to use in a particular radar application is determined by the practicality of implementation. The matched filter, or an approximation, has been generally preferred in the vast majority of applications.

1.2. Decision Criteria for Radar Signal Detection

The statistical detection problem consists of examining the received radar waveform $r(t)$ in a resolution cell to determine which of the following two hypotheses is true. The first hypothesis H_1 asserts that a target is present, and the received signal contains the target signature and noise. The second hypothesis H_0 states that the target is absent and only noise is present in the received signal. The problem can be compactly stated as

$$H_1: r(t) = s(t) + n(t) \tag{9}$$

$$H_0: r(t) = n(t)$$

The conditional probability density function completely describes the received signal statistically in both cases:

$$\begin{aligned}
 p(r|H_1) &= \text{conditional probability density function with} \\
 &\quad \text{target present}
 \end{aligned}
 \tag{10}$$

$$\begin{aligned}
 p(r|H_0) &= \text{conditional probability density function with} \\
 &\quad \text{target absent}
 \end{aligned}$$

For reasons of simplicity, r is assumed to be a single sampled point of the received radar signal. The extension from a single sampled point to multiple sampled points is straightforward. The likelihood ratio is defined as

$$\Lambda(r) = \frac{p(r|H_1)}{p(r|H_0)} \tag{11}$$

The likelihood ratio $\Lambda(r)$ is also called the likelihood statistic. It is a random variable since it is a function of the random variable r . The *maximum likelihood (ML) decision criterion*, which chooses the hypothesis that most likely causes the observed signal, is

$$\begin{aligned}
 &H_1 \\
 \Lambda(r) &\geq 1 \\
 &H_0
 \end{aligned}
 \tag{12}$$

This expression means that H_1 is selected if $\Lambda(r)$ is greater than 1; otherwise H_0 is selected. It can be seen that the ML criterion is a very simple decision criterion.

To describe the detection performance better, the probabilities of detection and false alarm are used in radar detection. The probability of detection refers to the probability of asserting the presence of a target when the target is indeed present

$$P_d = \int_{R_0}^{\infty} p(r|H_1) dr \quad (13)$$

where R_0 is the decision boundary. The proper value of the boundary R_0 depends on the criterion of decision. The probability of false alarm is the probability of asserting the presence of a target when the target is actually absent:

$$P_{fa} = \int_{R_0}^{\infty} p(r|H_0) dr \quad (14)$$

A sketch of the two density functions is shown in Fig. 5, where P_d and P_{fa} are, respectively, shown by the vertically and the horizontally hatched areas. If the observed value r is large, we would be confident in picking H_1 . If r is small, we would pick H_0 , as shown in Fig. 5.

Obviously, a decision rule should be selected to maximize P_d while restricting the P_{fa} . The simplest rule in this class, which is extensively used in radar detection, is the *Neyman–Pearson criterion*. This criterion specifies a decision boundary that maximizes the probability of detection (P_d) while maintaining a fixed probability of false alarm P_{fa} . The detection problem under the Neyman–Pearson criterion can be formulated as follows:

$$\text{Maximum: } P_d = \int_{R_0}^{\infty} p(r|H_1) dr \quad (15)$$

$$\text{Under constraint: } P_{fa} = \int_{R_0}^{\infty} p(r|H_0) dr = \alpha$$

The optimum decision region can be found by using the calculus of extrema and forming the objective function

$$J = P_d + \eta(\alpha - P_{fa}) \quad (16)$$

where η is a Lagrange multiplier. This can be written as

$$J = \eta\alpha + \int_{R_0}^{\infty} [p(r|H_1) - \eta p(r|H_0)] dr \quad (17)$$

Figure 5. Probability of false alarm P_{fa} and probability of detection P_d , which are function of the threshold R_0 .

The integration interval in Eq. (17) is related to choosing the hypothesis H_1 , as illustrated in Fig. 5. It is clear that J and hence P_d are maximized by choosing the hypothesis H_1 when

$$p(r|H_1) - \eta p(r|H_0) > 0 \quad (18)$$

and by choosing the hypothesis H_0 when

$$p(r|H_1) - \eta p(r|H_0) < 0 \quad (19)$$

To this end, the decision rule based on the Neyman–Pearson criterion is

$$\begin{aligned} &H_1 \\ \Lambda(r) &\geq \eta \\ &H_0 \end{aligned} \quad (20)$$

and η is determined by the required false-alarm probability α . In radar detection, the choice of α is based on operational considerations, that is, the need to keep the false-alarm rate within acceptable bounds (e.g., a few false alarms per second). A typical value of α for radar detection is 10^{-6} .

Other popular criteria are the *Bayes criterion* and the *minimum error probability (MEP) criterion*. The Bayes criterion minimizes the average cost of the decision. Symbols denoted by C_{00} , C_{01} , C_{10} , and C_{11} represent the costs for a correct miss (no target is declared when no target is present), a false dismissal (no target is declared when a target is present), a false alarm, and a correct detection, respectively. Also denoted are the a priori probabilities $P(H_0)$ and $P(H_1)$ by P_0 and P_1 , respectively. The Bayes rule makes the likelihood ratio test

$$\begin{aligned} &H_1 \\ \Lambda(r) &\geq \eta \\ &H_0 \end{aligned} \quad (21)$$

where $\eta = [P_0(C_{10} - C_{00})]/[P_1(C_{01} - C_{11})]$. If we select the cost of an error to be 1 and the cost of a correct decision to be 0, $C_{01} = C_{10} = 1$, and $C_{00} = C_{11} = 0$. In this case, minimizing the average cost is equivalent to minimizing the probability of error. Therefore, the MEP rule is the same as expression Eq. (21), but with $\eta = P_0/P_1$. If the a priori probabilities are equal, that is, $P_0 = P_1$, the MEP rule coincides with the ML rule with $\eta = 1$.

1.3. Implementation of Decision Criteria

Let us suppose that the observed signal r has the following Gaussian distribution conditional probability density functions

$$p(r|H_0) = \frac{1}{\sqrt{2\pi}\sigma} e^{-r^2/(2\sigma^2)} \quad (22)$$

$$p(r|H_1) = \frac{1}{\sqrt{2\pi}\sigma} e^{-(r-\mu)^2/(2\sigma^2)} \quad (23)$$

where μ denotes the mean of the received signal value and σ^2 represents the noise variance. The likelihood ratio

test is therefore

$$\Lambda(r) = \frac{e^{(r-\mu)^2/(2\sigma^2)} H_1}{e^{r^2/(2\sigma^2)} H_0} \geq \eta \quad (24)$$

After taking the logarithm of both sides, the criterion becomes

$$R_0 \geq \frac{\sigma^2}{\mu} \ln \eta + \frac{\mu}{2} \quad (25)$$

In Eq. (25) it is seen that the likelihood ratio test, in which $\Lambda(r)$ of Eq. (24) is compared with a threshold η , is transformed into a comparison of the observable r with the threshold in Eq. (25), which is a function of η . As an example, supposing $P(H_0)$ and $P(H_1)$ are known, with $P(H_0)/P(H_1) = 2$, then the decision rules are choose H_1 if

For the maximum likelihood ($\eta = 1$): $R_0 > \frac{\mu}{2}$ (26)

For the minimum error probability ($\eta = 2$): $R_0 > \frac{\mu}{2} + \frac{\sigma^2 \ln 2}{\mu}$ (27)

Since the a priori probability of H_0 is twice that of H_1 , the MEP rule requires a larger value of R_0 for the selection of H_0 than the ML, in which this information is not used. The MEP scheme therefore yields a better decision rule in this case.

For a Neyman–Pearson criterion, suppose a value of $P_{fa} = 10^{-4}$ can be tolerated. The threshold η is determined from

$$P_{fa} = 10^{-4} = \int_{R_0}^{\infty} \frac{1}{\sqrt{2\pi}\sigma} e^{-x^2/(2\sigma^2)} dx \quad (28)$$

to be $\eta = 3.72 \sigma$. So H_1 is chosen if for the Neyman–Pearson rule ($P_{fa} = 10^{-4}$),

$$R_0 > 3.72\sigma \quad (29)$$

A typical illustration of these thresholds for this example’s three decision criteria is given in Fig. 6. An important observation is that these criteria employ the likelihood ratio test. In other words, the test is performed by simply processing the received data to yield the likelihood ratio and then comparing it with the threshold, which depends upon the criterion used. Thus, in practical situations where the a priori probabilities and the cost may vary, only the threshold changes, and the computation of the likelihood ratio is not affected.

As observed previously, in radar detection it is very hard to define the Bayes cost C_{ij} ; moreover, it is also practically impossible to define or evaluate the a priori probabilities P_0 and P_1 , that is, the probabilities that, in a given resolution interval, a target is present or absent. These are the main reason why the Bayes and minimum error probability criteria cannot be used in radar detection. In contrast, for the same reason, the Neyman–Pearson

Figure 6. Decision thresholds for different decision criteria.

criterion is particularly well suited to radar detection, owing to its concept of the “ P_{fa} threshold” fixed a priori, while P_d is maximized.

1.4. Receiver Operating Characteristic

A graph showing the probability of detection, P_d , versus the probability of false alarm, P_{fa} , with the threshold as a parameter is referred to as a receiver operating characteristic (ROC) curve. We note that the ROC depends on the conditional density function of the observed signal under each hypothesis, that is, $p(r|H_i)$, $i = 0,1$, and not on the assigned costs, or a priori probabilities.

Suppose that the observed signal r has the probability density functions of Eqs. (22) and (23). Varying the threshold R_0 , P_d of Eq. (13), and P_{fa} of Eq. (14) produces the corresponding ROC curves for $\sigma = 1$ and $\mu = 1,2,3$ as shown in Fig. 7.

The two extreme points on the ROC for $P_{fa} = P_d = 1$ and $P_{fa} = P_d = 0$ are easily verified. P_d of Eq. (13) may be rewritten as a function of the likelihood ratio $\Lambda(r)$ as

$$P_d = \int_{\eta}^{\infty} p_{\Lambda}(\lambda|H_1) d\lambda \quad (30)$$

where η is threshold of the likelihood ratio just as R_0 is the threshold of the observed signal, and $p_{\Lambda}(\lambda|H_1)$ in Eq. (30) is the conditional probability density function of the variable Λ . Similarly, P_{fa} of Eq. (14) is rewritten as

$$P_{fa} = \int_{\eta}^{\infty} p_{\Lambda}(\lambda|H_0) d\lambda \quad (31)$$

Figure 7. ROC curves for different values of μ .

Since Λ is a ratio of two nonnegative quantities, it takes on values from 0 to ∞ . When the threshold η is 0, the hypothesis H_1 is always true and thus $P_{fa} = P_d = 1$. When the threshold η is ∞ , the hypothesis H_0 is always true and thus $P_{fa} = P_d = 0$. These are clearly depicted in Fig. 7.

Of course, ROC curves may be drawn for any hypothesis test involving a threshold, but the ROC curves have particularly useful properties for the likelihood ratio test. One is the fact that the slope of the ROC at a particular point on the curve represents the threshold value of the likelihood ratio η . Taking the derivative of Eqs. (30) and (31) with respect to η we have

$$\frac{dP_d}{d\eta} = -p_{\Lambda}(\eta|H_1) \quad (32)$$

and

$$\frac{dP_{fa}}{d\eta} = -p_{\Lambda}(\eta|H_0) \quad (33)$$

Also,

$$\begin{aligned} P_d &= \int_{R_0}^{\infty} \Lambda(r)p(r|H_0) dr \\ &= \int_{\eta}^{\infty} \lambda p_{\Lambda}(\lambda|H_0) d\lambda \end{aligned} \quad (34)$$

Taking the derivative of Eq. (34) with respect to η , we obtain

$$\frac{dP_d}{d\eta} = -\eta p_{\Lambda}(\eta|H_0) \quad (35)$$

Combining Eqs. (32), (33), and (35), the slope of the ROC curve obtained is

$$\frac{dP_d}{dP_{fa}} = \frac{p_{\Lambda}(\eta|H_1)}{p_{\Lambda}(\eta|H_0)} = \eta \quad (36)$$

In the Neyman–Pearson criterion, the slope of the ROC curve at a particular point represents the likelihood ratio threshold η of achieving P_d and P_{fa} at that point. In the Bayes criterion, the threshold η is determined by a priori probabilities and the costs. Consequently, P_d and P_{fa} are determined on the point of the ROC at which the tangent has a slope of η .

Since the ROC curves are always concave and facing downward, it is possible to determine an “optimum” value (the knee) for P_{fa} , such that a small decrease of its value causes a fast decrease of P_d , while any increase has a very small effect (the saturation zone, where the rate of change is nearly 0.)

Finally, we note that the most important part of the ROC curve is the upper left-hand (northwest) corner. This is the so-called high-performance corner, where a high-detection probability occurs with a low false-alarm probability. This part of the plot could be stretched out by the use of appropriate (such as logarithmic) scales.

2. ANALYSIS OF A MATCHED FILTER

2.1. Derivation of the Matched Filter

The matched filter achieves the maximum output SNR, which is

$$\frac{S}{N} = \frac{\text{(maximum instantaneous output signal power)}}{\text{(output noise power)}} \quad (37)$$

Consider a signal $s(t)$ with the spectrum $S(f)$ and finite energy

$$E_s = \int_{-\infty}^{\infty} |s(t)|^2 dt = \int_{-\infty}^{\infty} |S(f)|^2 df \quad (38)$$

For the input signal $s(t)$ and the filter with transfer function $H(f)$, the instantaneous power of the output signal $y(t)$ is

$$|y(t)|^2 = \left| \int_{-\infty}^{\infty} S(f)H(f)e^{j2\pi ft} df \right|^2 \quad (39)$$

For white noise with a two-sided noise power spectral density $N_0/2$, the output power spectral density is $|H(f)|^2 N_0/2$. Therefore, the noise power at the filter output is

$$\sigma^2 = \frac{N_0}{2} \int_{-\infty}^{\infty} |H(f)|^2 df \quad (40)$$

Using Eqs. (39) and (40) in Eq. (37) leads to the following

$$\frac{S}{N} = \frac{\left| \int_{-\infty}^{\infty} S(f)H(f)e^{j2\pi fT} df \right|^2}{(N_0/2) \int_{-\infty}^{\infty} |H(f)|^2 df} \quad (41)$$

where T denotes the time at which the maximum value of $|y(t)|^2$ occurs.

Using Schwarz' inequality

$$\left| \int_{-\infty}^{\infty} f(x)g(x) dx \right|^2 \leq \int_{-\infty}^{\infty} |f(x)|^2 dx \int_{-\infty}^{\infty} |g(x)|^2 dx \quad (42)$$

we obtain

$$\frac{S}{N} \leq \frac{\int_{-\infty}^{\infty} |S(f)|^2 df \int_{-\infty}^{\infty} |H(f)|^2 df}{(N_0/2) \int_{-\infty}^{\infty} |H(f)|^2 df} \quad (43)$$

It follows that the signal-to-noise ratio will be a maximum when

$$H(f) = kS^*(f)e^{-j2\pi fT} \quad (44)$$

yielding the requirement of the matched filter. From discussions above it is evident that the maximum

signal-to-noise ratio can be expressed as

$$\text{SNR}|_{\max} = \frac{2E_s}{N_0} \tag{45}$$

Equation (45) indicates that the detection capability of a particular signal depends only on its energy content, and not on the time structure of the signal. However, it is necessary to process the signal through a matched filter to obtain this condition in practice. We note that E_s/N_0 is defined as the input SNR, and it is clear from Eq. (45) that the maximum output SNR for the matched filter is twice that of the input SNR if the noise is white.

In general case, when the noise is nonwhite (colored noise), the derivation of the matched filter can be carried out in a similar way. If the power spectral density of the nonwhite noise is $N(f)$, then Eq. (40) is written as

$$\sigma^2 = \int_{-\infty}^{\infty} N(f)|H(f)|^2 df \tag{46}$$

Therefore, by multiplying and dividing the integrand of the numerator of Eq. (41) by $\sqrt{N(f)}$ and using Eq. (46)

$$\begin{aligned} \frac{S}{N} &= \frac{\left| \int_{-\infty}^{\infty} \frac{S(f)}{\sqrt{N(f)}} H(f) \sqrt{N(f)} e^{j2\pi fT} df \right|^2}{\int_{-\infty}^{\infty} N(f) |H(f)|^2 df} \\ &\leq \frac{\int_{-\infty}^{\infty} |S(f)|^2 / N(f) df \int_{-\infty}^{\infty} |H(f)|^2 / N(f) df}{\int_{-\infty}^{\infty} |H(f)|^2 N(f) df} \\ &= \int_{-\infty}^{\infty} |S(f)|^2 / N(f) df \end{aligned} \tag{47}$$

and the maximum is achieved when

$$H(f) = \frac{kS^*(f)e^{-j2\pi fT}}{N(f)} \tag{48}$$

The conjugate is not needed in the denominator because $N(f)$ is always real (and nonnegative). If the noise is white—that is, if $N(f)$ is a constant over the band of $H(f)$ —then Eq. (48) is the same as Eq. (44) for the white noise. The matched filter for nonwhite noise can be interpreted as the cascade of two filters. The first one, whose transfer function is $1/\sqrt{N(f)}$, is the “whitening” filter. This filter makes the noise spectrum flat (white). The second one is matched to the signal filtered by the whitening filter, that is, to the whitening signal with the spectrum $S(f)/\sqrt{N(f)}$.

We note that it is not necessary that the noise be Gaussian for Eq. (45) to hold, but only that its power spectral density be flat over the frequency band of interest. To summarize, the matched filter maximizes the output SNR over all probability densities, provided the power spectral density (PSD) is a constant. In the event that the noise PSD is nonwhite (colored noise), the matched

impulse response corresponds to the modified signal spectrum $S^*(f)e^{-j2\pi fT}/\sqrt{N(f)}$ rather than simply $S^*(f)e^{-j2\pi fT}$.

2.2. Justification of the Signal-to-Noise Ratio Criterion

We derived the matched filter under the criterion of maximizing the output SNR. We remark here that the matched filter can also be derived under the likelihood ratio criterion [1]. In this section, we want to justify the maximum output SNR criterion, and more specifically derive the relationship between the output SNR and the system performance in terms of the probability of error.

The total probability of error for a radar receiver consists of the false-alarm probability P_{fa} and the false-dismissal probability P_{fd} . A false dismissal declares no target when a target is present:

$$P_{fd} = \int_{-\infty}^{R_0} p(r|H_1) dr \tag{49}$$

For equal a priori probabilities $P(H_0) = P(H_1) = \frac{1}{2}$, the total probability of error is

$$\begin{aligned} P_e &= \frac{1}{2}(P_{fd} + P_{fa}) \\ &= \frac{1}{2} + \frac{1}{2} \int_{-\infty}^{R_0} [p(r|H_1) - p(r|H_0)] dr \end{aligned} \tag{50}$$

Supposing $p(r|H_i)$, $i = 0,1$ is a Gaussian distribution that is given by Eqs. (22) and (23), P_e can be expressed as

$$\begin{aligned} P_e &= \frac{1}{2} - \frac{1}{2} \left(\frac{1}{\sqrt{\pi}} \int^{(\mu-R_0)/\sqrt{2\sigma}} e^{-r^2} dr + \frac{1}{\sqrt{\pi}} \int_0^{R_0/\sqrt{2\sigma}} e^{-r^2} dr \right) \\ &= \frac{1}{2} - \frac{1}{4} \left[\text{erf} \left(\frac{\mu - R_0}{\sqrt{2\sigma}} \right) + \text{erf} \left(\frac{R_0}{\sqrt{2\sigma}} \right) \right] \end{aligned} \tag{51}$$

where

$$\text{erf}(x) = \frac{2}{\pi} \int_0^x e^{-r^2} dr \tag{52}$$

is the error function. The minimum of P_e occurs when $R_0 = \mu/2$, and

$$P_e|_{\min} = \frac{1}{2} \text{erfc} \left(\frac{\mu/2}{\sqrt{2\sigma}} \right) \tag{53}$$

where

$$\text{erfc}(x) = 1 - \text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_x^{\infty} e^{-r^2} dr \tag{54}$$

is the complementary error function. Recalling that μ is the expectation of the matched filter output at time T under the H_1 hypothesis

$$\mu = E[y(T)|H_1] = E \left[\int_0^T [s(\tau) + n(\tau)]s(\tau) d\tau \right] = E_s \tag{55}$$

and

$$E[y(T)|H_0] = E\left[\int_0^T n(\tau)s(\tau) d\tau\right] = 0 \quad (56)$$

Defining σ^2 to be the variance of $y(T)$ under the H_0 or H_1 hypotheses, it is given that

$$\begin{aligned} \sigma^2 &= \text{Var}[y(T)|H_1] = \text{Var}[y(T)|H_0] \\ &= \int_0^T \int_0^T E[n(t)n(\tau)]s(t)s(\tau) dt d\tau \\ &= \frac{N_0}{2} \int_0^T \int_0^T \delta(t-\tau)s(t)s(\tau) dt d\tau \\ &= \frac{1}{2} E_s N_0 \end{aligned} \quad (57)$$

The application of Eqs. (55) and (57) to Eq. (53) leads to the following minimum probability of error:

$$\begin{aligned} P_{e|\min} &= \frac{1}{2} \text{erfc}\left(\sqrt{\frac{E_s}{4N_0}}\right) \\ &= \frac{1}{2} \text{erfc}\left(\sqrt{\frac{\text{SNR}|_{\max}}{8}}\right) \end{aligned} \quad (58)$$

It is clear from Eq. (58) that $P_{e|\min}$ is inversely proportional to $\text{SNR}|_{\max}$, because $\text{erfc}(x)$ is a monotonic decreasing function. In other words, a lower probability of error means a higher output SNR, and requires a higher input SNR. Figure 8 shows the relationship between $P_{e|\min}$ and $\text{SNR}|_{\max}$. This curve should be shifted to the left by 3 dB if it is plotted with respect to the input SNR, since $\text{SNR}|_{\max}$ is twice the input SNR. For example, a 10^{-5} error probability corresponds to an output SNR of 18.6 dB, and 15.6 dB of input SNR is required. Therefore, it is justifiable to use the signal-to-noise ratio criterion in radar detection.

Figure 8. Minimum error probability $P_{e|\min}$ versus maximum output signal-to-noise ratio $\text{SNR}|_{\max}$.

3. NONCOHERENT DETECTIONS

A received radar signal is a *bandpass* random process because it is modulated on a carrier. Radar detection is classified into coherent and noncoherent detections depending upon whether the carrier phase at the receiver is available. Specifically, the matched filter and the cross-correlation discussed previously are coherent because they require the knowledge of the carrier phase. The envelope and all the other nonlinear detections are noncoherent due to their ignorance of the phase information in the received signal. To understand the nonlinear detections, we introduce the representations of bandpass signals and bandpass processes.

3.1. Representation of Bandpass Signals

The concept of a bandpass signal is a generalization of the concept of monochromatic signals. A bandpass signal is a signal $x(t)$ whose spectrum $X(f)$ is nonzero for frequencies in a usually small neighborhood of some high frequency f_0 , that is

$$X(f) = 0 \text{ for } |f - f_0| \geq W \quad (59)$$

where the frequency f_0 is referred to as the central frequency (carrier frequency) of the bandpass signal. A radar signal that is modulated on a carrier is a bandpass signal. It is assumed that the bandpass signal is real-valued. Figure 9a illustrates the spectrum of a bandpass

Figure 9. (a) Amplitude spectrum of a bandpass signal $x(t)$; (b) amplitude spectrum of pre-envelope $x_+(t)$; (c) amplitude spectrum of complex envelope $\tilde{x}(t)$. The spectrum of $x_+(t)$ is twice the positive spectrum of $x(t)$, and the spectrum $\tilde{x}(t)$ is a lowpass version of that $x_+(t)$.

signal $x(t)$. A real-valued bandpass signal $x(t)$ can be represented as the real part of a complex signal $x_+(t)$, called the *preenvelope* or *analytic signal* of $x(t)$, where

$$x_+(t) = x(t) + j\hat{x}(t) \tag{60}$$

and

$$\hat{x}(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} d\tau \tag{61}$$

is the Hilbert transform of $x(t)$. The spectrum of the preenvelope signal is readily found from the Fourier transform of Eq. (60) to be

$$X_+(f) = X(f) + X(f) \operatorname{sgn}(f) = \begin{cases} 2X(f), & f > 0 \\ X(0), & f = 0 \\ 0, & f \leq 0 \end{cases} \tag{62}$$

The spectrum of the preenvelope signal is obtained by deleting the negative frequencies from $X(f)$ and multiplying the positive frequencies in $X(f)$ by 2, as illustrated in Fig. 9b.

The spectrum of the *complex envelope* is obtained by shifting $X_+(f)$ to the left by f_0 , that is

$$\tilde{X}(f) = X_+(f + f_0) \tag{63}$$

and

$$\tilde{x}(t) = x_+(t) e^{-j2\pi f_0 t} \tag{64}$$

The amplitude spectrum of $\tilde{x}(t)$ is illustrated in Fig. 9c.

It is clear that $\tilde{x}(t)$ is a lowpass signal, meaning that its frequency components are located around the zero frequency. $\tilde{x}(t)$ is the lowpass representation of the bandpass signal $x(t)$. In general, $\tilde{x}(t)$ is a complex signal having $x_c(t)$ and $x_s(t)$ as its real and imaginary parts

$$\tilde{x}(t) = x_c(t) + jx_s(t) \tag{65}$$

where $x_c(t)$ and $x_s(t)$ are lowpass signals, respectively, and are called the *in-phase* and *quadrature* components of the bandpass signal $x(t)$. Notice that $x(t)$ is the real part

of $x_+(t)$. Using Eq. (65), we obtain

$$x(t) = \operatorname{Re} [\tilde{x}(t) e^{j2\pi f_0 t}] \tag{66} = x_c(t) \cos(2\pi f_0 t) - x_s(t) \sin(2\pi f_0 t)$$

This is the *canonical representation* for a bandpass signal in terms of the in-phase component $x_c(t)$ and quadrature component $x_s(t)$ of the complex envelope associated with the signal.

The complex envelop can be employed to find the outputs of bandpass systems driven by bandpass signals. Accordingly, by analyzing the complex envelope representation of a bandpass signal, we may develop the complex lowpass representation of the bandpass system by retaining the positive-frequency half of the transfer function $H(f)$, and shift it to the left by f_0 . Let $\tilde{H}(f)$ denote the transfer function of the complex lowpass system so defined. The analysis of the bandpass system with transfer function $H(f)$ driven by the bandpass signal with spectrum $X(f)$, as depicted in Fig. 10a, is replaced by an equivalent but simpler analysis of a complex lowpass system with transfer function $\tilde{H}(f)$ driven by a complex lowpass input with spectrum $\tilde{X}(f)$, as shown in Fig. 10b. The complex lowpass output $\tilde{y}(t)$ is obtained from the inverse Fourier transform of $\tilde{Y}(f)$. Having determined $\tilde{y}(t)$, we may find the desired bandpass output $y(t)$ simply by using the relation

$$y(t) = \operatorname{Re} [\tilde{y}(t) e^{j2\pi f_0 t}] \tag{67}$$

The bandpass to lowpass transformation is also true for bandpass random processes. $X(t)$ is a bandpass process if its power spectral density $S_x(f) = 0$ for $|f - f_0| \geq W$. $X(t)$ can be represented by its in-phase component $X_c(t)$ and quadrature component $X_s(t)$ in the same way that a bandpass signal does. Specifically

$$X(t) = X_c(t) \cos(2\pi f_0 t) - X_s(t) \sin(2\pi f_0 t) \tag{68}$$

where $X_c(t)$ and $X_s(t)$ are two lowpass processes representing the real and imaginary parts of the complex envelope process $\tilde{X}(t)$ respectively. $X(t)$ can be found from the complex envelope process $\tilde{X}(t)$ by

$$X(t) = \operatorname{Re} [\tilde{X}(t) e^{j2\pi f_0 t}] \tag{69}$$

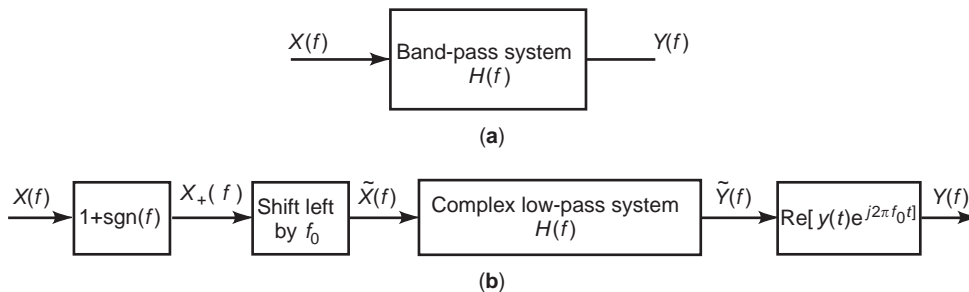

Figure 10. (a) Bandpass description and (b) complex envelope description of a system. Complex envelope description simplifies the analysis of a bandpass signal.

3.2. Envelope Detection and Square-Law Detection

The matched filter is the optimal detection for an exactly known signal (i.e., phase, amplitude, and Doppler frequency are known) in a background of white noise. However, both the matched filter and the cross-correlation need to generate a synchronous reference, which is difficult to realize. In a typical radar application, the range between the target and the radar represents a very large number of transmitted signal wavelengths. This makes specifying the phase of the return signal extremely difficult, and we usually assume that the signal phase of the return signal is a random variable uniformly distributed over an angle of 2π rad. The matched-filter detection is often used to set a standard of performance, as it represents the optimal detection when all signal parameters are exactly known.

The synchronization problem in the matched-filter detection is obviated in a practical system by employing an envelope detection. The envelope $V(t)$ of a bandpass signal $x(t)$ is given by

$$V(t) = \sqrt{x_s^2(t) + x_c^2(t)} \quad (70)$$

The complex envelope $\tilde{x}(t)$ can be represented more compactly as

$$\tilde{x}(t) = V(t)e^{j\theta(t)} \quad (71)$$

where

$$\theta(t) = \arctan \frac{x_s(t)}{x_c(t)} \quad (72)$$

The procedure for obtaining the envelope is shown in Fig. 11, which is the extraction of the in-phase and quadrature components and the derivation of the envelope from them. Specifically, the multiplication of $x(t)$ by $2 \cos(2\pi f_0 t)$ in the in-phase channel yields

$$\begin{aligned} 2x(t) \cos(2\pi f_0 t) &= 2 \cos(2\pi f_0 t) [x_c(t) \cos(2\pi f_0 t) \\ &\quad - x_s(t) \sin(2\pi f_0 t)] \\ &= x_c(t) + x_c(t) \cos(4\pi f_0 t) \\ &\quad - x_s(t) \sin(4\pi f_0 t) \end{aligned} \quad (73)$$

The mixing operation produces two images besides the expected lowpass component. The product $2x(t) \cos(2\pi f_0 t)$ is passed through an ideal lowpass filter (the integrator in Fig. 11), which rejects the images and leaves $x_c(t)$. Similar operations in the quadrature channel produce $x_s(t)$. The square sum of the quadrature components yields the envelope $V(t)$.

Removing the square-root operation from Fig. 11 yields the square-law detection. A detailed performance analysis of these detections is given in Section 4.

The envelop can be extracted alternatively by passing the bandpass signal $x(t)$ through a rectified and a lowpass filter, as illustrated in Fig. 12. Such a description can

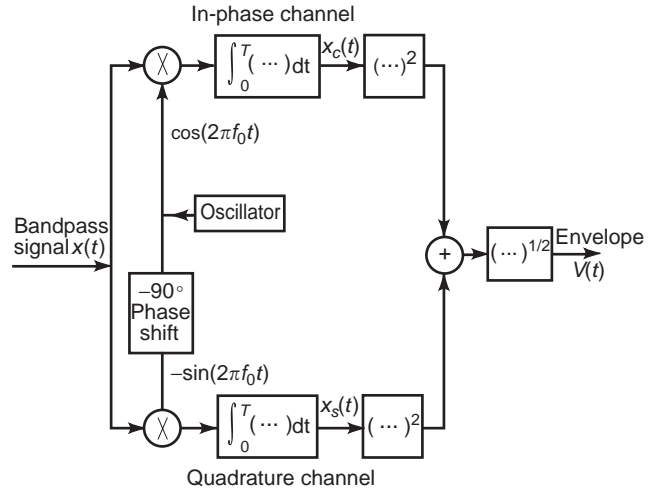

Figure 11. Block diagram of the envelope detection.

sometimes simplify the analysis and is easier to implement physically because the various rectifiers are readily available from the diodes and the transistors. The output of the full-wave linear rectifier is proportional to the magnitude of its input, while the output of the full-wave square-law (quadratic) rectifier is proportional to the squared magnitude of its input. The half-wave rectifier, of course, gives only the positive portion of its input. Fig. 13 shows these transfer characteristics. Referring to Fig. 12, we may write

$$V(t) = \text{Env}[x(t)] = \text{LF}[|x(t)|] \quad (74)$$

where LF indicates the low-frequency portion. Also, considering the full-wave quadratic rectifier in place of the full-wave linear rectifier, we may write

$$V^2(t) = \text{LF}[x^2(t)] \quad (75)$$

The band-pass signal $x(t)$ in Eqs. (74) and (75) has the following form:

$$x(t) = V(t) \cos[2\pi f_0 t + \theta(t)] \quad (76)$$

Then in the case of the square-law rectifier, we have

$$\begin{aligned} x^2(t) &= V^2(t) \cos^2[2\pi f_0 t + \theta(t)] \\ &= \frac{1}{2} V^2(t) + \frac{1}{2} V^2(t) \cos[4\pi f_0 t + 2\theta(t)] \end{aligned} \quad (77)$$

Since the envelope $V(t)$ is slowly varying compared to the carrier frequency f_0 , the first term in Eq. (77) is concentrated around zero frequency. The fact that the term is the square of the envelop means that the bandwidth will be somewhat greater than that of $V(t)$. The second term in Eq. (77) will be concentrated around $2f_0$ with a bandwidth

Figure 12. Envelope detection with a linear rectifier.

that depends on both the envelop square $V^2(t)$ and the phase modulation $\theta(t)$. In most cases of interest, the bandwidth of the total modulation will be small enough compared to f_0 so that the lowpass filter following the rectifier will easily separate the low-frequency portion of Eq. (77).

In the case of the full-wave linear rectifier, we may write

$$\begin{aligned}
 |x(t)| &= V(t) |\cos[2\pi f_0 t + \theta(t)]| \\
 &\approx \frac{2V(t)}{\pi} \left\{ 1 + \frac{2}{3} \cos[4\pi f_0 t + 2\theta(t)] \right. \\
 &\quad \left. - \frac{2}{15} \cos[8\pi f_0 t + 4\theta(t)] + \dots \right\}
 \end{aligned}
 \tag{78}$$

The lowpass filter will remove all of the terms in the curly bracket except for the first term. Thus, if the bandwidth of $V(t)$ is not too large, a very good approximation of the envelope can be obtained. A similar analysis can be carried out to show that the half-wave linear and the half-wave quadratic rectifiers extract the envelope $V(t)$.

We note that the envelope detection is referred to as a linear detection, due to its transfer characteristic stipulating that the output is proportional to the input when the input is positive, as illustrated in Fig. 13a. The operation of the envelope detection, however, is of course highly nonlinear, and as a result the output consists of a DC term proportional to the envelope, plus an infinite number of harmonics of the input at $2f_0$, $4f_0$, and so on. It is for this reason that the envelope detection must be passed through a lowpass filter, thus eliminating the unwanted harmonics. Similar comments apply to the square-law detection.

3.3. Justification of the Noncoherent Detections

The justification of the envelope and the square-law detections by the likelihood ratio criterion is given in

Figure 13. Various rectifier characteristics for (a) full-wave linear rectifier, (b) half-wave linear rectifier, (c) full-wave square-law (quadratic) rectifier, and (d) half-wave square-law (quadrature) rectifier.

this subsection. The radar detection process may include downconversion of the carrier frequency to a more manageable intermediate frequency (IF). This step, however, is irrelevant to the results we are going to obtain and is therefore omitted. Consider the signal to be a carrier pulse of the form

$$s(t) = \begin{cases} A \cos(2\pi f_0 t + \theta), & 0 \leq t \leq T \\ 0, & \text{otherwise} \end{cases}
 \tag{79}$$

The two hypotheses are

$$\begin{aligned}
 H_1 : r(t) &= s(t) + n(t) = A \cos(2\pi f_0 t + \theta) + n(t) \\
 H_0 : r(t) &= n(t)
 \end{aligned}
 \tag{80}$$

for $0 \leq t \leq T$, and $n(t)$ is a Gaussian white-noise process with two-sided spectral density $N_0/2$.

The detection problem described by Eq. (79) consists of examining the received waveform $r(t)$ and determining whether it consists of a signal plus noise or noise alone. The optimal detection, as described previously, forms the likelihood ratio which is compared against a threshold.

The sampling bandwidth B , which is the reciprocal of the sampling interval, must be sufficiently large to pass along essentially all of the signal energy, which will be the case if $B \geq 1/T$. In this case, by the sampling theorem we know that the number of samples k is given by $k = 2BT$. Given these conditions, the likelihood ratio can be written as

$$\begin{aligned}
 \Lambda(r) &= \frac{\exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^{2BT} [r(t_i) - s(t_i)]^2\right)}{\exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^{2BT} r^2(t_i)\right)} \\
 &= \exp\left(\frac{1}{2\sigma^2} \sum_{i=1}^{2BT} [2r(t_i)s(t_i) - s^2(t_i)]\right)
 \end{aligned}
 \tag{81}$$

where the noise variance σ^2 is $(N_0/2)2B = N_0B$. Recall from the sampling theorem [2,3] that for any two band-limited functions $u(t)$ and $v(t)$ we can write

$$\begin{aligned}
 &\int_{-\infty}^{\infty} u(t)v(t) dt \\
 &= \sum_n \sum_m u\left(\frac{n}{2B}\right)v\left(\frac{m}{2B}\right) \int_{-\infty}^{\infty} \frac{\sin 2\pi B(t - n/2B)}{2\pi B(t - n/2B)} \\
 &\quad \frac{\sin 2\pi B(t - m/2B)}{2\pi B(t - m/2B)} dt \\
 &= \frac{1}{2B} \sum_{n=-\infty}^{\infty} u\left(\frac{n}{2B}\right)v\left(\frac{n}{2B}\right)
 \end{aligned}
 \tag{82}$$

Applying this to Eq. (81), we have

$$\begin{aligned}\Lambda(r) &= \exp\left(\frac{1}{N_0} \int_0^T [2r(t)s(t) - s^2(t)] dt\right) \\ &= \exp\left(\frac{1}{N_0} \int_0^T [2r(t)A \cos(2\pi f_0 t + \theta) \right. \\ &\quad \left. - A^2 \cos^2(2\pi f_0 t + \theta)] dt\right)\end{aligned}\quad (83)$$

Because the signal is of finite duration, the approximation in passing from the discrete to the continuous representation improves as B is allowed to become very large.

In the noncoherent case, θ in Eq. (83) is unknown. Since no auxiliary information about θ is available, it is reasonable to assume θ to be uniformly distributed over 2π rad. An average likelihood ratio is

$$\begin{aligned}\Lambda(r)_{\text{av}} &= \int_0^{2\pi} \Lambda(r)p(\theta) d\theta \\ &= \frac{\exp(-A^2 T/2N_0)}{2\pi} \int_0^{2\pi} \\ &\quad \left[\exp\left(-\frac{2A}{N_0} \int_0^T r(t) \cos(2\pi f_0 t + \theta) dt\right) \right]\end{aligned}\quad (84)$$

The exponent in the integrand can be written as

$$\begin{aligned}-\frac{2A}{N_0} \int_0^T r(t) \cos(2\pi f_0 t + \theta) dt \\ = -\frac{2A}{N_0} X_c \cos \theta + \frac{2A}{N_0} X_s \sin \theta\end{aligned}\quad (85)$$

where

$$X_c = \int_0^T r(t) \cos(2\pi f_0 t) dt, \quad X_s = \int_0^T r(t) \sin(2\pi f_0 t) dt \quad (86)$$

and Eq. (84) becomes

$$\begin{aligned}\Lambda(r)_{\text{av}} &= \exp\left(-\frac{A^2 T}{2N_0}\right) \int_0^{2\pi} \exp\left(-\frac{2A}{N_0} (X_c \cos \theta - X_s \sin \theta)\right) \frac{d\theta}{2\pi} \\ &= \exp\left(-\frac{A^2 T}{2N_0}\right) I_0\left(\frac{2AV}{N_0}\right)\end{aligned}\quad (87)$$

where $V = \sqrt{X_c^2 + X_s^2}$ and I_0 is the modified Bessel function of order zero. The likelihood ratio test is therefore

$$\ln \left[I_0\left(\frac{2AV}{N_0}\right) \right] \underset{H_0}{\overset{H_1}{\geq}} (E_s/N_0)\eta \quad (88)$$

where the signal energy $E_s = A^2 T/2$. Thus the natural logarithm of the modified Bessel function I_0 is the optimum noncoherent detection characteristic. For a large SNR, the likelihood ratio test can be approximated as

$$\ln \left[I_0\left(\frac{2AV}{N_0}\right) \right] \underset{H_0}{\overset{H_1}{\approx}} \frac{2AV}{N_0} \geq (E_s/N_0)\eta \quad (89)$$

and for a small SNR

$$\ln \left[I_0\left(\frac{2AV}{N_0}\right) \right] \underset{H_0}{\overset{H_1}{\approx}} \frac{A^2 V^2}{2N_0^2} \geq (E_s/N_0)\eta \quad (90)$$

The implementation of the likelihood ratio test of Eq. (89) has been shown in Fig. 11, where the in-phase and the quadrature channels generate the x_c and x_s in Eq. (86), respectively. Summation of the square of x_c and x_s yields the square-law detection of Eq. (90). Taking the square root in addition to the square-law detection yields the envelope detection of Eq. (89).

4. PERFORMANCE ANALYSIS OF COHERENT AND NONCOHERENT DETECTIONS

4.1. Detection Probability Analysis

From the mean and the variances given by Eqs. (55)–(57), the false-alarm probability P_{fa} for the coherent detection is determined by

$$\begin{aligned}P_{\text{fa}} &= \int_{R_0}^{\infty} \frac{1}{\sqrt{\pi E_s N_0}} \exp(-x^2/E_s N_0) dx \\ &= \frac{1}{\sqrt{\pi}} \int_{R_0/\sqrt{E_s N_0}}^{\infty} e^{-x^2} dx \\ &= \frac{1}{2} \operatorname{erfc}\left(\frac{R_0}{\sqrt{E_s N_0}}\right)\end{aligned}\quad (91)$$

The detection probability P_d is given by

$$\begin{aligned}P_d &= \int_{R_0}^{\infty} \frac{1}{\sqrt{\pi E_s N_0}} \exp(-(x-E_s)^2/E_s N_0) dx \\ &= \frac{1}{\sqrt{\pi}} \int_{(R_0-E_s)/\sqrt{E_s N_0}}^{\infty} e^{-x^2} dx \\ &= \frac{1}{2} \operatorname{erfc}\left(\frac{R_0-E_s}{\sqrt{E_s N_0}}\right)\end{aligned}\quad (92)$$

For the noncoherent detection, the in-phase and the quadrature components from Eq. (86) are

$$\begin{aligned}
 X_c &= \int_0^T r(t) \cos(2\pi f_0 t) dt = \int_0^T A \cos(2\pi f_0 t + \theta) \cos(2\pi f_0 t) dt \\
 &+ \int_0^T n(t) \cos(2\pi f_0 t) dt = \frac{AT}{2} \cos \theta \\
 &+ \int_0^T n(t) \cos(2\pi f_0 t) dt \\
 X_s &= \frac{AT}{2} \sin \theta + \int_0^T n(t) \cos(2\pi f_0 t) dt \tag{93}
 \end{aligned}$$

For white Gaussian noise with two-sided spectral density $N_0/2$, we have the following quantities:

$$\begin{aligned}
 E[X_c] &= \frac{AT}{2} \cos \theta \\
 E[X_s] &= \frac{AT}{2} \sin \theta \\
 \text{Var}[X_c] &= \text{Var}[X_s] \tag{94} \\
 &= E \left[\int_0^T \int_0^T n(s)n(t) \cos(2\pi f_0 t) \cos(2\pi f_0 s) dt ds \right] \\
 &= \frac{N_0 T}{4}
 \end{aligned}$$

and therefore the joint probability density functions can be written as

$$\begin{aligned}
 p_1(X_c, X_s | \theta) &= \frac{1}{\pi N_0 T / 2} \\
 &\exp \left(- \frac{(X_c - AT \cos \theta / 2)^2 + (X_s - AT \sin \theta / 2)^2}{N_0 T / 2} \right) \tag{95} \\
 p_0(X_c, X_s) &= \frac{1}{\pi N_0 T / 2} \exp \left(- \frac{X_c^2 + X_s^2}{N_0 T / 2} \right)
 \end{aligned}$$

under the H_1 and H_0 hypotheses, respectively. The averaged joint probability density function of $p_1(X_c, X_s | \theta)$ is

$$\begin{aligned}
 p_{1,av}(X_c, X_s | \theta) &= \int_0^{2\pi} \frac{1}{2\pi} p_1(X_c, X_s | \theta) d\theta \\
 &= \int_0^{2\pi} \frac{1}{2\pi} \frac{1}{\pi N_0 T / 2} \\
 &\exp \left(- \frac{X_c^2 + X_s^2 - AT(\cos \theta)X_c - AT(\sin \theta)X_s + A^2 T^2 / 4}{N_0 T / 2} \right) d\theta \\
 &= \frac{1}{\pi N_0 T / 2} \exp \left(- \frac{X_c^2 + X_s^2 + A^2 T^2 / 4}{N_0 T / 2} \right) \\
 &I_0 \left(\frac{2\sqrt{A^2 T^2 (X_c^2 + X_s^2) / 4}}{N_0 T / 2} \right) \tag{96}
 \end{aligned}$$

For an envelope ($V = \sqrt{X_c^2 + X_s^2}$) detection, let $X_c = V \cos \theta$, $X_s = V \sin \theta$, then $dX_c dX_s = V dV d\theta$. We have

$$\begin{aligned}
 p_{1,av}(V) &= \int_0^{2\pi} p_{1,av}(V, \theta) d\theta \\
 &= \int_0^{2\pi} \frac{V}{\pi N_0 T / 2} \exp \left(- \frac{V^2 + A^2 T^2 / 4}{N_0 T / 2} \right) I_0 \left(\frac{2AV}{N_0} \right) d\theta \\
 &= \frac{4V}{N_0 T} \exp \left(- \frac{V^2 + A^2 T^2 / 4}{N_0 T / 2} \right) I_0 \left(\frac{2AV}{N_0} \right) \tag{97}
 \end{aligned}$$

which is a Rice distribution.

Under the H_0 hypothesis, we substitute $A = 0$ and use $I_0(0) = 1$ in Eq. (97) to obtain the following Rayleigh distribution:

$$p_0(V) = \frac{4V}{N_0 T} \exp \left(- \frac{V^2}{N_0 T / 2} \right) \tag{98}$$

The threshold R_0 is therefore determined from the false-alarm probability P_{fa} using

$$P_{fa} = \int_{R_0}^{\infty} \frac{4V}{N_0 T} \exp \left(- \frac{V^2}{N_0 T / 2} \right) dV = \exp \left(- \frac{R_0^2}{N_0 T / 2} \right) \tag{99}$$

as

$$R_0 = \sqrt{-\frac{N_0 T}{2} \ln P_{fa}} \tag{100}$$

And the detection probability P_d is given by

$$P_d = \int_{R_0}^{\infty} \frac{4V}{N_0 T} \exp \left(- \frac{V^2 + A^2 T^2 / 4}{N_0 T / 2} \right) I_0 \left(\frac{2AV}{N_0} \right) dV \tag{101}$$

This can be put into a more convenient dimensionless form with the changing of variable $x = V / \sqrt{N_0 T / 4}$ from which

$$P_d = \int_{(-2 \ln P_{fa})^{1/2}}^{\infty} x \exp \left(- \frac{x^2 + \alpha^2}{2} \right) I_0(\alpha x) dx \tag{102}$$

where

$$\alpha^2 = A^2 T / N_0 = 2E_s / N_0 \tag{103}$$

For a square-law ($Z = X_c^2 + X_s^2$) detection, let $X_c = \sqrt{Z} \cos \theta$, $X_s = \sqrt{Z} \sin \theta$; then $dX_c dX_s = \frac{1}{2} dZ d\theta$. From Eq. (96) we have

$$\begin{aligned}
 p_{1,av}(Z) &= \int_0^{2\pi} \frac{1}{\pi N_0 T} \exp \left(- \frac{Z + A^2 T^2 / 4}{N_0 T / 2} \right) I_0 \left(\frac{\sqrt{A^2 T^2 Z}}{N_0 T / 2} \right) d\theta \\
 &= \frac{2}{N_0 T} \exp \left(- \frac{Z + A^2 T^2 / 4}{N_0 T / 2} \right) I_0 \left(\frac{\sqrt{A^2 T^2 Z}}{N_0 T / 2} \right) \tag{104}
 \end{aligned}$$

which is a noncentral χ^2 distribution. Under H_0 , we have the following central χ^2 distribution:

$$p_0(Z) = \frac{2}{N_0 T} \exp\left(-\frac{Z}{N_0 T/2}\right) \quad (105)$$

The threshold R_0 can be determined from the false-alarm probability P_{fa} , which is given by

$$\begin{aligned} P_{\text{fa}} &= \int_{R_0}^{\infty} \frac{2}{N_0 T} \exp\left(-\frac{Z}{N_0 T/2}\right) dZ \\ &= \exp\left(-\frac{R_0}{N_0 T/2}\right) \end{aligned} \quad (106)$$

to be

$$R_0 = -\frac{N_0 T}{2} \ln P_{\text{fa}} \quad (107)$$

The detection probability P_d is given by

$$\begin{aligned} P_d &= \int_{R_0}^{\infty} \frac{2}{N_0 T} \exp\left(-\frac{Z + A^2 T^2/4}{N_0 T/2}\right) \\ &\quad \times I_0\left(\frac{\sqrt{A^2 T^2 Z}}{N_0 T/2}\right) dZ \end{aligned} \quad (108)$$

Changing the variable $x = Z/N_0 T/4$ in Eq. (108) yields a more convenient dimensionless form

$$P_d = \int_{-2 \ln P_{\text{fa}}}^{\infty} \frac{1}{2} \exp\left(-\frac{x + \alpha^2}{2}\right) I_0(\alpha \sqrt{x}) dx \quad (109)$$

where α is given by Eq. (103). Changing the variable $y = \sqrt{x}$ in Eq. (109) leads to the interesting result that P_d is identical to that given by Eq. (102) for the envelope detection. Note that the difference between the envelope and the square-law detector concerns the presence or absence of the square-root operation. Supposing for a square-law detection that an observation value is greater than R_0 of Eq. (107); then the square root of this value must be greater than R_0 of Eq. (100) for the envelope detection. Therefore, the square-law detection and the envelope detection bear the same detection characteristics.

The P_d 's in Eqs. (92), (102), and (109) show explicitly that the detection probabilities depend only on P_{fa} and the signal-to-noise ratio E_s/N_0 . Note that, in addition to P_{fa} , the detection threshold R_0 depends on the received signal energy in the coherent case of Eq. (91), but only on the noise and the integration time in the noncoherent case of Eqs. (100) and (107), which is somewhat more convenient.

A comparison of coherent and noncoherent detections is presented in Fig. 14 in terms of the value of P_d that can be achieved for a given value of P_{fa} as a function of signal-to-noise ratio E_s/N_0 . We note the following: (1) For small values of E_s/N_0 (say, less than 3 dB) for any given value of P_{fa} , noncoherent detection requires 2–3 dB more SNR than that required by coherent detection in order to achieve the

same value of detection and (2) for large values of E_s/N_0 (say, greater than 10 dB) the difference in SNR required by the two schemes is less than approximately 1 dB, and it is clear that with further increase E_s/N_0 , the difference eventually becomes negligible.

4.2. Output Signal-to-Noise Analysis

To evaluate the detection performance, we can compare output SNRs of different schemes other than the detection probabilities we used in the last section. Recall that the SNR is the ratio between the signal power and the noise variance. The signal power is the square of the mean of the detection statistic under H_1 . Thus only the mean and the variance are required to compute the SNR. In contrast, the detection probability requires full knowledge of the probability density function, which may not be available sometimes. Therefore the output SNR, which is easier to obtain, is also used to evaluate the detection performance. Of course the detection-probability-based performance evaluation, if it is available, is more accurate than the SNR-based evaluation. In this section, the output SNR will be used to compare the detection performance between the matched filter and the square-law detection.

The matched filter output Y for an input signal $A \cos(2\pi f_0 t)$ can be written as

$$Y = \int_0^T [A \cos(2\pi f_0 t) + n(t)] \cos(2\pi f_0 t) dt \quad (110)$$

The bandpass noise $n(t)$ can be expressed in the form

$$n(t) = n_c(t) \cos(2\pi f_0 t) + n_s(t) \sin(2\pi f_0 t) \quad (111)$$

Hence

$$\begin{aligned} Y &= \frac{AT}{2} + \int_0^T [n_c(t) \cos(2\pi f_0 t) + n_s(t) \sin(2\pi f_0 t)] \cos(2\pi f_0 t) dt \\ &= \frac{AT}{2} + \frac{n_c(t)T}{2} \end{aligned} \quad (112)$$

Equation (112) indicates that the quadrature noise $n_s(t) \sin(2\pi f_0 t)$ has been rejected by the lowpass filter from the output. The first term in Eq. (112) is the signal component with output signal power $A^2 T^2/4$, while the second term represents the in-phase noise component with output noise power $E[n_c^2(t)]T^2/4$. Using Ref. 2

$$E[n_c^2(t)] = E[n_s^2(t)] = E[n^2(t)] = \sigma^2 \quad (113)$$

we obtain the output SNR

$$\text{SNR}_{\text{out}} = \frac{A^2}{\sigma^2} \quad (114)$$

The input signal power is $A^2/2$ and the input noise power is $E[n^2(t)] = \sigma^2$. The input SNR is therefore

$$\text{SNR}_{\text{in}} = \frac{A^2}{2\sigma^2} \quad (115)$$

Figure 14. Detection probability for coherent and noncoherent detection.

and we have the following relationship between the input and output SNRs for coherent detection:

$$\text{SNR}_{\text{out}} = 2\text{SNR}_{\text{in}} \quad (116)$$

It is clear that coherent detection gives a 3 dB improvement in SNR. The reason for this improvement is that the multiplier and lowpass filter in Eq. (110) eliminate the quadrature noise component $n_s(t) \sin(2\pi f_0 t)$.

On the other hand, in the noncoherent case both the in-phase and the quadrature noise components come into play. To analyze the square-law detection easily, we use the equivalent scheme of Fig. 12 with the square-law rectifier characteristic of $y = x^2$, as shown in Fig. 13c, replacing the linear rectifier. The output Z of a square-law detection for the following received signal

$$A \cos(2\pi f_0 t) + n_c(t) \cos(2\pi f_0 t) + n_s(t) \sin(2\pi f_0 t) \quad (117)$$

can be written as [4]

$$Z = \frac{T}{2} [A^2 + 2An_c(t) + n_c^2(t) + n_s^2(t)] \quad (118)$$

This output can be regarded as composed of three terms. The first term, $A^2T/2$, is the desired output signal component with output signal power $(A^2T/2)^2$. The second term, $ATn_c(t)$, represents the carrier-noise component with the associated output noise power $A^2T^2\sigma^2$. The third term, $\frac{1}{2}[n_c^2(t) + n_s^2(t)]$, is the self-noise component. The associated

noise power is

$$\begin{aligned} & \frac{T^2}{4} E\{[n_c^2(t) + n_s^2(t)]^2\} - \frac{T^2}{4} \{E[n_c^2(t) + n_s^2(t)]\}^2 \\ &= \frac{T^2}{2} \{E[n_c^4(t) + \{E[n_c^2(t)]\}^2] - T^2\{E[n_c^2(t)]\}^2\} \\ &= T^2\sigma^4 \end{aligned} \quad (119)$$

where $E[n^4(t)] = 3\{E[n^2(t)]\}^2 = 3\sigma^4$ has been used in the last step. With these results, we can write the output SNR as

$$\text{SNR}_{\text{out}} = \frac{A^4/(4\sigma^4)}{A^2/\sigma^2 + 1} = \frac{\text{SNR}_{\text{in}}^2}{2\text{SNR}_{\text{in}} + 1} \quad (120)$$

If the input SNR is much larger than 1, the output SNR is approximately equal to $\frac{1}{2}\text{SNR}_{\text{in}}$, with the square-law detection thus causing a 3 dB reduction in signal-to-noise ratio. For input signal-to-noise ratios that are much less than 1, 2SNR_{in} is negligible compared with 1, and Eq. (120) shows that SNR_{out} is now equal to SNR_{in}^2 . In this case, the square-law detection causes a very serious degradation of the signal-to-noise ratio.

The relationship between SNR_{out} and SNR_{in} for the matched filter and the square-law detection is shown in Fig. 15. It is clear from both Fig. 14 and Fig. 15 that the noncoherent detection is inferior to the coherent detection for low input signal-to-noise ratios and approximates the coherent detection for high input signal-to-noise ratios

Figure 15. Output signal-to-noise ratios for the matched filter and the square-law detection.

in the detection probability and the output signal-to-noise ratio.

5. DETECTION OF THE LINEAR FREQUENCY-MODULATED SIGNAL

In the previous sections, we have considered the detection of the narrowband signal such as the single-frequency sinusoidal pulses given by Eq. (79). The product of time duration T and bandwidth B is essentially 1. There is an inherent conflict between long-range detection and high-range-resolution capability for such signals. Because the received signal energy E_s attenuates rapidly as the range increases, the long range requires large transmitted signal amplitudes in order to have a sufficiently large value of E_s/N_0 for reliable detection and range estimation. But all radar systems have a limitation on the peak transmitted signal power, which imposes an upper limit on the transmitted signal amplitude. Of course, the required value of E_s can also be obtained by maintaining the transmitted signal amplitude at some maximum value A and increasing the signal duration T . In this case the signal bandwidth B , which is approximately $1/T$, is small. But since the signal bandwidth B is inversely proportional to the range resolution [5], then achieving the required E_s by increasing T reduces B , thereby degrading range resolution capability.

On the other hand, if B can be increased essentially independently of T , there is no such conflict. This is why modern radar systems employ large time-bandwidth product (BT) signals. In the radar system, the earliest and most widely used large BT signal is the linear frequency-modulated (LFM) signal [1,3]. In addition to providing a solution to the long-range-high-resolution problem, the LFM signal is also a form of Doppler-invariant waveform [3].

We note that in military communication systems, a large time-bandwidth product signal is referred to as a spread-spectrum signal [2]. It provides resistance to jamming and has a low interception probability because the signal is transmitted at low power. Among various

spread-spectrum signals, the direct-sequence spread-spectrum (DSSS) signal, where the transmitted signal is modulated by a pseudorandom sequence, is used in code-division multiple-access (CDMA) communications [6]. The frequency-hopped spread spectrum (FHSS) is another widely used spread-spectrum signal in modern communication systems [2,7].

5.1. Wigner-Ville Distribution and Ambiguity Function of an LFM Signal

For an LFM signal, the analytic form is

$$s(t) = \begin{cases} \exp\left[j\left(2\pi f_0 t + \frac{m}{2}t^2\right)\right], & 0 \leq t \leq T \\ 0, & \text{otherwise} \end{cases} \quad (121)$$

The instantaneous frequency in Eq. (121) is

$$f_i(t) = f_0 + mt \quad (122)$$

which has an initial frequency f_0 and increases at a frequency rate m . Since an LFM signal is a nonstationary signal, the best way to describe it is through such distribution functions as the Wigner-Ville distribution (WVD) and the ambiguity function (AF). The WVD of a signal $s(t)$ is defined as

$$\text{WVD}(t, f) = \int_{-\infty}^{\infty} s(t + \tau/2)s^*(t - \tau/2)e^{-j2\pi f\tau} d\tau \quad (123)$$

WVD is the Fourier transform (with respect to the delay τ) of the signal's correlation function. It relates the time and the instantaneous frequency of a signal. Substituting the LFM signal of Eq. (121) into this definition yields [15]

$$\text{WVD}(t, f) = \begin{cases} 2(T - 2|t - T/2|)\text{sinc}\{(T - 2|t - T/2|)[f - f_i(t)]\} & 0 \leq t \leq T \\ 0, & \text{otherwise} \end{cases} \quad (124)$$

where $f_i(t)$ is given in Eq. (122) and the sine function is defined as

$$\text{sinc}(t) = \begin{cases} \sin(\pi t)/(\pi t) & t \neq 0 \\ 1 & t = 0 \end{cases}$$

Figure 16 shows the WVD for an LFM signal with $f_0 = 20$, $m = 12$, and $T = 2$. It is seen from the WVD that the instantaneous frequency linearly increases with the time in accordance with Eq. (122), whereas this relationship is not observable from the spectrum of the signal, which is also shown at the top of Fig. 16.

The ambiguity function (AF) is defined as

$$\text{AF}(\tau, \zeta) = \int_{-\infty}^{\infty} s(t + \tau/2)s^*(t - \tau/2)e^{-j2\pi\zeta\tau} dt \quad (125)$$

where ζ and τ denote the frequency shift and the delay, respectively. AF is the Fourier transform (with respect to the time t) of the signal's correlation function, and it

Figure 16. Spectrum (top) and WVD (bottom) of an LFM signal.

relates the delay and the Doppler frequency (or frequency shift). Note that the AF and the WVD form a two-dimensional (2D) Fourier pair, that is

$$\begin{aligned} \tau \xrightarrow{\mathcal{F}} f \quad \xi \xrightarrow{\mathcal{F}^{-1}} t \quad [\text{AF}(\tau, \xi)] &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \text{AF}(\tau, \xi) e^{j2\pi\xi t} e^{-j2\pi f \tau} d\xi d\tau \\ &= \text{WVD}(t, f) \end{aligned} \quad (126)$$

where \mathcal{F} and \mathcal{F}^{-1} denote the Fourier and its inverse operators, respectively. Applying Parseval's theorem $\int u(t)v^*(t) dt = \int U(f)V^*(f) df$ to Eq. (125), we obtain

$$\text{AF}(\tau, \xi) = \int_{-\infty}^{\infty} S^*(f)S(f + \xi)e^{j2\pi f \tau} df \quad (127)$$

The AF can therefore be regarded as the matched-filter output with a different delay τ and frequency shift ξ .

The AF has proved to be an important tool in analyzing and constructing radar signals by relating range and velocity resolutions. By constructing signals having a particular ambiguity function, desired performance characteristics are achieved. For example, the magnitude AF of the LFM signal in Eq. (121) is

$$|\text{AF}(\tau, \xi)| = \begin{cases} (T - |\tau|)\text{sinc}[(T - |\tau|)(\xi - m\tau)], & |\tau| \leq T \\ 0, & \text{otherwise} \end{cases} \quad (128)$$

which is shown in Fig. 17 for the same LFM signal in Fig. 16. The AF is symmetric about the origin $\tau = \xi = 0$, and the greatest value appears above the origin. The time delay τ is related to the range, and the frequency shift ξ is related to the Doppler shift. Thus AF describes the range-

Figure 17. Ambiguity function of the LFM signal. The AF is symmetric about the origin, and its greatest value appears above the origin.

Doppler ambiguity of the transmitted signal. An ideal radar signal is the one whose AF is a thumbtack function because it leaves the least ambiguity in resolving the range and Doppler shift.

5.2. Detection of Multiple LFM Signals

The matched-filter detection is the optimal detection if all of the signal information (phase, initial frequency, and frequency rate) is available. However, these parameters are difficult to specify because accurate values of the range, the velocity, and the acceleration of a target are not available. Noncoherent detection is thus preferred. Next, we are going to consider the noncoherent detection of multiple LFM signals in a noise background.

For multiple LFM signal detection, it is often the case that the frequency rate is the only parameter of interest in practice [8]. In other words, the frequency rates distinguish different LFM signals. Such a scenario occurs in the radar detection of a small, fast-moving missile launched from a relatively slow-moving aircraft. Multiple LFM signals can be detected by locating maxima in the frequency rate in many applications.

5.2.1. AF of Multiple LFM Signals. The input signal to be analyzed is modeled by a linear sum of 2 (may be extended to more than 2) LFM signals with frequency rates m_0 and m_1 as given by

$$r(t) = \sum_{i=0}^1 \exp \left[j \left(\omega_i t + \frac{1}{2} m_i t^2 \right) \right] \quad (129)$$

Here ω_i represent the carrier (or the initial) frequency, which is proportional to the velocity of the target, and the frequency rate m_i is proportional to the acceleration. The AF defined by

$$\text{AF}_r(\tau, \omega) = \int_{-\infty}^{\infty} r(t + \tau/2)r^*(t - \tau/2)e^{-j\omega t} dt \quad (130)$$

is computed for the signal $r(t)$ of Eq. (129) to yield

$$\begin{aligned} \text{AF}_r(\tau, \omega) = & \delta(\omega - m_0\tau)e^{j\omega_0\tau} + \delta(\omega - m_1\tau)e^{j\omega_1\tau} \\ & + \exp\left[j\left(\frac{\omega_0 + \omega_1}{2}\tau + \frac{m_0 - m_1}{8}\tau^2\right)\right] Q_1 \\ & + \exp\left[j\left(\frac{\omega_0 + \omega_1}{2}\tau + \frac{m_1 - m_0}{8}\tau^2\right)\right] Q_2 \end{aligned} \quad (131)$$

where

$$\begin{aligned} Q_1 = & \exp\left(-j\frac{[-2\omega + (m_0 + m_1)r + 2\omega_0 - 2\omega_1]^2}{8(m_0 - m_1)}\right) \int_{-\infty}^{\infty} \\ & \exp\left[j\frac{m_0 - m_1}{2}\left(t + \frac{-2\omega + (m_0 + m_1)r + 2\omega_0 - 2\omega_1}{2(m_0 - m_1)}\right)^2\right] dt \\ Q_2 = & \exp\left(-j\frac{[-2\omega + (m_0 + m_1)r + 2\omega_1 - 2\omega_0]^2}{8(m_1 - m_0)}\right) \int_{-\infty}^{\infty} \\ & \exp\left[j\frac{m_1 - m_0}{2}\left(t + \frac{-2\omega + (m_0 + m_1)r + 2\omega_1 - 2\omega_0}{2(m_1 - m_0)}\right)^2\right] dt \end{aligned}$$

The last two terms of Eq. (131) are interference terms generated by the two LFM components in the signal $r(t)$, due to the nonlinearity of the AF. Using the following identity

$$\int_{-\infty}^{\infty} e^{-jmt^2} dt = \sqrt{\frac{\pi}{m}} \exp\left(-j\frac{\pi}{4}\right), \quad m > 0 \quad (132)$$

Q_1 and Q_2 are combined to give

$$\begin{aligned} \text{AF}_r(\tau, \omega) = & \delta(\omega - m_0\tau)e^{j\omega_0\tau} + \delta(\omega - m_1\tau)e^{j\omega_1\tau} + 2\sqrt{\frac{2\pi}{m_0 - m_1}} \\ & \times \exp\left[j\left(\frac{\omega(\omega_0 - \omega_1) + \omega_1 m_0\tau - \omega_0 m_1\tau}{m_0 - m_1}\right)\right] \\ \text{Re}\left\{ \exp\left[j\left(\frac{m_0 m_1 \tau^2 + \omega^2 + (\omega_0 - \omega_1)^2 - \omega(m_0 + m_1)\tau}{2(m_0 - m_1)} - \frac{\pi}{4}\right)\right] \right\} \end{aligned} \quad (133)$$

Figure 18(a) shows the AF [Eq. (133)] of a signal composed of two LFM signals that may represent two targets with different velocities and accelerations. Although there is cross-term interference, we can identify the two straight lines representing the bicomponent signal in Fig. 18a. However, the two LFM signals are not obvious if they are corrupted by noise. Figure 18b is identical to Fig. 18a except that the two signals are corrupted by Gaussian white noise with SNR = -6 dB.

5.2.2. Detecting Multiple LFM Signals using Radon Ambiguity Transform. Recall that the radon transform [9], commonly used for the reconstruction of images in computer tomography, is defined by

$$R_{s,\phi}\{f(x,y)\} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x,y) \delta(x \sin \phi + y \cos \phi - s) dx dy \quad (134)$$

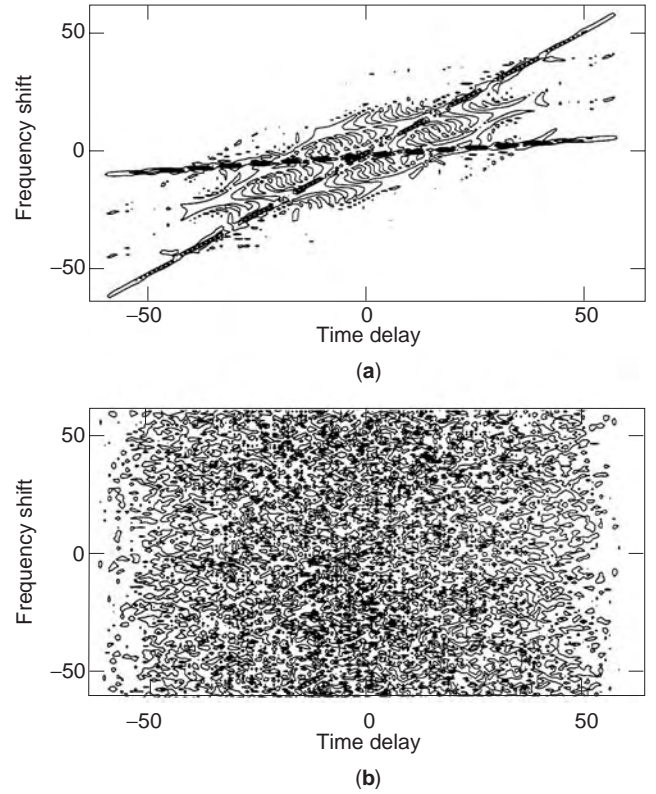

Figure 18. The ambiguity functions of bicomponent LFM signal (a) without noise, and (b) with the additive white Gaussian noise (SNR = -6 dB).

for $-\infty < s < \infty$ and $-\pi/2 < \phi < \pi/2$, where the δ function specifies the direction of integration. The parameter s represents the shifted location of the origin. Equation (134) actually represents the sum of the values of $f(x,y)$ along the line that makes an angle ϕ with the x axis and is located at a distance s from the origin. The Radon-Wigner transform [9,10] is a special case when $f(x,y)$ in Eq. (134) takes the WVD of a multicomponent LFM signal. The WVD of a bicomponent signal is graphically drawn in Fig. 19a. The Radon-Wigner transform of Fig. 19a should produce two maxima in the resulting α - ω plane. Figure 19b is the AF of the same signal in Fig. 19a. The AF is the 2D Fourier transform of the WVD; thus they share the same angles of α_0 and α_1 as shown in the WVD. However, the initial frequencies shown in Fig. 19a have disappeared in Fig. 19b, since they have been mapped into the phase of the AF. This also explains why the AFs of the two chirps pass through the origin in the τ - ζ plane. Thus, by applying the Radon transform to the *phase-free* ambiguity function, detection of multicomponent signals can be reduced from the 2D search problem in the Radon-Wigner transform to a 1D search problem. The advantage of the ambiguity function over the WVD has been shown in the kernel design for the time-frequency analysis [11]. This work can be extended to the detection of multicomponent signals [12].

Since all directions of interest pass through the origin of the ambiguity plane, the Radon transform with parameter s set to 0 is applied to the phase-free ambiguity

Figure 19. (a) The WVD of a bicomponent signal; (b) the AF of the bicomponent signal.

function of Eq. (133). We essentially compute the line integral along a straight line with its direction specified by the δ function $\delta(\xi - m\tau)$ in the ambiguity plane. Therefore the detection statistic can be formed by the so-called Radon ambiguity transform [12] as

$$\begin{aligned} \eta(m) &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |\text{AF}_r(\tau, \zeta)| \delta(\zeta - m\tau) d\tau d\zeta \\ &= \int_{-\infty}^{\infty} |\text{AF}_r(\tau, m\tau)| d\tau \end{aligned} \tag{135}$$

Since the infinite in Eq. (135) usually diverge, it is necessary to first remove the constant term from the integrand. Specifically, for $m \neq m_i$ ($i = 0, 1$) and assuming $m_0 - m_1 > 0$, we have from Eq. (133)

$$\begin{aligned} &|\text{AF}_r(\tau, m\tau)| \\ &= \left| 2\sqrt{\frac{2\pi}{m_0 - m_1}} \cos(a_m \tau^2 + b) \right| \\ &= 4\sqrt{\frac{2}{\pi(m_0 - m_1)}} \left(1 + \sum_{n=1}^{\infty} \frac{2(-1)^{n-1}}{(2n)^2 - 1} \right. \\ &\quad \left. \times \cos(2na_m \tau^2 + 2nb) \right) \end{aligned} \tag{136}$$

with

$$\begin{aligned} a_m &= \frac{m_0 m_1 + m^2 - m(m_0 + m_1)}{2(m_0 - m_1)}, \\ b &= \frac{(\omega_0 - \omega_1)^2}{2(m_0 - m_1)} - \frac{\pi}{4} \end{aligned} \tag{137}$$

Removing the constant from Eq. (136) and substituting it into Eq. (135) yield

$$\begin{aligned} \eta(m) &= 4\sqrt{\frac{2}{a_m(m_0 - m_1)}} \sum_{n=1}^{\infty} \frac{2(-1)^{n-1}}{(2n)^2 - 1} \sqrt{\frac{1}{n}} \\ &\quad \times \sin\left(2nb + \frac{\pi}{4}\right) \end{aligned} \tag{138}$$

For $m \neq m_0$ or m_1 (i.e., $a_m \neq 0$), it is clear that $\eta(m)$ is finite. By Eqs. (137) and (138), we have $\eta(m) \rightarrow \infty$ as $m \rightarrow m_0$ or $m \rightarrow m_1$. Therefore, by calculating $\eta(m)$ and comparing it to a preset threshold, the multicomponent signals can be detected.

5.2.3. Finite-Length Signal. Now we consider a bicomponent finite-length signal as given by

$$r(t) = \begin{cases} \frac{1}{\sqrt{T}} \exp\left[j\left(\omega_0 t + \frac{1}{2}m_0 t^2\right)\right] \\ + \frac{1}{\sqrt{T}} \exp\left[j\left(\omega_1 t + \frac{1}{2}m_1 t^2\right)\right] & \text{for } |t| \leq \frac{T}{2} \\ 0 & \text{for } |t| > \frac{T}{2} \end{cases} \tag{139}$$

with the assumption that $\omega_0 = \omega_1$ and $m_0 > m_1$ for simplicity purposes. The modulus of the ambiguity function of $r(t)$ for $\omega = m\tau$ can be calculated by making use of the following integral

$$\int e^{j(px^2 + 2qx)} dx = \sqrt{\frac{\pi}{2p}} e^{-jq^2/p} \left[C\left(\frac{px+q}{\sqrt{p}}\right) + jS\left(\frac{px+q}{\sqrt{p}}\right) \right] \tag{140}$$

to yield

$$\begin{aligned} &|\text{AF}_r(\tau, m\tau)| \\ &= \begin{cases} \frac{2 \sin\left((T - |\tau|)\frac{\tau}{2}(m - m_0)\right)}{T\tau(m - m_0)} + \frac{2 \sin\left((T - |\tau|)\frac{\tau}{2}(m - m_1)\right)}{T\tau(m - m_1)} \\ + \frac{2}{T} \sqrt{\frac{\pi}{m_0 - m_1}} \times \{ [C(X_0) + C(X_1)] \cos(a_m \tau^2) \\ + [S(X_0) + S(X_1)] \sin(a_m \tau^2) \} & \text{for } |\tau| \leq T \\ 0 & \text{for } |\tau| > T \end{cases} \end{aligned} \tag{141}$$

where

$$C(x) = \int_0^x \cos\left(\frac{\pi t^2}{2}\right) dt, \quad S(x) = \int_0^x \sin\left(\frac{\pi t^2}{2}\right) dt$$

are the Fresnel integrals, and

$$\begin{aligned} X_0 &= \sqrt{\frac{m_0 - m_1}{8}} \left(T + \frac{2(-m + m_1)}{m_0 - m_1} \tau \right) \\ X_1 &= \sqrt{\frac{m_0 - m_1}{8}} \left(T + \frac{2(m - m_0)}{m_0 - m_1} \tau \right) \end{aligned}$$

while a_m in Eq. (141) is defined by Eq. (137). For $|\tau| \leq T$, the first two terms in Eq. (141) represent the auto terms of the signal, while the rest express the cross-terms. Figure 20 shows the integral of Eq. (141) over τ , that is,

Figure 20. The $\eta(m)$ of two equal-amplitude LFM signal with $T = 40$, $m_0 = 200\pi/T^2$, $m_1 = 100\pi/T^2$. Solid line: $\eta(m)$. Dashed line: auto terms only. Dotted line: cross-terms only. The two peaks indicate the existence of the equal-amplitude \angle FM signals.

$\eta(m)$, for two LFM signals with equal amplitudes. Also shown in Fig. 20 are the integrals of the auto terms and cross-terms of Eq. (141).

5.2.4. Output Signal-to-Noise Ratio Analysis. The output SNR of the statistics η in Eq. (135) can be analyzed by making use of the following quantities [12]

$$E(\eta|H_0) = N_0$$

$$E(\eta|H_1) = A + N_0$$

$$\text{Var}(\eta|H_0) = N_0^2$$

$$\text{Var}(\eta|H_1) = 2AN_0 + N_0^2$$

to find

$$\text{SNR}_{\text{out}} = \frac{A^2}{2AN_0 + N_0^2} = \frac{\text{SNR}_{\text{in}}^2}{2\text{SNR}_{\text{in}} + 1} \quad (142)$$

It is seen from Eq. (142) that there is a 3 dB loss in SNR between the input and the output when the input SNR is high, and the output SNR degrades severely when the input SNR is low, illustrating a typical nonlinear detection characteristic.

6. CONCLUSION

We have presented the techniques of radar signal detection, as well as the related performance analyses. The following conclusions can be drawn:

- Among various detection criteria, the Neyman–Pearson criterion is particularly well suited to radar

detection, owing to its concepts of a priori fixed P_{fa} and maximized P_{d} .

- The coherent detection, in the form of a matched filter or a cross-correlation, is the optimal detection for an exactly known signal (i.e., phase, amplitude, and Doppler frequency are known) in a background of white noise.
- In a typical radar application, the range between the target and the radar represents a very large number of transmitted signal wavelengths. This makes specifying the phase of the return signal extremely difficult, and a noncoherent detection has to be used.
- The noncoherent detection is inferior to the coherent detection for low input signal-to-noise ratios and approximates the coherent detection for high input signal-to-noise ratios.
- There is an inherent conflict between long-range detection and high-range-resolution capability for the unity time-bandwidth signal. Large time-bandwidth signals such as an LFM signal do not have such a conflict.
- Large time-bandwidth signals can be described by the ambiguity function or the Wigner–Ville distribution. The Radon ambiguity transform can be used to detect multiple LFM signals.

RADAR SIGNAL PROCESSING

1. FUNDAMENTALS OF RADAR SIGNAL PROCESSING

The capability of radar in acquiring information about targets and environments has been greatly improved over the decades, not only owing to the advent of sophisticated hardware, but also the development of advanced signal processing techniques. Conventional radar is used mainly for detection, localization, and tracking of targets. High-resolution imaging radar can provide more information such as target size, shape, and image and hence can be used for target recognition, which is desired by modern radar. Signal processing plays a key role in most modern radar operations. *Radar signal processing* commonly refers to the techniques that are used to extract desired information about a target from the received signals. Such information usually includes target presence and the position, velocity, trajectory, and image of the target.

According to their objectives, the signal processing techniques can be divided into two categories. The techniques in the first category are used mainly to enhance the useful signal and suppress interference, thus enabling the radar to work satisfactorily in less-than-ideal environments. The techniques in the second category are developed to improve the resolving capability of radar, thus enabling the radar to extract complex information, such as target size and shape.

1.1. Signal Enhancement and Interference Suppression

Extraction of desired information from radar echoes is not an easy task under most circumstances, since the wanted signal has to compete with unwanted signals, such as noise, clutter, and external interference. Noise includes thermal noise and other noise-like disturbances and errors introduced into the receiving channels of radar. It is normally modeled as a Gaussian random process with a uniform power spectrum (white). Clutter is the echo from targets of no interest. For example, if the target of interest is an aircraft, the echoes from the ground, clouds, and rain will produce clutter. Unlike that of noise, the spectrum of clutter is not uniform and is determined by the Doppler frequency and strength of the clutter source. External interference can be generated either by hostile jamming devices or other microwave equipment operating nearby. Radars usually operate in such a combined environment. Different techniques are required to suppress noise, clutter, and jamming since they have different properties.

We first consider coping with noise. In order to ensure reliable detection and processing, it is desirable to maximize the signal-to-noise ratio (SNR). The optimum filter that achieves the maximum SNR is the *matched filter*. The matched filter is widely used in radar systems and is often considered part of the radar receiver, because the intermediate-frequency (IF) amplifier in the radar receiver is normally designed as the matched filter. The matched filter is also an important element in pulse compression. The theory of matched filter is discussed in detail in another article in this encyclopedia, RADAR SIGNAL DETECTION. This article briefly introduces the concept of matched filter.

Denote the input signal and its Fourier transform by $s(t)$ and $S(\omega)$, respectively. The input noise is assumed to be white and stationary. Its spectral density in watts/hertz is $N_0/2$. The frequency response of the matched filter is [1]

$$H(\omega) = kS^*(\omega) \exp(-j\omega t_0) \quad (1)$$

where the asterisk denotes the complex conjugate, k is a gain constant, and t_0 is a time delay that makes the filter physically realizable. The impulse response of the matched filter is the inverse Fourier transform of Eq. (1), which is

$$h(t) = ks(t_0 - t) \quad (2)$$

So the impulse response is the image or time inverse of the input signal.

The SNR used here is defined as the ratio of the peak instantaneous signal power and the average noise power. It is maximized at the output of the matched filter as $\text{SNR}_{\max} = 2E/N_0$, where E is the signal energy. It is an interesting fact that the output SNR is independent of the waveform shape of the input signal.

Clutter reduction is also a major concern for many radar applications. Moving-target indication (MTI) is an important technique that can discriminate moving targets from fixed or slowly moving clutter. MTI is based on the phenomenon that the target moving with finite radial

velocity produces a Doppler frequency whereas the fixed target does not. So the difference in Doppler frequency can be utilized to filter out the fixed clutter.

For radars operating in military environment, antijamming capability is a crucial performance indicator. In this case, the technique of frequency-domain filtering is ineffective, since the interfering signal usually has similar Doppler properties as the desired signal. However, a jamming source is confined to within a certain spatial angle and is usually not in the same direction as the target. So it can be removed by spatial filtering. The technique of spatial filtering is known as *beamforming*. By combining the signals of individual elements of a phased-array antenna, it can synthesize a beam pattern whose mainlobe points to the desired target and a very low sidelobe points to the jamming source.

However, no practical techniques can completely suppress these unwanted signals. The residual interference will lead to a higher false-alarm rate when a fixed threshold is used to decide the presence of a target. Having too many false alarms is unacceptable for the radar detector. Moreover, it also increases the computational load of subsequent data processors. Therefore, a device is needed to control the threshold adaptively in order to maintain an approximately constant false-alarm rate (CFAR).

1.2. Improvement of Resolving Capability

Radar has two main tasks: detection and information extraction. Early radar only has the capability to extract simple target information, such as range, angle, and velocity. Modern radar is able to acquire complicated information such as target size, shape, and image. This is largely a result of the advancement of radar signal processing. Extracting such information requires the radar to have high resolution in one or two (or even three) dimensions.

Range resolution is the ability of radar to distinguish adjacent targets in range direction. If the radar transmits a short pulse of single frequency, range resolution is decided by the pulse duration T . In this case, two scatterers adjacent in range can be distinguished by the radar if their echoes are separated in time delay by more than the pulsewidth. So the range resolution is

$$\rho_r = cT/2 \quad (3)$$

where c is the speed of light and the factor 2 is introduced by the two-way time delay.

Thus, the shorter the pulse, the finer the range resolution. However, a very short pulse carries little energy, and it is impractical, if not impossible, to generate short pulses of very large amplitudes. Hence, a detection range would be shortened, due to fixed SNR requirement of the receiver. To overcome this drawback, high-resolution radars usually adopt long-duration, wideband, coded pulses, which can be compressed to very short pulses after reception by an operation called *pulse compression*.

High range resolution makes it possible for the radar to acquire information on target size and shape. On the other hand, if the target image is needed, the radar must have

high resolution in the azimuth direction as well. For conventional radar, this corresponds to the angular resolution, which is actually the antenna beamwidth, because the radar can distinguish two scatterers in the azimuth only if their angular separation is greater than the antenna beamwidth. The beamwidth is decided by the ratio of the signal wavelength to the aperture size of the antenna. The larger the aperture, the sharper the beam.

However, it is usually impractical to increase the aperture size of a real antenna to a great extent. For instance, assuming a signal wavelength of 3 cm, a whopping 300 m antenna aperture is needed in order to resolve two targets located 1 m apart at a range of 10 km. The synthetic aperture radar (SAR) is developed to overcome this limitation. In SAR, the radar is installed on a moving platform, such as an aircraft or a satellite. The radar transmits and receives a series of pulses while moving with the platform. This is equivalent to obtaining discrete samples of a long aperture. The long antenna aperture can be synthesized by a coherent summation of these samples after proper phase adjustment. Thus, SAR achieves high resolution in azimuth in a practical way. It presents the image of the target by resolving the backscattering intensity of each small range-azimuth cell.

1.3. Radar Signal Processor

In a radar system, the device that performs the operations of radar signal processing is termed the *radar signal processor*. The radar signal processor is sometimes considered part of the radar receiver in early days. In modern radars, it incorporates more and more important functions and is usually considered a separate subsystem due to its significance.

Figure 1a shows the block diagram of the receiving and processing channel of the radar system. The receiver accepts radiofrequency (RF) signals from the antenna and downconverts then to an intermediate frequency. The signals are then amplified, converted to videofrequency (baseband), and sent to the analog-to-digital converter (ADC). The digital samples of the signals are the input to the signal processor. Finally, the output of the signal processor goes to the data processor and display devices.

Figure 1b gives an inside view of the radar signal processor, which encompasses all major functions of radar signal processing. The configurations of practical signal processors may vary according to the main function of radar. A typical signal processor usually does not contain all the components depicted in the block diagram, and may not incorporate them in the given order.

1.4. Coherent Signal Processing

Most functions of the radar signal processor require coherent processing, which means that both signal amplitudes and phases are utilized. Noncoherent processing only uses signal amplitudes. A device called *synchronous detector* or *phase-sensitive detector*, as shown in Fig. 2, obtains coherent video signals. It consists of two orthogonal channels denoted by I (in-phase) and Q (quadrature), which correspond to the real and imaginary part of a signal, respectively.

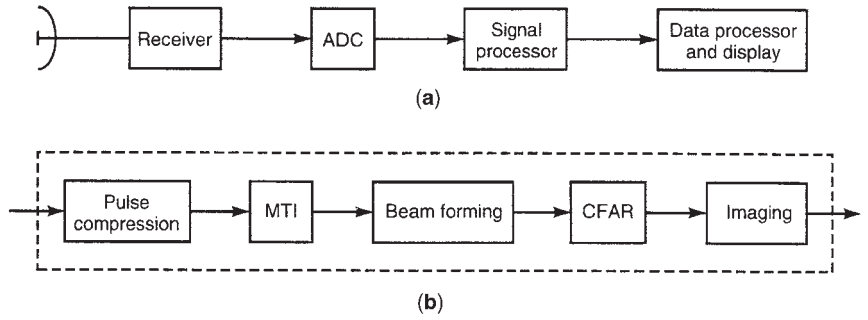

Figure 1. (a) Position of the radar signal processor in the receiving and processing channel of a radar system; (b) An inside view of the radar signal processor. The configurations vary in practical processors.

The input is usually an IF signal, which has the general form of

$$s(t) = A(t) \cos[2\pi f_c t + \phi(t)] \quad (4)$$

where $A(t)$ is the amplitude or envelope, f_c is the IF frequency, and $\phi(t)$ is the phase. It is mixed with the following orthogonal signals in the two channels:

$$r_1(t) = \cos 2\pi f_c t, \quad r_Q(t) = \sin 2\pi f_c t \quad (5)$$

The output of the multiplier in the I channel is

$$s(t)r_1(t) = \left(\frac{1}{2}\right)A(t) \cos[2\pi(2f_c t + \phi(t))] + (1/2)A(t) \cos \phi(t) \quad (6)$$

The first term has a doubled frequency and is thus removed by the subsequent lowpass filter (LPF). The final output of the I channel is

$$I(t) = \left(\frac{1}{2}\right)A(t) \cos \phi(t) \quad (7)$$

Similarly, the output of the Q channel is

$$Q(t) = \left(\frac{1}{2}\right)A(t) \sin \phi(t) \quad (8)$$

The complex video signal can be reconstructed as

$$v(t) = 2[I(t) + jQ(t)] = A(t) \exp[j\phi(t)] \quad (9)$$

Figure 2. The synchronous detector consists of two orthogonal channels, corresponding to the real and imaginary parts of a signal. Its output is a complex video signal.

This complex signal is the so-called *complex envelope* of $s(t)$. It contains the information of the amplitude as well as the phase.

2. MOVING-TARGET INDICATION

Discrimination of moving targets from strong, fixed clutter is necessary for many radar applications, for example, air surveillance and air-traffic control. The MTI achieves this goal by means of the Doppler effect generated by a moving target. The transmitted signal is a series of pulses with a pulse repetition frequency (PRF) f_r . The Doppler frequency f_D of a moving target will introduce a varying phase term into the received signal. The total phase of the received signal becomes

$$\phi(t) = 2\pi f_D t + \phi_0 \quad (10)$$

where ϕ_0 is the initial phase. The output video signals of the synchronous detector are

$$x_I(t) = A(t) \cos(2\pi f_D t + \phi_0) \quad (11)$$

$$x_Q(t) = A(t) \sin(2\pi f_D t + \phi_0) \quad (12)$$

In the frequency domain, their spectra are centered at $\pm f_D$. On the other hand, a fixed target has zero Doppler frequency. The different spectral locations makes it possible to separate moving targets from fixed clutter.

The I or Q components or both can be used in the MTI process. If only one channel is used, the signal of a moving target may be lost in some special cases. For example, a moving target generating a Doppler frequency f_D that equals half the sampling frequency may not be detected if the samples happened to fall at the zero crossings. Using both I and Q channels can overcome this problem. In this case, the signals of I and Q are fed into two separate MTI filters.

2.1. Delay-Line Cancelers

The delay-line canceler is a widely used form of MTI. Since the video signal of a fixed target does not vary from pulse to pulse, it can be subtracted using adjacent pulses. The *single canceler* is the simplest implementation of the MTI. Figure 3 shows its structure. The delay line therein introduces a delayed time that exactly equals one interpulse period, which is the reciprocal of the PRF, that is,

Figure 3. The single canceler utilizes only two pulses. The delay time T_r exactly equals one interpulse period.

$T_r = 1/f_r$. The single canceler utilizes only two pulses, and the output signal is

$$y(t) = x(t) - x(t - T_r) \quad (13)$$

The frequency response of a single canceler can be obtained via the Fourier transform of Eq. (13)

$$Y(\omega) = X(\omega) - X(\omega) \exp(-j\omega T_r) \quad (14)$$

where $\omega = 2\pi f_D$, since the frequency of the video signal is actually its Doppler frequency, as shown in Eqs. (11) and (12). So the frequency response of the single canceler is

$$H(\omega) = Y(\omega)/X(\omega) = 1 - \exp(-j\omega T_r) \quad (15)$$

The magnitude of the frequency response is

$$|H(\omega)| = 2 \sin(\omega T_r/2) = 2 \sin(\pi f_D/f_r) \quad (16)$$

Figure 4 shows the filtering mechanism of the delay-line canceler. The solid line is the magnitude of the frequency response of the single canceler. It forms notches at the zero Doppler frequency and the integer multiples of f_r . The moving target whose Doppler frequency is not zero will pass the filter.

The spectrum of completely fixed clutter is an impulse at zero Doppler frequency and can be removed by the single canceler. However, practical ground clutter usually has a finite spectrum due to the slow motion of clutter scatterers, for example, the trees swaying in the wind. The common model of the ground clutter is the Gaussian-shaped power spectrum centered on zero Doppler frequency, as depicted in Fig. 4. It can be seen that the notches of the single canceler are not wide enough to remove most of the clutter spectrum. An improved solution is to use a double canceler.

A *double canceler* is formed by cascading two single cancelers and utilizes three signal pulses, as shown in Fig. 5a. The frequency response of the double canceler is

$$\begin{aligned} H(\omega) &= [1 - \exp(-j\omega T_r)]^2 \\ &= 1 - 2 \exp(-j\omega T_r) + \exp(-2j\omega T_r) \end{aligned} \quad (17)$$

The magnitude of the frequency response, depicted by the dashed line in Fig. 4, is

$$|H(\omega)| = 4 \sin^2(\omega T_r/2) = 4 \sin^2(\pi f_D/f_r) \quad (18)$$

Compared with the single canceler, the double canceler provides broader rejection notch and thus removes more

Figure 4. The solid line is the frequency responses of the single canceler. It has rejection notches at zero Doppler frequency and nf_r , where n is an integer. The double canceler, shown as the dashed line, provides broader notches and thus removes more clutter. Blind speed occurs when the Doppler frequency of the target equals nf_r .

clutter. The second equation of Eq. (17) indicates that the double canceler can be implemented by a transversal filter, or finite impulse response (FIR) filter, as shown in Fig. 5b.

It is also possible to construct a triple or multiple canceler using similar methods. One advantage of the delay-line canceler is that it is able to process all target and clutter echoes, regardless of range.

2.2. Performance of Moving-Target Indicator

Many indicators have been used to describe MTI performance. Among them, the MTI improvement factor is the most widely used. Other indicators used are clutter attenuation, MTI gain, subclutter visibility, cancellation ratio, and clutter visibility ratio.

2.2.1. MTI Improvement Factor. This is defined [2] as “the signal-to-clutter ratio at the output (s_o/c_o) of the clutter filter divided by the signal-to-clutter ratio at the input (s_i/c_i) of the clutter filter, averaged uniformly over all target radial velocities of interest.” The improvement factor accounts for both clutter attenuation and target gain. It

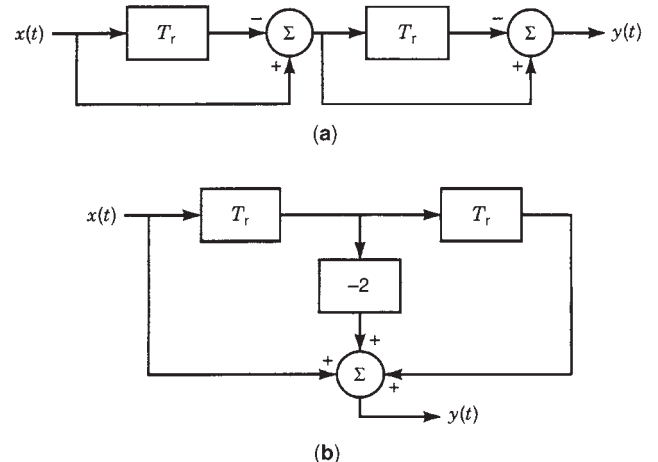

Figure 5. (a) Double canceler is constructed by cascading by two single cancelers. An equivalent implementation is shown in (b), which is a transversal filter, or FIR filter.

can be expressed mathematically as

$$I = \frac{\overline{(s_o/c_o)}}{\overline{(s_i/c_i)}} \quad (19)$$

For the clutter with a zero-mean Gaussian-shaped spectrum, the improvement factors of the single canceler and the double canceler are given, respectively, as [3]

$$I_1 \approx 2(f_r/2\pi\sigma_c)^2 \quad (20)$$

$$I_2 \approx 2(f_r/2\pi\sigma_c)^4 \quad (21)$$

where σ_c is the standard deviation of the clutter power spectrum.

2.2.2. Clutter Attenuation. The ratio of clutter power at the input of the MTI to the power of residual clutter at the output.

2.2.3. MTI Gain. The ratio of signal power at the output of the MTI to signal power at the input, averaged over all target radial velocities of interest.

From the definitions of the improvement factor, the clutter attenuation, and the MTI gain, the relationship between them can be expressed by

$$I = \frac{\overline{(s_o/c_o)}}{\overline{(s_i/c_i)}} = \frac{\overline{(s_o)}}{\overline{(s_i)}} \frac{c_i}{c_o} = GCA \quad (22)$$

where G is the MTI gain and CA is the clutter attenuation.

2.2.4. Subclutter Visibility. This is defined [2] as the ratio by which the target echo power may be weaker than the coincident clutter echo power and still be detected with specified detection and false-alarm probabilities. Target and clutter powers are measured on a single pulse return, and all target radial velocities are assumed equally likely. Subclutter visibility measures the capability of the MTI to detect moving target in the presence of clutter. For example, 20 dB of subclutter visibility means that the moving target can be detected even though the clutter echo power is 100 times the target echo power.

2.3. Other Moving-Target Indicators

2.3.1. Blind Speed and Staggered-PRF MTI. As shown in Fig. 4, the frequency responses of the single and double canceler have periodic nulls at multiples of PRF f_r . If the moving target produces a Doppler frequency that exactly equals f_r , or multiples of f_r , its echo will also be canceled by the MTI. In other words, radar is not able to detect a target moving at one of these radial velocities. So such a speed is named a blind speed.

Blind speed is actually an inherent phenomenon of pulsed radars in which a sinusoidal signal with the Doppler frequency f_D is discretely sampled at the frequency f_r . In the case that $f_D = nf_r$, the sampling occurs at the same point in each corresponding Doppler cycle. Then the moving target looks as if it is stationary.

The problem of blind speed can be alleviated by staggering the PRF, because a speed that is blind at one PRF is generally not blind at another PRF. In this case, the interpulse period of the transmitted signal is changed from pulse to pulse. Time delay in the MTI canceler is also changed correspondingly. This type of MTI is called staggered-PRF MTI. It has a much higher first blind speed than that of the conventional MTI.

In staggered-PRF MTI, the ratio of interpulse periods is usually expressed by a set of prime integers, which has no common divisor other than 1. If N interpulse periods are staggered by $d_1: d_2: \dots : d_N$, the increase of the first blind speed V can be expressed by

$$\frac{V}{V_B} = \frac{d_1 + d_2 + \dots + d_N}{N} \quad (23)$$

where V_B is the blind speed corresponding to the average interpulse periods.

2.3.2. Moving-Target Detector. The moving-target detector (MTD) is an enhanced version of traditional MTI. The basic structure of a MTD is a MTI precanceler followed by a Doppler filterbank. The Doppler filterbank performs the Doppler filtering or Doppler frequency analysis and is typically implemented by the fast Fourier transform (FFT). A Doppler filterbank using N -pulse FFT divides the whole frequency band into N parts, which are processed separately.

The Doppler filterbank provides the following advantages: (1) the SNR is improved since the signal in a certain filter competes only with interference that can pass the filter, (2) the Doppler frequency of a target can be measured to a high accuracy, (3) moving clutter with a nonzero mean of Doppler shift can be rejected by separately adjusting the threshold of each filter, and (4) a clutter map can be generated using the output from the filterbanks.

2.3.3. Adaptive MTI. The adaptive MTI is able to adaptively shift its rejection notch to the location of the clutter spectrum. It is very useful for canceling moving clutter, whose Doppler frequency is not zero. An example of adaptive MTI implementation is the time-averaged-clutter coherent airborne radar (TACCAR) [4]. A phase-error circuit estimates the phase change of clutter signals between pulses, which is caused by its Doppler frequency. The averaged estimate of phase error is used to control the coherent oscillator (COHO) to produce a phase-shifted reference signal for mixing with the return signal. This is equivalent to shifting the Doppler center of the moving clutter to zero. Then a conventional MTI can be used to cancel the clutter. Other implementation methods of adaptive MTI includes changing the weights of the MTI filter and using modern spectral estimation method.

2.3.4. Airborne MTI. The airborne MTI (AMTI) refers to the MTI techniques utilized by a moving radar. The relative motion between radar and fixed clutter displaces the Doppler spectrum of clutter from zero. Thus, the adaptive MTI is one of the AMTI techniques. Another adverse

effect of platform motion is the loss of signal correlation between adjacent pulses, because the illuminated area is slightly displaced from one pulse to the next. The effects of platform motion can be mitigated by physically or electrically displacing the antenna phase center along the plane of the aperture. This technique is called displaced phase center antenna (DPCA).

A relatively new technique is named spacetime adaptive processing (STAP). It simultaneously cancels clutter in angle (space) and Doppler (time) domain. For example, the clutter coming from the antenna mainlobe is spread out in Doppler frequency due to platform motion and is not easy to be canceled in the Doppler domain. The STAP technique can effectively resolve the clutter within the beam width into angle Doppler cells. Targets can be detected in cells that are not occupied by clutter.

3. BEAM FORMING

The radar often encounters jamming interference in the military environment. The jamming source usually occupies the same frequency band as the desired signal and is difficult to eliminate by frequency filtering. Fortunately, the spatial location of jamming source is usually different from that of the target. Spatial filtering can thus be used to separate them in the space domain.

Spatial filtering in radar is achieved by forming a specific radar antenna beam pattern. A narrow mainlobe means good selectivity, and low sidelobes means strong rejection capability. However, producing an antenna with very low sidelobes in all directions is difficult to achieve in practice. High-power interfering signals can still come into the receiver through sidelobes and degrade the desired signal. Furthermore, the direction of jamming source may change with time. The beamforming technique deals with this problem. It is able to adaptively form an antenna beam pattern with a very low sidelobe in the direction of the interference.

Beam forming utilizes array antennas and considers only signal reception. The array elements are discrete spatial samples over the entire antenna aperture. The signals received by each element are weighted and summed to form the array output. When the weights of array elements can be adaptively adjusted, it is called *adaptive beamforming*.

3.1. Linear Array Model and Classical Beamforming

An ideal linear array consists of identical, omnidirectional, equispaced sensors that are located along a straight line. Figure 6 shows a linear array beamformer for processing narrowband signals. At time instant k , each sensor samples the arriving signal. The output of the beamformer is calculated as

$$y(k) = \sum_{n=1}^N w_n^* x_n(k) \quad (24)$$

where $x_n(k)$ is the input signal of sensor n at time k . For the convenience of notation, a complex conjugate is applied to the weight w_n . Equation (24) can be rewritten in

Figure 6. In the linear array model for processing narrowband signals, the signals received by each element are weighted and summed to form the array output.

the following vector form

$$y(k) = \mathbf{w}^H \mathbf{x}(k) \quad (25)$$

where \mathbf{w} and \mathbf{x} are N -dimensional column vectors and H denotes the transposed conjugate.

The array receives plane waves from a target if it is located in the far field. Assume that the signal has a carrier frequency f and comes from direction θ , which is defined as the angle of incidence with respect to the broadside of the array. If two adjacent array elements are separated by a distance d , the signals they received have a phase difference of

$$\phi(\theta, f) = 2\pi(f/c)d \sin \theta \quad (26)$$

where c is the speed of light. In the following analysis, we assume a fixed carrier frequency f . So $\phi(\theta, f)$ is simply denoted by $\phi(\theta)$. At time instant k , if the signal received by the first element is $A(k)\exp[j\phi_1(k)]$, that received by the n th element is $A(k)\exp[j(\phi_1(k) - (n-1)\phi(\theta))]$.

If the first element is used as reference, which means the phase of its signal, $\phi_1(k)$, is set to zero, then the phase of each array element can be written as

$$\mathbf{d}(\theta) = (1, \exp[j\phi(\theta)], \dots, \exp[j(N-1)\phi(\theta)])^H \quad (27)$$

This vector is termed the steering vector, which is also known as the direction vector, array manifold, or array response vector. The output of the beamformer can be expressed as

$$y(k) = \mathbf{w}^H \mathbf{x}(k) = A(k) \mathbf{w}^H \mathbf{d}(\theta) \quad (28)$$

The normalized output is denoted by

$$r(\theta) = \mathbf{w}^H \mathbf{d}(\theta) \quad (29)$$

where $r(\theta)$ is called the beamformer response. The square of $r(\theta)$ is defined as the beam pattern.

In classical beamforming, the objective is to approximate the ideal response that is unity in a desired direction and zero elsewhere. The classical beamformer, also known as the conventional beamformer, is used to receive a desired signal coming from a known direction θ_0 . The solution is to choose the weight as $\mathbf{w} = \mathbf{d}(\theta_0)$. From Eq. (29) the

beamformer response is

$$r(\theta) = \sum_{n=0}^{N-1} \exp\{-jn[\phi(\theta) - \phi(\theta_0)]\} \tag{30}$$

$$= S_N\{[\phi(\theta) - \phi(\theta_0)]/2\}$$

where $S_N(x)$ is defined as

$$S_N(x) = N \sin(Nx)/(N \sin x) \tag{31}$$

and is called the periodic sinc function. The peak of the response is located at angle θ_0 . So the mainlobe of the beam points to θ_0 . It is also said that the beam is steered to θ_0 . In practice, amplitude tapering or weighting is usually used to control the sidelobe levels. As $r(\theta)$ is the summation of the phase-shifted output of each element, the beamformer is also termed a *phased array*.

3.2. Adaptive Beamforming

3.2.1. Multiple Sidelobe Canceler. As stated earlier, strong jamming sources usually come into the receiver through antenna sidelobes. It is thus desirable to form a beam pattern with nulls in the directions of the jamming sources. The multiple sidelobe canceler (MSC) is the earliest beamformer that achieves this goal. An MSC consists of a main antenna and one or more auxiliary antennas, as shown in Fig. 7. The mainlobe of the main antenna points to the target of interest. Interfering signals are assumed to enter through its sidelobes. It is assumed that the auxiliary antennas only receive interfering signals and noise. The weight of each element can be adaptively adjusted to produce an output that estimates the interfering signals in the main channel. Subtracting the output from the main channel by this estimate effectively cancels the interference in the main channel.

Denote the signal in the main channel by y_m , the input of auxiliary antennas by \mathbf{x}_a , and the weight vector by \mathbf{w} . The output of the auxiliary array is $y_a = \mathbf{w}^H \mathbf{x}_a$. Since y_a is assumed not to contain the target signal, successful cancellation of interference is equivalent to minimization the

Figure 7. The multiple sidelobe canceler consists of a main antenna and an auxiliary adaptive beamformer. The latter estimates the interference in the main channel, which is then subtracted from the main channel.

overall output power $E[|y_m - y_a|^2]$:

$$P_{\min} = \min_w E(|y_m - \mathbf{w}^H \mathbf{x}_a|^2) \tag{32}$$

The weight that satisfies this equation is called the optimum weight, which is given by [5]

$$\mathbf{w}_{\text{opt}} = \mathbf{R}_a^{-1} \mathbf{p}_{\text{am}} \tag{33}$$

where $\mathbf{R}_a = E[\mathbf{x}_a \mathbf{x}_a^H]$ is the covariance matrix of input data in auxiliary antennas, and $\mathbf{p}_{\text{am}} = E[\mathbf{x}_a y_m^*]$ is the cross-correlation vector of \mathbf{x}_a and y_m .

One should notice the assumption that the target signal is absent in the auxiliary antennas. This is necessary. Otherwise, it will cause cancellation of target signal in the final output. However, the MSC can still work well with slight signal loss if the target signal in the auxiliary antennas is very small.

3.2.2. Linearly Constrained Adaptive Beamforming. Another popular class of adaptive beamforming techniques is the linearly constrained adaptive beamforming. It prevents the loss of desired signal by imposing linear constraints on the weights. Equation (29) shows that the beamformer response to a signal from direction θ is $\mathbf{w}^H \mathbf{d}(\theta)$. If the direction of interest is θ_0 , the constraint can be expressed as $\mathbf{w}^H \mathbf{d}(\theta_0) = f$, where f is constant. It ensures that the desired signal from angle θ_0 will pass the beamformer with response f . Thus, minimizing the overall output power, $E[|y|^2] = \mathbf{w}^H \mathbf{R}_x \mathbf{w}$, will minimize the output produced by interference and noise from directions other than θ_0 . The linearly constrained beamforming can be expressed as

$$\min_w \mathbf{w}^H \mathbf{R}_x \mathbf{w} \text{ subject to } \mathbf{w}^H \mathbf{d}(\theta_0) = f \tag{34}$$

The solution of the optimum weight is

$$\mathbf{w} = f^* \frac{\mathbf{R}_x^{-1} \mathbf{d}(\theta_0)}{\mathbf{d}^H(\theta_0) \mathbf{R}_x^{-1} \mathbf{d}(\theta_0)} \tag{35}$$

When $f=1$, the beamformer is also termed the minimum variance distortionless response (MVDR) beamformer. There is only one constraint on \mathbf{w} in Eq. (34). In fact, multiple constraints can also be used to add more control on the beam former response [6].

The generalized sidelobe canceler (GSC) [7] is an alternative approach to the linearly constrained adaptive beamforming. It converts the constrained optimization of Eq. (34) to unconstrained optimization by separating out the constraint. Figure 8 shows the structure of the GSC. The upper or main branch is a classical beamformer, which has a fixed weight \mathbf{w}_c . The weight \mathbf{w}_c is chosen so that the response of the main beamformer satisfies the constraint in Eq. (34). So the desired signal from angle θ_0 will pass the main beam former with desired response f . Interference and noise will produce some output determined by \mathbf{w}_c . The lower branch is an adaptive beamformer, which is used to estimate the output produced by

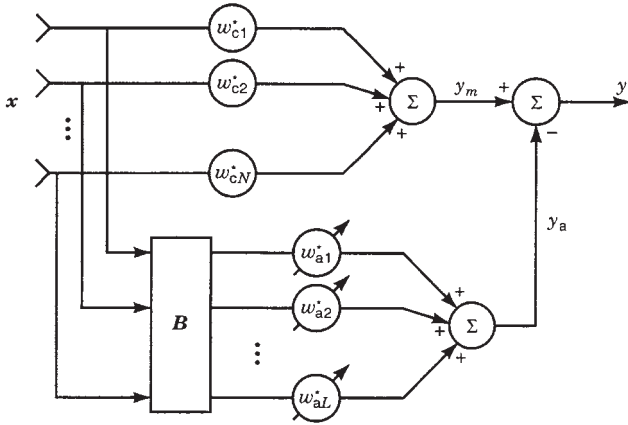

Figure 8. The upper channel of the generalized sidelobe canceler is a classical beamformer, which has a constant response to the desired signal. The lower channel is an adaptive beamformer. It estimates the interference in the upper channel, which is then subtracted from the upper channel. The blocking matrix B blocks desired signal and thus prevent signal cancellation.

interference and noise in the main beamformer. The estimate is then subtracted from the main branch to cancel the interference and noise in the final output. This is similar to that in the MSC. The difference is that there is a preprocessing matrix B in the lower branch of the GSC. The purpose of B is to block the desired signal and thus to prevent signal cancellation in the final output. So B is named the blocking matrix. For an array that is not pre-steered, B needs to satisfy $d^H(\theta_0)B = 0$. The columns of B are linearly independent, and the number of columns L should be less than the number of array elements.

The overall output of the GSC is $y = y_m - y_a$, where y_m and y_a are the output of the upper and lower beamformers, respectively. Since y_a does not contain the desired signal, cancellation of interference and noise is again equivalent to minimize the overall output power

$$\min_{w_a} E[|y_m - y_a|^2] \quad (36)$$

The solution to the unconstrained optimization is

$$w_a = (B^H R_x B)^{-1} B^H R_x w_c \quad (37)$$

where $R_x = E[\mathbf{x}\mathbf{x}^H]$ is the covariance matrix of input data.

Besides the MSC and the GSC, there are some other criteria for constructing an adaptive beam former, such as using a reference signal or maximizing the SNR.

3.2.3. Adaptive Algorithms. Calculation of the optimum weights for the adaptive beam formers discussed before requires knowledge of second-order statistics, especially the covariance of the input signal. Such information is normally not available and needs to be estimated from received data. The optimum weights are usually estimated and adjusted by adaptive algorithms.

It can be proved that the adaptive beamforming problem is equivalent to the adaptive filtering. So the many adaptive algorithms developed for adaptive filtering can

be utilized for adaptive beamforming. One popular class of adaptive algorithms is based on the gradient, for example, the widely used least-mean-square (LMS) algorithm. Another important class is based on the least-square estimation, such as the sample matrix inversion (SMI) and the recursive least square (RLS) algorithm. There is a separate article in this encyclopedia, RADAR SIGNAL DETECTION, that discusses the adaptive filtering technique. For details of these adaptive algorithms, please refer to that article.

4. CONSTANT FALSE-ALARM RATE

A radar detector makes decision of target presence or absence from the echo of each resolution cell. If the echo is stronger than a prespecified threshold, the decision of target presence is made. Otherwise, it declares no target. The basic parameters of a radar detector are the probability of false alarm and the probability of detection. The article RADAR SIGNAL DETECTION in this encyclopedia discusses basic theories of radar detection. This article focuses on an advanced technique for the detector to maintain approximately constant false-alarm rate (CFAR).

4.1. CFAR Principles

We first investigate the principles of CFAR in the background of Gaussian interference. In this case, the interfering signals in both channels of I and Q, denoted by x and y respectively, are Gaussian processes with zero mean and variance (power) of σ^2 . This is a common model for noise and many types of clutter. A linear envelope detector produces the signal envelope or magnitude, $r = \sqrt{x^2 + y^2}$, which is used for target detection. The r has a Rayleigh probability density function (pdf) as

$$p(r) \frac{r}{\sigma^2} \exp\left(-\frac{r^2}{2\sigma^2}\right) \quad (38)$$

The mean value of r is

$$E[r] = \sigma\sqrt{\pi/2} \quad (39)$$

The false-alarm probability P_{FA} for a given threshold r_t can be calculated as

$$P_{FA} = \int_{r_t}^{\infty} p(r) dr = \exp(-r_t^2/2\sigma^2) \quad (40)$$

The P_{FA} is extremely sensitive to the changes of interference power σ^2 . For example, doubling the interference power can increase the value of P_{FA} from 10^{-8} to 10^{-4} . Hence, it is necessary to maintain approximately constant false-alarm rate in order to ensure that the radar works well when the intensity of interference changes. This can be achieved by adaptively adjusting the threshold according to the interference power. An equivalent method is to normalize the interference signal so that its pdf will be independent of its power σ^2 .

Normalization of the Gaussian processes x and y is done by computing x/σ and y/σ . Correspondingly, the normalized envelope is

$$r_N = \sqrt{(x/\sigma)^2 + (y/\sigma)^2} = r/\sigma \tag{41}$$

Its pdf becomes

$$\begin{aligned} p(r_N) &= p(r = \sigma r_N) / |dr_N/dr| \\ &= r_N \exp(-r_N^2/2) \end{aligned} \tag{42}$$

The false-alarm probability is

$$P_{FA} = \int_{q_t}^{\infty} p(r_N) dr_N = \exp(-r_t^2/2) \tag{43}$$

It can be seen that the new false-alarm probability is independent of the interference power σ^2 . This is the desired property of CFAR. Therefore, if σ can be estimated from the received signals, the normalization process r/σ will produce the constant false-alarm rate. From Eq. (39), we know that an estimate of σ can be obtained by estimating the mean value of r .

An alternative method is to use a square-law envelope detector. The magnitude squared of the envelope is produced, denoted by $q = r^2$, and used for deciding the presence of the target. The pdf of q can be calculated from Eq. (38) as

$$\begin{aligned} p(q) &= p(r = \sqrt{q}) / |dq/dr| \\ &= \frac{1}{2\sigma^2} \exp\left(\frac{-q}{2\sigma^2}\right) \end{aligned} \tag{44}$$

The mean value of q is

$$E[q] = 2\sigma^2 \tag{45}$$

Normalization of q can be done as

$$q_N = r_N^2 = r^2/\sigma^2 = q/\sigma^2 \tag{46}$$

The pdf of the normalized variable q_N is

$$\begin{aligned} p(q_N) &= p(q = \sigma^2 q_N) / |dq_N/dq| \\ &= \exp(-q_N/2)/2 \end{aligned} \tag{47}$$

In this case, the false-alarm probability for a preset threshold q_t is

$$P_{FA} = \int_{q_t}^{\infty} p(q_N) dq_N = \exp(-q_t/2) \tag{48}$$

The false-alarm probability is independent of σ^2 . So the CFAR property is achieved by the normalization of q/σ^2 . Equation (45) indicates that an estimate of σ^2 can be obtained by estimating the mean value of q .

The CFAR principle in the presence of Gaussian interference has been discussed for the linear and square-law envelope detectors. For non-Gaussian interference, its envelope cannot be represented by the Rayleigh pdf model. Specific models, such as the lognormal or the Weibull distribution must be used according to the environment and application. In such cases, the CFAR can still be achieved by proper normalization of the interference signal. The CFAR processing protects the radar detector from excessive numbers of false alarms. The cost is that the probability of detection will be slightly reduced compared with similar cases of thermal-noise-only environment.

4.2. Cell-Averaging CFAR

As analyzed before, for Gaussian interference, the normalization factor can be obtained by estimating the mean value of the signal output from the envelope detector. One basic approach of CFAR is to estimate the mean value by averaging the signals of a set of reference cells around the cell under test. This technique is called cell-averaging CFAR (CA-CFAR). The reference cells can be either in range, angle, or Doppler frequency. The basic assumption in CA-CFAR is that the interference is statistically homogeneous over the reference cells and the cell under test.

Figure 9 shows the structure of the CA-CFAR processor that uses reference cells in range. The envelope detector can have either a linear characteristic that produces the envelope r or a square-law characteristic that produces the magnitude squared of envelope q . The received signals from the reference cells are averaged to produce an estimate of their mean value. The immediate neighbors of the test cell are sometimes discarded in case a strong target signal extended into them. The signal of the test cell is then normalized by dividing it by the estimated mean and multiplying it with a scaling constant k . We know from Eqs. (39) and (45) that $k = \sqrt{\pi}/2$ for the linear detector

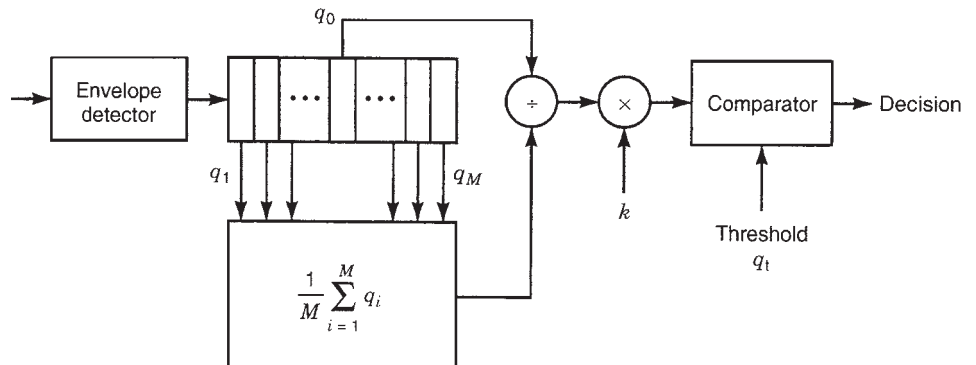

Figure 9. A number of reference cells around the cell under test are used to estimate the interference power in the cell-averaging CFAR processor. The estimate is used to normalize the signal, which is equivalent to adaptively adjusting the threshold.

and $k=2$ for the square-law detector. Finally the normalized envelope of the test cell is compared with a preset threshold to decide if a target is present.

The CA-CFAR principle is applicable to both linear and square-law detection. The analysis that follows is developed for square-law detection without loss of generality. Denote the magnitude squared of envelope of the test cell by q_0 , and that of the reference cells by $q_i (i=1, \dots, M)$. These random variables are statistically independent and have the same probability density function in a homogeneous environment as given in Eq. (44). Their joint density function is

$$p(q_0, \dots, q_M) = \prod_{i=0}^M \frac{1}{2\sigma^2} \exp\left(\frac{-q_i}{2\sigma^2}\right) \quad (49)$$

Denote the sum of the M reference cells by $q_M = \sum q_i$. The normalization of q_0 is

$$q_{0N} = kMq_0/q_M = 2Mq_0/q_M \quad (50)$$

q_{0N} is then compared with a threshold q_t , and the target-present decision is made when

$$q_{0N} > q_t \quad (51)$$

In practice, only a limited number of reference cells M can be utilized to estimate the mean value. Intuitively, the performance of CA-CFAR must be dependent on M . Substituting Eq. (50) into Eq. (51), we get

$$q_0/q_M > q_t/(2M) \quad (52)$$

For random variables $q_i (i=1, \dots, M)$ having the density function given by Eq. (49), the ratio q_0/q_M , called f variate, is known to have the following pdf [8]:

$$p(f) = M/(1+f)^{M+1}, \quad 0 \leq f < \infty \quad (53)$$

The false-alarm probability can then be calculated as

$$P_{FA} = \int_{q_t/2M}^{\infty} p(f)df = \left(1 + \frac{q_t}{2M}\right)^{-M} \quad (54)$$

It can be seen from Eq. (54) that the CFAR property can be achieved even for small values of M , since the false-alarm probability is independent of the interference power σ^2 . Equation (54) approximates the ideal performance when M is very large such that

$$\lim_{M \rightarrow \infty} \left(1 + \frac{q_t}{2M}\right)^{-M} = \exp(-q_t/2) \quad (55)$$

For a limited number of reference cells, higher signal-to-noise ratio is needed to achieve the required false-alarm probability and detection probability. This is referred to as the CFAR loss.

For Swerling I and II targets, one can find the detection probability using similar methods. The signals of a Swerling I or II target in I and Q channels are also modeled as a

zero-mean Gaussian process with a variance of σ_s^2 . The overall variance is thus $\sigma_s^2 + \sigma^2$ when the target is present. Denote the signal-to-noise ratio by $\text{SNR} = \sigma_s^2/\sigma^2$. A similar analysis shows the detection probability P_d is

$$P_d = \left(1 + \frac{q_t}{2M(1+\text{SNR})}\right)^{-M} \quad (56)$$

and

$$\lim_{M \rightarrow \infty} P_d = \exp\left(-\frac{q_t}{2(1+\text{SNR})}\right) \quad (57)$$

For given P_{FA} and P_d , the SNR for M reference cells, denoted by SNR_M , can be derived from Eqs. (54) and (56). On the other hand, the SNR for $M \rightarrow \infty$, denoted by SNR_∞ , can be obtained from Eqs. (55) and (57). The CFAR loss is defined as the ratio of SNR_M and SNR_∞ . It is a function of P_{FA} , P_d , and M . It has been shown [9] that for large M , the CFAR loss can be approximated by $P_{FA}^{-1/2M}$.

4.3. Ordered-Statistics CFAR

The CA-CFAR does not work well for nonhomogeneous interference. One example is when there are interfering targets in the reference cells. Another case is when the background clutter varies dramatically along either range or azimuth or both. Cell averaging can no longer produce the correct estimate, which results in the loss of detection performance. The ordered-statistics CFAR (OS-CFAR) has been proven to have better performance in such environments.

In the OS-CFAR, the threshold is determined by multiplying one of the ranked cell by a scaling factor. Assume that the reference cells have the signals of $q_i (i=1, \dots, M)$ after the envelope detector. They are ranked as $q_1 \leq q_2 \leq \dots \leq q_K \leq \dots \leq q_M$. The variable K is the rank of the cell to be used for calculating the threshold, which is

$$q_t = \alpha q_K \quad (58)$$

The scaling factor α provides a mechanism to control the false-alarm probability.

4.4. Clutter-Map CFAR

The clutter-map CFAR is an effective approach for dealing with nonhomogeneous interference. It utilizes the statistics of past observations on the test cell itself rather than that of the reference cells. It assumes that the statistics of the test cell do not change during the observations so that time averaging can be performed. In fact, the average of previous observations on each cell produces a clutter map—an estimate of clutter power in each corresponding cell.

The principle of clutter-map CFAR is similar to that of the CA-CFAR. The basic analysis of CA-CFAR is applicable to clutter-map CFAR. In clutter-map CFAR processing, the M reference samples are obtained from M scans on the test cell. They are averaged in the same way as that in CA-CFAR to produce an estimate of the interference power. Further processing is also similar to CA-CFAR. In a new

scan, if the target-present decision is made, the power estimate will not be updated. Otherwise, the new sample is used to compute a new average.

A simplified implementation is to store only the estimate by previous samples, denoted by \hat{p}_{n-1} from previous $n - 1$ scans, and updates the estimate with the new sample q_n :

$$\hat{p}_n = (1 - w)\hat{p}_{n-1} + wq_n \tag{59}$$

This is actually an exponential smoothing, since

$$\hat{p}_n = w \sum_{i=0}^{\infty} (1 - w)^i q_{n-i} \tag{60}$$

The value of w determines the length of the exponential window. In practice, the length of the window should be chosen to commensurate with the rate of change of the interference power.

5. PULSE COMPRESSION

Pulse compression is a technique that obtains high range resolution while maintaining good detection range. Signals used for pulse compression should have large bandwidth. There are two approaches to increase the bandwidth: frequency modulation (FM) and phase coding. The device that performs the pulse compression is the matched filter.

5.1. Frequency Modulation Waveforms

The linear FM signal is the earliest pulse compression waveform. Techniques for linear FM pulse compression are well developed and widely used. Another relatively new technique adopts the stepped-frequency waveforms.

5.1.1. Principles of Linear FM Pulse Compression. The linear FM signal, whose carrier frequency varies linearly during the pulse, is the most widely used waveform. It is also known as the *chirp* signal and can be expressed by

$$s_i(t) = A \cos(2\pi f_0 t + \pi \mu t^2), \tag{61}$$

$$-T/2 \leq t \leq T/2$$

where f_0 is the carrier frequency. The constant μ is called the chirp rate. The instantaneous frequency of the signal is $f_i = f_0 + \mu t$, which starts at $f_0 - \mu T/2$ and ends at $f_0 + \mu T/2$. The signal bandwidth is $B = \mu T$.

It can be shown [10] that the matched filter for the linear FM pulse compression can be expressed as

$$h(t) = \sqrt{j\mu} \exp[j2\pi(f_0 t - \mu t^2/2)] \tag{62}$$

The $h(t)$ has an inverse chirp rate as compared with the input signal. The output of the matched filter is

$$s_0(t) = \int_{-\infty}^{\infty} s_i(\tau)h(t - \tau) d\tau$$

$$= \sqrt{j\mu} \int_{-T/2}^{T/2} \exp\{j2\pi[f_0 \tau + \mu \tau^2/2 + f_0(t - \tau) - \mu(t - \tau)^2/2]\} d\tau$$

$$= \sqrt{j\mu T^2} \frac{\sin(\pi \mu T t)}{\pi \mu T t} \exp[j2\pi(f_0 t - \mu t^2/2)] \tag{63}$$

The envelope of the output signal is a sinc function:

$$e_o(t) = \sqrt{\mu T^2} \frac{\sin(\pi \mu T t)}{\pi \mu T t} \tag{64}$$

For the sinc function, the peak-null pulsewidth is defined as the distance from the peak to the first null. For $\sin x/x$, the first null occurs at $x = \pi$. So the width of the compressed pulse is

$$T' = \frac{1}{\mu T} = \frac{1}{B} \tag{65}$$

It equals the reciprocal of the signal bandwidth. The pulse compression ratio is defined as the ratio of the pulsewidth before and after the pulse compression processing. From Eq. (65), we have

$$D = T/T' = TB \tag{66}$$

Therefore, the pulse compression ratio is equal to the time-bandwidth product of the signal.

From Eq. (3), the range resolution after pulse compression is

$$\rho_r = \frac{cT'}{2} = \frac{c}{2B} \tag{67}$$

It should be noted that the peak-null pulsewidth corresponds to the mainlobe width at -4 dB (power) points. Another definition of pulsewidth is the mainlobe width at -3 dB, which is called half-power pulsewidth and can be expressed as K_w/B , where K_w is a constant factor. For the sinc function, $K_w = 0.866$.

It is well known that the sinc function has high sidelobes. To reduce sidelobes, one approach is to apply weighting in the compression filter. It can greatly reduce the sidelobes at the cost of mainlobe broadening. Table 1 lists some popular weighting functions with the corresponding peak sidelobe levels and mainlobe width at -3 dB. Another approach to reduce the sidelobes is to use nonlinear FM waveforms. In this case, the spectrum of the transmitted signal is weighted, which also provides low sidelobes in the compressed pulse.

Table 1. Properties of Weighting Functions

Weighting Function	Peak Sidelobe Level (dB)	Mainlobe Width at -3 dB, K_w/B
Rectangular	-13.26	$0.886/B$
Hanning	-31.5	$1.42/B$
Hamming	-42.5	$1.32/B$
Taylor, $\bar{n} = 5$	-35	$1.19/B$
Taylor, $\bar{n} = 6$	-40	$1.25/B$
Dolph-Chebyshev	-40	$1.20/B$

5.1.2. Implementation of Linear FM Pulse Compression.

The commonly used analog devices for linear FM pulse compression are the dispersive delay lines, in which the signal delay is dependent on its frequency. The most popular one is the surface acoustic wave (SAW) device. The electrical signal is converted into a surface wave at the input, which propagates through the medium at acoustic speed. The dispersive property of the device achieves the matched filtering. At the output the wave is converted back to the electrical signal. Another type of ultrasonic device is the bulk acoustic wave device, which is less energy-efficient than the SAW device. These ultrasonic devices can process signals with bandwidth greater than 1000 MHz [10].

Linear FM pulse compression can also be implemented by digital methods. The received signal is sampled by an ADC and transformed into the frequency domain via FFT. The matched filtering is performed in the frequency domain by multiplying the signal spectrum with the frequency response of the matched filter. The result is then transformed back into the time domain.

A third technique is called stretch processing, which can process signals with very large time-bandwidth products. Figure 10 shows its principle. Echoes from a set of scatterers are linear FM signals whose starting points correspond to the ranges of each scatterer. They are mixed with a reference signal, which is also a linear FM with the

Figure 10. The stretch processing can reduce the signal bandwidth by dechirping the return signal. The dechirped signal is then digitized and transformed by an FFT, which accomplishes pulse compression.

same chirp rate as that of the transmitted signal. The mixing (dechirping) process removes the frequency modulation of the received signal. Each dechirped signal has a constant frequency that corresponds to its range. An ADC then samples these dechirped signals. Finally, a frequency analysis by FFT distinguishes each scatterer in the range. The stretch processing is also widely used in high-resolution radars.

5.1.3. Stepped-Frequency Waveforms. In this pulse compression technique, the radar transmits a burst of narrowband pulses, and the carrier frequency changes discretely from pulse to pulse by a stepsize Δf . Compared with the linear FM waveform, the stepped-frequency waveforms can be regarded as discrete modulation in frequency. If there are N pulses in a burst, the overall bandwidth of the transmitted signal is $B = N\Delta f$.

Each received pulse is then downconverted to baseband, and a pair of I and Q samples is collected in a desired range gate. The length of the range gate is determined by Δf , which is $r = c/(2\Delta f)$. The ensemble of I and Q samples represent results that the received signal within the desired range gate is discretely sampled in the frequency domain over the bandwidth B . There is a condition to be satisfied. That is, the duration of the baseband response of each pulse should extend the whole desired range gate. This is ensured if $T_p \geq 1/\Delta f$, where T_p is the duration of each pulse.

Pulse compression is accomplished by applying the inverse discrete Fourier transform on the N pairs of I and Q samples. The result is a high-resolution range profile with N complex samples over the desired range gate. The length of the range profile is r , and the resolution is

$$\rho_r = \frac{c}{2B} = \frac{c}{2N\Delta f} \quad (68)$$

Pulse compression using the stepped frequency avoids the requirements of wide instantaneous bandwidth and high sampling rates. However, transmitting multiple pulses require relatively long time. When there is large motion between the radar and the target, the motion-induced phase errors between pulses must be compensated before the pulse compression can be performed.

5.2. Phase-Coded Waveforms

The phase-coded signal is a constant-amplitude sinusoid that is divided into N equal segments. The phase of the sine wave in each segment is selected according to given code sequence. If the phase is set at either 0 or π , it is called *binary*, or biphase, coding. If the code sequence contains more than two values, it is called *polyphase coding*.

The pulse compression principle can be demonstrated by correlation processing, which is equivalent to matched filtering. Consider a binary-coded signal with N segments. Denote the value of the k th segment by a_k , which is either 1 or -1. The aperiodic autocorrelation function of this waveform can be written as

$$\Phi(m) = \sum_{k=1}^N a_k a_{k+m}, \quad -(N-1) \leq m \leq N-1 \quad (69)$$

If $m = 0$, then $a_k a_{k+m} = 1$ for each segment k , and the summation equals N . When $m \neq 0$, the value of the autocorrelation function is much smaller than N . Thus the correlation processing produces a narrow pulse, whose mainlobe locates at $m = 0$ with the amplitude of N . The regions where $m \neq 0$ are sidelobes. A well-designed code sequence can produce a pulse with very low sidelobes.

The Barker codes are the binary codes that have the lowest peak sidelobe. The aperiodic autocorrelation of Barker codes has the value of either 0 or 1 for $m \neq 0$, and hence the peak sidelobe is 1. With respect to the mainlobe, the peak sidelobe level is $\frac{1}{13}$, or -22.3 dB. However, no Barker codes whose length is greater than 13 have been found. The pulse compression ratio for Barker codes is limited to the maximum value of 13. So it is important to find longer sequences with good sidelobe properties.

The minimum peak sidelobe codes are the binary sequences that attain the lowest peak sidelobes for a given length. Of course, the Barker codes belong to this class of codes. Codes with length of 14–48 have been found [11]. For example, for length 48, the best peak sidelobe that can be achieved is 3, which is -24.1 dB with respect to the mainlobe. Other types of long binary codes are random and pseudorandom codes, in which the phase value of 0 or π are chosen in a random or essentially random manner, each with a probability of 0.5.

All binary codes have the common weakness that they are quite sensitive to the Doppler shift in the received signal. Their performance degrades significantly for large Doppler frequencies. The polyphase codes exhibit better Doppler tolerance and have relatively good sidelobe characteristics. Frank codes and P4 codes are commonly used polyphase codes. They can be thought of as discrete approximations to the linear FM waveform.

The two devices to implement the phase-coded pulse compression are the all-range compressor and cross correlator. The former is suitable for signals with varying delays, and works well for all target range. The latter is usually used when the target range is approximately known.

6. HIGH-RESOLUTION RADAR IMAGING

A radar image is the spatial distribution of microwave reflectivity corresponding to the object. Besides high range resolution, an imaging radar also requires a high azimuth resolution. It thus requires a large antenna aperture in azimuth direction. To avoid practical difficulties in constructing a large antenna, the synthetic aperture technique is developed.

6.1. Principles of Synthetic Aperture Techniques

The azimuth resolution of a real antenna is discussed first. Consider the linear array model of Fig. 6. For simplicity, we assumed that there is no beamsteering and uniform weighting is applied to each array element, that is, $\mathbf{w} = [1, 1, \dots, 1]^T$. Similar to Eq. (30), the array response

can be found as

$$r(\theta) = \sum_{n=0}^{N-1} \exp[-jn\phi(\theta)] \tag{70}$$

$$= N \frac{\sin[N\pi(d/\lambda) \sin \theta]}{N \sin[\pi(d/\lambda) \sin \theta]}$$

where $\lambda = c/f$ is the wavelength. The $r(\theta)$ is also periodic sinc function similar to Eq. (31). The peak of its mainlobe is at $\theta = 0$. Its first null occurs when $\sin \theta = \lambda/(Nd)$, where $Nd = D$ is the entire array aperture. When D is very large, $\sin \theta$ is very small, and $\sin \theta \approx \theta$. So the first null occurs at $\theta = \lambda/D$. The peak-null beamwidth, the distance from the peak to the first null, is thus

$$\beta_\theta = \lambda/D \tag{71}$$

Although the result is derived from the array antenna, it is applicable to continuous-aperture antennas. The azimuth resolution of a real antenna at range R is $R\lambda/D$.

Synthesizing a large antenna aperture can be achieved by mounting a small-aperture antenna on a moving platform. The antenna transmits and receives signals while the platform moves. The received data can then be used to synthesize a large aperture. Such a system is called synthetic aperture radar (SAR).

Figure 11 shows two common operating modes of SAR: strip map and spotlight. In stripmap SAR, the antenna beam is fixed relative to the flight path. The moving antenna sweeps out a strip of terrain that is parallel to the flight path. In spotlight SAR, the beam is steered to continuously illuminate a relatively small patch of terrain. There is another widely used mode that is called inverse synthetic aperture radar (ISAR). In ISAR, the radar is usually stationary (although it can also be moving), and the target being imaged is moving. After motion compensation, the relative motion between the radar and the target is similar to that of the spotlight SAR.

The azimuth resolution of SAR can be derived from Fig. 12 by finding the synthetic-array response. The cross-range (azimuth) direction, denoted by x , is defined in the

Figure 11. (a) Stripmap-mode SAR. Its resolution is limited by the antenna beamwidth β_θ due to the fixed antenna pointing. (b) Spotlight-mode SAR. The antenna tracks a small imaging area. Its resolution can be very high, but imaging area is limited by antenna beamwidth.

Figure 12. The cross-range resolution of SAR can be derived from this array model. It is compensated to an arc array in the focused SAR processing.

flight direction. SAR processing can be of focused or unfocused type. In focused processing, the phases of the signals are compensated so that each array element receives a signal from the origin O with the same phase. It is equivalent to transforming the linear array into an arc array. The unfocused processing does not perform such phase compensation and has a low resolution. The cross-range resolution is derived here only for focused processing.

The movement of the radar along the arc path introduces a relative rotation between the radar and the target. The observing angle from radar to the origin O will change an amount of $\delta\theta$ between two adjacent elements. Assume that there are N elements in all, and the central element is the reference. The n th element has an observing angle of $n\delta\theta$ ($-N/2 \leq n \leq N/2$).

Denote the distance from the origin to each element on the arc array by R_0 . Since only the cross-range resolution is of interest, we consider a point P at $(x, 0)$. It is in the far field with respect to the real antenna and $x \ll R_0$. So the distance from P to the n th element is

$$R_n(x) \approx R_0 - x \sin n\delta\theta \quad (72)$$

The phase of the signal caused by the two-way time delay is

$$\phi_n(x) = \frac{4\pi}{\lambda} R_n(x) \approx \frac{4\pi}{\lambda} R_0 - \frac{4\pi}{\lambda} x \sin n\delta\theta \quad (73)$$

The first term in Eq. (73) is a constant phase and can be removed. The term $n\delta\theta$ is usually very small, and thus $n\delta\theta \approx n\delta\theta$. So the array response is

$$\begin{aligned} r(x) &\approx \sum_{n=-N/2}^{N/2} \exp\left(-j \frac{4\pi}{\lambda} x n \delta\theta\right) \\ &= N \frac{\sin[(2\pi/\lambda)N\delta\theta x]}{(2\pi/\lambda)N\delta\theta x} \end{aligned} \quad (74)$$

It is a sinc function. The peak is at $x = 0$, and the first null occurs at $(2\pi/\lambda)N\delta\theta x = \pi$. So the cross-range resolution

measured by the peak-null beamwidth is

$$\rho_x = \frac{\lambda}{2\Delta\theta} \quad (75)$$

where $\Delta\theta = N\delta\theta$ is the total integration angle. The cross-range resolution expressed by Eq. (75) is applicable to strip-map SAR, spotlight SAR, and ISAR. It can also be expressed by the synthetic aperture length L since $\Delta\theta = L/R_0$. Thus

$$\rho_x = \frac{\lambda R_0}{2L} \quad (76)$$

In stripmap SAR, the synthetic aperture length L and the integration angle $\Delta\theta$ are limited by the beamwidth of the real antenna β_θ due to the fixed beamsteering. As shown in Fig. 11, the maximum value of $\Delta\theta = \beta_\theta$, which is expressed by Eq. (71). Therefore, the maximum cross-range resolution in stripmap SAR is

$$\rho_{x \max} = \frac{\lambda}{2(\lambda/D)} = \frac{D}{2} \quad (77)$$

where D is the aperture length of the real antenna.

6.2. Stripmap SAR Image Formation

The most common method for stripmap SAR image formation is the range-Doppler (RD) algorithm. Consider the geometry of data collection shown in Fig. 13, where r denotes the slant range and x denotes the cross-range. Assume that the transmitted pulse is

$$s_t(t) = a(t) \exp\{j[\omega t - \phi(t)]\} \quad (78)$$

where $a(t)$ is a rectangular window of unity amplitude over the pulse duration, and $\phi(t)$ represents the phase modulation. The distance from the radar to a target at $x = 0$ varies according to

$$R(x, r) = \sqrt{r^2 + x^2} \approx r + x^2/(2r) \quad (79)$$

Figure 13. Data collection geometry of the stripmap SAR.

The received signal from this point after demodulation is

$$s_r(t, x, r) = \sigma a [t - 2R(x, r)/c] \exp(-j\{4\pi R(x, r)/\lambda + \phi[t - 2R(x, r)/c]\}) \quad (80)$$

where σ is the radar cross section of the target. The change of antenna gain is assumed to be small and can be omitted. The normalized form of Eq. (80) is the impulse response:

$$h(t, x, r) = a [t - 2\Delta R(x, r)/c] \exp(-j\{4\pi\Delta R(x, r)/\lambda + \phi[t - 2\Delta R(x, r)/c]\}) \quad (81)$$

where

$$\Delta R(x, r) = R(x, r) - r \approx x^2/(2r) \quad (82)$$

which is the well-known range migration (RM). RM can be neglected if β_θ is small. It is also omitted in the unfocused processing. In the focused processing, the integration of the signal must be along the curved locus, or the curved locus must be straightened (RM-compensated) before integration.

The return signal from an extended target $\sigma(x, r)$ is

$$s_r(x, r) = \sigma(x, r) \otimes h(x, r) \quad (83)$$

where \otimes denotes a two-dimensional convolution. It can be shown (12) that Eq. (83) can be expressed by

$$s_r(x, r) = [\sigma(x, r) \otimes h_1(x, r)] \otimes h_2(x, r) \quad (84)$$

where

$$h_1(x, r) = \delta(r - \Delta R(x, r)) \exp[-j4\pi\Delta R(x, r)/\lambda] \quad (85)$$

$$h_2(x, r) = (2/cv)\delta(x)a(r) \exp[-j\phi(r)] \quad (86)$$

where v is the along-track speed of the radar and $\delta(x)$ is Dirac's delta function. It can be seen that the received signal is obtained by sequentially convolving $\sigma(x, r)$ with two impulse response h_1 and h_2 . Therefore $\sigma(x, r)$ can be reconstructed by sequentially correlating the return signal $s_r(x, r)$ with h_2 and h_1 . Equation (86) shows that h_2 is actually a one-dimensional (1D) function of range r , and has the same waveform as the transmitted pulse. Correlation of $s_r(x, r)$ with h_2 is thus the conventional pulse compression in range.

The h_1 is a 2D function, due to the RM effect. The RM compensation is usually implemented by an interpolation in the range-Doppler domain, which straightens the curved locus. The signal is then compressed in azimuth after the correction [12–14]. To further reduce the phase errors, a technique called secondary range compression [13–15] can be adopted.

Besides the RD algorithm, two wavenumber domain algorithms have also been developed for SAR processing: the range migration algorithm (RMA) [16] and the chirp scaling algorithm (CSA) [17]. Denote the Fourier transform of $h(t, x, r)$ by $H(\omega, k_x, k_r)$, where k_x and k_r are spatial frequencies and are usually called x and r wavenumbers; ω is the temporal frequency, and $k_r = 2\omega/c$.

The RMA first transforms the received data $s_r(x, t)$ to $S_r(k_x, \omega)$ by a 2D Fourier transform. Then it maps the data from the $k_x - \omega$ domain to the $k_x - k_r$ domain by a process called Stolt interpolation. A 2-D phase compensation is performed in this domain, which corrects the range migration effect. The image is finally constructed by a 2D inverse Fourier transform.

The RMA is capable of imaging a large terrain area with fine resolutions. Its drawback is that the Stolt interpolation is time consuming. Figure 14 shows an example of SAR image processed by the RMA. The raw data were collected by ESAR-2, and made available by German Aerospace Research Establishment (DLR). The image resolution is about 3 m in range and 0.2 m in azimuth.

The difficulty of RM correction is that scatterers located at different positions have different migration loci, and thus a large amount of computational effort is need. On the other hand, with its unique procedures, the chirp scaling algorithm is able to adjust all the different loci to the same trajectory in the 2D spatial-frequency domain

Figure 14. An example of an ESAR-2 stripmap SAR image. It is processed by the range-migration algorithm. [The ESAR-2 data were made available by courtesy of the German Aerospace Research Establishment (DLR).]

without much computational effort. Then the range-migration correction can be easily performed by a phase multiplication to each point.

The CSA requires only FFTs and complex multiplies. No interpolation is needed. So it is computationally efficient. However, it has been shown (18) that the CSA implements only the shift and linear components of the Stolt mapping. So the RM compensation is not complete. Nonetheless, such approximate compensation can produce satisfactory results for most applications.

6.3. Image Formation in Spotlight SAR and ISAR

The spotlight SAR and ISAR are developed mainly for imaging a small terrain or target with high resolutions. To take the advantage of the small imaging area, spotlight SAR and ISAR systems usually adopt the linear FM signal and the stretch processing technique described earlier. Stretch processing can largely reduce the analog signal bandwidth, and thus requires low AD sampling rates, and small storage memory.

Recall the principles of stretch processing depicted in Fig. 10. Here the reference signal for dechirping (mixing) process is chosen to be the replica of the return signal from the center of the scene being imaged. The return signals from the scene center after mixing have zero Doppler frequency, which means that there is no relative radial motion between the radar and the scene center. So it is also referred to as motion compensation with respect to the scene center. While this procedure compensates the translational motion, it retains the rotational motion between the radar and the scene center, which forms an ideal arc synthetic array.

It can be shown [18] that the motion compensation dechirpes received signals in both range and azimuth directions and transforms the data into the $k_r - k_x$ domain. As discussed earlier, this is the two-dimensional spatial-frequency (wave-number) domain. Thus, the image can be constructed by a 2D inverse Fourier transform. The question is that the data samples in the $k_r - k_x$ domain are not located on a rectangular grid. Rather, they are on the polar coordinates. The data support is a ribbon whose size is determined by the transmitted bandwidth B and the integration angle $\Delta\theta$, as shown in Fig. 15.

For a small scene size, if the values of B and $\Delta\theta$ are small, which means low resolutions in range and azimuth, the small ribbon can be directly approximated by a rectangle. Then the 2D inverse Fourier transform can be performed by two 1D inverse FFTs in range and azimuth. This method is referred to as a rectangular format algorithm. A scatterer can be well focused by this algorithm if it does not move through resolution cells during the whole observation. For large scene size and high resolutions, the scatterer's motion through resolution cells will cause image defocus. So the data must be stored in the polar format. Since the Fourier transform does not have fast algorithms in polar format, a 2D interpolation is needed to map the data from polar to rectangular grid. Finally the image can be constructed via two 1D inverse FFTs. This method is called polar format algorithm.

Figure 15. Support area of spotlight SAR signals after motion compensation to the scene center. Its size is determined by the signal bandwidth and the integration angle. Data samples are located on the polar format.

The range-migration algorithm and the chirp scaling algorithm discussed in the preceding section can be utilized for spotlight SAR image formation. They do not require motion compensation to the scene center. Another method known as convolution backprojection algorithm, which is widely used in computer-aided tomography (CT), can also be used for spotlight SAR image formation, since the geometry of data collection in spotlight SAR is very similar to that in CT [19].

6.4. Autofocus Techniques

Even in a well-design SAR system, it is still difficult to measure the relative motion between the radar and the target with high accuracy over the whole synthetic aperture. The case is even worse in ISAR because the target is usually non-cooperative. In such cases, phase errors will be introduced to the received signals. Such phase errors are space-invariant, which means all the range bins have the same phase error during one observation. Autofocus is a useful technique to estimate and remove the space-invariant phase errors.

Many autofocus algorithm have been presented, such as the map drift (MD) algorithm [18], the dominant scatterer algorithm (DSA) [20], the phase gradient autofocus (PGA) algorithm [21], and the weighted least-square (WLS) algorithm [22].

Autofocus usually begins in the range-compressed phase history domain, where the data are compressed in range but not compressed in azimuth. Suppose the strongest scatterer in the n th range bin has the Doppler frequency f_n and the initial phase $\psi_{0,n}$. Other smaller scatterers are treated as clutter. So the phase of the signal at range bin n and aperture position m is

$$\Phi_n(m) = 2\pi f_n m + \psi_{0,n} + \phi_n(m) \quad (87)$$

where $\phi_n(m)$ is the phase fluctuation caused by clutter. Clutter is commonly assumed independent from range bin

to range bin. When corrupted by a phase error $\gamma(m)$, Eq. (87) becomes

$$\Phi_n(m) = \gamma(m) + 2\pi f_n m + \psi_{0,n} + \phi_n(m), \quad (88)$$

$$n = 1, 2, \dots, N$$

where N is the number of range bins. $\gamma(m)$ is the same for all range bins, since it is space-invariant.

Autofocus is carried out in two steps: estimation and correction. The challenge is the estimation of $\gamma(m)$. Once the estimate $\hat{\gamma}(m)$ is obtained, correction can be done by multiplying the range-compressed phase history data by $\exp[-j\hat{\gamma}(m)]$.

The WLS algorithm is an optimal estimation of $\gamma(m)$ in the sense that it minimizes the variance of the residual phase error. It is capable of estimating and removing all kinds of phase errors, no matter if they are of low order, high order, or entirely random. The first step in the WLS algorithm is to shift the strongest scatterer in each range bin to the center of the image, thus removing its Doppler frequency offset. The initial phase $\psi_{0,n}$ is a constant and can also be removed by proper processing. Then Eq. (88) becomes

$$\Phi_n(m) = \gamma(m) + \phi_n(m), \quad n = 1, 2, \dots, N \quad (89)$$

The task is to estimate the error $\gamma(m)$ from Eq. (89). Since $\phi_n(m)$ causes estimation errors, the objective of the WLS estimation is to minimize the variance of the estimation error. Rewriting Eq. (89) using vector notations, we have

$$\Phi(m) = \mathbf{H}_\gamma(m) + \phi(m) \quad (90)$$

where $\Phi(m) = [\Phi_1(m), \Phi_2(m), \dots, \Phi_N(m)]^T$, $\phi(m) = [\phi_1(m), \phi_2(m), \dots, \phi_N(m)]^T$ and $\mathbf{H} = [1, 1, \dots, 1]^T$.

Denote the variance of the phase term $\phi_n(m)$ by σ_n^2 . The covariance matrix of $\phi(m)$ is

$$\mathbf{R} = \text{diag}[\sigma_1^2, \sigma_2^2, \dots, \sigma_n^2] \quad (91)$$

The weighted least-square estimate of $\gamma(m)$ is

$$\hat{\gamma}_{\text{wls}}(m) = (\mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1} \mathbf{H}^T \mathbf{R}^{-1} \Phi(m) \quad (92)$$

Figure 16 shows a real ISAR image of an aircraft that is auto-focused by the WLS algorithm. The image resolution is approximately 0.4×0.4 m.

Figure 16. A real ISAR image of an aircraft. It is autofocused by the WLS algorithm.

The PGA is a widely used algorithm in SAR community. It has an iterative procedure for phase error correction. The first step is the same as that in the WLS algorithm, that is, moving the strongest scatterer of each range bin to the image center. The second step is the windowing of each shifted image. The window is centered on the strongest scatterer. Windowing increases the SNR by preserving the width of dominant blur while discarding scatterers that cannot contribute to the phase error estimation.

The next step is to estimate the phase error, or rather, the phase gradient or phase difference. Denote the range-compressed phase history data by $g_n(m) = |g_n(m)| \exp\{j[\gamma(m) + \phi_n(m)]\}$, where $\phi_n(m)$ is the phase fluctuation caused by the clutter within the window. A linear unbiased minimum variance estimate of the gradient of the phase error is

$$\hat{\gamma}(m) = \frac{\sum_n \text{Im}[g_n^*(m) \{\dot{g}_n(m)\}]}{\sum_n |g_n(m)|^2} \quad (93)$$

Another estimate of the phase difference is

$$\Delta\hat{\gamma}(m) = \angle \left[\sum_n g_n(m+1) g_n^*(m) \right] \quad (94)$$

where \angle denotes the angle of the complex quantity computed on $[-\pi, \pi]$. This is a maximum likelihood estimate.

The estimated phase gradient or phase difference is integrated to obtain the estimate of phase error $\hat{\gamma}(m)$. It is used for correction after removing any bias and linear component. Then the PGA goes back to its first step and adopts a narrower window. The process is repeated until the image is well focused.

7. SUMMARY

This article has discussed major techniques of radar signal processing. These techniques can be divided into two categories. The first category includes the techniques for suppressing interference and enhancing the useful signal. They ensure reliable detection and processing, and are listed as follows:

- *Matched Filter.* It is the optimum filter that achieves the maximum SNR.
- *MTI.* It discriminates moving target from fixed clutter by Doppler filtering.
- *Beamforming.* It mitigates against jamming sources by spatial filtering.
- *CFAR.* It maintains a constant false-alarm rate even if the clutter intensity varies.

The techniques in the second category are developed mainly for improving the resolving capability of radar. They enable radar to acquire complex information like target size, shape, and image:

- *Pulse Compression.* It achieves high resolution in range direction without sacrificing the detection range.

- *Radar Imaging*. The synthetic aperture radar is developed to attain high resolution in azimuth direction. The signal processing techniques in SAR are discussed in some details, including methods for image formation, motion compensation, and autofocus.

It is foreseeable that radar will advance with the advancement of signal processing techniques and hardware technology. It will be more robust when working in less-than-ideal environments and have stronger capability for acquiring complex information.

RADAR TARGET RECOGNITION

KIE B. EOM
The George Washington
University
Washington, DC

1. INTRODUCTION

Recent (as of 2003) advances in radar provides sufficient resolution and enough information to recognize tactical targets from radar returns [21]. For target recognition applications, different types of radar, such as synthetic aperture radar (SAR), millimeter-wave (MMW) real aperture radar (RAR), and interferometric synthetic aperture radar (IFSAR), have been explored [1–4]. Modern radar system also provides extensive data including fully polarimetric and Doppler channels [14,26,32], but there still are many challenges for target recognition using radar returns [16,17]. This is because special characteristics of radar and recent advances of radar technology make the recognition of targets difficult. For example, the radar profile changes drastically for the small change in viewing angle, and the recent development of stealth technology significantly alters the radar signature. In radar target recognition, many different approaches for different radar types are suggested, and are discussed in this article.

Synthetic aperture radar provides high resolutions for both range and azimuth directions, and have been used widely for target recognition applications. Since SAR is an imaging radar, it can provide detailed images of target area with cloud-penetrating characteristics. When its fully polarimetric data is utilized, targets can be recognized with high accuracy. The SAR target recognition is typically done in multiple stages [18]. The first stage of a typical SAR target recognition algorithm is a prescreener, where regions of interest are located in this stage. Constant false-alarm rate (CFAR) detection algorithm is often used in the first stage. The second stage may be a discriminator, where natural clutter false alarms are rejected. In this stage, textural features are extracted from the target-size windows applied to the neighborhood of pixels located by CFAR detection. The third stage is typically a classifier, where the targets are classified and manmade discretely are rejected. Extensive studies in statistical pattern recognition have been done, and many different pattern classifiers are used in target recognition applications.

For SAR target recognition, spatial matched filters have been investigated [18] for the recognition of ground vehicles. Novak's [18] spatial matched filter approach in target recognition is explained in later sections.

Although SAR technology provides many advantages over real aperture radar (RAR), there are many applications where RAR is important. The azimuth resolution of SAR is much better than that of RAR, but it is typically based on the assumption that the movement of the radar is at constant speed and direction in SAR processing. When the radar is moving at rapidly changing speed and trajectory, as in the case of the radar mounted at fighter airplanes or self-guidance weapons, the assumptions for SAR processing are not correct. Millimeter-wave (MMW) RAR represents the next generation of military smart sensors for detection, tracking, and surveillance because of its high-range resolution, which is critical in target recognition [6]. The MMW RAR technology is sufficiently advanced, and the range resolution of MMW radar is sufficiently high to discriminate tactical targets at a distance of several kilometers [31]. The target recognition by hierarchical modeling of high-range resolution (HRR) millimeter-wave (MMW) radar signatures is discussed in this article.

The artificial neural network (ANN) has been widely used in target recognition. The use of ANN in radar target recognition is also discussed in this article. ANNs are used as pattern classifiers, feature extractors, model adaptation, fuzzy classification, and in other applications in radar target classification. Feedforward neural networks have been used as pattern classifiers after the training with known target samples. The learning algorithm of neural networks provides a powerful tool for adaptation of the classifier to input vectors [24]. A self-organizing feature map has been used as a feature extractor [27] for radar target recognition. In combination with Kohonen's learning vector quantizer (LVQ) for supervised classification, it has been applied to the recognition of ground vehicles from MMW HRR radar signatures [27]. Perlovsky et al. [19] suggested that the model-based neural network to include a priori information to an ANN. This approach can reduce the search space of the neural network by incorporating a priori information to the adaptability of an ANN. The fuzzy neural network (FNN) approach [25] is also suggested to classify targets that may belong to more than one class. The advances in neural network approaches can potentially improve the performance of target recognition algorithms further. There are many approaches to incorporate information from many different sources for radar target recognition. By fusing the information from more than one sensor, the accuracy of radar target recognition may be improved. Two approaches in utilizing information from multiple sensors are discussed in this article. Interferometric synthetic aperture radar (IFSAR) provides elevation information, in addition to two-dimensional radar image, by processing interference between radar returns received by two different antennas. By processing IFSAR image and fusing to SAR of visual images, the accuracy of the target recognition can be improved substantially. The approach of combining IFSAR and visual images using the image registration approach is

discussed in this article. There are statistical approaches in data fusion, and Bayesian data fusion approaches are used in radar target recognition [13]. In this approach, features from polarimetric SAR images are fused to improve the recognition accuracy.

Radar target recognition is a complex problem, and no single algorithm performs better than other algorithms with different types and modes of radar. In this article, different approaches for radar target recognition is discussed in terms of radar types and approaches.

2. HIERARCHICAL MODELING APPROACH FOR NONCOOPERATIVE TARGET RECOGNITION

The target recognition using hierarchical modeling of MMW RAR radar signatures is considered in Ref. 10, and the algorithm is tested with MMW radar data from non-cooperative target identification (NCTI) database. In radar target recognition problems, the targets may be shifted and scaled from the trained data. The change in viewing angle results scale change in radar signature, and the change in azimuth angle change results shifting in radar signature. Therefore, a classifier using features extracted from the radar signatures should classify targets reliably even when radar signatures are shifted or scaled. In general, parameters of time-series models such as ARMA (autoregressive moving-average) are not scale-invariant [20,22]. Thus, the classification of scaled targets with model parameter features can result in poor classification accuracy. There are a few approaches to make a classifier more reliable to shifting and scaling. For example, the use of scale-invariant features or a training with scaled samples can make a classifier more robust to scaling.

Hierarchical ARMA modeling approach is briefly discussed as follows. Suppose that a continuous signal $x(t)$ is a training sample. The classifier need to classify scaled signal of $x(t)$ correctly as the same class as $x(t)$. The scaled signal of $x(t)$ is given by

$$y_x(t) = \frac{1}{\alpha} x(\alpha t) \quad (1)$$

One approach to achieve this is to train a classifier with features extracted from scaled signals of $x(t)$. For example, different features at m different scales are extracted from scaled signals $y_{x_1}(t), y_{x_2}(t), \dots, y_{x_m}(t)$, then the classifier is trained with these multiscale features. If the number of scales included in the training is large enough, the classifier will classify signals having large scale changes.

However, there are at least two potential problems with this approach if the signal is a discrete signal $\{x(i), i = 1, \dots, N\}$: (1) the original signal is defined only at discrete points—the signal at the finer scale is not defined at certain points; and (2) feature extraction is performed multiple times with a single training sample, and the computational complexity increases linearly as the number of scales increases. These difficulties can be solved by the hierarchical modeling approach. The hierarchical modeling approach presented in this section extracts multiscale features without adding much computational complexity.

Figure 1. A decimation filter.

A discrete signal can be scaled to a coarser scale or a finer scale by decimation filtering or interpolation, respectively [7,8,11,12]. We will first consider the decimation filtering of a signal, and its effect to the statistical model, and then we will consider the scaling to a finer scale as a modeling process. A decimation filter is defined as a local averaging (FIR filtering) followed by a downsampling process as shown in Fig. 1 [29,35]. If the downsampling rate is m , the decimation-filtered signal represents the signal at the scale reduced by a factor of m .

Let H be a FIR filter of length r and \downarrow be the downsampling operator of factor m :

$$H(\delta) = \sum_{k=0}^{r-1} h_k \delta^k, \quad \text{where } \delta \text{ is a unit delay operator} \quad (2)$$

$$(\downarrow x)(i) = x(mi) \quad (3)$$

Suppose that a signal at a coarser scale $y_m(i)$ is obtained by decimation filtering of the original signal $x(i)$:

$$y_m(i) = H(\delta)x(im), \quad i = 1, \dots, N/m \quad (4)$$

Suppose that the signal $\{x(i), i = 1, \dots, N\}$ follows an ARMA(p, q) model

$$x(i) = \sum_{j=1}^p \alpha_j x(i-j) + \sum_{j=0}^q b_j w(j), \quad i = 1, \dots, N \quad (5)$$

where $\{w(i)\}$ is a zero mean white-noise sequence with variance σ_w^2 and the a_j and b_j terms are real coefficients. Equation (5) can be rewritten as

$$A_p(\delta)x(i) = B_q(\delta)w(i), \quad i = 1, \dots, N \quad (6)$$

where

$$A_p(\delta) = 1 - a_1\delta^1 - a_2\delta^2 - \dots - a_p\delta^p, \quad (7)$$

$$B_q(\delta) = 1 + b_1\delta^1 + b_2\delta^2 + \dots + b_q\delta^q$$

and δ is the unit delay operator, and we assume that the roots of $A_p(\delta)$ and $B_q(\delta)$ lie inside of the unit circle for stability and invertability of the model.

To find features at coarser scale, the model at a coarser scale should be considered. The following theorem summarizes the results on the modeling of a decimation-filtered ARMA process.

Theorem 1. The decimation-filtered process $\{y_m(i)\}$ defined in (4) follows an ARMA(p, q^*) model, where the order of AR polynomial is p and the order of the MA polynomial is $q^* = [(p(m-1) + r + q - 1)/m]$, and the model parameters can be obtained from the model parameters of $x(i)$

$$C_p(\delta)y_m(i) = D_{q^*}(\delta)v(i) \quad (8)$$

where

$$C_p(\delta) = 1 - c_1\delta^1 - c_2\delta^2 - \dots - c_p\delta^p \quad (9)$$

$$D_{q^*}(\delta) = 1 + d_1\delta^1 + d_2\delta^2 - \dots + d_{q^*}\delta^{q^*},$$

Also the AR polynomial $C_p(\delta)$ of aggregated data satisfies the following relation:

$$\begin{aligned} C_p(\delta) &= 1 - c_1\delta^1 - \dots - c_p\delta^p \\ &= (1 - r_1^m\delta)(1 - r_2^m\delta) \dots (1 - r_p^m\delta) \end{aligned} \quad (10)$$

where r_1, \dots, r_p are roots of $A_p(\delta)$.

The proof can be found in Ref. 10.

The ARMA model parameters are shift-invariant because the model's parameters depend only on mean and correlations. Power spectral density can be estimated by using ARMA model parameters, and is also shift-invariant and provides features that are intuitively appealing. For example, spectral peaks or notches represents presence or absence of a frequency component in the signal. For radar signal classification, ARMA power spectrum features at multiple scales are used. Power spectral density of an ARMA process can be estimated by an extended least-squares (ELS) method.

Suppose that $x(i)$ is an ARMA(p, q) process and $w(i)$ is the input white sequence with variance σ^2 as defined in Eq. (5). Let $R_{xx}(k)$ be the autocorrelation functions of $x(i)$, and $R_{xw}(k)$ be the cross-correlation between $x(i)$ and $w(i)$. The Yule-Walker equation for the ARMA process $x(i)$ is given by the following equation:

$$R_{xx}(k) = \begin{cases} \sum_{i=1}^p a_i R_{xx}(k-i) + \sum_{i=1}^q b_i R_{xw}(k-i), & k = 0, \dots, q \\ \sum_{i=1}^p a_i R_{xx}(k-i), & k > q \end{cases} \quad (11)$$

The AR (autoregressive) parameters are estimated by solving these Yule-Walker equations. By using the estimated AR parameters, MA (moving-average) component of $x(i)$ can be obtained by filtering AR component from $x(i)$:

$$\hat{x}_{\text{ma}}(i) = x(i) - \sum_{k=1}^p \hat{a}_k x(i-k) \quad (12)$$

The power spectral density of the ARMA process $x(t)$ is estimated from the correlations of $x_{\text{ma}}(t)$ and the AR parameters estimated by Yule-Walker equations. The ELS power spectrum estimation algorithm is summarized below.

ELS Spectrum Estimation Algorithm

Step 1. Compute sample correlations $R_{xx}(k)$ for $k = 0, \dots, p+q$:

$$\hat{R}_{xx}(k) = \frac{1}{N-k} \sum_{i=1}^{N-k} x(i)x(i+k) \quad (13)$$

Step 2. Estimate AR parameters a_1, \dots, a_p by

$$\begin{bmatrix} \hat{a}_1 \\ \vdots \\ \hat{a}_p \end{bmatrix} = \begin{bmatrix} R_{xx}(q) & \cdots & R_{xx}(q+1-p) \\ \vdots & \ddots & \vdots \\ R_{xx}(q+p-1) & \cdots & R_{xx}(q) \end{bmatrix}^{-1} \begin{bmatrix} R_{xx}(q+1) \\ \vdots \\ R_{xx}(q+p) \end{bmatrix} \quad (14)$$

Step 3. Compute the sample correlation of MA component $x_{\text{ma}}(i)$, which is obtained by removing AR component:

$$\begin{aligned} \hat{R}_{\text{ma}}(k) &= R_{xx}(k) - \sum_{j=1}^p a_j R_{xx}(k-j) - \sum_{j=1}^p a_j R_{xx}(k+j) \\ &+ \sum_{j=1}^p \sum_{l=1}^p a_j a_l R_{xx}(k-j+l), \quad k=0, \dots, q \end{aligned} \quad (15)$$

Step 4. Compute the ARMA power spectrum:

$$S_{xx}(\omega) = \frac{R_{\text{ma}}(0) + 2 \sum_{k=1}^q R_{\text{ma}}(k) \cos(\omega k)}{\|1 - \sum_{k=1}^p \hat{a}_k e^{-j\omega k}\|^2} \quad (16)$$

For each training sample $x(i)$, the models at the other scales (both coarser and finer scales) are obtained by the hierarchical modeling approach presented in this section. The model at a coarser scale is obtained using Theorem 1. The AR polynomial is obtained by Eq. (10), and the correlation of the signal at the coarse scale is obtained with a proper choice of smoothing filter H , such as the Gaussian filter. Thus, the spectral density of the signal at a coarser scale is obtained by the ELS algorithm. The model at a finer scale is obtained by the approach explained in the next step sequence. The AR polynomial of the signal at a finer scale are obtained under a no-hidden-periodicity assumption [34,35]. The correlation function at a finer scale is obtained by disaggregation [10], and the ARMA spectrum at a finer scale is obtained by the ELS estimation algorithm. The multiscale feature extraction algorithm is summarized below.

Multiscale Spectral Feature Extraction Algorithm

Step 1. Each radar return is normalized to zero mean and unit variance by

$$\bar{x}(i) = \frac{x(i) - \hat{m}}{\hat{\sigma}} \quad (17)$$

where \hat{m} and $\hat{\sigma}^2$ are sample mean and sample variances of $x(i)$. M K -dimensional features from M scales (including coarser and finer scales) are ob-

tained from the normalized radar returns by the following procedure.

Step 2. For each training sample, the AR parameters and correlations are estimated by the ELS algorithm. For $k=0,1,\dots,K-1$, the power spectrum is estimated at $\omega = \pi k/K$. The logarithm of the power spectral density forms a K -dimensional feature vector.

Step 3. At each coarser scale, a feature vector is obtained by estimating the power spectrum using the ELS method with model parameters obtained by the hierarchical modeling approach. The logarithm of the power spectral density forms a K -dimensional feature vector at a coarser scale. Feature vectors at multiple scales are obtained by repeating this step at coarser scales.

Step 4. At each finer scale, a feature vector is obtained by estimating the power spectrum using the ELS method with model parameters obtained by the hierarchical modeling approach. This is repeated for other finer scales, and multiple K -dimensional feature vectors are obtained from the logarithm of the power spectral density.

Classification is done by a minimum-distance classifier with multiple prototypes. In this approach, each training sample generates M prototypes corresponding to M scales. Therefore, if there are N training signals for each class, then NM prototypes will be available for each class. Let us assume that there are N_k prototypes $\mathbf{z}_k^1, \dots, \mathbf{z}_k^{N_k}$ in the class $k \in \{1, \dots, K\}$. For a test pattern \mathbf{x} , the distance to the class k is defined by

$$D_k = \min\{d(\mathbf{x}, \mathbf{z}_k^l)\} \quad (18)$$

where the intersample distance $d(\mathbf{x}, \mathbf{z})$ is the Euclidian distance between \mathbf{x} and \mathbf{z} . The distance D_i is the smallest of the distances between \mathbf{x} and each prototype of the class k . The test pattern \mathbf{x} is classified by the minimum-distance decision rule: \mathbf{x} is classified into class k if $D_k < D_i$ for all $i \neq k$.

In Ref. 10, the hierarchical model-based features are tested with NCTI data. Figure 2 shows a typical NCTI radar signature, and estimated power spectral density. In Ref. 10, about 95% of classification accuracy is reported with 5000 MMW RAR radar signatures.

3. NEURAL NETWORKS APPROACHES

Neural networks have been widely used in radar target recognition applications [19,24,25,27]. A good survey on the use of neural networks in target recognition can be found in Ref. 24. Neural network approaches have been popular because they have many promising qualities in target recognition applications. Neural networks have the capability for adaptation to additional targets and environments. The existence of powerful learning algorithms is one of the main strengths of the neural network approach [24]. They also offer techniques for selecting, developing, clustering, and compressing features into a

Figure 2. A HRR radar signature from NCTI database and its power spectrum estimated by hierarchical modeling.

useful set, and provide automatic knowledge acquisition and integration techniques for target recognition systems.

Feedforward neural networks have been used as pattern classifiers for target recognition [23]. Let x_i be the multidimensional feature vector extracted from a radar image, and let S be the index set of the target patterns:

$$S = \{i | i \in \text{target pattern}\} \quad (19)$$

The optimum receiver [23] defined by

$$R_s(x_1, \dots, x_N) = \sum_{i \in S} x_i \quad (20)$$

can be implemented as a neural network

$$y_s = \Theta \left(\sum_i W_{Si} x_i - T \right) \quad (21)$$

where T is the threshold and $\Theta(x)$ is the Heaviside step function. Roth [23] showed that detection of target patterns out of a set of P of patterns can be handled by the feedforward neural network presented above.

Neural networks have been also used as a feature extractor for target recognition. Kohonen's self-organizing map (SOM) and learning vector quantizer (LVQ) have been used in the two-stage target recognition approach [27]. SOM is based on unsupervised competitive learning where only one output node, or one per local group of nodes at a time, gives the active response to the current input signal, clusters input vectors into preselected C classes by adapting connection weights to nodes in the network, and is used as a feature extractor [27]. At each

iteration of the SOM algorithm, the best matching node c is selected by

$$c = \operatorname{argmin}\{\|x - m_i\|\} \quad (22)$$

where x is the current input vector and $\{m_1, \dots, m_C\}$ is the set of nodes (cluster centers). Then each node m_i located in the neighborhood of the node c is adapted by the learning rule

$$m_i(t+1) = m_i(t) + \eta_i(t)[x(t) - m_i(t)] \quad (23)$$

where the gain $\eta_i(t)$ can be a simple monotonically decreasing function of time or a Gaussian gain function defined by

$$\eta_i(t) = \alpha(t) \exp \frac{-\|r_c - r_i\|^2}{2\sigma^2(t)} \quad (24)$$

The learning rate $\alpha(t)$ and the kernel width $\sigma(t)$ are monotonically decreasing functions, and their exact forms are not critical. LVQ is used as a supervised classifier of the features extracted by SOM [27]. Stewart et al. [27], reported greater than 94% accuracy in the target recognition experiment with MMW data having five types of ground vehicles.

The model-based neural network (MBNN) was introduced [19] to combine a priori knowledge of models of data with adaptivity to changing data properties. Both learning and adaptation of the MBNN is done by iterative estimation of association weights and model parameters. Different statistical models for different physical processes, background clutter, outlier, target pixels, and other elements are also introduced in Ref. 19. This approach has a potential for improving target recognition performances by allowing the inclusion of a priori information in addition to the adaptability of a neural network.

Fuzzy neural networks are also used in radar target recognition. Fuzzy ARTMAP and EMAP neural networks are suggested [25] for radar target recognition. The fuzzy neural network allows one to make soft decisions in classifying a target, and each input vector can belong to more than one class. The fuzzy association between the input vector and the classified target can potentially improve the performance and the complexity of the adaptation.

4. EXPLOITATION OF ELEVATION DATA FROM IFSAR

IFSAR is a technique to generate high-resolution Digital Elevation Map (DEM) based on the phase difference in SAR signals received by two spatially separated antennas [36]. There are drawbacks in height maps derived from IFSAR data: The data are noisy and the spatial resolution is far inferior to that of visual data. The spatial resolution is further degraded by the noise removal step. Figure 3 shows a height map produced by a real IFSAR. A typical IFSAR elevation image is noisy and needs to be filtered before it can be used reliably. Also, there are regions with "no data," resulting either from the fact that the original scene was not on a rectangular grid or from radar geometry effects that cause some points not to be mapped.

Figure 3. An IFSAR image.

Interpolation and nonlinear filtering techniques are used to filter the elevation data.

Positioning of IFSAR and visual data allows for the fusion of clues from both sensors for target recognition. It is needed to overcome various difficulties resulting from the limitations of the sensor. For example, building detection requires the extraction and grouping of features such as lines, corners, and building tops to form buildings [9]. The features extracted from visual data usually include many unwanted (spurious) edges and lines that do not correspond to buildings. The grouping stage requires complex and computationally intensive operations. Further, the height of a building is typically estimated by extracting shadows and sun angle when available, and is not reliable when the shadows are cast on adjacent buildings. Another drawback of methods based exclusively on visual data lies in their sensitivity to imaging conditions.

IFSAR elevation data can be used in conjunction with visual data to overcome the abovementioned difficulties. Current IFSAR technology provides sufficient elevation resolution to discriminate building regions from surrounding clutter. These building regions are not well defined from a visual image when the buildings have the same intensity level as their surrounding background. Similarly, a building having different colors may be wrongly segmented into several buildings. IFSAR data are not affected by color variations in buildings and therefore are better for building detection.

Figure 4 shows a visual image and edges detected by the Canny operator for the area shown in Fig. 3. The left portion of Fig. 4 shows a building with two different roof colors and roof structures on many buildings. Many spurious edges not corresponding to the building appear in the edge map shown on the right of Fig. 4. Using the IFSAR elevation map shown in Fig. 3, buildings and ground regions are labeled using a two-class classifier. The IFSAR and visual images are registered. Figure 5 shows the

Figure 4. Visual image and edges detected by the Canny operator.

result of registration of a visual image and the segmented elevation image. Features corresponding to roads, parked cars, trees, and other objects are suppressed from the visual images using the segmented buildings derived from the IFSAR image.

The location and the directions of edges in the segmented image are estimated, and are used to locate edges of buildings in the visual image. In the visual image, an edge pixel corresponding to each edge pixel in the registered height image is searched in the direction perpendicular to the estimated direction in the height image. If an edge is found within a small neighborhood, the edge pixel is accepted as a valid edge of a building. If such a pixel is not found in the neighborhood, the edge is not accepted. Figure 6 shows the refined edges obtained by searching in the neighborhoods of height edges. Most of building edges in the height image are found while the unwanted edges are removed.

Figure 5. Buildings segmented from the IFSAR image overlaid to visual image.

5. SPATIAL MATCHED-FILTER CLASSIFIERS FOR SAR

A typical target recognition using SAR is done in multiple stages, and is illustrated by the block diagram in Fig. 7. In

Figure 6. Edges Refined using IFSAR result.

the first stage, a CFAR detector prescreens by locating potential targets on the basis of radar amplitude. Since a single target may produce multiple detections, the CFAR detections are clustered (grouped together). Then a region of interest (RoI) around the centroid of each cluster is passed to the next stage of the algorithm for further processing.

The second stage takes each RoI as its input and analyzes it. The goal of this discrimination stage is to reject natural clutter false alarms while accepting real targets. This stage consists of three steps: (1) determining the position and orientation of the detected object, (2) computing simple texture features, and (3) combining the features into a discrimination statistic that measures how “target-like” the detection object is.

The third stage is classification, where a 2D pattern-matching algorithm is used to (1) reject clutter false alarms caused by manmade clutter discretely (buildings, bridges, etc.) and (2) classify the remaining detected objects. Those detected objects that pass the second stage are matched against stored reference templates of targets. If none of the matches exceeds a minimum required score, the detected object is classified as clutter; otherwise, the detected object is assigned to the class with the highest match score.

Matched filters are investigated in [18] as pattern-matching classifiers in target recognition system shown in Fig. 7. They are the synthetic discriminant function (SDF), the minimum average correlation energy (MACE) filter, the quadratic distance correlation classifier (QDCC), and the shift-invariant 2D pattern-matching classifier. The basic structures of the SDF and the MACE filter are characterized in the frequency domain by

$$H = AX(X^\dagger AX)^{-1}U \quad (25)$$

where H denotes the DFT of the spatial matched filter. The matrix X is composed of a set of target training vectors obtained by taking the DFT of the target training images. The vector U represents a set of constraints imposed on the values of the correlation peaks obtained when the training vectors are run through the spatial matched filter. The matrix A represents a positive definite weighting matrix. A is an identity matrix for SDF, and is the inverse of the following matrix D

$$D = \sum_{i=1}^N \text{diag}[|X_i(1)|^2, |X_i(2)|^2, \dots, |X_i(p)|^2] \quad (26)$$

where N is the number of training images and p is the dimension of the training vectors.

In the QDCC, the DFT of the spatial matched filter is expressed by

$$H = S^{-1}(m_1 - m_2) \quad (27)$$

where m_1 and m_2 are means of the DFTs of the training images for classes 1 and 2, respectively. S is a diagonal matrix defined by

$$S = \frac{1}{N} \left[\sum_{i=1}^N (X_i - M_1)^\dagger (X_i - M_1) + \sum_{i=1}^N (Y_i - M_1)^\dagger (Y_i - M_1) \right] \quad (28)$$

Figure 7. Block diagram of a typical base-line target recognition system (adapted from Novak [17]).

where M_1 and M_2 are matrices with elements of m_1 and m_2 placed on the main diagonal and X_i and Y_i are i th training vectors from classes 1 and 2, respectively.

In the shift-invariant 2D pattern matching classifier, the correlation scores are calculated by

$$\rho_i = \max\{\text{DFT}^{-1}[R_i \times T^*]\} \quad (29)$$

where T is the DFT of the decibel-normalized test image and R_i is the i th reference template.

Novak et al. [18] did extensive experiment with the high-resolution (1 ft \times 1 ft) fully polarimetric SAR data. In the four-class classification experiment using four types of spatial matched filter classifiers, it is reported that all targets are correctly classified [18].

6. MULTISENSOR FUSION

There has been research on multisensor fusion for target recognition [28]. Some of the motivating factors of such research are increased target illumination, increased coverage, and increased information for recognition. Significant improvement in target recognition performance has been reported [13] when multiple radar sources were utilized using sensor fusion approaches. Tenney and Sandell [30] developed a theory for obtaining the distributed Bayesian decision rules. Chair and Varshney [5] presented an optimal fusion structure given that detectors are independently designed. The target recognition using multiple sensors is formulated as a two-stage decision problem in Ref. 13. A typical radar target recognition approach using data fusion is illustrated in Fig. 8. After the prescreening, Single-source classifications are performed first; then the fusion of decisions is performed.

The data fusion problem is treated as an m -hypothesis problem with individual source decisions being the observations. The decision rule for m hypothesis is written as

$$\text{Decide } w_i \text{ if } g_i(u) > g_j(u) \text{ for all } j \neq i \quad (30)$$

For Bayes' rule, $g_i(u)$ is an a posteriori probability:

$$g_i(u) = p(w_i | u) \quad (31)$$

Since the a priori probability and the distribution of features cannot be estimated accurately, a heuristic function is used [13]. It is a direct extension of Bayesian approach introduced by Chair and Varshney [5], and the function $g_i(\cdot)$ is generalized to include the full threshold range

$$g_i(u) = \log \frac{P_1}{P_0} + \sum_{\Omega_1} \log \frac{P_i^d}{P_i^f} + \sum_{\Omega_0} \log \frac{1 - P_i^d}{1 - P_i^f} \quad (32)$$

where P_0 and P_1 are prior probabilities, Ω_1 and Ω_0 are the sets of all i such that $\{g_i(u) \geq T_i\}$ and $\{g_i(u) < T_i\}$ respectively, where T_i is the individual source threshold for partitioning decision regions, and the probabilities P_i^f and P_i^d are false-alarm rates and probabilities of detections of each local sensor. The probabilities P_i^f and P_i^d are defined by the cumulative distribution function (cdf) for each decision statistic. In practice, the cdf is quantized and estimated from training on the individual sensor's classifier error probabilities. In a distributed scenario, the weighting can be computed at each sensor and transmitted to the fusion center where they will be summed and compared to the decision threshold. In Ref. 13, the data fusion approach is applied to multiple polarimetric channels of a SAR image, and substantially improved classification performance is reported.

7. SUMMARY

In radar target recognition, different types of radar are employed for different applications. Each radar system has different characteristics, and target recognition approaches using different radar are discussed.

Figure 8. A typical data fusion approach for target recognition (adapted from Hauter et al. [13]).

RADAR TRACKING

JOSEPH A. BRUDER
Air Force Research Laboratory

Radar tracking is the ability to determine the position and velocity vector of a target at any particular instant in time, to predict its position in the future, and to distinguish the desired target from other targets and clutter. For a typical radar, the direction from the radar antenna (or antennas) to the target is generally determined in the polar coordinates of range (distance), azimuth (horizontal) angle, and possibly vertical angle. For a sophisticated coherent radar, tracking targets in Doppler frequency space may also be required. Thus radar tracking can be one dimensional (range, angle, or Doppler), two-dimensional (range and

azimuth angle), three-dimensional (range, azimuth angle, and elevation angle), or four-dimensional (range, azimuth angle, elevation angle, and Doppler). For some systems, radar information is converted to Cartesian coordinates, and the tracking functions are performed in coordinates such as latitude, longitude, and height.

Target tracking is necessary for a number of reasons. In order to direct a weapon such as a missile or a projectile to a target, the range, future range, and angles from the radar to the target must be determined by the radar. By knowing the position of the target relative to that of the missile, the guidance computer can direct the missile to the target. Aircraft controllers must know an aircraft's location relative to other aircraft in the vicinity, and by tracking the positions of all the aircraft in their assigned sectors, they can control the spacing of the aircraft to ensure flight safety.

1. EXAMPLES OF RADAR TRACKERS

A police radar can determine the speed of the vehicle in the field of view of the radar by measuring the Doppler frequency of the return (echo) signal from the vehicle because the Doppler frequency is directly proportional to the vehicle's velocity. Most police radars must track the Doppler frequency over a given period of time to ensure measurement. A missile guidance radar must continually track the target's range, azimuth angle, and elevation angle in order to predict the future target position; thus, it is an example of a three-dimensional tracker. An airborne radar such as the APG-70 in the F15-E aircraft utilizes Doppler processing for clutter rejection, as well as range, azimuth angle, and elevation for target-tracking purposes, and is thus an example of a four-dimensional tracking radar. A phased-array radar must be capable of maintaining track simultaneously on multiple targets, while still scanning its field of regard for new targets.

2. HISTORY OF RADAR TRACKING

In the early days of radar, range and angle-tracking functions were performed manually. Using a device such as a track ball, the operator could keep the crosshairs positioned on the range and azimuth angle of a detected target viewed on a display such as a plan position indicator (PPI) display. The PPI display, such as that shown in Fig. 1, provides a two-dimensional display of range and azimuth angle for a radar with an azimuth-scanning antenna. Targets result in blips on the display where the brightness (and size) of the blips are related to the amplitude of the target echoes at the receiver. The output of the track ball can provide readout of the target range and azimuth angle or provide the required range and angle information to weapons systems for targeting purposes. Although this was a satisfactory technique for tracking slow-moving targets such as ships, it is certainly a tedious process.

To aid in the tracking of ships and aircraft, a rate-aided device was added to some systems. With rate-aided tracking, the operator needed to make only fine adjustments to

Figure 1. PPI radar display showing targets and clutter.

account for changes of the target range and angle rates with respect to the radar. With this configuration, the radar operators were better able to track faster-moving objects such as aircraft. Still, this tracking function required the constant attention of the radar operator.

Automated target tracking evolved as a necessary tool to allow the radar operator to perform the tracking function efficiently. After range and angle trackers are locked onto the target, the tracker then senses any error between the current target position and that predicted by the tracker and automatically and continuously adjusts the tracker functions either on a pulse-to-pulse or scan-to-scan basis. As a result, automatic radar tracking can maintain target track more accurately than a human operator and can better follow fast maneuvering targets.

3. TRACKING BASICS

For automatic target tracking, a sequential procedure must be used to acquire the target and initiate track. The three steps are target detection, target acquisition, and target track.

3.1. Target Detection

In order for the received echo signal from the target to be detected by the radar, the receive signal strength in that particular range cell must be stronger than the residual noise in the radar and other interfering signals in that range cell. For a target separated from clutter, the primary interfering source is receiver noise. Although it is desired to declare a target's presence with high probability, it is also necessary to keep the probability of false

alarm (declaring a target detection when no target is present) as low as possible. The two values are tied closely together: for a given signal-to-noise (SNR), lowering the detection threshold to increase the probability of detection threshold also increases the probability of false alarm. Depending on the target detection criteria, a SNR of 8–15 dB is generally required to keep the probability of detection reasonably high, while keeping the probability of false alarms at or below 10^{-6} . Probability of detection vs. false alarm curves are available in Blake [1] and a number of other sources.

In many cases, the single-pulse SNR may be below the threshold, but the SNR can be improved by integrating a number of pulses. For coherent operation, the SNR improvement is directly proportional to n , the number of pulses coherently integrated. For noncoherent operation, the SNR improvement for small n , is usually near $n^{0.8}$ in practical radar systems where $n < 20$. Most real targets are composed of complex reflecting surfaces; the scattering contributions of these separate reflecting surfaces tend to add and subtract vectorially to the overall radar cross section (RCS) of the target. The fluctuations in RCS caused by these surfaces will affect the probability of detection and false alarm. Swerling [2] has derived the probability of detection and false-alarm curves for both slowly varying and rapidly varying target RCS fluctuations. For these cases, the required SNR required can be obtained from this set of curves.

3.2. Target Acquisition

Target acquisition for tracking can be done either manually or automatically. For manual target acquisition, the operator needs to point the radar antenna (or an angle cursor) on the azimuth angle to the target and designate the desired target range. Alternately, the operator could use a lightpen if available to designate the target azimuth angle and range to the tracker. When the particular target is within the acquisition limits of the tracker, the acquisition process can be initiated to lock the tracker up on the target range and azimuth.

For automatic target acquisition, the tracker must have either a designated philosophy for selecting the target for track acquisition, or the tracker must have sufficient capability of tracking all the targets satisfying the track initiation criteria. For example, for a radar altimeter, the track would be initiated on the closest radar returns to the radar. For a scanning surveillance radar, the tracker would need to have sufficient capability to track all the targets satisfying the track criteria.

4. RANGE TRACK

When the target has been acquired by the tracker, the tracker must determine not only the range and angular positions but also the velocity vector of the target, and it must determine the velocity components in range and angle in order to maintain track on the target. This is especially important in order to maintain track during conditions of track fade or during momentary passage of other targets or clutter returns. Target trackers differ in

complexity and include (1) dedicated single target trackers, (2) track-while-scan target trackers, and (3) multiple target trackers. For scan-to-scan and multiple target trackers, association algorithms are required to keep track of the targets, especially during crossing target events.

4.1. Dedicated Range Trackers

Dedicated target trackers generally use radars with antennas that spotlight the desired target with the antenna beam and keep the antenna beam spotlighted on the target during the entire tracking process. This type of tracker is generally used with weapon systems that require continuously updated position information on the target. This is a relatively simple type of tracker and will be used to explain the principles of tracking. The tracking process will be described as composed of the following process: range tracking, angle tracking, and Doppler tracking.

For a radar system, the range from the radar to a target is precisely determined from the time delay between the transmission of the radar signal and the receipt of the radar echo from the target arriving back at the radar's receive antenna. The range (R) from the radar antenna to the target is then given by

$$R = \frac{c\tau}{2}$$

where

c = speed of light (2.997×10^8 m/s)

τ = delay time between transmit and receive target echo

Because radar signals travel at the speed of light, the range to the target is approximately 150 m for each microsecond of time delay between the time the radar signal is transmitted and when the return echo signal reflected from the target arrives at the receiver.

4.1.1. Range Tracking with an FMCW Radar. The simplest type of radar used for range tracking is that of frequency-modulated carrier wave (commonly referred to as an FMCW) radar. One of the prime advantages of using an FMCW radar is that, for a given signal-to-noise ratio, the average transmit power is much less than the peak power required for a pulse-type radar. Transmit signal frequency is generally swept linearly over a period of time, such as shown in Fig. 2. This signal is transmitted toward the target and returns with a time delay (τ). By comparing

Figure 2. FMCW transmit and receive waveforms.

Figure 3. Typical FMCW circuit.

the frequency of the received signal with that currently being generated by the transmitter, the time delay (and hence the range) can be determined from the equation

$$R = \frac{c\tau}{2} = \frac{c\Delta f}{2} \left(\frac{dt}{df} \right)$$

where

- Δf = difference frequency between the received signal and the transmit signal
- df/dt = rate of change in frequency versus time for the transmit signal

The circuitry for a FMCW ranging system is rather simple, as shown in Fig. 3. The transmitter is coupled to the antenna through a circulator, for example, to isolate the transmit signal from the receiver input. Transmit signal is reflected by the target, received by the antenna, and then mixed with the current transmit signal. The mixed signal is then amplified, filtered to remove the radiofrequency (RF) transmitter and receive signal components, and coupled to a frequency discriminator circuit. The frequency discriminator provides an output voltage that is proportional to the input frequency. Thus the output signal is proportional to the range to the target.

For a moving target, the frequency of the returns from the target are not only affected by the range to the target but also by the target velocity with respect to the radar. In

order to separate frequency change effects resulting from range from those resulting from target velocity, an up/down ramp waveform, such as that shown in Fig. 4 can be used. The frequency change caused by velocity essentially moves the entire receive frequency up or down, and by averaging the frequency difference between the up frequency and down frequency portions of the waveform, both the range and the target velocity can be determined from the following equations. The range is determined from the average of the frequency differences during the positive frequency ramp and the negative frequency ramp, thus

$$R = \frac{c \left(\frac{\tau_p + \tau_n}{2} \right)}{2} = \frac{c(\Delta f_p + \Delta f_n)}{4} \left(\frac{dt}{df} \right)$$

The velocity of the target relative to that of the radar is a function of the frequency difference between the positive ramp portion and the negative ramp portion. The velocity of the target in the direction toward the radar (positive Doppler frequency) is then

$$v = \frac{\lambda f}{2} = \frac{\lambda(\Delta f_n - \Delta f_p)}{4}$$

where λ is the wavelength of the transmit frequency.

Range tracking using an FMCW radar can be accomplished simply by averaging the output voltage from the frequency discriminator, which is proportional to the time delay between the transmit and receive signals, and hence is proportional to the target range. Extreme linearity and slope calibration of the frequency sweep is required for accurate range determination. For example, a 1% error in the linearity of the linearity or slope, can have an equivalent error in the range determination.

4.1.2. Range Tracking with Pulsed Radar. For pulsed radar, the target range is measured from the time delay (τ) between transmit pulse and received echo from the target. Figure 5 shows the basic configuration of a range tracker used with pulsed radar. The “heart” of a range tracker is the time discriminator that enables the tracker to determine the time difference between the range reference (estimated delay time) and the actual range of the target return. The range error (ϵ_r) is normally bipolar and proportional to the range (or time) difference between the estimated range and measured range. The range error is then input to a range and velocity estimator (and possibly acceleration estimator) circuit. The function of the range

Figure 4. FMCW waveform for resolving target range from velocity.

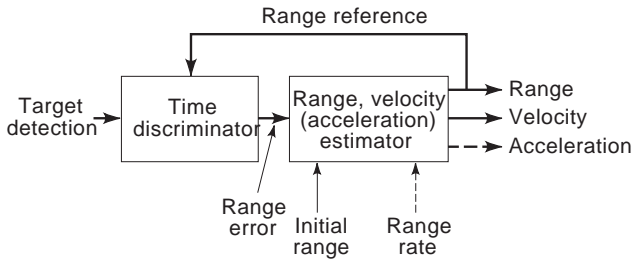

Figure 5. Basic pulsed radar range tracker.

error output is to drive estimated range to the measured range. In most cases, an initial range (and possibly range rate) in the general vicinity of the target range must be input to the range, velocity estimator circuit in order to enable it to acquire the target.

There are three basic classes of range trackers, which will be designated as analog, digital, and computer tracker range trackers. The most common analog-type tracker range trackers. The most common analog-type tracker circuit uses early and early-late gates, such as those shown in Fig. 6. The detected target video is input to both early and late gates. During the early gate time, the portion of the video signal existing during that time period is fed through to an integrator circuit, which integrates the signal energy during that time period. The late gate likewise feeds the video signal during the late gate time period to a second integrator. The outputs of the two integrators are compared in a difference circuit. If there is more video energy in one of the integrators, an error signal proportional to the difference is generated. The polarity of the error signal depends on which integrator output is greater. The error voltage then is provided to the range servo loop circuit, which generates voltages proportional to the estimated range, velocity, and possibly acceleration. The range voltage (estimated range) drives the timing generator, which generates the early and late gate times dependent upon the range voltage. If more video energy is in the late gate time, the error voltage causes the range voltage to increase so that the partition between the early and late gates moves out in range and becomes aligned on the centroid of the video pulse. In order for the range tracker to initially acquire track, the early-late gates must be positioned so that a significant portion of

the target video energy appears in the early or late gate times. An operator can accomplish this by observing a radar display and setting the initial range into the track circuit.

The range tracking accuracy of the range tracker is dependent upon the signal-to-noise power ratio (SNR) of the signal compared to the noise in the early and late gate time periods. According to Barton [3], the standard deviation of the range error (σ_{r1}) on a single pulse basis is given by

$$(\sigma_{r1}) = \frac{1}{2B\sqrt{\text{SNR}}} \text{ for } (B\tau_o \geq 1)$$

where

B = receiver frequency bandwidth
 τ_o = pulsewidth

Normally, the servo loop integrates a number of pulses to provide smoothing of the range voltage, which reduces the effects of noise jitter on the range determination. For noncoherent operation, the range error is effectively reduced by $1/n$, the number of pulses integrated. The resulting range error is then given by

$$\sigma_r = \frac{1}{2B\sqrt{f_r t_o (\text{SNR})}}$$

where

f_r = pulse repetition frequency
 t_o = observation time

Digital range trackers can be implemented using a number of techniques. In most cases, the range information (estimated range) is stored in a digital counter and is updated (up- or downcounted) depending on the actual range compared to the estimated range. An early-late gate discriminator, such as that shown for the analog range tracker can be used, and the error voltage then drives the up/down count. A simpler method for accomplishing the discrimination function is shown in Fig. 7. For this case, a range window is positioned about the radar video, and the video voltage is sampled at equal increments across the

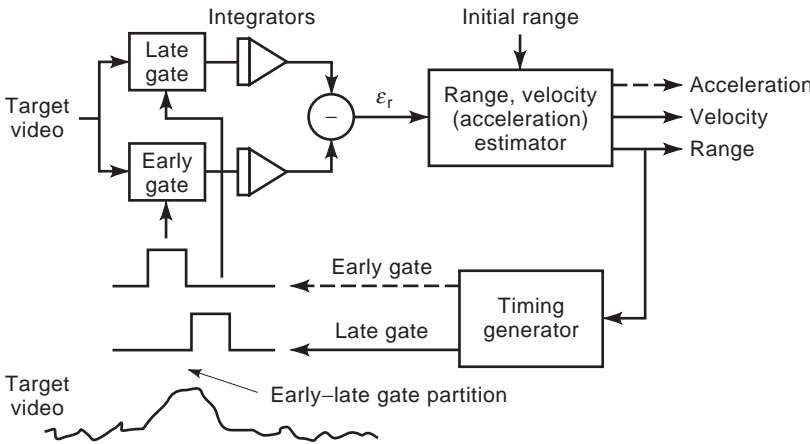

Figure 6. Analog early-late gate range tracker.

Figure 7. Digital range track sampler.

pulse. It should be noted that the digital discriminator of Fig. 7 requires that the signal be passed through an approximately matched filter prior to sampling, if the SNR is to be optimized. The split-gate tracker performs the matched filter function by averaging over the gates, and hence can be preceded by an IF amplifier with wider bandwidth. The digital circuit then drives the center of the range window to the centroid of the target video signal by equalizing the voltages in the early and late sample times. Three samples are required, as a minimum, for this type of discriminator: an early sample, a late sample, and an on-target sample. When the tracker is centered on the target, the on-target sample voltage is maximized, thus indicating that a true target is being tracked, rather than noise. Again, the range window must initially be set to the approximate target range or caused to slew automatically until a target is detected.

The analog and digital trackers described earlier are intended primarily for range tracking a single target, and in most cases the radar antenna is boresighted on the target either manually or by using an angle tracker. Tracking circuits, either analog or digital, can be designed to track targets using continuously scanning antennas. For this case, the target returns are received only by the radar during the time when the antenna beam scans by the target, and the tracker must use prediction algorithms to estimate the position of the target on the next scan. If multiple targets are to be tracked, then individual analog or digital tracking circuits must be used for each target tracked. In most cases where multiple targets are to be tracked, especially in scanning-type radars, the tracking functions are performed in a computer using specialized tracking algorithms. Because track-while-scan tracking normally involves angle tracking as well as range tracking, the discussion on multiple target computer tracking will be deferred.

5. ANGLE TRACKING

Angle tracking can differ depending on the application. For dedicated target-tracking radars, the antenna is kept boresighted on the target by the angle-tracking circuits and the antenna servo. With a continuously scanning antenna, the centroid of the target returns is measured each time the radar scans by the target, and uses an estimator to predict the position of the target on the next scan. For multifunction or phased-array radars, the target track is updated each time the antenna is scanned to the target location. Because track-while-scan and multitarget trackers normally require range (and possible Doppler tracking), the angle tracking described in this section is limited to a single target, boresighted angle tracking systems. The most common types of on-boresight trackers use conical scan, sequential lobe, or monopulse angle-sensing techniques.

5.1. Conical Scan Angle Trackers

Conical scan is the simplest angle-sensing technique in that only a single receiver channel is required. As shown in Fig. 8, the antenna beam is squinted off the antenna rotational axis. The squinted antenna beam is rotated about the antenna boresight by either rotating the antenna or nutating an offset feed. If the target is located on the antenna boresight, the target video signal maintains a constant amplitude as the antenna rotates. However, if the target moves off boresight, the target video signal will have a sinusoidal amplitude variation given by

$$E_t = E_0[1 + K_s \varepsilon \cos(\omega_s t + \phi)]$$

where

- E_0 = average magnitude of received signal
- ε = angular distance of target from boresight
- K_s = antenna error slope
- ω_s = antenna rotator scan frequency
- ϕ = phase angle of the return modulation relative to the scan rotation

In order to determine the transverse (azimuth) and elevation angle error components, the equation can be rewritten in the form

$$E_t = E_0[1 + K_s \varepsilon_t \cos \omega_s t + K_s \varepsilon_e \cos \omega_s t]$$

where

- ε_t = transverse (azimuth) angle error component
- ε_e = elevation angle error component

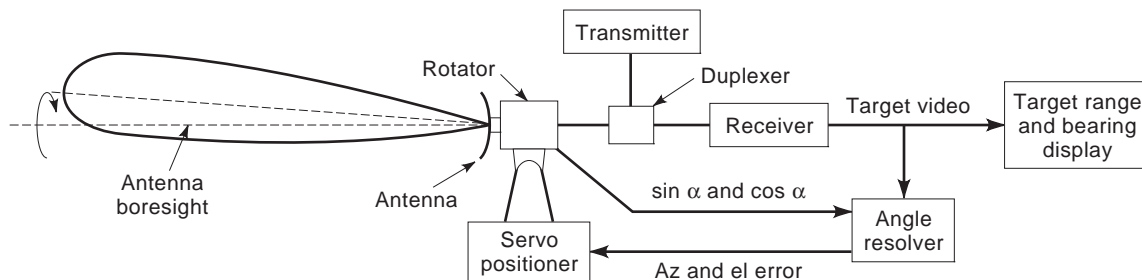

Figure 8. Conical scan radar.

By using the preceding equation, the angle resolver can determine the azimuth and elevation error components of the target direction from boresight. These angle error components are then coupled into the azimuth and elevation inputs of the antenna servo positioner, which then drives the antenna boresight onto the target direction. Although this is conceivably the easiest angle-sensing technique, it is susceptible to tracking errors produced by amplitude fluctuations of the target. Also, for military applications, because the conical scan modulation can be detected, modulation jammers can drive the antenna off the target.

5.2. Sequential Lobe

Sequential lobe angle sensing is similar to that of conical scan, except that the beam is switched electronically between beam positions. For dual-axis (azimuth and elevation) angle sensing, generally four beam positions are used (up, down, left, right). By comparing the amplitude of the received signals in the upper and lower beams, and knowing the shape of the antenna beams, the angular elevation angle of the target from the antenna boresight can be determined. A similar technique can be used for azimuth angle sensing. The technique can either use a single receiver channel or separate receivers for azimuth and elevation angle sensing. The advantage of the technique is that the switching of the beams can be accomplished on a pulse-to-pulse basis, thus making it less vulnerable to target radar cross-sectioned fluctuations. It, however, still has a vulnerability to modulation-type jammers.

“Lobe on receive only” (LORO) is a variation of sequential lobe sensing. With this technique, the transmitter either uses a separate transmit horn on boresight or transmits simultaneously through all four horns. The sequential lobing is accomplished only on receive, through sequential sampling of the signals in the four horns. The advantage of LORO is that modulation jammers cannot detect the sequential modulation pattern of the receivers.

5.3. Monopulse

Monopulse sensing provides the ability to determine the angle of arrival in a single pulse by simultaneously processing the signals in multiple receive beams. Figure 9

shows an example of a four-horn monopulse configuration for dual-plane (elevation and azimuth) angle sensing. The four-horn configuration shown in Fig. 9 is useful for a description of the basic process, but practical radars built since the 1960s have used more complex feed systems to optimize the sum gain, difference error slopes, and sidelobes of all channels. Amplitude-type monopulse uses simultaneous antenna beams squinted at angles off the elevation and azimuth boresights. The relative amplitude of receive signals determines the angular distance of the target off the boresight. Another type of monopulse, referred to as phase-sensing monopulse, uses separate receive apertures spaced a short distance apart, but with the beams pointed parallel with the antenna boresight. For this type of monopulse sensing, the phase difference between the receive signals determines the angular distance of the target from boresight. The monopulse feed, such as shown in Fig. 9, is normally used either to illuminate a paraboloidal reflector directly or to illuminate a subreflector for a Cassegrain-type antenna. The monopulse feed is normally attached directly to a Σ and Δ comparator. The Σ and Δ comparator combines the received signals in the four beams to form a Σ signal, a Δ_{AZ} signal, and a Δ_{EL} signal. According to Rhodes (4), amplitude sensing and phase sensing are equivalent and can be converted to Σ and Δ sensing. Within the 3 dB beamwidth of the Σ pattern of the monopulse antenna, the function Δ/Σ is approximately linear. The target azimuth angle θ off the azimuth boresight and the elevation angle β off the elevation boresight can be determined from

$$\theta \approx K \frac{|\Delta_{AZ}|}{|\Sigma|} \cos \phi_{AZ}$$

$$\beta \approx K \frac{|\Delta_{EL}|}{|\Sigma|} \cos \phi_{EL}$$

K = antenna slope (a function of the squint angle of the beams)

ϕ_{AZ} = phase angle of the Δ_{AZ} signal relative to the Σ signal

ϕ_{EL} = phase angle of the Δ_{EL} signal relative to the Σ signal

For a pointlike target (target extent \ll less than the antenna beamwidth), the phase angle between the Σ and

Figure 9. Four-horn monopulse antenna beam patterns.

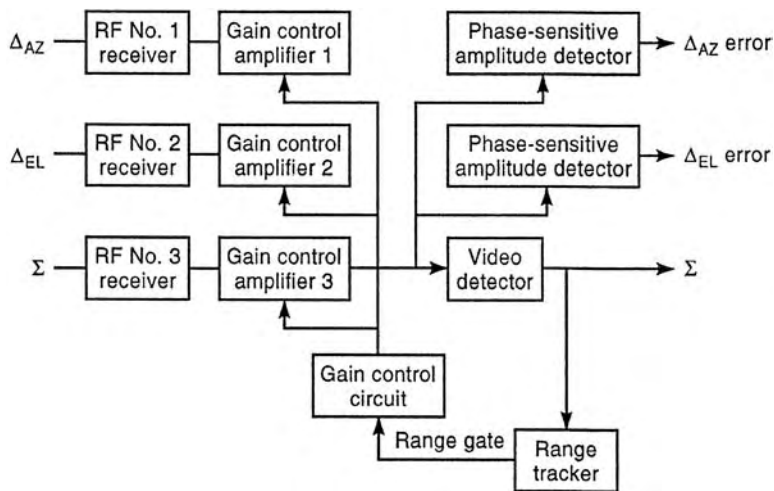

Figure 10. Three-channel monopulse circuit.

Δ signals is normally either 0° or 180° , depending on which side of the boresight the target is located.

A typical configuration for a three-channel monopulse receiver is shown in Fig. 10. The Σ and Δ signals, after down-conversion to IF, are amplified in gain-controlled amplifiers. The Δ IF outputs from the gain-controlled amplifiers are input to amplitude-sensitive phase detectors, along with the Σ IF outputs. The phase-sensitive amplitude detector provides a video output signal proportional to the amplitude of the Σ signal and the cosine of the phase angle between the Δ signal and the Σ signal. In order to maintain a constant number of volts per degree for the output phase amplitude phase detectors, the gain of the receivers must be maintained to provide a constant output signal level at the range of the target. To do this, the sum signal is detected to provide a Σ video signal to a range tracker circuit, which then locks the range onto the target. The output video signal is then sampled at the range of the target, and this is then used to form the gain control voltage in the three receiver channels. This Σ signal normalization maintains the desired number of output volts per degree from the Δ channel receivers. Close tolerances on gain and phase track of the three

gain control amplifiers are required to provide the integrity of the angle error calibration.

Figure 11 shows an example of a two-channel monopulse receiver. The Σ , Δ_{AZ} , and Δ_{EL} microwave signals out of the monopulse comparator are switched in a RF commutator so that on receive pulse 1, $\Sigma + \Delta_{AZ}$, and $\Sigma - \Delta_{AZ}$ signals are in receiver channels 1 and 2, respectively. On the second receive pulse, $\Sigma + \Delta_{EL}$, and $\Sigma - \Delta_{EL}$ are coupled in to receive channels 1 and 2. On the third receive pulses, the Δ polarities are switched, so that the $\Sigma - \Delta_{AZ}$, and $\Sigma + \Delta_{AZ}$ signals are input to channels 1 and 2 on the third pulse, and the $\Sigma - \Delta_{EL}$, and $\Sigma + \Delta_{EL}$ signals are in channels 1 and 2 on the fourth pulse. The receive signals in channels 1 and 2 are down-converted from RF to intermediate frequency (IF), amplified in gain-controlled amplifiers and subsequently converted to video. The decommutator circuit then uses the difference in the video outputs to form the Δ_{AZ} error and the Δ_{EL} error signals. The error signals are then coupled into the antenna servo to maintain the antenna boresight on the tracked target.

In order for the angle circuit to maintain a constant number of volts per degree for the angle error output, the gain of the receivers must be maintained to provide a

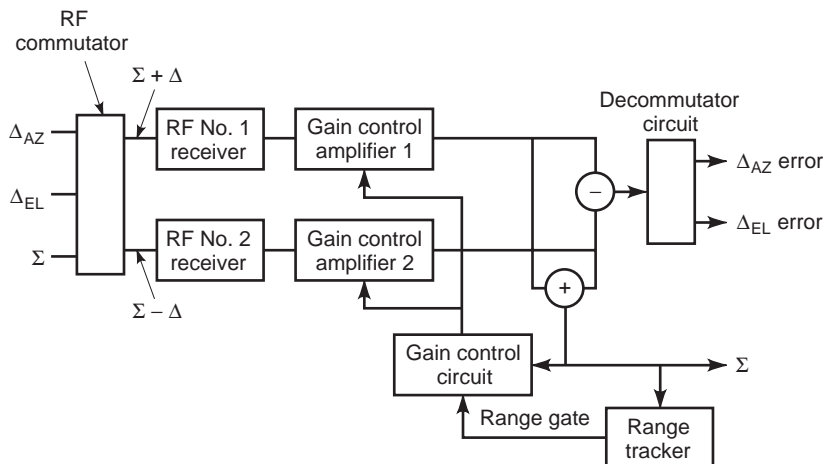

Figure 11. Two-channel monopulse circuit.

constant (on the average) output signal level at the target range. In order to accomplish this, the sum of the video receive signals is provided to a range tracker circuit, which then determines the range to the tracked target. The output video signal is then sampled at the range of the target, and this is then used to form the gain control voltage to both the receiver channels, in order to maintain relatively constant target output levels in the receivers.

The advantage of the two-channel receiver is that it eliminates the need for a third receiver channel, and that it eliminates any zero drift in the phase-sensitive amplitude detectors. This is at the expense of 3 dB less efficiency (as compared to the three-channel configuration), and potential sensitivity to target amplitude fluctuation if the two channel gains are not identical. The disadvantage is that the angle error is only determined on alternate pulses, and any noise or differential losses in the switching process will tend to degrade the accuracy and precision of track. Thus, some sacrifice in tracking precision will be suffered in comparison to a full three-channel monopulse angle tracker.

5.4. Angle Error Sources

The accurate determination of the angle to the target is influenced by a number of factors including radar-dependent errors, target-dependent errors, and propagation effects. Radar-dependent errors include the effects of thermal noise, antenna misalignment and cross coupling errors, and radar instrumentation error sources. The angular errors resulting from thermal noise can be quantified and are primarily dependent upon the signal-to-noise ratio. For a conical scan radar, the variance in the angle determination is given by

$$\sigma_t = \frac{1.4\theta_c}{K_s \sqrt{B\tau(\text{SNR})(f_r/\beta_n)}}, \text{ for SNR} > 4$$

where

- K_s = conical scan angle error slope
- θ_c = antenna 3 dB bandwidth
- SNR = signal-to-noise power ratio
- f_r = pulse repetition frequency
- β_n = servo bandwidth
- B = receiver bandwidth
- τ = pulsewidth

For a monopulse angle tracker, the variance is given by

$$\sigma_t = \frac{\theta_m}{K_m \sqrt{B\tau(\text{SNR})(f_r/\beta_n)}}, \text{ for } B\tau > 1$$

where

- K_m = monopulse error slope
- θ_m = antenna 3 dB Σ beamwidth

Glint is one of the most significant target dependent, angle error sources for complex targets such as aircraft and

ships. Complex targets consist of multiple scatterers separated in angle and range. Rather small variations in target aspect angle can change the phase relationship of the separate scatterers, resulting in large variations of the amplitude and indicated angle to target. Depending on the extent of the scatterers and their phase relationships, the indicated angle to the target can actually be outside the physical dimensions of the target. In order to understand the phenomena, the slope of the phase front resulting from two isolated point targets is given by Dunn and Howard [5] as

$$\delta' = \frac{L \cos \psi}{2} \left[\frac{1 - a^2}{1 + 2^2 + 2a \cos(\phi + \frac{2\pi L}{\lambda} \sin \psi)} \right]$$

where

- a = relative amplitude of the one scatterer to the stronger scatterer
- L = lateral distance separating the two scatterers
- ϕ = relative phase of the two scatterers
- ψ = angle between the perpendicular bisector of the scatterers and direction to the radar

If ψ is set equal to zero, then

$$\delta' = \frac{L}{2} \left[\frac{1 - a^2}{1 + a^2 + 2a \cos \phi} \right]$$

The preceding equation has been plotted in Fig. 12 for $a = 0.9$. As can be seen from the plot, when the relative phase angle between the two scatterers approaches 180° , the indicated angular position is outside the directions to the two scatterers.

Propagation effects such as multipath and ducting can also affect the angular indication, especially for elevation angle sensing. Multipath is a severe problem for low angle tracking of targets, where the multipath return from the terrain is in the main beam (or possibly even the sidelobes) of the antenna. Multipath contributions can be both from

Figure 12. Phase front warpage caused by two scatterers.

specular and diffuse reflections from the terrain, and their contributions are a function of the surface roughness. For specular reflections, the return signals can be expressed as

$$E = A_t f(\theta_t) + A_r \rho_o f(-\theta_r) e^{-j\alpha}$$

where

- A_t = free-space target amplitude at the antenna
- A_r = free-space multipath (target image) amplitude at the antenna
- $f(\theta_t)$ = antenna voltage gain in the direction of the target
- $f(-\theta_r)$ = antenna voltage gain in the direction of the multipath return
- ρ_o = magnitude of the reflection coefficient
- α = relative phase angle between the direct and the multipath return

In a sense, the angular errors caused multipath effects are similar to those associated with the two-point scatterer situation.

6. DOPPLER TRACKING

Tracking targets in a clutter background is one of the major problems for radar trackers. Fortunately, terrain clutter generally has a narrow specular extent. If the target is moving, the Doppler frequency of its return is normally outside that of the terrain clutter. Doppler filtering can then be used to reject clutter, while keeping the target returns. The simplest type of Doppler filtering is obtained by using moving-target indication (MTI) processing. More advanced Doppler processing enables the determination of the Doppler frequency (and hence the radial velocity) of the target. MTI or Doppler filtering must be applied to both sum and difference channels of a monopulse tracker, and in conical scan or lobing radar must be able to cancel the modulation induced on the clutter by scanning.

6.1. MTI Processing

For a ground-based radar system, MTI processing provides the capability to reject clutter by filtering out the returns whose spectral content is close to the pulse repetition frequency (PRF) of the radar. This is accomplished by comparing the phase and amplitude of the target returns on successive pulse intervals. Coherent radar operation is normally used for MTI processing, however, coherent on-receive MTI processing can be used with noncoherent radars to provide most of the benefits achieved with coherent radar processing. In MTI processing, if the phase and amplitude of the returns stay constant over two, three, or more pulse intervals, then the returns are assumed to be associated with clutter and are rejected. The phase (and possibly the amplitude) of moving target returns will change on a pulse-to-pulse basis and are not rejected by the MTI filtering. MTI-filtered target returns can then be tracked by range and angle tracking circuits.

6.2. Doppler Filtering

Full Doppler tracking requires coherent radar operation and can improve the tracking ability of the radar using narrow filter bandwidths, thus increasing the sensitivity of the radar. The Doppler filtering can also enable the determination of the actual Doppler frequency of the radar returns, thus providing an exact determination of the target radial velocity. In addition, for airborne radars, the Doppler frequencies of the clutter returns are a function of the aircraft velocity and the aspect angles to the clutter patch. Thus MTI processing cannot be used for clutter rejection with airborne radars.

Continuous-wave (CW) radar provides the ability to track a moving target while rejecting clutter. Normally, separate transmit and receive antennas are used for CW tracking radars. An example of a Doppler phase-locked loop, a simplified version of that shown by Morris [6], is given in Fig. 13. The Σ signal input is mixed down to the center frequency (f_2) of the narrow bandpass filter. The input to the Σ signal mixer is derived from a combination of the output of the phase-locked oscillator (PLO), which is then mixed with the IF local-oscillator (IF LO) frequency to provide the IF signal necessary to mix the Σ signal down to frequency f_2 . Any increase or decrease in the Doppler frequency (f_D) will cause the PLO output frequency to change in order to maintain the input to the bandpass filter at frequency f_2 . The Δ_{AZ} and Δ_{EL} signals are also mixed down to frequency f_2 . The Δ_{AZ} and Δ_{EL} signals are narrowband filtered, and used to derive the Δ_{AZ} error and Δ_{EL} error signals.

For a high PRF pulsed Doppler radar, a narrow pass-band filter is normally used to limit the receive spectrum to $f_0 \pm PRF/2$. This has the effect of converting the pulsed signal to CW, at which time the CW Doppler tracking configuration described earlier can be used for the Doppler and angle tracking. If range tracking of the signal is also required, the signal must first be sampled at the range of the target prior to narrowband filtering. A minimum of two adjacent range cell samplers, each followed by narrowband Doppler filter, are required to accomplish range tracking. In this case, the range samplers act as early and

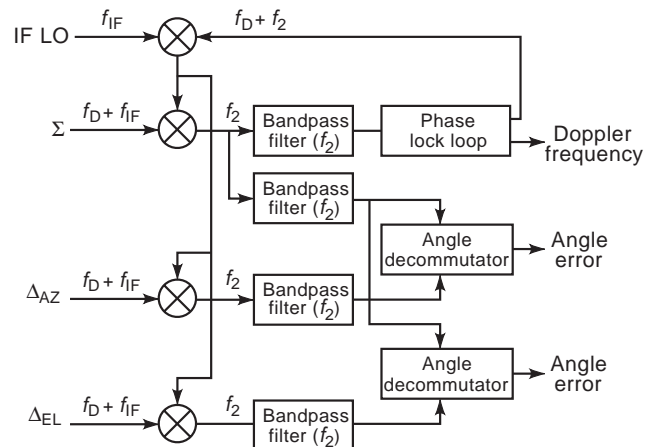

Figure 13. Doppler phase-locked loop.

late gate samplers, and by comparing the output Doppler amplitudes, the range tracker can keep the received pulses centered between the two range samplers. Acquisition with a pulsed Doppler tracker can be a complicated process. In order for the Doppler tracker to acquire the target, both the range and Doppler frequency must be established in order to provide the Doppler output signals required for tracking. Thus, unless the range and the Doppler frequency is known (and normally they are not), a search process both in range and Doppler frequency must be initiated to find the target and initiate track. Other configurations exist for Doppler filter trackers. Barton [3] describes a technique using narrowband filters offset above and below from a center frequency. By comparing the amplitudes out of the high- and low-frequency narrowband filters, an estimate of the Doppler frequency can be obtained on a single-pulse basis.

6.3. Digital Doppler Processing

With the advent of high-speed digital processors, the Doppler frequencies can be computed directly. For this type of processing, the receive signals are normally converted to I and Q digital format using high-speed analog to digital converters. The range-sampled I and Q signals can be stored for a selected number of pulse repetition intervals (PRI), and input to fast Fourier transform (FFT) computational routines. The FFT computes the detected amplitude versus Doppler frequency for each sampled range. Tracking algorithms can then use the detected targets out of the FFT processor to establish the range track, and subsequently angle and Doppler track.

7. RADAR AMBIGUITIES

Generally radars are classified as low-, medium-, or high-PRF radars. For low PRF radars, all the target (and clutter) returns are received prior to transmission of the next radar pulse. With high PRF radars, the Doppler frequencies of all the target (and clutter) signals are less than that of the radar PRF. Low PRF radars, which are unambiguous in range, are generally ambiguous in Doppler, whereas high PRF radars are normally highly ambiguous in range. Medium PRF radars can be ambiguous in both range and Doppler.

7.1. Range Ambiguities and Eclipsing

Figure 14 shows receive signals over several PRI. The returns from target 1 occur within the same PRI as the transmit pulse that initiated the target returns, and so target 1 range is unambiguous. The returns from target 2 occur at the same times when other transmit pulses are being generated. Because receiver returns are normally disabled during the transmit pulse times to prevent receiver saturation (and possibly burnout), target 2 returns are eclipsed, and not detected in the receiver. The returns from target 3 are from a range exceeding the unambiguous range, so that the returns in the current PRI are associated with pulses transmitted several pulses

Figure 14. Range ambiguities and eclipsing.

earlier. Thus, from the radar display, the returns from target 3 appear to be from a much closer range.

Range eclipsing occurs quite frequently in high PRF radars because of the relatively high transmit time duty factors. Even on medium PRF radars eclipsing must be avoided for reliable target detection. Eclipsing can be avoided by changing the PRF when the radar determines that the tracked target range is approaching an eclipse situation. An alternate solution is to switch between two or more PRI, so that the target will be visible in the PRIs in which it is not eclipsed.

Clutter returns with delay times exceeding the PRI (second-time around returns) can cause serious problems to an MTI radar. This is because many MTI radars employ pulse-to-pulse stagger to avoid blind ranges. With PRF-staggered MTI radar, second time around clutter returns are not canceled because the apparent range changes from pulse to pulse. In general, range ambiguities need be resolved, especially for medium- and high-PRF radars. Even for relatively low PRF radar, such as the AN/MPS-36 instrumentation tracking radar with a 320-Hz PRF (unambiguous range of 253 nm), the radar when its return is augmented by a transponder can track missiles many thousands of miles. A number of methods are available for resolving range ambiguities. One method is to use a form of PRF stagger in which the transmission time is varied on a pulse-to-pulse basis. The only receive pulses that align on a pulse-to-pulse basis are those corresponding to the destagger associated with that specific number of PRI. Another method is to apply intrapulse coding on the transmit pulse in which the coding is changed on a pulse-to-pulse basis. On receipt, receive signals can then be associated with the particular transmit pulse responsible for the target returns.

7.2. Doppler Ambiguities and Blind Speeds

Figure 15 illustrates receive signals (in frequency space) for a pulsed coherent radar. The spectral content of the clutter returns are centered about the PRF frequency lines denoted by $f_0 \pm n_{PRF}$. Target 1 has a Doppler frequency that is less than the PRF, and so its Doppler can be determined unambiguously. Target 2 Doppler frequency is at a multiple of the PRF, and because the clutter returns are normally much higher than those of the target, it is highly unlikely that the target will be detected. In fact, most coherent radars intentionally reject frequencies around the $f_0 \pm n_{PRF}$ frequencies, specifically to reject clutter. Target speeds associated with Doppler frequencies

Figure 15. Doppler ambiguity and blind speeds.

of $f_0 \pm nPRF$ are referred to as blind speeds. Target 3 Doppler frequency exceeds that of the PRF so that the actual Doppler frequency cannot be determined from the receive spectrum.

Blind speeds can be avoided by several methods. Many coherent MTI radars avoid blind speeds by varying the PRF on a pulse-to-pulse basis. By appropriately selecting a number of different PRFs, and switching PRFs on a pulse-to-pulse basis, blind speeds can be avoided over a large range of target velocities. However, as noted previously, second-time-around clutter returns will pose a problem to this type of processing. Most Doppler radars require a constant PRF during the coherent processing interval (CPI). Doppler radars can avoid blind speeds by switching to a different PRF when it notes that it is approaching a blind speed. Alternately, the radar could transmit groups of pulses at different PRFs so that at most only one group would be at the blind speed.

Resolving Doppler ambiguities can be accomplished by several techniques. If the radar is tracking the target range, the range rate determination is generally accurate enough to enable determination of which PRF multiple the target Doppler is located. If two or more groups of Doppler PRFs are used, the ambiguity can often be resolved from the measured Doppler frequencies resulting from the multiple PRFs.

7.2.1. Multiple-Target Tracking. In many cases there is a need to track multiple targets simultaneously. Continuously scanning surveillance radars, such as the FAA’s ASR-9 airport surveillance radars, must track all the targets (airplanes) within their coverage regime. This tracking must be performed on a scan-to-scan basis, and thus this type of tracking is commonly referred to as track-while-scan processing. Phased-array radars are also multiple target trackers, because they normally interleave switched-beam locations to track a number of targets, with scanning for new targets, as well as performing other possible functions. With these radars, the targets (or aircraft) are only viewed for a number of pulses on a scan-to-scan (or look-to-look) basis.

Most modern scan-to-scan (or look-to-look) radars use computers for multiple target tracking. Because the aircraft positions typically change on a look-to-look basis, tracking algorithms must be derived to predict the estimated target positions on the next scan, based on previous scans. The accuracy of these predicted positions is limited by the maneuver capabilities of the targets being tracked, so that the predicted positions are only estimates of their actual positions. Association algorithms must then be used to determine (1) if detected target is associated with an established track, (2) which established target track the target should be associated with, and (3) to determine if a new track should be established, if no track association is made.

Figure 16 shows a typical flow diagram for a multiple target tracker. The raw target position information, such as range and azimuth angle (and possibly elevation angle or height), is derived in the radar. Most multiple target tracker associative algorithms prefer to track in rectangular coordinates (R_N, R_E, R_V) rather than polar coordinates so that the conversion must be made from polar coordinates. If North is assumed to be at zero degrees, then

$$R_N = R \cos \theta \cos \beta$$

$$R_E = R \sin \theta \cos \beta$$

$$R_V = R \sin \beta$$

where

R = range

θ = azimuth angle

β = elevation angle

The current target position (R_C) is then

$$R_C = \sqrt{(R_N)^2 + (R_E)^2 + (R_V)^2}$$

After the coordinate transformations are performed on the incoming radar target data, present target detections are

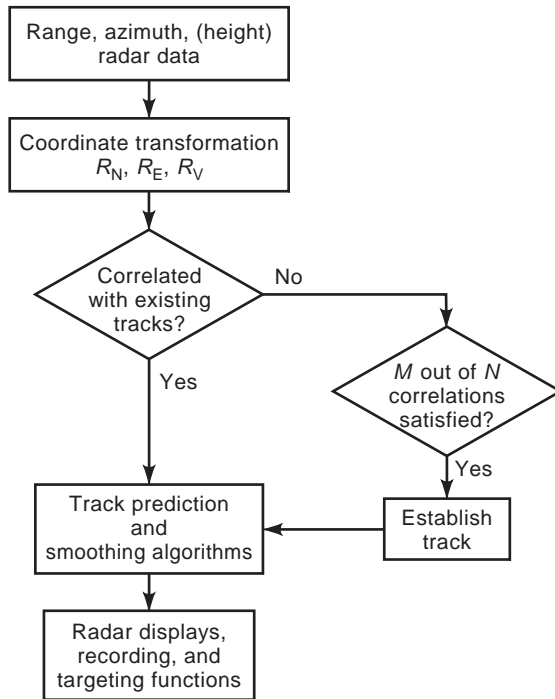

Figure 16. Multiple target tracking.

then compared in association algorithms to determine if the target data are associated with established target tracks. For the FAA airport surveillance radars, the radar target detections are also associated with the secondary (beacon) radar target reports. The beacon returns also include aircraft identification and reported aircraft height. The combined associations are then used to update the target tracks and predict the aircraft locations on the next scan using the track prediction and smoothing algorithms. If the target detection is not associated with any of the present target tracks, then the position information is considered for the establishment of a new target track. In order to establish a new target track, generally the target must be associated with m on n of the previous scans in order to establish a new track. After the m out of n association is made, a new track is established, and the past position information on those target detections is used to predict the target location on the next scan. Target tracks are generally dropped after a certain number of successive target track associations are missed. The information on established target tracks is then routed to radar displays and possibly to weapons systems.

7.3. Smoothing and Prediction Algorithms

Radar measurements of target positions and velocities are often imprecise as a result of a number of factors, such as signal-to-noise ratio, target RCS fluctuations, multipath, and clutter contamination. Various algorithms can be used for the track smoothing and prediction to mitigate the effects of scan-to-scan position and velocity measurement errors, and thus to improve the accuracy of tracking. Kalman filters [7] are probably the best-known smoothing and prediction algorithms. Alpha, beta (α, β or α, β, γ) trackers are a subset of the Kalman filters and are the simplest

because they use precomputed fixed gains. The $\alpha, \beta, \tilde{\alpha}$ equations applied to position and velocity smoothing are

$$\hat{R}_C = \hat{R}_{PC} + \alpha(R_C - \hat{R}_{PC})$$

$$\hat{R}_C = \hat{R}_C + \beta \frac{(R_C - \hat{R}_{PC})}{T}$$

$$\hat{R}_C = \hat{R}_{PC} + \gamma \frac{(\hat{R}_C - \hat{R}_{PC})}{T}$$

and for prediction are

$$\hat{R}_{P(C+1)} = \hat{R}_C + \hat{R}_C T + (T^2/2)\hat{R}_C$$

$$\hat{R}_{P(C+1)} = \hat{R}_C + \hat{R}_C T$$

$$\hat{R}_{P(C+1)} = \hat{R}_C$$

where

T = sampling period

R_C = measured position

\hat{R}_C = smoothed estimate of current position

\hat{R}_{PC} = predicted position at the time of the measurement

$\hat{R}_{P(C+1)}$ = predicted position T s later

\hat{R}_C = smoothed estimate of current velocity

\hat{R}_{PC} = predicted velocity at the time of measurement

$\hat{R}_{P(C+1)}$ = predicted velocity T s later

\hat{R}_C = smoothed current acceleration

$\hat{R}_{P(C+1)}$ = predicted acceleration T s later

T = time between measurements

The precomputed fixed gains α, β, γ can vary between zero and one, with values toward one giving the greatest emphasis toward the current measurements, whereas values toward zero provide the greatest smoothing. Benedict and Bordner [8] analyzed the gains for an α, β for track-while scan application and determined the optimal selection for this application as

$$\beta = \alpha^2 / (2 - \alpha)$$

The performance of the α, β, γ trackers are limited by the selection of the fixed gains, which may not be optimal for all situations. Bar-Shalom and Li [9] discusses the use of Bayesian data association techniques, as well as multiple model estimators for providing superior performance for multitarget tracking.

RADIATION EFFECTS

JAMES R. SCHWANK
 FRED W. SEXTON
 PAUL E. DODD
 MARTY R. SHANEYFELT
 Sandia National Laboratories
 Albuquerque, New Mexico

Significant damage can occur to semiconductor devices exposed to ionizing and other types of radiation. In the last three to four decades, considerable work has been performed investigating the effects of radiation on semiconductor devices. Some of the earlier work investigating these effects focused on radiation-induced damage in minority-carrier devices (e.g., bipolar transistors) caused by displacement damage and on transient radiation effects caused by high-dose-rate pulses of ionizing irradiation. Displacement damage occurs as a high-energy particle; for example, a proton or neutron collides with an atom in a material. The high-energy particle can knock an atom from its lattice site to an interstitial site, creating a vacancy/interstitial pair. This results in the creation of deep and shallow trap sites in the material that can compensate majority carriers, cause carrier removal, and act as generation, recombination, and trapping centers. Displacement effects are important primarily for minority-carrier and optoelectronic devices. A high-dose-rate pulse of ionizing radiation will generate many electron–hole pairs in a short period of time. Photocurrents will be generated that may cause temporary loss of stored information or disrupt functional operation of an IC (dose rate upset). In some cases, permanent damage to a device results.

In 1964, Hughes and Giroux [1] found that MOS devices were very sensitive to ionizing irradiation. Prior to this work, it was commonly believed that ionizing irradiation would have little effect on MOS devices. Since the initial work by Hughes and Giroux, a large amount of work has been performed investigating the mechanisms for ionizing radiation effects in MOS devices and methods

for hardening MOS devices to ionizing irradiation. Total-dose ionization degradation can occur as energetic particles (e.g., protons, electrons, X rays, gamma rays) ionize atoms in the material, creating electron–hole pairs. Ionizing radiation can induce significant charge buildup in oxides (e.g., the gate oxide of a MOS transistor or the field oxide of a MOS or bipolar IC), causing large threshold voltage shifts, and decreases in carrier mobility and bipolar transistor gain. This can result in large increases in the static power supply of an IC, degradation in timing, and potential loss of functionality. Total-dose ionizing radiation often results in permanent or long-term degradation. There are many potential environments that can expose devices to ionizing irradiation (e.g., space environments).

In addition to causing total-dose ionization degradation and displacement damage, energetic particles, such as protons, alpha particles, and heavy ions associated with space environments, can also cause single-event effects (SEEs). As a single high-energy particle (e.g., energetic heavy ion, proton, alpha particle, or neutron) strikes a material, it generates a dense plasma of electron–hole pairs along the path of the particle, which can trigger a variety of SEEs. Single-event effects are classified into two types: *soft errors*, which cause no permanent damage and may be correctable, and *hard errors*, which result in permanent damage to the device. A single-event upset (SEU) is an example of a soft error, where only the logic state of the circuit is changed. SEUs were first observed in space in 1975 [2]. Soft errors can be corrected by reloading the original information into a memory element or by restarting an algorithm in a CPU. If the error rate caused by single-event upsets is too high, performance degradation and even system failure can result. Hard errors are observed in circuits where high electric fields are present across insulating layers, such as nonvolatile memories, thin gate oxides, and capacitors used in analog technologies. For example, permanent damage can be induced by energy deposition in a small region of the dielectric after the passage of a high-energy particle. This effect is termed *single-event gate rupture* (SEGR). Protons and heavy ions may also trigger high-current conditions that can result in permanent circuit failure. Examples of this type of hard error are single-event latchup (SEL) in silicon controlled rectifiers (SCRs) and CMOS and bipolar ICs, single-event snapback (SESB) in nMOS devices, and single-event burn-out (SEB) in power transistors.

The early studies of radiation effects on electronic devices were funded primarily through military programs. Government funding constituted a significant fraction of the funding for advanced semiconductor device development, and government agencies had some influence on the course of device development. Consequently, the major focus was on investigating the effects of and hardening devices to radiation from nuclear radiation environments and on improving device performance to displacement, total-dose ionization, and high-dose-rate pulse effects. Single-event effects were relatively unimportant because devices were relatively simple and operated at high voltage levels. Hardening devices to SEE was relatively straightforward. Many commercial semiconductor suppliers

worked with government laboratories to manufacture radiation-hardened devices.

Today, the emphasis of radiation effects studies has changed dramatically. With the end of the cold war, government funding spent on nuclear radiation effects studies has dropped substantially. Commercial IC development is rapidly progressing, and government funding constitutes only a small fraction of that spent on advanced semiconductor development. As such, individual government agencies have little influence on the course of commercial IC development. Only a few commercial IC suppliers are willing to work with government laboratories to manufacture radiation-hardened devices.

Meanwhile, the number of commercial and military space programs has increased dramatically. The complexity of ICs in space systems (both commercial and military) is rapidly advancing. As a result, more emphasis is now placed on single-event effects. As dimensions of integrated circuits (ICs) continue to shrink and power supply levels are decreased, less radiation-induced charge is required to upset electronics, and present-day ICs are becoming more susceptible to single-event effects. Single-event effects are no longer a problem just for devices in space systems. Naturally occurring terrestrial radiation can also induce single-event upsets on Earth and in low-altitude aircraft. As electronic technologies continue to advance, radiation-induced effects on IC reliability are becoming increasingly important even for commercial electronics used on Earth.

The reduction in government funding and the number of suppliers of radiation-hardened devices has also increased the use of nonhardened commercial off-the-shelf (COTS) components in space systems. For COTS devices, the total-dose irradiation margin between device failure and system requirements can be small. This makes methods for ensuring device hardness in space environments based on laboratory measurements increasingly important. A larger fraction of government funding is now spent on developing techniques for improving hardness assurance test guidelines.

Because of the changing emphasis of radiation effect studies, we focus the following discussion on those effects pertinent to space and terrestrial radiation environments, namely, single-event and total-dose ionization effects. Emphasis is placed on those effects relevant to MOS transistors and ICs. MOS devices constitute a major portion of the electronics of nearly all modern space systems. The material covers radiation effects in both commercial and hardened devices. Although we focus on MOS technology, special issues relevant to other types of devices, for example, low-dose-rate effects in bipolar technologies and single-event upset in GaAs ICs, are also discussed.

To place the discussion of radiation effects in its proper context, we first give an overview of the space and terrestrial radiation environments. Single-event effects are covered in Section 2, which begins with a discussion of the charge collection mechanisms that are the basis for all single-event effects. Circuit issues relevant to single-event effects, including both soft and hard errors, are then presented. The final topic is total-dose ionization effects. The mechanisms for total-dose effects are first reviewed, followed by a discussion of charge buildup in ICs. We close

with a review of present methods for improving total-dose hardness.

1. SPACE AND TERRESTRIAL RADIATION ENVIRONMENTS

The particle flux of the natural radiation environment varies widely in composition from Earth's surface to the interplanetary environment of space probes. In the space environment, only protons and heavy ions have sufficient mass and energy to cause soft errors, while both protons and electrons contribute to total-dose damage. In the terrestrial environment, cosmic rays and secondary-particle showers cause upsets in ground-based electronics and in aircraft electronics. A detailed understanding of the radiation environment is necessary in order to estimate device reliability and, ultimately, the useful lifetime of a system.

In this section we describe the radiation environment in more detail, including a description of the dependence of the particle flux on energy, spacecraft altitude, inclination, and shielding. Understanding these dependencies and building accurate models of the environment experienced by spacecraft is important for error rate predictions. We also discuss the influence of the near-Earth environment on terrestrial and low-altitude radiation environments.

1.1. Definition of Terms

Before proceeding, it is important to define a few commonly used terms to describe space and terrestrial radiation environments. As a particle passes through a material, it loses energy by collisions with the electrons (electronic stopping) and nuclei (nuclear stopping) of the target material [3]. The rate of energy loss per unit pathlength dE/dx , from both mechanisms is called the *total stopping power* and is expressed in units of ergs/cm. Mass stopping power is the energy loss per unit mass per area $1/\rho dE/dx$, where ρ is the density of the target material. In SEE studies, we normally consider the amount of energy transferred per unit pathlength to a given material, where linear energy transfer (LET) is given in units of $\text{MeV mg}^{-1} \text{cm}^2$ (or $\text{MeV} \cdot \text{cm}^2/\text{mg}$). LET considers only the energy deposited along or near the particle's path, while stopping power considers all energy lost to the material. This distinction is important when considering energy deposition and collection on a microscopic scale, where track structure may be important. In most cases, however, mass stopping power is used to estimate LET, and the terms will be used synonymously in the remaining text. The dependence of LET on energy has a peak, which, in silicon, is roughly equal to the atomic number of the ion. A carbon atom, for example, has a peak LET of about $6 \text{ MeV} \cdot \text{cm}^2/\text{mg}$, and LET decreases on either side of this peak. The energy at which the peak occurs (known as the *Bragg peak*) increases with the mass of the ion.

In many environments, particle flux is isotropic and may strike a system from any direction. Here it is defined as the number of particles per square meter per second impinging on a unit sphere from all directions. When flux is anisotropic, it is defined as the number of particles (#) passing through the center of a sphere from a unit solid

angle. This measure has units of $\#/m^2 \cdot \text{steradian} \cdot s$, and is, by definition, 4π smaller than the isotropic flux. Fluence is simply the flux integrated over time and is given in units of $\#/m^2$ or $\#/m^2 \cdot \text{steradian}$ for isotropic or anisotropic fluence, respectively.

Total-dose ionizing radiation is normally specified in either units of rad or gray (Gy); $1 \text{ rad} = 100 \text{ Gy}$. A rad is equal to 100 ergs of energy deposited per gram of material. The energy deposited must be specified for the material of interest. For example, for a MOS transistor, total dose is measured in units of rad(Si) or rad(SiO_2). For a space satellite, the dose rate can vary over a wide range, from less than 10^{-6} to mid- 10^{-3} rad(Si)/s. For a 5-year space mission, these dose rates correspond to a total-dose range of less than 1 krad(Si) to more than 5 Mrad(Si).

1.2. Natural Space Radiation Environment

The natural space radiation environment consists of a steady-state component and a transient component. The former consists of energetic charged particles trapped within Earth's radiation belts, the solar wind, and very energetic galactic cosmic rays that originate outside our solar system. The environment changes over a period of years as it is moderated by solar activity and by precession of Earth's magnetic field with respect to Earth's axis of rotation. The transient environment is influenced primarily by energetic solar events, such as coronal mass ejections (CMEs), solar flares, and solar storms. This section discusses the major factors from the steady-state and

transient environments that influence the performance of integrated circuits and semiconductor devices in space.

1.2.1. Earth's Radiation Belts. Energetic charged particles in the near-Earth environment are trapped in Earth's magnetic field-forming regions that have been called the *van Allen radiation belts* after James van Allen, who designed the first instruments to measure and analyze Earth's radiation belts [4]. The structure of Earth's magnetic field, the magnetosphere, defines the shape of the radiation belts, which, to first order, can be described as a series of concentric shells of decreasing magnetic flux with increasing altitude. Each shell (called *L shells*) is given as a dimensionless number in units of Earth radii ($R_e = 6371 \text{ km}$). Because the magnetic field lines in a dipole field converge at the north and south magnetic poles, the distance between L shells decreases at polar latitudes, while the shells extend farthest at the magnetic equator, which is tilted 11° from Earth's geographic equator. A more detailed description of Earth's magnetosphere and its effect on the radiation environment can be found in Ref. 4.

The radiation belts, depicted in Fig. 1, begin at an altitude of about 1000 km at the magnetic equator. The most abundant particles are electrons and protons; however, some low-energy heavy ions are also found. The distribution of trapped protons with energy greater than 10 MeV consists of one region that peaks at about 5000 km and extends to about 18,000 km (3.8 Earth radii). Higher energies are confined to lower L shell, so, for example, the

Figure 1. Density of the van Allen radiation belts formed by Earth's magnetosphere. The proton belt has a single peak at about 1.5 R_e , and the electron belt is double peaked at 1.4 R_e and 4.9 R_e . Note that the belts are actually toroidal but are separated here for clarity.

>400 MeV distribution extends only from $L=1.2-2$. Normal intensities for proton flux are on the order of $10^6/\text{cm}^2 \cdot \text{s}$. The electron belts are divided into *inner* and *outer* radiation belts. The inner belt peaks at approximately 4000 km, and extends to about 9600 km (2.8 Earth radii), while the outer belt ranges from 11,500 km to about 70,000 km (12 Earth radii). In low-Earth orbit (LEO), spacecraft encounter both inner-belt electrons and protons, while in geosynchronous orbit (GEO), about 35,775 km, primarily outer-belt electrons are encountered. The most intense total-dose radiation environment is encountered at half geosynchronous orbit, about 17,500 km.

1.2.2. The South Atlantic Anomaly. Above the Atlantic Ocean off the South American coast the magnetosphere dips toward Earth, causing a region of increased proton flux, called the *South Atlantic anomaly* (SAA). This region extends as low as 500 km. The proton flux of particles with energy greater than 30 MeV is 10^4 times more intense at 1000 km in the SAA than at comparable altitudes over other regions of Earth. At higher altitudes the magnetosphere is more uniform and the proton flux depends only on L shell.

1.2.3. Galactic Cosmic Rays. Galactic cosmic rays (GCRs) originate outside the solar system and propagate throughout all space. The relative composition of the GCR flux is highly dependent on the ion species, as shown in Fig. 2 [5]. Its composition is roughly 85% protons, 14% alpha particles, and 1% heavy nuclei, and spans more than 11 orders of magnitude in flux. Note that there are four orders of magnitude difference in the intensity of iron; the most abundant are high-LET heavy ion and protons. The flux for each species peaks at energies of 100–1000 MeV/nucleon, then tails off to energies as high as 100 GeV/nucleon [6]. At these energies it is virtually impossible to shield circuits from heavy-ion strikes. The galactic cosmic ray flux provides a steady background radiation on the order of tens of particles/ $\text{cm}^2 \cdot \text{s}$ that, because of their high

Figure 2. Galactic cosmic ray particle spectrum as a function of mass. Protons and helium ions are the most abundant elements, but there are a significant number of heavier elements up to Fe. Because of their high LET, even the low flux of ions heavier than Fe must be considered [5].

LET, must be considered in spacecraft system design to ensure survival.

1.2.4. Solar Flares. Solar flares contain high fluxes of protons, electrons, and some energetic heavy ions, and generally last from hours to days [7]. Because these fluxes are orders of magnitude higher than the steady-state flux of the radiation belts and the GCR flux, peak error rates in satellites are dominated by solar protons and heavy ions. Proton fluence during a large flare can exceed 10^{10} protons/ cm^2 , and can have energies greater than 100 MeV. Depending on the energy spectrum of a given flare, solar protons can extend to altitudes as low as 5 Earth radii. Flares can also inject energetic particles into Earth's radiation belts, some of which are trapped and form new radiation belts persisting for months [8]. Early researchers thought that large flares were anomalous events. It is now known, however, that the fluence distribution of flares forms a continuum that is well described by an extreme value distribution [9], which predicts a 10% chance per year of a large flare during the 7 active years of the 11-year solar cycle.

Coronal mass ejections (CMEs) are solar events in the Sun's chromosphere that eject large quantities of highly ionized gas into interplanetary space and have an associated magnetic bubble [10]. When this magnetic bubble hits Earth's magnetosphere, the resulting shock can accelerate charge particles into the radiation belts. For large CME, the magnetosphere can be significantly perturbed, reducing the magnetic shielding experienced by satellites. Magnetic storms are perturbations of the magnetosphere, and can persist for hours to days after a large transient and are associated with CMEs, flares, and changes in the embedded solar magnetic field. The solar wind is a steady stream of protons, electrons, doubly ionized helium, and a small quantity of heavier ions that emanate from the sun's outer atmosphere and permeate throughout the solar system and beyond [11]. While the solar wind has an average variation that follows solar activity, it can change by orders of magnitude in a period of hours during CMEs and flares. Electrons dominate the total-dose contribution from the solar wind. However, their energies are in the eV-keV range and are easily stopped by thin shields. CMEs and the solar wind do not contribute significantly to total dose or SEE in spacecraft systems. However, they can cause significant charging on exposed dielectric surfaces. After a critical charge is reached, these insulators can destructively discharge. Dielectric charging must be considered in overall system design.

1.2.5. Dependencies. In Earth orbit, the contribution of the GCR and solar flare fluxes to the total particle flux depends on solar activity. The galactic component, for example, is affected by the screening effect of the solar wind; as solar activity decreases, the galactic component increases. On the other hand, the interplanetary and flare components increase with solar activity, since they are composed primarily of particles originating in the Sun. The change in the integral LET spectra (total flux of particles with LET greater than or equal to a given LET) as a

Figure 3. The integral LET spectra under (a) solar maximum conditions, (b) solar minimum conditions, and (c) Adam's 10% worst-case environment. Integral LET curves give the flux for all particles with a given LET or less [14].

function of solar activity is shown in Fig. 3 for a spacecraft in geosynchronous orbit. These particular curves were calculated for 25 mils of aluminum. The lowest intensity (curve *a*) occurs at solar maximum excluding solar flares. This represents the absolute minimum at geosynchronous orbit. The environment at solar minimum (curve *b*) describes the environment for approximately 40% of the time. This is the pure galactic cosmic ray spectrum. If we add solar flares to this, the 90% environment results (curve *c*). Alternatively, we say that the environment is more severe than curve *c* only 10% of the time. This curve, called "Adams' 90% worst-case environment," has been used quite frequently to represent the space environment in error rate calculations [12]. With the development of improved solar flare models, however, the solar minimum environment with a separate model for solar flares is now considered the best estimate of the worst-case environment [13].

Earth's magnetosphere screens out particles below a specific energy determined by the particle's magnetic rigidity, defined as the momentum per unit charge, and the local field strength. The magnetic field deflects particles with lower rigidity and prevents their further penetration. Near the equator the Earth magnetic field screens all but the most energetic ions, while at the poles the particle flux is not significantly attenuated.

The penetration range of cosmic rays in a material depends on their energy. Therefore, the skin of a spacecraft and electronic boxes provides some degree of shielding to electronic components. The degree to which a spectrum is affected by shielding depends on the hardness of the spectrum. Additional shielding may prove effective against low-energy components, but is relatively ineffective in reducing hard components such as high-energy protons and the galactic cosmic ray spectrum. For example, the GCR spectrum is only marginally reduced for aluminum thicknesses in the 2–10-g/cm² range (300 mils to 1.45 in. thicknesses). Only when shielding is on the order of 50–100 g/cm² is appreciable attenuation of this spectrum realized [14]. Spacecraft walls are normally about 100 mils thick, and more recent honeycomb construction to reduce weight provides even less shielding.

Figure 4. Annual ionizing dose accumulated as a function of altitude with shielding thickness of 100–300 mils of aluminum.

The combined contribution of trapped electrons, protons, and solar flare protons to ionizing dose accumulated to a spacecraft is shown in Fig. 4 as a function of altitude and aluminum shielding thickness. Two peaks are evident; the first, at 3000 km, is due primarily to trapped protons, while the second peak, at 17,500 km, is due to trapped electrons. As shielding thickness increases from 100 to 300 mils, the first peak decreases a factor of 3, while the second peak decreases more than 60 fold. This clearly illustrates the effectiveness of shielding against electrons, and the difficulty of shielding against high-energy protons. As an example of how this information is useful for ensuring survival of a space-based system, consider the annual dose accumulated to a system in three different orbits with 100 mils of aluminum shielding. A spacecraft in a low-Earth orbit of 800 km will receive an annual dose of only 300 rad(Si), while a spacecraft in geosynchronous orbit at 35,000 km will receive about 10 krad(Si) per year and a system in half-geosynchronous orbit, 17,500 km, will receive a dose in excess of 100 krad(Si) per year. For a 10-year design lifetime these three systems require electronics that can survive doses of 3, 100, and 1000 krad(Si), respectively. Clearly, the design issues for a low-Earth orbit are much more tractable than those for a system in the middle of the radiation belts.

1.3. The Terrestrial Radiation Environment

As they interact with Earth's upper atmosphere, galactic cosmic rays produce a shower of secondary particles that includes protons, neutrons, pions, muons, electrons, and photons. The density of secondaries is highly dependent on altitude, latitude, longitude, and the variation of the primary GCR flux with solar activity. It peaks at an altitude of about 15 km, just above commercial airplane altitudes, and decreases at lower altitudes due to absorption and thermalization processes that remove secondaries [15]. The neutron flux in the energy range 1–10 MeV has a maximum at an altitude of 18.3 km [60 kft (kilofeet)], but is significant as low as 9 km (30 kft). Taber and Normand [16] have shown a strong correlation between the upset

Figure 5. Single-event upsets measured in a 16-kbit SRAM as a function of aircraft altitude and neutron flux. The interaction of galactic cosmic rays with the upper atmosphere generates secondary showers of energetic nucleons whose flux peaks at about 60 kft. SEU in avionics are well correlated with the neutron flux of the secondary showers [16].

rate observed in a 64,000-bit memory and measured neutron flux as a function of altitude, as shown in Fig. 5. Note that the error rate has been scaled by a factor of 10^7 to plot on the same graph. Similar correlations have been demonstrated as a function of latitude. Secondary protons have been considered as a possible cause for in-flight SEUs; however, their latitude dependence doesn't correlate with the measured data.

SEUs are also being observed at ground level, and their frequency and distribution are consistent with terrestrial cosmic rays. Ziegler [15] showed that the frequency of errors in large computer memory systems, for example, scales linearly with altitude of the city in which they are located. In a test of both SRAM and DRAM (static and dynamic random access memory)-based systems, a 13x increase in error rate was observed as altitude increased from sea level to 10,000 ft (Leadville, CO). Similarly, error rate decreased as concrete absorber thickness increased. More recently, Lage et al. [17] showed that terrestrial cosmic ray induced SEUs present a lower limit to system error rates after other sources of bit errors, such as package alphas, have been considered.

Terrestrial cosmic ray induced upset poses a significant challenge to the reliability of future systems. Although error detection and correction (EDAC) techniques are successful for mitigating upsets in memory systems, the possibility that new upset mechanisms will surface with next-generation technologies, such as logic upsets, cannot be discounted. Also, new materials being used for improved performance in advanced IC technologies can introduce new sources of particle flux. Solder bump interconnects in flip-chip packaging can be a source of alpha particles if high-purity lead is not used. The effect of

technology and design changes on SEU is now a first-order consideration for next-generation ICs.

2. SINGLE-EVENT EFFECTS

The field of single-event effects (SEE) deals with the response of semiconductor devices and ICs to the passage of a single energetic atomic particle, such as a highly accelerated proton, or a heavily ionized iron nucleus. There are a wide variety of effects, but the classic one, termed *single-event upset* (SEU), describes the corruption of information stored in solid-state memory devices. As an energetic charged particle transits the semiconductor material it deposits energy to the lattice atoms, generating a dense plasma of free electrons and holes as the lattice atoms are ionized (holes are the absence of an electron, and act electrically like a positively charged particle). When this excess charge is collected across a high-field region, such as a p-n junction in a semiconductor device, a current pulse results that the device can interpret as a valid signal. For memory devices, this event can change stored information. For complex ICs, such as microprocessors, it can result in improper execution of a program, and even in the processor locking up.

SEU was first observed experimentally in 1975, when Binder et al. [2] attributed bit-flips in bipolar *J-K* flip-flops in a communication satellite to galactic cosmic rays. A few years later, May and Woods [18] observed upsets in dynamic random access memories (DRAMs) caused by alpha particles from the decay of radioactive material in ceramic packages. That same year, Pickel and Blandford [19] reported soft errors in NMOS DRAMs in space. Proton- and neutron-induced upsets were observed by Guenzer and coworkers in 1979 [20]. Since that time, upsets have been observed in many satellite systems and are a major design consideration for any space-based system.

Single-event effects have traditionally been a concern only for semiconductors that are used in space environments, where devices can be exposed to a high flux of radiation. The continuing decrease of feature size in ICs and the commensurate decrease in charge representing information has led to an increased SEU sensitivity. The universality of this trend was noted by Petersen and Marshall [21], who observed a power-law dependence of critical charge to upset as a function of technology feature size for a wide variety of technologies (Fig. 6). At technology scaling levels of $0.5\mu\text{m}$ and below, they predicted that critical charge would decrease to less than 5 fC (Femto-coulombs). In fact, upsets due to terrestrial cosmic rays are now being observed in large memory systems at sea level [22], and in avionics systems at altitudes from 30 to 60 kft [23]. Johnston [24] noted that data from submicrometer IC technologies suggest this trend may not continue unabated, as chip manufacturers try to reduce alpha-particle sensitivity. However, it is now known that many manufacturers are in fact already below the alpha-particle threshold for upset and error rates are continuing to increase in today's advanced low-voltage technologies.

The field of SEE encompasses a wide range of disciplines including high-energy physics, cosmic ray physics,

Figure 6. Critical charge as a function of critical dimensions for various technologies. Historically, power-law dependence has been observed [21].

solid-state physics, electrical engineering, IC processing, circuit design and analysis, system architecture, and computer modeling. Despite the breadth of overlap with many areas of research, a working knowledge of the important effects can be obtained by mastery of a few concepts from these diverse areas.

2.1. See Mechanisms: Charge Deposition

There are two primary methods by which ionizing radiation releases charge in a semiconductor device: direct ionization by the incident particle itself, and ionization by secondary particles created by nuclear reactions between the incident particle and the struck device. Both mechanisms can lead to integrated circuit malfunction.

2.1.1. Direct Ionization. When an energetic charged particle passes through a semiconductor material it frees electron-hole pairs along its path as it loses energy. When all its energy is lost, the particle comes to rest in the semiconductor, having traveled a total pathlength referred to as the particle's *range*. We frequently use the term *linear energy transfer* (LET) to describe the energy loss per unit path length of a particle as it passes through a material. LET has units of $\text{MeV} \cdot \text{cm}^2/\text{mg}$, because the energy loss per unit pathlength (in MeV/cm) is normalized by the density of the target material (in mg/cm^3), so that LET may be quoted roughly independent of the target. We can easily relate the LET of a particle to its charge deposition per unit pathlength. In silicon, an LET of $97 \text{ MeV} \cdot \text{cm}^2/\text{mg}$ corresponds to a charge deposition of $1 \text{ pC}/\mu\text{m}$. This conversion factor of about 100 is handy to keep in mind to convert between LET and charge deposition. Direct ionization is the primary charge deposition mechanism for upsets caused by heavy ions, where we define a heavy ion as any ion with $Z \geq 2$ (i.e., particles other than protons, electrons, neutrons, or pions). Lighter particles such as protons seldom produce enough charge by direct ionization to cause upsets in memory circuits.

2.1.2. Indirect Ionization. Although direct ionization by light particles rarely produces enough charge to cause

upsets, this does not mean that we can ignore these particles. Protons and neutrons can both produce significant upset rates due to indirect mechanisms. As a high-energy proton or neutron enters the semiconductor lattice, it may undergo an inelastic collision with a target nucleus. Any one of several nuclear reactions may occur, including (1) elastic collisions that produce Si recoils; (2) the emission of alpha (α) or gamma (γ) particles and the recoil of a daughter nucleus (e.g., Si emits α -particle and a recoiling Mg nucleus); and (3) spallation reactions, in which the target nucleus is broken into two fragments (e.g., Si breaks into C and O ions), each of which can recoil. Any of these reaction products can now deposit energy along their paths by direct ionization. Because these particles are much heavier than the original proton or neutron, they deposit higher charge densities as they travel and therefore may be capable of causing an SEU. Once a nuclear reaction has occurred, the charge deposition by secondary charged particles is the same as from a directly ionizing heavy-ion strike.

2.2. See Mechanisms: Charge Collection

The dense plasma of electrons and holes that are generated along the track of a heavy-ion strike are collected through a variety of mechanisms. Considering charge collection in the semiconductor itself, these processes include drift collection in high electric field regions, and diffusive charge collection outside field regions. These processes are illustrated in Fig. 7a. Charge carriers that are generated in the initial depletion region are separated by the existing electric field and are rapidly collected. Holes are swept to the p-type side of the junction, and electrons are swept to the n-type side of the junction, resulting in a current pulse. The charge plasma surrounding the ion track can be dense enough to perturb the initial electric field lines of the junction, so that it reaches well beyond the extent of the original depletion region of the p-n junction into the more lightly doped side of the junction. As equilibrium is re-established, the extended field collapses sweeping additional charge into the junction where it is collected. This is the field funnel process first explained by Hsieh et al. [25] using 2D simulation, and subsequently described analytically by McLean and Oldham [26]. Dodd et al. [27] provided a graphic depiction of this process using 3D modeling. These prompt charge collection processes occur in tens to hundreds of picoseconds depending on doping levels in the substrate. These times are faster than circuit response times in present technologies.

Outside the high-field regions of the junction and the field funnel, charge is collected by diffusive processes that are driven by concentration gradients in quasineutral regions of the semiconductor as described by Kirkpatrick [28] for single-event upset. This process occurs later in time, and can extend to as long as 10 ns, which is on the order of the circuit response time or slower. The shape of the charge collection transient can be a first-order concern for determining upset sensitivity, depending on the technology and circuit design. This is discussed further in the next section.

In some IC technologies, parasitic three-layer n-p-n and p-n-p structures are formed that can be sources of

Figure 7. Charge collection mechanisms include photocurrent collection due to (a) drift in the depletion and field funnel regions and diffusive charge collection and (b) charge collection when regions of like doping are connected by a plasma shunt.

shunt current or bipolar amplification when charge is generated in the base region. In the first case, a heavy-ion strike can connect regions of similar doping that are separated by a region of opposite doping, as seen in Fig. 7b. A charge can flow between like regions when a potential difference exists. This *shunt* effect was observed by Hauser et al. [29], in CMOS test structures and by Sexton et al. [30] in pass-gate transistors in a CMOS technology. Bipolar amplification can significantly reduce the SEU hardness of some technologies. It has been shown to be especially important for partially depleted silicon-on-insulator (SOI) transistors [31,32] and GaAs MESFET [33–35] transistors as a heavy-ion strike liberates carriers in the body region of an SOI transistor or in the substrate of a GaAs transistor below the active region of the device. While minority carriers recombine quickly, the lifetime of majority carriers can be very long. Majority carriers that don't recombine can drift toward the source region and lower the source-to-body potential, which can cause the injection of minority carriers from the source into the body. This process can greatly increase the amount of charge collection. Another mechanism that can reduce the SEU hardness of GaAs ICs is carrier-induced channel modulation or the backchannel turnon mechanism [36–38]. This mechanism arises from excess holes located

in low-field regions below the active channel region that tend to “backgate” the channel. Near pinchoff, small modulations of the fields in the channel can give rise to large increases in channel conduction. These charge amplification mechanisms lead to very low LET thresholds ($<1 \text{ MeV} \cdot \text{cm}^2/\text{mg}$) and very high saturation upset cross sections ($>10^{-5} \text{ cm}^2/\text{bit}$) in GaAs ICs, resulting in very high upset rates in space environments [39].

A technique that has been suggested to reduce charge amplification in GaAs ICs is to grow the active transistor regions on top of a low-temperature (LT)-grown buffer layer [40]. The lifetime of carriers in LT GaAs layers is extremely short. This will reduce the time that holes (majority carriers) remain in the substrate and substantially reduce the charge collected via both the bipolar amplification and channel modulation mechanisms.

The region from which charge is collected is referred to as the *sensitive volume* (SV). As the discussion above indicates, multiple mechanisms can contribute to charge collection, making it difficult to clearly define a SV. Additionally, circuits that are sensitive to the rate at which charge is collected will have a SV that varies with circuit operation. In spite of these complexities, the SV concept is widely used because of the intuitive insight it gives to the underlying physical processes, and is useful as a mathematical construct in error rate prediction methodologies (discussed in Section 2.9.).

2.3. Single-Event Upset (SEU)

The sensitivity of an IC to single-event upset is expressed as the ratio of number of upsets to the total particle fluence, that is, $\# \text{ upsets}/\# \text{ (particles/cm}^2\text{)}$. Because this term has units of cm^2 , it is referred to as the *error cross section*. Experimental cross section data are normally plotted as a function of LET, for particles striking the IC normal to the surface. Two key parameters are determined from cross section curves: the threshold LET for upset L_0 and the saturation cross section σ_{sat} . The threshold LET is a measure of the minimum LET required to upset the most sensitive region of the chip, while the saturation cross section should equal the total area of the sensitive regions of the chip. These parameters are used to estimate the error rate for a given IC in a specific environment. In Fig. 8 we show an ideal and a measured cross section curve for a typical commercial memory chip. The ideal cross-sectional curve (dashed line) is a step function with a well-defined threshold and saturation cross section. Below threshold no cell upsets, while above threshold all sensitive cells upset. For a real device, however, there is a distribution of thresholds due to variation of charge collection across a cell and cell-to-cell variation in sensitivity, resulting in a smoothly increasing cross section with LET. As LET increases, more regions of the device are sensitive to upset. The measured cross section increases until all sensitive regions upset and the cross section curve saturates. Also shown in Fig. 8 is a fit to the data based on the Weibull distribution function (solid line), which is often used in reliability estimation techniques.

Cross-section curves are sometimes plotted as a function of linear charge deposited (LCD) with x-axis units of

Figure 8. A typical upset cross-sectional curve is compared to an ideal curve. The ideal curve has an abrupt threshold and a well-defined saturation cross section, whereas measured curves show a gradual threshold and an ambiguous saturation cross section.

pC/μm (for silicon, 1 MeV·cm²/mg is equivalent to 0.0104 pC/μm). Measured upset curves such as this are taken over a range of LET, where LET is increased by using higher Z ions (for C to Ni ions used here, LET ranged from 2.5 to 28 MeV·cm²/mg). LET is also varied by increasing the angle of the ion strike relative to the surface normal, thereby increasing the pathlength through the SV and increasing the amount of charge deposited in the SV. This results in a higher “effective LET,” which is given by

$$L_{\text{eff}} = L_0 \cos(\theta) \tag{1}$$

where L_0 is the ion LET at normal incidence and θ is angle of incidence relative to the surface normal. The effective LET approximation has been used extensively in the past for large-geometry devices that have large, flat sensitive volumes. It breaks down, however, as device geometries shrink and the dimensions of the SV are nearly equal. In this case, a more involved correction for angle of incidence is required [41].

Dynamic circuits, such as a dynamic RAM (DRAM) cell, depend on charge storage on a circuit node or in a region of silicon for proper operation. For a DRAM, the amount of charge necessary for proper circuit operation is a function of the sensitivity of the sense amplifiers, the memory cell capacitance, and the bitline capacitance. A 1-transistor DRAM memory cell is shown schematically in Fig. 9. Information is stored on capacitor C_{cell} , which is written and refreshed through the access transistor. When the cell is subsequently accessed by turning this transistor on, the bitline is pulled down and the complement state of the cell is sensed on the bitline. The critical charge representing a bit of information on capacitor C_{cell} can be as small as 0.1–0.5 pC. This is equivalent to only 5×10^5 to 3×10^6 electrons. If an ion strike results in charge collection to the memory node on the same order of magnitude as the original charge on the node, a bit error will occur. In subsequent refresh cycles the error will be maintained, since the new state of the memory cell appears to be valid information. The primary consideration for dynamic circuits

Figure 9. Circuit schematic of a one-transistor DRAM memory cell. Information is stored as charge on the capacitor C_{cell} and is accessed through the single transistor.

like this is whether the collected charge exceeds the critical charge required to represent a logic state on the memory node. If the critical charge is exceeded, an upset occurs. Massengill [42] discusses DRAM upset in more depth.

In static circuits, such as a CMOS static RAM (SRAM) or D-latch, upset is controlled by the rate at which charge is collected. A schematic diagram of a 6-transistor (6T) memory cell is shown in Fig. 10. Each series connection of n- and p-channel transistors forms an inverter whose input is the common gate, and whose output is the common drain. When the output of each inverter is coupled to the input of the other inverter, a bistable memory element is formed. In this diagram feedback resistors are shown in the cross-coupling links. Feedback resistors (R_{FB}) are used to slow the response of the circuit to the ion strike [43], thereby hardening the memory to upset, but there is a commensurate performance penalty. Following an ion

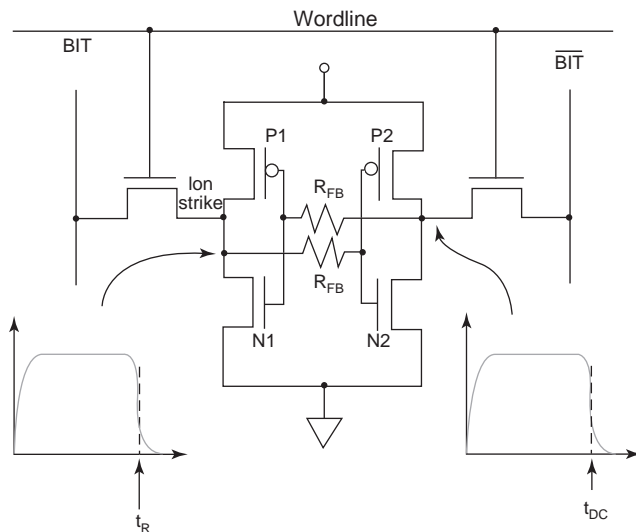

Figure 10. Logic diagram and circuit schematic for a 6-transistor CMOS SRAM memory cell. The cross-coupled inverters form a bistable memory element. Each inverter is composed of a series-connected n- and p-channel transistor. The voltage transients following a heavy-ion strike to an OFF-biased p drain are shown. Feedback resistors R_{F} are inserted in the cross-coupling links to reduce SEU sensitivity [43].

strike to the off-biased drain of transistor P1 (labeled “ion strike” in the figure), a current spike is observed on the drain node of the inverter formed by transistors N1 and P1. If charge is collected by the drain of P1 faster than it is removed by the unstruck n-channel transistor N1 (called the *restoring transistor*), the node voltage will rise to a diode drop above V_{DD} (see the lower left waveform in Fig. 10) and an upset may occur.

Whether an upset occurs depends on the competing processes of removing excess charge at the struck node, and changing the state of the opposing inverter of the memory cell [43]. The time required for the struck node to recover to one-half the voltage swing at the node is defined as the recovery time t_R . The time required to switch the opposing inverter formed by transistors N2 and P2 is defined as the decoupling time t_{DC} (see the lower right waveform in Fig. 10). Upset will occur in this analysis if t_R is greater than t_{DC} . Memory cells can be hardened to SEU by adding feedback resistors in the cross-coupling link between inverters (shown as R_{FB} in the figure). This effectively increases t_{DC} , and gives the cell more time to remove excess charge before responding to the transient.

As packing density increases, the charge deposited by a single ion strike can be collected by the sensitive volumes of more than one memory cell and multiple bits are upset. Zoutendyk et al. [44] first observed this phenomena experimentally, called *multiple-bit upset* (MBU), and it has since been measured in many different technologies. MBU has also been observed in closely spaced trench capacitor storage cells used in advanced DRAMs. In this case upset was attributed to a shunt connecting two adjacent storage regions [45]. Most error detection and correction (EDAC) implementations are able to detect and correct one bit upset in a single word and can detect two bit upsets without correction in a word. If a memory chip is laid out such that multiple bits in a single word are topographically adjacent, MBU can defeat these EDAC schemes. More complex EDAC approaches can be applied, but these require additional bits of memory and much more error correction overhead. The better approach is to ensure at the chip design level that logical bits in a word are not located physically close to each other.

2.4. Single-Event Transients (SETs)

An area that is becoming increasingly important is the propagation of single-event transients (SETs) in digital logic circuits. SETs are momentary voltage or current disturbances that, although they don't cause an upset in the circuit actually struck by an energetic particle, are propagated through subsequent circuitry and eventually cause an SEU. The problem here is that as circuit speeds rise, the probability that a momentary glitch will be clocked as valid data and propagated through subsequent circuitry increases. For example, even particles well below the upset threshold can cause a momentary flip in the state of an SRAM cell. Consider the case where this memory cell is actually a digital latch circuit in a microprocessor. If this latch value is accessed immediately after an ion strike and the value is clocked down the line, it matters little that the struck latch eventually returns to its original state,

because the corrupt value has already been passed on to the next stage of the circuit. These types of errors are likely to become a pervasive problem as clock speeds continue to increase, and will be difficult to protect against, especially in commercial microprocessors where speed is paramount. It has been predicted that for circuits built in technologies below $0.35\mu\text{m}$, propagated SETs will be a major single-event failure mode [46].

2.5. Single-Event Functional Interrupt (SEFI)

Single-event functional interrupts are a complex failure mode whereby a particle strike triggers an IC test mode, a reset mode, or some other mode that causes the IC to temporarily lose functionality [47]. As devices become increasingly complex, they may be more likely to exhibit SEFIs. For example, synchronous DRAMs are very complicated ICs that incorporate built-in self-test (BIST) modes and self-repairing boot sequences that remap nonfunctional bits in the memory with redundant bits on the chip. An ion strike to a SDRAM with such circuits may initiate a BIST mode, cause a chip reset to occur, or throw the IC into an idle state [48]. These events can have serious consequences on system operation, sometimes requiring device reset to clear the condition [49].

2.6. Hard Errors

2.6.1. Single-Event Latchup (SEL). The single most important effect that designers of space-based systems must consider is catastrophic damage resulting from single-event latchup. Latchup is a high current condition that results from thyristor [also known as a *silicon controlled rectifier*, (SCR)] action in four-layer p-n-p-n structures. Because four-layer p-n-p-n structures do not occur in standard SOI ICs, SOI ICs are latchup-immune. Latchup creates a low-resistance path from power supply to ground in CMOS ICs, which are vulnerable to this failure condition because of the complementary structure required for this technology [50]. As shown in Fig. 11, a pair of coupled parasitic bipolar transistors are associated with the p-well structure. A vertical n-p-n transistor is formed from the n-type substrate, p-well, and n-channel source, while the p-well, n-type substrate, and p-channel source form a lateral p-n-p transistor. The lumped-parameter equivalent circuit is shown on the right-hand side of the figure.

Latchup is triggered in SCR structures by excess current in the base of the lateral p-n-p transistor. When sufficient current flows in the substrate (across R_S), the emitter base junction of the p-n-p transistor is forward-biased and injects a large current into the p-well. This current induces a voltage drop in the p-well (across R_W) which turns on the vertical n-p-n transistor. As the n-p-n transistor turns on, it reinforces the initial current in the substrate and a regenerative condition exists which results in high current and low resistance. The holding voltage for latchup is on the order of 1 V. Latchup is triggered on the order of hundreds of nanoseconds, and destructive burnout occurs on the order of hundreds of microseconds [51]. The threshold for latchup decreases with increasing temperature and power supply voltage [52,53]. Latchup

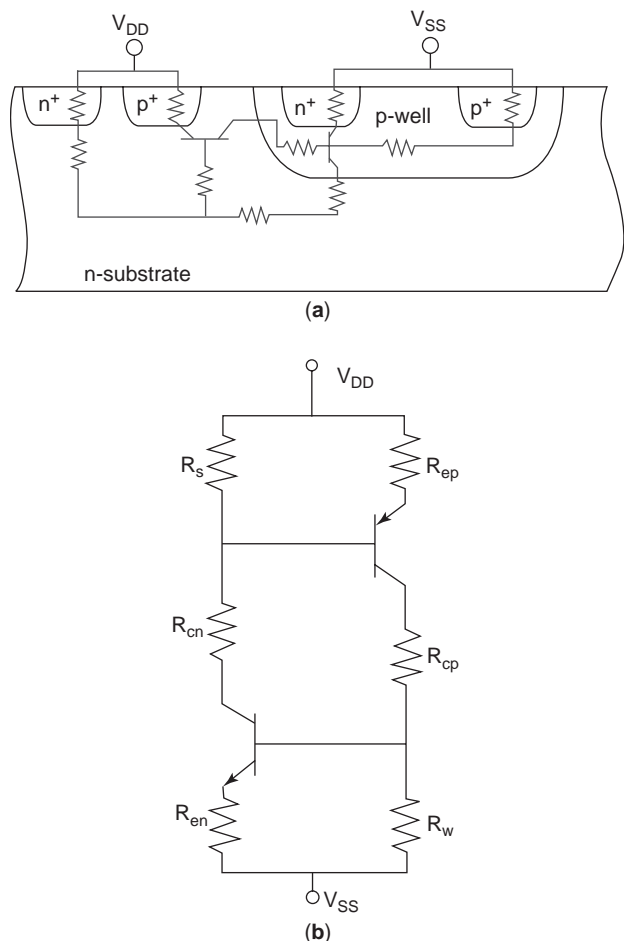

Figure 11. Cross section of a CMOS technology showing (a) the vertical n-p-n lateral p-n-p transistors formed in this p-well technology and (b) a circuit schematic indicating how the parasitic elements are electrically connected [50].

susceptibility in advanced technologies is addressed by Johnston [52,54].

During SEL measurements, latchup cross section is calculated in the same manner as upset cross section, that is, the number of upsets divided by the fluence to latchup, and is plotted as cross section versus LET.

2.6.2. Single-Event Gate Rupture (SEGR). Another major consideration for designers is a catastrophic failure known as *single-event gate rupture* (SEGR) [55,56]. This effect can occur under conditions of high field, such as during a write or clear operation in a nonvolatile SRAM or E²PROM [electrically erasable programmable read-only memory (also abbreviated EEPROM)]. It has become a concern for advanced technologies as oxide thicknesses scale below 10 nm and oxide fields increase above 5 MV/cm [57]. As a heavy ion passes through the dielectric, a highly conductive plasma path is formed, which allows the capacitor formed by this structure to discharge. If sufficient energy is stored on the capacitor as a result of high electric fields, excessive heating during discharge can create a thermal runaway condition [55]. Temperatures can be high enough

Figure 12. Cross section of a typical power MOSFET structure.

to cause the dielectric to melt and the overlying conductive layers to evaporate.

In a power MOSFET, the requirement for a standoff voltage on the order of 100s of volts is satisfied by dropping this potential over the thickness of the silicon substrate. A typical cross section of a power MOSFET is shown in Fig. 12. In normal operation, the MOSFET gate induces a channel between the source and drain regions. Current flows from the source to the drain near the surface, then is collected in the heavily doped substrate. The lightly doped epi layer doping and thickness determine the ON resistance of the device. As a heavy ion passes through the substrate, the large bias on the drain is electrically coupled into the oxide electric field, resulting in gate rupture at voltages well below the rated standoff voltage. This mechanism is described in detail by Brews et al. [58]. Figure 13 shows the set of V_{GS} and V_{DS} biases that result in SEGR as a function of various heavy ions for a power MOSFET rated to 70 V with a 50-nm gate oxide. The data cover an LET range from 3 MeV · cm²/mg for F to 82 MeV · cm²/mg for Au. The control data shown in the graph (open circles and dashed line) denote nominal rupture voltages with no heavy-ion exposure, which are -40 and 73 V for V_{GS} and V_{DS} , respectively. During exposure to heavy ions, however, the V_{GS} at which SEGR occurs decreases as V_{DS} increases. An empirical equation that fits this dependence has been developed by Wheatley et al. [56]:

$$V_{GS} = 0.84 \left(1 - \exp \frac{-L}{17} \right) \times V_{DS} - \frac{50}{1 + L/50} \quad (2)$$

where V_{GS} is the gate bias at which rupture occurs, V_{DS} is drain-source voltage, and L is the incident ion LET. This

Figure 13. Dependence of single-event gate rupture as a function of drain–source bias, gate–source bias, and ion species. Breakdown voltages without ion irradiation are shown as a dashed curve (control), and the manufacturer’s suggested derating in space is shown by the dotted curve [56].

equation correctly fits the observed trend of decreasing V_{GS} with increasing V_{DS} and LET. The first term describes the coupling of drain bias from the substrate into the gate, while the second term accounts for the effect of the ion passing through the oxide itself. Fits to this equation are shown as solid lines in Fig. 13. Each line denotes the safe operating range for this part as a function of heavy ion. Note that the safe operating range decreases for increasingly heavy ions (higher LET). The manufacturer’s recommended derating for SEGR is shown as a dotted line in Fig. 13. This represents a 50% decrease in maximum V_{GS} and V_{DS} to account for SEGR.

The industry trend toward increasing electric fields as oxide thickness and feature size scale down in advanced technologies raises the concern that SEGR may be a limiting factor for integrated circuits (ICs) in space applications. It has been suggested that, as devices scale to 0.25 μm and below, SEGR by Fe ions will occur, leading to a large increase in catastrophic failures in space hardware. Sexton et al. [57] found that as oxide thickness decreased below 10 nm, the increasing breakdown strength of the oxides resulted in a higher-than-expected gate voltage for rupture, contrary to earlier predictions. Their results suggest that advanced technologies will be more SEGR-resistant at a given electric field than expected. They caution, however, that SEGR will continue to be a significant concern for devices that operate with gate oxide electric field above 5 MV/cm. Massengill also found that in highly scaled (ultrathin) gate oxides and in alternate high- k dielectrics SEGR should not be a limiting factor in advanced technologies [59]. Although there can be considerable variation in the voltage to hard breakdown for different dielectrics, for all the dielectrics investigated by Massengill [59], the breakdown voltages were above the power supply voltages that will be seen in future highly scaled commercial technologies as suggested by the SIA National Technology Roadmap for Semiconductors. As such, it does not appear that SEGR will be a significant problem for highly scaled commercial technologies.

2.6.3. Single-Event Burnout (SEB). Destructive failure resulting from heavy-ion exposure is observed in bipolar power transistors and in power MOSFETS [60–62]. In this phenomenon, the excess current generated by the passage of a heavy ion triggers a secondary photocurrent that overheats the device and causes catastrophic failure. In power MOSFETS, a parasitic n-p-n bipolar transistor exists between the epi layer (collector), the p-type body (base), and the n-type source (emitter) (see Fig. 12). When a heavy ion passes through this parasitic transistor, excess current is generated in the base region. Excess hole current flows toward the body contact, raising the local potential along the base–emitter junction. If sufficient current flows to raise this potential to the turnon voltage of this junction, the base–emitter junction becomes forward-biased, turning on the n-p-n transistor. Following turnon, the transistor enters a second breakdown condition where thermal runaway reinforces the mechanism caused by avalanching at the epi–substrate junction. This condition has been called current-induced avalanche (CIA) [63]. If the external circuit can provide sufficient current, local overheating in a portion of the device will occur, destroying the device. There is a definite threshold voltage required for burnout to occur, and this is often well below the normal breakdown voltage for the device. Fischer [62] has measured failure threshold voltages ranging from 22 to 90% of the rated breakdown voltage for devices from several manufacturers.

2.6.4. Snapback. Snapback is a high current, low resistance condition that occurs only in n-channel transistors. It has an IV characteristic that is similar to latchup exhibiting a negative-resistance region, and a low-resistance region. Like latchup, it can be triggered by external stimuli that inject sufficient current into the p-channel regions well to cause the n source to become forward-biased. Snapback initiation has been observed by avalanche induced breakdown at the n drain [64], by excess photocurrents generated during moderate dose rate gamma irradiation [64], and by heavy-ion strikes to sensitive n-drain or p-channel regions [65].

A significant difference between latchup and snapback is that the holding voltage is on the order of several volts depending on channel length and doping levels, much higher than the 1 V holding voltage seen in latchup. Snapback can be sustained only when the load circuit on the n-channel device can provide sufficient holding current. For CMOS ICs, the load devices are p-channel transistors. Since holding current is on the order of milliamps, snapback is normally observed in output buffers and internal bus drivers. Although latchup is not a concern for SOI technologies, snapback (also known as single-transistor latch) can be a significant problem for SOI technologies, especially those using wide-gate partially depleted transistors [66].

2.7. Proton-Induced Effects

Because of the small stopping power for protons, insufficient charge is generated to induce SEE at current levels of sensitivity. Interaction of a proton with the

semiconductor lattice can generate secondary particles with higher LET that can cause SEE [67]. Elastic scattering of target nuclei, for example, can deposit enough energy to cause soft errors. Of more importance is the contribution to upset from inelastic scattering events, where the incident proton reacts with the target nucleus. About one of every 10^5 protons will experience an inelastic collision with the target lattice. As the composite nucleus decays, it can emit alpha particles and lower-energy protons. In addition, the daughter nucleus can recoil with enough energy to cause upset through direct ionization. The composite nucleus can also decay through a spallation reaction, where the compound nucleus breaks up into two heavy fragments, both of which recoil and deposit energy. Researchers have observed proton-induced upset, latchup, and burnout. To date, no instance of SEGR has been attributed to protons.

2.8. SEU Mitigation

Depending on the application, a low rate of SEU is acceptable in systems. EDAC circuitry and software are often included to handle these errors [68,69]. Some examples of EDAC include use of parity bits, Reed–Solomon encoding, and Hamming codes. If errors occur too frequently, however, the error-handling architecture of a system may be overwhelmed and system failure can result. In mission-critical applications, such as circuitry for a satellite attitude control system, SEU hardened devices must be used to reduce the probability of system failure.

Special design and fabrication techniques are available to harden circuitry to SEU. Circuit design techniques include increasing the size of transistors to remove excess charge faster [70] and use of redundant circuits and voting logic to determine the correct state [71]. Feedback resistors and capacitance can be added to internal nodes of memory cell to reduce sensitivity to transients [72]. All these techniques incur some degree of performance penalty. Increased size carries a density penalty, and adding redundant circuitry increases chip power and reduces functional density. Use of feedback resistors and capacitors reduce the speed of the device.

A more direct approach to SEU mitigation centers on reducing the amount of charge collected following a heavy-

ion strike. A prime example of this approach is the use of silicon-on-insulator (SOI) substrates. The SEU tolerance of a nonhardened SRAM design can be increased by fabricating the design in a SOI-based technology. Figure 14 is a cross section of a SOI transistor. The active silicon channel region is built on top of an insulating layer (buried oxide) instead of a silicon substrate. Because SOI/MOS transistors are fabricated on an insulating layer, the amount of p-n junction area and the sensitive volume are greatly reduced, potentially making SOI/MOS ICs superior to bulk silicon ICs for single-event upset. Also, because there are no possible parasitic bipolar transistors between n- and p-channel transistors, and consequently, no four-layer structures, it is impossible to latchup SOI-based technologies. However, to take full advantage of SOI technology, steps must be taken to reduce or mitigate parasitic effects (e.g., floating effects). SOI transistors operate in two modes: partially depleted and fully depleted. *Partially depleted transistors* are defined as transistors where the silicon thickness is greater than the maximum depletion width formed by the conducting channel. In *fully depleted transistors*, the conducting channel and depletion region extend throughout the thickness of the silicon layer. The presence of a floating-body region of nondepleted silicon between the edge of the depletion region and the silicon/buried oxide interface in a partially depleted technology provides a place where excess charge can build up. As a result, the SEU hardness of SOI transistors can be reduced by bipolar amplification, similar to that for GaAs ICs. A common method for reducing bipolar amplification in SOI transistors is to use body ties, which can provide a convenient means to connect the body region to a voltage reference (e.g., normally a transistor source diffusion) [73–76]. Thus, the body tie connects the floating body region of a partially depleted transistor to a fixed potential. This can provide an efficient path for majority carriers liberated in the body region to drift out of the body region, greatly reducing bipolar amplification. For the same technology generation and equivalent device structure, by using body ties, hardened partially depleted SOI ICs can be fabricated that have LET thresholds considerably higher than hardened bulk-silicon ICs. In a fully depleted technology, excess charge is more readily swept out by the high fields in the channel region, and the effects of bipolar amplification are significantly reduced.

Figure 14. Cross section of a SOI transistor. The active silicon channel is built on top of an insulating oxide leading to a lower sensitive charge collection volume and reduced p-n junction area. These properties make SOI ICs superior to bulk silicon ICs for single-event upset and high-dose-rate pulsed-irradiation hardness.

2.9. Error Rate Prediction

Error rate predictions are based on an estimation of the particle flux that is expected for a given part during its lifetime and a measurement of the SEE sensitivity of the part. The environment has been discussed earlier. Part sensitivity is often described in terms of its critical charge Q_C , defined as the minimum collected charge necessary to upset a circuit. (Note that for simplicity it is assumed that collected charge and deposited charge are equal. When this condition does not apply, other corrections are required.) For dynamic circuits this concept is easily applied because the collected charge negates the stored charge at a node. However, in the case of CMOS latches and memory cells, a critical charge is more difficult to define since these circuits are sensitive to the rate at which charge is collected, and charge collection is modulated by the circuit response. Here critical charge can be estimated by considering the response of the circuit and integrating only charge collected during the time that the circuit is vulnerable to upset. This approach was taken by Dodd and Sexton [77], who clearly demonstrated the need to differentiate between deposited and collected charge. See Ref. 78 for an excellent review of various error rate prediction methodologies that have been used and recommended approaches.

For error rate calculations, the problem is one of determining the probability of any ion, from the full spectrum of ions available, with a given LET or greater passing through the SV at any angle such that it deposits sufficient energy to cause upset. Because flux is isotropic, we must consider all possible pathlengths, and the longer the path through the sensitive volume the more energy (charge) is deposited. In other words, with longer pathlength, ions with lower LET can cause upset. Mathematically, error rate is determined from

$$R(E_C) = A_p \int \Phi[L_t(s, E_C)] f(s) ds \quad (3)$$

where the integration is performed over the distribution of all pathlengths s through the SV. In this equation A_p is the average projected area of the SV, Φ is the LET spectrum for a given environment, L_t is the threshold LET for any path s and Q_C , and $f(s)$ is the distribution of pathlengths through the SV.

This form of the error rate calculation has the following underlying assumptions: (1) the shape of the SV is assumed to be described by an RPP, (2) ion LET is constant through the SV, (3) track structure can be ignored, (4) charge collection by diffusion from outside the SV can be ignored, (5) the SV is augmented by a funnel length that is invariant with ion LET or energy, (6) all charge generated within the SV is collected, and (7) there is a sharp threshold for upset. Because the measured cross section curve is not a step function but has a gradual rise from an onset threshold, current practice is to integrally weight the error rate based on the measured data. Mathematically this is described by

$$R = \int R(E) f(E) dE \quad (4)$$

where the integral is performed from the measured onset threshold to saturation and $f(E)$ is a probability density function that describes the experimental data.

Error rate calculations using Eqs. (3) and (4) are readily performed using an error rate code, such as CREME96 [79], or a commercially available software package called SPACERAD [80]. Both of these codes include the latest environment models, and can include shielding models. The latter also includes utilities that take into account discontinuities that arise in the dataset due to the geometry of the SV as described by Connell et al. [81].

Error rate calculations from proton-induced upset proceeds along a different path. Here the measured sensitivity of a part is given as a function of particle energy, so the error rate is simply the integral of error cross section over the fluence of particles with energy sufficient to cause upset. Mathematically this is given by

$$R(E) = \int_0^\infty \sigma(E) \Phi(E) dE \quad (5)$$

where $\sigma(E)$ is the error cross section and $\Phi(E)$ is the proton spectrum of the environment. Note that no pathlength calculation involving and assumed RPP is required, because the nuclear reaction of the proton in the SV is assumed to be isotropic and independent of angle. Further, the statistics of the proton interaction are included in the $\sigma(E)$ data. For further information, the reader is referred to Ref. 82.

2.10. Terrestrial Single-Event Effects

The occurrence of soft errors in terrestrial microelectronics manifested itself shortly after the first observations of SEU in space [83]. This watershed paper from authors at Intel found a significant error rate in DRAMs as integration density increased to 16,000 and 64,000, spurring a flurry of terrestrial SEU-related work in the late 1970s [84]. The primary cause of soft errors at the ground level was quickly diagnosed as alpha-particle contaminants in packaging materials [83]. For example, according to Ziegler, the Intel problem was traced to a new LSI (large-scale integration) ceramic packaging plant that had just been built downstream from the tailings of an abandoned uranium mine [85]. Radioactive contaminants in the water used by the factory were contaminating the ceramic packages they manufactured. By using low-activity materials for IC fabrication and on-chip shielding coatings [85,86], the terrestrial soft-error problem essentially disappeared for several years. Occasionally, changes in suppliers or procedures have caused semiconductor manufacturers temporary but considerable headaches due to raised radioactive contaminant levels in materials such as nitric and phosphoric acid [85,87]. The march toward higher integration densities has made soft-error concerns a continual design consideration for advanced DRAM and SRAM development since the early 1980s. A particular area of concern is flip-chip packaging technologies that place a source of alpha particles (Pb-Sn solder bumps) right on the die itself, where they cannot be shielded by coating layers

[88]. Elimination of materials rich in ¹⁰B, such as borophosphosilicate glass (BPSG) dielectric layers, has been shown to reduce the thermal neutron soft-error rate (SER) by several orders of magnitude [89,90].

Even in the absence of on-chip sources of radiation, recent studies have conclusively proved that terrestrial cosmic rays (primarily neutrons) are a significant source of soft errors in both DRAMs and SRAMs [91,93]. Upsets have been observed both at ground level and in aircraft and have been convincingly correlated to the altitude and latitude variation of the neutron flux [91,93,94]. Lage et al. have shown that even without alpha particles, a baseline of cosmic ray upsets still exists for high-density SRAMs [92]. O’Gorman has shown that neutron upsets disappear for DRAMs placed 200 m underground in a salt mine, while they increase dramatically for systems operated above 10,000 ft in Leadville, CO [91]. In addition to SEU observed in memories used in large computer systems and aircraft, upsets have been observed in SRAMs used in implantable medical devices such as cardiac defibrillators [95].

Figure 15 shows the measured cosmic ray neutron soft error rate (SER) versus power supply voltage in several generations of SRAMs from a variety of vendors [96]. Terrestrial soft-error failure rate specifications are usually given in terms of FIT rates, where FIT = failure in time = 1 error in 10⁹ device hours. In this figure, SER is reported in FIT/Mbit of memory to allow comparison between memories of different sizes. For reference, an uncorrected SER of 1000/Mbit would lead to 1 error every 3 weeks in a system with 256 Mbytes of memory. From this figure, it is clear that low-voltage SRAMs exhibit unacceptably high SER without error correction, and that different IC technologies can have SER varying by two orders of magnitude at a given voltage. Because of the high SER that exists in many modern memory technologies, error detection and correction (EDAC) is often built into memories to reduce FIT rates [97].

Figure 15. Terrestrial soft error failure rate as a function of power supply voltage for SRAMs manufactured in several different technologies by several vendors.

Destructive single-event effects can also occur in ground-based systems. For example, neutron-induced single-event burnout has caused destructive failures in large-area, high-voltage power diodes used for railroad applications in Europe [98]. It has been experimentally demonstrated that significant neutron-induced latchup rates can occur in high-density SRAMs at ground level [96]. For example, the ground-level neutron-induced latchup FIT rate of a 0.25-μm, 3.3-V 4-Mbit SRAM is shown in Fig. 16. At the maximum rated voltage (3.6 V) at room temperature the latchup FIT rate is 336 FIT/Mbit. At this FIT rate, a 256-Mbyte system using these SRAMs could experience 0.0165 latchups per day, or about 1 latchup every 60 days. Even worse, at this part’s maximum permitted operating temperature of 85°C, the ground-level latchup FIT rate rises to 566 FIT/Mbit at 3.6 V, or nearly one latchup per month in a 256-Mbyte system! These SRAMs exhibited latchup even at 1.5 V, and indeed at 85°C the latchup rate is still more than 100 FIT/Mbit at this voltage. It is also important to note that latchup can’t be circumvented using error correction.

Revelations such as these have significant implications for manufacturers of commercial memory chips and computer systems because systems can’t realistically be shielded against incident neutrons. Meeting specified failure rates is expected to be a significant challenge for commercial semiconductor manufacturers. A typical specification is to maintain a FIT rate less than 1000 [92]. A complicating factor is that since FIT rates are often specified *per device*, meeting a constant FIT rate specification actually requires reducing the error rate *per bit* as the number of bits per device is increased.

It has been suggested that because manufacturers of commercial microelectronics for terrestrial applications have had to deal with alpha-particle-induced upsets from packaging materials, commercial parts will by design remain hard to at least the alpha-particle threshold [99]. Indeed, there is historical evidence supporting this view as data from more than 10 years of microprocessor evolution show a constant upset threshold just above the threshold for alpha-particle upset [99]. However, it is also

Figure 16. Terrestrial neutron-induced latchup failure rate in 0.25-μm, 3.3-V 4-Mbit SRAM as a function of power supply voltage and operating temperature.

known that many manufacturers have specific soft-error-driven design rules for placement of devices relative to on-chip solder bumps and/or use hardened circuit designs for I/O circuitry that must be in the vicinity of such on-chip alpha sources [100]. This clearly implies that many devices being manufactured are in fact already below the alpha-particle threshold for upset.

Many of the techniques traditionally used in the radiation effects community to SEU-harden devices are of such a nature that they are unlikely to be adopted by commercial manufacturers. They tend to consume more power, reduce manufacturability, and severely impact IC performance or integration density. Commercial DRAMs have generally exhibited a fairly constant SEU performance because DRAM manufacturers have intentionally maintained the unit cell capacitance through the use of clever modifications to the storage cell [97,101]. The nodal capacitance for SRAMs, however, has been steadily shrinking [92]. To counteract increased terrestrial soft-error rates, manufacturers may find it necessary to explicitly add capacitance to high-density SRAMs. Lage et al. have predicted that this will be necessary for the 4-Mbit generation of SRAMs and beyond [92]. Design-hardened circuits are useful for critical logic paths or circuitry, but because of area penalties will likely not be adopted on a large scale except as a last resort. The use of error-correcting memory architectures is already becoming more common again, and this trend will likely continue. Mitigating soft errors in high-speed digital logic circuits will be especially challenging. Fault-tolerant systems are routinely used in aircraft mechanical systems and seem a natural choice for preventing neutron-induced SEU in avionics [102]. SOI is a possible solution to the terrestrial SEU problem, although, as noted previously, SOI is not automatically upset immune.

3. TOTAL-DOSE IONIZATION EFFECTS: MOS DEVICES

Electronic devices in satellite systems orbiting Earth can be exposed to very high flux levels of ionizing radiation. Ionizing radiation can cause significant degradation and permanent failure of electronic components. In the natural space environment, both electrons and protons can contribute to total-dose ionizing radiation-induced degradation. Manmade systems, including high-energy particle accelerators and some types of IC processing equipment (e.g., X ray lithography radiation sources and scanning electron microscopes) can also expose electronics to high ionizing radiation levels.

MOS devices are particularly susceptible to ionizing radiation damage. The harsh radiation environment of space has long been known to cause significant radiation-induced degradation of MOS devices [1]. Radiation-induced charge buildup in gate, field, and SOI buried oxides can all contribute to device degradation. Much of the early work investigating the mechanisms for total-dose effects in MOS devices focused on gate oxides. Moreover, much of this work focused on device response at short times after a pulse of ionizing radiation. Gate oxides were relatively thick, and radiation-induced charge buildup in

gate oxides was a major contributor to device degradation in ionizing radiation environments. Although a good part of the work identifying the mechanisms for device degradation was gained by examining device response at short times after a pulse of ionizing radiation, the same mechanisms to a large degree also govern device response in low-dose-rate space environments. In more contemporary devices, as gate oxides are becoming extremely thin, radiation-induced charge buildup in field oxides and SOI buried oxides dominates device degradation in ionizing radiation environments. As will be discussed below, radiation-induced charge buildup in oxides rapidly decreases with oxide thickness, making standard thermal gate oxides of advanced technologies very hard to ionizing radiation.

There is still some controversy over the details for the mechanisms for radiation-induced charge buildup in oxides, especially in nontraditional oxides such as the base oxides of bipolar devices, which can lead to enhanced low-dose-rate sensitivity (ELDRS) effects in bipolar devices. Nevertheless, identification of the general mechanisms for radiation-induced charge buildup in oxides has been vital for the development of reliable qualification test guidelines for MOS devices. The development of reliable qualification test guidelines is still an active area of investigation and continues to benefit from improvements in our knowledge of the mechanisms for radiation effects.

In this section, we review the mechanisms for radiation-induced charge buildup in MOS oxides. The effects of charge buildup in gate, field, and SOI buried oxides on IC performance are described. Mechanisms for the time-dependent buildup and neutralization of radiation-induced charge leading to different failure levels and mechanisms in different radiation environments are highlighted. Techniques for reducing radiation-induced charge (device hardening) are also discussed.

3.1. Basic Mechanisms: Gate Oxides

As a MOS oxide is exposed to high-energy ionizing radiation, electron-hole pairs will be created uniformly throughout the oxide. The carriers generated by ionizing irradiation induce buildup of charge in the oxide, which leads to device degradation. Figure 17 [103] is a schematic band diagram of a MOS capacitor under positive gate bias and depicts the mechanisms by which ionizing irradiation induces charge buildup in an oxide. Under a positively applied bias as shown in Fig. 17, unrecombined radiation-generated holes will transport to the Si/SiO₂ interface. A fraction of these holes will be trapped near the interface, creating a positive oxide-trapped charge. As a result of the hole transport and trapping process, hydrogen is liberated in the oxide which can drift to the Si/SiO₂ interface to form interface traps. The total threshold voltage shift ΔV_{th} for a transistor is given by the sum of the threshold voltage shifts due to interface trap and oxide-trapped charge. Therefore

$$\Delta V_{th} = \Delta V_{ot} + \Delta V_{it} \quad (6)$$

where ΔV_{ot} and ΔV_{it} are the threshold voltage shift due to oxide-trapped and interface trap charge, respectively. The

Figure 17. Schematic band diagram of a MOS capacitor under positive bias illustrating the mechanisms for radiation-induced charge buildup. Positive oxide-trapped charge occurs as holes are trapped in the oxide, and interface trap buildup results from the release of hydrogen during the hole transport and trapping process [103].

mechanisms for these charge components are now discussed in detail.

3.1.1. Charge Yield. If an electric field exists across the oxide of an MOS transistor, once released, electrons in the conduction band and holes in the valence band will immediately begin to transport in opposite directions. Electrons are extremely mobile in silicon dioxide and are normally swept out of silicon dioxide in picoseconds [104,105]. However, even before the electrons can leave the oxide, some fraction of the electrons will recombine with holes in the oxide valence band. This is referred to as *initial recombination*. The fraction of holes that do not recombine is referred to as the *charge yield*. The amount of initial recombination is highly dependent on the electric field in the oxide and the energy and type of incident particle [103,106]. In general, strongly ionizing particles form dense columns of charge where the recombination rate is relatively high. On the other hand, weakly ionizing particles generate relatively isolated charge pairs, and the recombination rate is lower [103].

3.1.2. Oxide-Trapped Charge. Under positive bias, holes that escape initial recombination will transport toward the Si/SiO₂ interface at a rate much slower than electrons. Holes are believed to transport through the Si/SiO₂ by polaron hopping through localized states in the oxide [107,108]. The time that it takes holes to hop through the oxide is dependent on temperature, electric field, and oxide thickness [107–110].

As the holes reach the vicinity of the Si/SiO₂ interface, some fraction of the holes will become trapped in the oxide near the Si/SiO₂ interface. This trapped charge results in a positive-charge buildup in the oxide and is referred to as *oxide-trapped charge*. The positive charge buildup causes a negative oxide-trapped charge threshold-voltage shift that can be calculated from

$$\Delta V_{ot} = -\frac{1}{C_{ox}t_{ox}} \int_0^{t_{ox}} \rho(x) x dx \quad (7)$$

where C_{ox} is the oxide capacitance, t_{ox} is the oxide thickness, and $\rho(x)$ is the spatial distribution of the net charged oxide traps in the oxide. For standard thermal oxides, most of the trapped holes are located close to the Si/SiO₂ interfaces [111]. For SOI buried oxides and other specially processed oxides, hole traps are often distributed throughout the bulk of the oxide [112–116].

The microscopic nature of several oxide trap point defects in thermally grown oxides has been identified by electron paramagnetic resonance experiments [117,118]. The most important of these is called the E' center. At least nine variations of the E' center have been detected. Most E' centers are characterized by an unpaired electron highly localized on a silicon atom bonded to three oxygen atoms. The chemical notation for the generic E' center is given by $\uparrow\text{Si}\equiv\text{O}_3$ or $\cdot\text{Si}\equiv\text{O}_3$.

Once holes are trapped, they can be neutralized by electron tunneling from the silicon [119–122] and by the thermal emission of electrons from the oxide valence band [120,123–125]. In addition to the neutralization of oxide traps by electron tunneling or thermal emission, oxide trap charge also can be compensated as electrons are trapped at electron trap sites associated with the trapped holes. Oxide-trapped charge neutralization can occur over very long periods of time, from seconds to years. In some cases, the rate of oxide-trapped charge neutralization can be relatively large, whereas, for some technologies little or no oxide-trapped charge neutralization has been observed. The rate of neutralization by thermal emission of electrons is dependent on temperature. The rate of neutralization by electron tunneling is dependent on the spatial distance of the oxide traps from the Si/SiO₂ interface and the electric field in the oxide. For neutralization to occur by electron tunneling, the traps must be located very close to the Si/SiO₂ interface. Therefore, the rate of oxide-trapped charge neutralization is highly dependent on the spatial and energy distribution of traps in the oxide.

Combining the effects of hole trapping and neutralization, we note that the amount of oxide trapped charge

Figure 18. Neutralization of oxide-trapped charge occurs after irradiation, leading to a logarithmic decrease in the magnitude of ΔV_{ot} with time [126].

and its associated threshold voltage shift (ΔV_{ot}) are time-dependent. For short times after a pulse of irradiation, little neutralization of trapped charge occurs and the magnitude of ΔV_{ot} can be very large. Long times after a pulse of irradiation, considerably more neutralization can occur and the magnitude of ΔV_{ot} may be small. Similarly, for devices exposed to ionizing irradiation in space, where the dose rate is very low, neutralization of oxide-trapped charge can occur constantly during irradiation and ΔV_{ot} may always be small. The time dependence for trapped-hole neutralization at room temperature is illustrated in Fig. 18 [126] where the voltage shift due to oxide trap charge ΔV_{ot} is plotted versus time for hardened n-channel polysilicon gate transistors irradiated to 100 krad(SiO_2) at dose rates from 6×10^9 to 0.05 rad(SiO_2)/s and then annealed at room temperature. The bias during irradiation and anneal was 6V, and the gate oxide thickness of the transistors was 60 nm. The largest voltage shift (~ -1.45 V) was for short times after the highest-dose-rate irradiation. For the lowest-dose-rate irradiation [0.05 rad(SiO_2)/s], the maximum voltage shift was approximately -0.4 V and occurred after irradiating transistors to 100 krad(SiO_2). During anneal, the decrease in ΔV_{ot} follows a logarithmic time dependence. Note that at each dose rate, ΔV_{ot} falls on the same straight line. Thus, the rate at which ΔV_{ot} is neutralized is dose-rate-independent.

The fraction of holes that is trapped and the rate of neutralization are dependent on processing conditions. The percent of trapped holes can vary from a few percent for specially processed hardened oxides to 100% for commercial oxides. One processing step that can significantly affect the amount of radiation-induced oxide-trapped charge is the temperature of processing steps after gate oxide deposition [127]. Figure 19 illustrates the effect of anneal temperature on oxide-trapped charge buildup. Plotted is ΔV_{ot} versus anneal temperature for polysilicon gate capacitors with an oxide thickness of 46 nm irradiated to 1 Mrad(SiO_2). ΔV_{ot} was measured shortly after irradiation. For temperatures above 850°C , increasing anneal temperature results in a large increase in ΔV_{ot} . The large increase in ΔV_{ot} with increasing temperature is due to the outdiffusion of oxygen from the oxide during the anneal, creating oxide traps [128].

3.1.3. Interface Traps. As holes are trapped near the Si/ SiO_2 interface and as holes transport to the interface, H^+ ions are released in the oxide. Under a positive bias as shown in Fig. 17, these hydrogen ions can drift to the Si/ SiO_2 interface. Once the H^+ ions reach the interface, they can react to form interface traps [129–135]. Density functional theory calculations [136–138] suggest that interface traps are created by the direct interaction of protons at the Si/ SiO_2 interface via the simple reaction

where $\text{H} - \text{Si} \equiv \text{Si}$ denotes a silicon atom bonded to one hydrogen atom and backbonded to three silicon atoms and $\cdot\text{Si}^+ \equiv \text{Si}$ denotes a silicon ion with a dangling bond (interface trap). With a positively applied bias, the positively charged trivalent interface trap $\cdot\text{Si}^+ \equiv \text{Si}$ will be rapidly transformed to a negatively charged site as it captures electrons from the silicon inversion layer [136]. The microscopic structure of the radiation-induced interface trap has been identified by electron paramagnetic resonance measurements as the P_b center [118]. A P_b center is

Figure 19. The increase in radiation-induced, oxide-trapped charge voltage shift with the annealing temperature after gate deposition during device fabrication. Processing temperatures above 850°C increase the amount of radiation-induced, oxide-trapped charge [127].

Figure 20. Effect of the amount of hydrogen used in the ambient gases of high-temperature anneals and oxidations following gate deposition during device fabrication on radiation-induced interface trap charge. Capacitors fabricated using process A were processed using the least amount of hydrogen, and capacitors fabricated using process C were processed using the maximum amount of hydrogen. Increasing the amount of hydrogen increases the amount of radiation-induced interface traps [139].

a trivalent silicon defect site similar to the E' center except that the P_b center is backbonded by three silicon atoms.

The magnitude of interface-trap buildup depends on the amount of hydrogen used in ambient gases for anneals and oxidations following gate deposition [139]. Figure 20 is a plot of threshold voltage shift due to interface traps ΔV_{it} for capacitors fabricated using anneals in ambients containing varying amounts of hydrogen. The capacitors fabricated using process A were processed using the least amount of hydrogen and the capacitors fabricated using process C were fabricated using the greatest amount of hydrogen. The capacitors had an oxide thickness of 101 nm and were irradiated to 100 krad(SiO₂). The capacitors fabricated using the greatest amount of hydrogen resulted in the largest radiation-induced interface trap charge voltage shifts.

Interface traps at the Si/SiO₂ interface are amphoteric and can act as either donor or acceptor traps. Traps in the upper half of the bandgap typically act as acceptors; thus, if the Fermi-level at the interface is above the trap energy level, the trap accepts an electron from the silicon and is negatively charged. Acceptor traps are most important for n-channel transistors. Thus, for n-channel transistors, interface traps are predominantly negatively charged. Interface traps in the lower half of the bandgap typically act as donors; that is, if the Fermi level at the interface is below the trap energy level, the trap donates an electron to the silicon, and is positively charged. Donor interface traps are most important for p-channel transistors. Thus, for p-channel transistors, interface traps are predominantly positively charged. If the Fermi level is near midgap, acceptor traps in the upper half of the bandgap will be empty, donor traps in the lower half of the bandgap will be filled, and the net interface trap charge will be close to zero. Because interface traps are located at the

Si/SiO₂ interface, they can rapidly respond to changes in applied bias.

The voltage shift due to interface trap charge is given by

$$\Delta V_{it} = \frac{-qN_{it}}{C_{ox}} \quad (9)$$

where q is the charge of an electron and N_{it} is the number of charged interface traps. Because interface traps for n-channel transistors are predominantly negatively charged, ΔV_{it} will be positive for n-channel transistors. Similarly, interface traps for p-channel transistors are predominantly positively charged and ΔV_{it} will be negative for p-channel transistors.

The rate of buildup of interface trap charge depends on the kinetics of hydrogen transport and interaction in the oxide and at the interface. This causes the buildup of interface traps to occur over long periods of time (compared to that of oxide-trapped charge buildup). The saturation of interface trap buildup can take thousands of seconds to occur. Figure 21 indicates the slow buildup of interface traps following pulses of ionizing irradiation [135]. Plotted is the radiation-induced increase in the density of interface traps ΔD_{it} for capacitors irradiated to 75 krad(Si) using a 10-MeV electron linear accelerator (LINAC) at dose rates from 1.3×10^7 to 1.4×10^9 rad(Si)/s. Capacitors were irradiated using short 10- μ s pulses with a repetition rate of 4 Hz. The dose rate is determined from the total dose divided by the total irradiation time. At the highest dose rate, the buildup follows an approximate linear-with-log time response from 3 to 3000 s. Interface trap buildup does not begin to saturate until more than 10^5 s after irradiation. Unlike oxide-trapped charge, interface traps do not undergo neutralization or anneal at room temperature. Thus, the maximum amount of interface trap buildup will occur after interface trap buildup has saturated, specifically, $> 10^5$ s for these capacitors. Some interface trap annealing at 100°C has been reported by several workers [140–142]. However, higher temperatures are normally

Figure 21. The increase in the density of interface traps following pulses of ionizing radiation. The buildup of interface traps does not saturate until more than 10^5 s after irradiation for these devices [135].

required to observe significant interface trap annealing [143,144].

In addition to causing a change in threshold voltage, a buildup of radiation-induced interface traps also can cause a decrease in carrier mobility. The degradation in carrier mobility μ with interface trap charge buildup follows the general relationship [145]

$$\mu = \frac{\mu_0}{1 + \alpha \Delta N_{it}} \quad (10)$$

where μ_0 is the preirradiation mobility and α is a constant. This equation is valid under most conditions, except for short times (<0.1 s) after a pulse of irradiation [146]. At short times after irradiation (~ 0.01 s), there can be a significant concentration of oxide-trapped charge close to the Si/SiO₂ interface, which can affect, and in some cases dominate, the degradation in mobility. As electrons tunnel from the silicon into the oxide, neutralizing oxide charge close to the interface, the importance of charged hole traps on mobility becomes decreasingly important.

3.1.4. Border Traps. Some oxide traps can be located close enough to the interface that they can exchange charge with the silicon on the time frames of an electrical measurement. These oxide traps will act electrically like interface traps, but are in fact, oxide traps. Oxide traps close to the interface that act electrically like interface traps are called *border traps* [147]. For an oxide trap to behave like a border trap, it must be within ~ 3 nm of the Si/SiO₂ or gate/SiO₂ interface [103,147]. Note that all oxide traps are likely to act as border traps for oxide thickness less than 6 nm (gate oxides of advanced IC technologies).

3.1.5. Effect of Oxide Thickness. A key process condition that has a very large effect on gate oxide hardness is oxide thickness. Fortunately, as the thickness of the gate oxide decreases, radiation hardness improves. The threshold voltage shifts due to oxide-trapped charge and interface trap charge decrease with slightly less than a t_{ox}^2 thickness dependence ($t_{ox}^{1.5}$ to $t_{ox}^{1.8}$). Because of the improvement in hardness with decreasing thickness, gate oxides in advanced commercial technologies can be extremely radiation-hard. The basic mechanisms of radiation effects for ultrathin oxides are different from those for moderately thick gate oxides. Ultrathin oxides are those in which oxide trap charge can be neutralized by electrons tunneling from either the gate or the Si/SiO₂ interface. Because a relatively higher number of the oxide traps will be accessible to electron tunneling, there will also be a relatively higher number of oxide traps that can act as border traps [147]. In fact, for very thin oxides (<6 nm), there may be no “bulklike” traps, and all traps in the oxide have the potential to function as border traps. Thus, for ultrathin oxides, it is possible to have no net positive radiation-induced oxide trap charge, and all traps may function electrically like interface traps (either true interface traps or border traps).

3.1.6. Alternate Gate Dielectrics. Silicon dioxide has been the primary gate insulator since MOS ICs were first developed. To achieve the drive currents required by advances in IC technology, SiO₂ gates are becoming extremely thin. They will soon reach a point where electron tunneling will cause prohibitively large increases in power consumption. To circumvent this problem, alternate gate dielectrics with high dielectric constants (also referred to as “high- k ” dielectrics) are being explored. With a high-dielectric-constant gate material a much thicker dielectric can be used to obtain the equivalent capacitance of much thinner SiO₂ gates. For these thicker high dielectric constant insulators, electron tunneling is reduced and oxide trap charge may be more significant.

At the present time, there is extremely little information on the radiation hardness of the dielectrics under consideration for replacing SiO₂. Because the dielectric gates will be physically thicker and deposited or grown using different techniques, it is possible that these dielectrics could trap significantly more charge than thinner thermally grown SiO₂ gates. As a result, the radiation-induced charge trapping in the gate insulator may once again affect IC radiation hardness. Two alternate dielectrics that have been explored are hafnium oxide, HfO₂ [148] and stacked Al₂O₃ and oxynitride gate dielectrics [149]. The hole-trapping efficiency for HfO₂ gate dielectrics has been determined to be around $\sim 28\%$, which is much larger than that for high-quality gate oxides. For stacked Al₂O₃ and oxynitride gate dielectrics, the oxide-trapped charge voltage shift has been shown to have approximately a t_{ox}^4 thickness dependence and is somewhat larger than that for high-quality gate oxides, and there is negligible interface trap buildup [149]. For gate insulator thicknesses of interest to advanced IC technologies, the threshold voltage shifts in these dielectrics should not be a major concern.

Another alternative dielectric that has been explored is reoxidized nitrided oxides (RNOs) [150–155]. Nitrided oxides can be fabricated by several different methods. One of the most straightforward methods is to anneal a thermal oxide in an ammonia (NH₃) ambient. An ammonia anneal results in a large concentration of nitrogen throughout the dielectric with peak concentrations at both interfaces. The primary difference between thermal and RNO dielectrics in ionizing radiation environments is the nearly total lack of interface trap buildup for RNO dielectrics [156]. Thick gate insulator RNO dielectrics (37 nm) have been fabricated in which there is no measurable interface trap buildup for transistors irradiated to total doses in excess of 50 Mrad(Si) [156]. This makes RNO gates attractive for space applications. The amount of oxide-trapped charge buildup in RNO dielectrics has also been shown to be less than that for comparable thermal oxides [156].

3.1.7. Total Threshold Voltage Shift. For a n-channel transistor, ΔV_{it} is positive and ΔV_{ot} is negative. Therefore, ΔV_{it} and ΔV_{ot} compensate each other as seen in Eq. (6). Because the timescales for ΔV_{it} buildup and ΔV_{ot} buildup and neutralization are different, the amount of compensation, and hence, ΔV_{th} , is time-dependent. For short times after a pulse of irradiation, ΔV_{ot} will dominate the

Figure 22. Radiation-induced, n-channel transistor threshold voltage shift versus dose rate of the radiation source. At high dose rates (short times), the threshold voltage shift is dominated by oxide-trapped charge and the threshold voltage shift is negative. At low dose rates (long times), the threshold voltage is dominated by interface trap charge and the threshold-voltage shift is positive [157,158].

threshold voltage shift and ΔV_{th} will be large and negative. For long times after a pulse of irradiation or for low-dose-rate exposures (e.g., space), ΔV_{it} may dominate the threshold voltage shift and ΔV_{th} may be large and positive. For p-channel transistors both ΔV_{ot} and ΔV_{it} are negative, they add together, and the radiation-induced threshold voltage shift is always negative. Figure 22 illustrates the change in ΔV_{th} with time (dose rate) for n-channel transistors [157,158]. Plotted is ΔV_{th} versus dose rate for transistors irradiated to 1 Mrad(Si). For low-dose-rate exposures (long times), interface trap buildup dominates and ΔV_{th} is large and positive. For higher dose rate exposures (shorter times), oxide-trapped charge dominates and ΔV_{th} is large and negative.

As illustrated in Figure 22, the radiation-induced threshold voltage shift for n-channel transistors can be either positive or negative. As the radiation dose is increased, the magnitude of the threshold voltage shift will increase negatively. This will result in a dramatic increase in the OFF-state leakage current (drain-to-source current I_{DS} measured at zero gate-to-source voltage V_{GS}) of individual transistors and a large increase in the static power supply current I_{DD} of an IC. If the increase in I_{DD} is high enough, functional failure can occur [159].

At low dose rates, the threshold voltage can be dominated by interface-trap charge. If this is the case, the threshold voltage can be large and positive. (Oxide-trapped charge can dominate the electrical response even at low dose rates for some technologies [160].) A large positive threshold voltage shift will decrease transistor drive. Coupled with a decrease in carrier mobility caused by the increase in number of charged interface

traps, the decrease in transistor drive will cause a degradation in IC timing parameters and potentially cause IC functional failure.

Neutralization of oxide-trapped charge and the buildup of interface trap charge with time will also affect IC electrical performance with time. Short times after a pulse of radiation, the magnitude of the threshold voltage shift of a n-channel transistor will be at its maximum value, causing the largest increase in I_{DS} and concomitantly the static power current of an IC (I_{DD}) will be at its maximum value. The threshold voltage will shift positively as oxide-trapped charge is neutralized. This will cause a decrease in I_{DS} at $V_{GS} = 0$ V. Thus, an IC that fails I_{DD} specifications shortly after a pulse of irradiation may pass I_{DD} specifications at longer times. However, as oxide-trapped charge continues to be neutralized (either at long times after a pulse of irradiation or during low-dose-rate exposure) and interface traps continue to build up, at some point transistor response may begin to be dominated by interface trap charge and ICs may begin to fail as a result of timing related issues. The change in n-channel transistor threshold voltage from negative to positive with time after irradiation is often referred to as the *rebound effect* [161]. To summarize, initially after a pulse of irradiation ICs may fail as a result of high leakage currents, moderate times after irradiation (or for moderate dose rate exposures) ICs may pass all specifications, and long times after irradiation (or for low-dose-rate exposures) ICs may fail because of timing related issues. The change in IC parametric and functional behavior with time makes it difficult to predict or assess IC failure in low-dose-rate satellite environments from moderate dose rate laboratory measurements.

3.2. Field Oxides

Even though the radiation hardness of commercial gate oxides may improve as the IC industry tends toward ultrathin oxides, field oxides of advanced commercial technologies will still be relatively thick and can be very soft to ionizing radiation. A relatively small dose in a field oxide [~ 10 krad(Si) for many commercial devices] can induce sufficient charge trapping to cause field-oxide-induced IC failure. As such, radiation-induced charge buildup in field oxides is the main cause of IC failure in many advanced commercial technologies.

Field oxides are much thicker than gate oxides. Typical field oxide thicknesses are in the range of 100–1000 nm. Unlike gate oxides, which are routinely grown by thermal oxidation, field oxides are produced using a wide variety of deposition techniques. The trapping properties in field oxides may be poorly controlled and can be considerably different from those for a gate oxide.

Two common types of field oxide isolation used today are local oxidation of silicon (LOCOS) and shallow-trench isolation (STI). LOCOS isolation has been used for many years. More recently, commercial IC suppliers have replaced LOCOS isolation with STI for advanced submicron technologies. Figure 23a [162] shows the cross section of an n-channel transistor with LOCOS isolation illustrating positive charge buildup in the bird's beak regions. Similar charge buildup will occur for STI as illustrated in Fig. 23b

Figure 23. Two common types of field oxide isolation: (a) LOCOS and (b) shallow-trench isolation [162]. Positive charge buildup in the oxides can invert the underlying p-type surfaces.

[162]. As positive radiation-induced charge builds up in the field oxide overlying a p-type surface, it can invert the surface forming an n-type region underneath the field oxide. As the surface inverts, conducting paths can be generated that will greatly increase the leakage current. One leakage path occurs at the edge of the gate oxide transistor between the source and drain. Another leakage path could occur between the n-type source and drain regions of a transistor and the n well of adjacent p-channel transistors. These two leakage paths will cause an increase static power supply current of an IC. Because radiation-induced charge buildup in field oxides is predominantly positive, its effect is usually most important for n-channel transistors.

The field oxide forms a parasitic field oxide transistor in parallel with the gate oxide transistor. For example, at the edges of the gate transistor the gate polysilicon extends over the field oxide region as shown in Fig. 23. The parasitic field oxide transistor consists of the gate polysilicon, a portion of the field oxide, and the source and drain of the gate transistor. The effect of the excess leakage current from a parasitic field oxide transistor on the gate oxide transistor is illustrated in Fig. 24 [163]. Plotted in Fig. 24 are the drain-to-source leakage current versus gate-to-source voltage curves for an n-channel gate oxide transistor with (combined curve) and without field oxide leakage and for a parasitic field oxide transistor. Because of the large thickness of the field oxide, the preirradiation threshold voltage of the parasitic field oxide transistor is relatively large, but as positive radiation-induced charge builds up in the field oxide, it can cause a very large negative threshold voltage shift of the parasitic field oxide transistor. If the threshold voltage shift of the parasitic field oxide transistor is large enough (as depicted in

Figure 24. Buildup of radiation-induced positive charge in a field oxide can cause large negative shifts in the threshold voltage of the parasitic field oxide transistor. If the shift is large enough, as shown in the figure, the parasitic field oxide leakage current will add to the leakage current of the gate oxide transistor [163]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Fig. 24), it will cause an OFF-state leakage current (gate voltage at zero volts) to flow, which can significantly add to the drain-to-source current of the gate oxide transistor. Hence, the field-oxide leakage prevents the gate oxide transistor from being completely turned off. This will greatly add to the static supply leakage current of an IC and might cause functional failure.

The amount of field oxide leakage depends greatly on IC process and topography. For example, for STI the topography of the shallow-trench and process conditions inherently lead to variations in the trench sidewall insulator thickness between the silicon trench and overlying conductors (e.g., polysilicon). This is especially pronounced at the top corner of the trench. At the top corner, the shallow insulator thickness can result in very high fields across the insulator. These high fields in trench corner regions have been shown to severely limit the radiation hardness [162]. As the magnitude of the electric field across the trench corner increases, the magnitude of the threshold-voltage shift of the parasitic field oxide transistor increases [162].

Several methods can be employed to improve the radiation hardness of field oxides. Increasing the doping level underneath the bird's beak region of LOCOS isolation or along the sidewall of STI, will increase the preirradiation threshold voltage of the parasitic field oxide transistor and increase the amount of radiation-induced charge required to invert the underlying p-type surfaces. For STI, process techniques that increase the insulator thickness around trench corners and using n⁺ pullback regions have been successfully used to improve the radiation hardness of STI ICs [162].

3.3. SOI Buried Oxides

The total-dose hardness of an SOI transistor depends on the radiation hardness of three oxides: (1) gate, (2) field

oxide or sidewall isolation, and (3) buried oxide. The mechanisms for the radiation-induced degradation of the gate oxide of a MOS/SOI transistor are identical to the mechanisms for the gate oxide of a MOS transistor fabricated on a bulk silicon substrate as discussed above. Most present-day SOI circuits use LOCOS or STI for transistor isolation. The radiation hardness of these oxides was discussed above. Some mesa-isolated SOI technologies include sidewall oxides. A sidewall oxide exists as the gate oxide extends over the edges of the silicon island and forms a parasitic transistor in parallel with the top transistor. In some cases, the sidewall oxide is less radiation-tolerant than the top oxide and can greatly increase the transistor leakage current. The sidewall-oxide-induced leakage forms a shoulder in the MOS transistor I/V curve and is similar to that caused by a parasitic field oxide transistor for a bulk silicon MOS transistor (see Fig. 24). Sidewall leakage can be eliminated by proper processing of the sidewalls [164–167]. For example, heavily doping the sidewall by selective implantation can be used to increase the threshold voltage of the parasitic sidewall transistor, reducing its importance to the radiation response [164,165].

The biggest difference between the total-dose response of SOI and bulk silicon technologies is radiation-induced charge buildup in the buried oxide of SOI transistors. As SOI buried oxides are exposed to ionizing radiation, radiation-induced charge will become trapped in the buried oxide. This radiation-induced trapped charge is predominantly positively charged. As illustrated in Fig. 23a, this charge buildup in the buried oxide can invert the backchannel interface forming a leakage path between the source and drain of the top-gate transistor. For simplicity, the charge buildup as illustrated in Fig. 25a is shown to be located close to the buried oxide/backchannel interface. However, in general, charge will be trapped throughout the buried oxide. Inversion of the backchannel interface can lead to large increases in leakage current of a partially depleted transistor. Because the top-gate transistor is electrically coupled to backgate transistor in a fully depleted

transistor, radiation-induced charge buildup in the buried oxide of a fully depleted transistor will cause a decrease in the threshold voltage of the top-gate transistor.

A simple method for quantifying the amount of radiation-induced charge buildup in the buried oxide is to measure the threshold voltage of the backgate transistor. The backgate transistor consists of the source and drain of the top-gate transistor, the buried oxide is the gate dielectric, and the substrate acts as the gate contact. The bias configuration for measuring the backgate I/V characteristics are shown in Fig. 25b. The bias configuration and measurement conditions are identical to those for measuring the top-gate I/V characteristics except that the gate bias is applied to the substrate. Typical I/V curves for the backgate transistor are shown in Fig. 26a. The transistors were irradiated with ^{60}Co gamma rays in the OFF ($V_{\text{GS}} = V_{\text{S}} = 0$ V; $V_{\text{DS}} = 5$ V) bias condition. As noted in the figure, positive charge buildup in the buried oxide can cause large negative shifts in the backgate transistor I/V curves. As the radiation-induced charge buildup becomes sufficiently large to cause an increase in the leakage current at zero backgate bias, the top-gate leakage current will begin to increase as illustrated in Fig. 26b. This leakage current resulting from radiation-induced charge buildup in the buried oxide will prevent the top gate from being completely turned off. If it is large enough, it can cause parametric and potentially functional failure.

The radiation response of buried oxides has been found to be highly dependent on the fabrication process [168,169]. Two common methods for fabricating SOI substrates are separation by implanted oxygen (SIMOX) and by wafer bonding. SIMOX substrates are formed by implanting a silicon substrate with oxygen ions to very high fluence levels and then annealing the substrate at very high temperatures (e.g., 1350°C) to form the buried oxide. Bonded SOI substrates are formed by growing an oxide on the surface of one wafer and then bonding the wafer to a second substrate. There are numerous methods for producing the thin top silicon layer of the SOI substrate. Common to all bonded wafer processes is a high-temperature bond-strengthening anneal (e.g., 1100°C). The high-temperature anneals used to fabricate SOI substrates (both SIMOX and bonded) cause oxygen to outdiffuse from the buried oxide, leaving behind numerous oxide defects. These defects can lead to radiation-induced trapped charge [170]. It is natural to expect that the high-fluence implants used to fabricate SIMOX substrates (and some bonded oxide substrates) may cause numerous implant-related defects throughout the buried oxide. Previous work [169,171–174,188–192] has shown that up to 100% of the radiation-generated holes are trapped in the bulk of the oxide at deep trap sites close to their point of origin. Once trapped, some of the holes are slowly neutralized by electrons by thermal detrapping at room temperature [169,171–174]. In addition to hole trapping, electrons are also trapped throughout the bulk of the buried oxide [169]. Most of the trapped electrons are thermally detrapped within < 1 s after a pulse of radiation. After the electrons are detrapped, the resultant charge is due to a high concentration of trapped holes causing large negative threshold-voltage shifts of the buried oxide.

Figure 25. (a) Cross section of a partially depleted SOI transistor illustrating radiation-induced charge buildup in the buried oxide and inversion of the backchannel interface. For simplicity, radiation-induced charge buildup in the buried oxide is depicted as a sheet of charge close to the backchannel interface, whereas in general positive charge is trapped throughout the buried oxide. (b) Bias configuration for measuring the backchannel threshold voltage. This measurement is useful for quantifying the net amount of positive charge in the buried oxide.

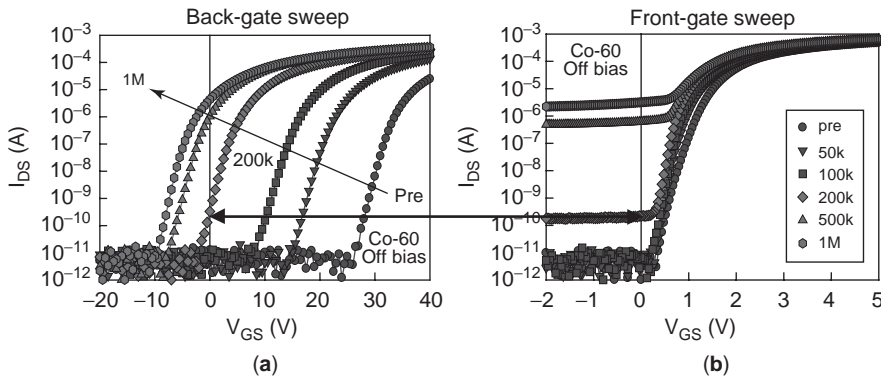

Figure 26. Gate voltage versus drain current I/V curves for (a) the backgate transistor and (b) top-gate transistor. Positive charge buildup in the buried oxide can cause large negative shifts in the backgate transistor threshold voltage and if large enough, as depicted in the figure, can cause large increases in the top-gate leakage current. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Several techniques have been proposed to mitigate the effects of radiation-induced charge trapping in the buried oxide on transistor performance. These techniques can be grouped into two general categories: techniques that reduce the amount of net positive radiation-induced trapped charge and techniques that reduce the effects of radiation-induced trapped charge on transistor performance. One technique that has been proposed to reduce the amount of net radiation-induced positive trapped charge is to implant the oxide with silicon [175,176].

A transistor structure that reduces the effect of radiation-induced charge trapped in the buried oxide on transistor performance is the body-under-source field-effect transistor (BUSFET) [177]. The BUSFET is similar to a standard SOI transistor except that the source penetrates only partially through the top silicon layer. (If the drain also penetrates only partially through the top silicon layer, there could be a large decrease in dose rate and single-event upset hardness due to additional junction area.) As radiation-induced charge is trapped in the buried oxide, the charge will invert the backchannel interface. However, because the source penetrates only partially through the buried oxide, the inverted layer cannot form a conducting path between the source and the drain and no increase in top-gate transistor leakage current will occur.

3.4. Hardness Assurance Issues

Radiation test guidelines have been written with the intent to ensure device functionality in space environments. One such guideline in the United States is MIL-STD 883, Method 1019 [178]. Knowledge of the basic mechanisms of radiation effects has led to considerable improvements in the test methods [178,179]. For example, the latest Method 1019 test guideline consists of a two-part test to ensure that a device will function within acceptable, bounded limits during its lifetime. The first part of the test is a laboratory irradiation at a dose rate between 50 to 300 rad(Si)/s to the specification requirement. As long as the laboratory dose rate is greater than the expected space dose rate, this test will ensure that the threshold voltage shift of gate or field oxide transistors will be more negative for the laboratory irradiation than in space. Thus, this part of the test bounds the contribution of oxide trap charge. The second part of the test is a 100°C, 1-week “rebound” test following an additional irradiation to 50% of the specification requirement. As long as the rebound

anneal does not anneal interface trap charge, this test will ensure that the threshold-voltage shift will be more positive than in space, and, thus, provide an effective way to test for interface-trap-related failures. Two other issues that can affect the reliability of hardness assurance testing are preirradiation elevated temperature stress effects and the optimum laboratory radiation source for qualifying devices in space radiation environments.

3.4.1. Preirradiation Elevated Temperature Stress (Burn-In) Effects. To improve system reliability, devices are often exposed to elevated temperature anneals (e.g., burnin anneal) prior to system assembly. These anneals increase the cost of devices. To reduce the cost of radiation characterization, devices used for radiation tests seldom have been subjected to reliability screens. Thus, devices used for radiation characterization are rarely exposed to the same elevated temperature anneals as those used in space systems.

Shaneyfelt et al. [180,181] showed that preirradiation elevated temperature stresses (PETSS) can affect device hardness. Examples of the effects of preirradiation elevated temperature anneals are illustrated in Fig. 27, which plots the “standby” power supply leakage current I_{DD} of

Figure 27. Standby power supply leakage current versus total dose for 16K SRAMs subjected to and not subjected to a preirradiation 150°C, 1-week elevated temperature stress. The devices exposed to a typical burn-in test show increased radiation-induced degradation [180]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

16,000 SRAMs with and without a preirradiation 150°C, one-week anneal, and irradiated with 10-keV X rays with a 5-V power supply voltage in a checkerboard pattern [180]. The ICs were measured in a checkerboard complement pattern. For the ICs not subjected to a preirradiation anneal, the maximum IC leakage current is approximately 3.5 mA and occurs at a total dose of 200 krad(SiO₂). For the ICs subjected to a preirradiation anneal, the maximum IC leakage current is approximately 45 mA and occurs at a 500 krad(SiO₂). The maximum IC leakage current for the ICs subjected to a preirradiation elevated temperature stress is more than an order of magnitude higher than for the ICs not subjected to an elevated temperature stress. Further, after irradiating to a total dose of 500 krad(SiO₂), the IC leakage current for the ICs subjected to a preirradiation temperature stress is more than two orders of magnitude higher than for the ICs not subjected to a preirradiation elevated temperature stress. Hence, these data show that PETS can significantly affect IC radiation hardness.

The effect of preirradiation elevated temperature stresses on IC radiation response is clearly a concern for hardness assurance testing. Note that when we refer to elevated temperature stresses, we are not limiting ourselves to those used for burnin and other reliability tests. High-temperature process steps used in device packaging, during system assembly and use, and elsewhere also could have large impacts on IC radiation response [181]. Preirradiation elevated temperature stresses have been addressed in the U.S. military test guideline MIL-STD-883, Method 1019. For each technology, one should determine if the devices are susceptible to PETS effects. Unless the technology has been shown not to exhibit PETS effects, radiation characterization must be performed on devices subjected to all elevated-temperature-biased stresses required by reliability qualification, packaging, or system requirements. This is especially true for technologies where IC failure is dominated by radiation-induced increases in leakage current. Otherwise, the amount of radiation-induced degradation may be severely underestimated.

3.4.2. Optimum Laboratory Radiation Sources for Hardness Assurance Testing. In space, electronic devices can be exposed to high fluences of electrons and protons. In the laboratory, however, ⁶⁰Co gamma- and X-ray sources are more cost-effective for routine evaluation of the radiation hardness of electronic devices for space environments. X-ray sources can operate at higher dose rates than most ⁶⁰Co sources and can be used to irradiate individual die at the wafer level. Because of these properties, X-ray sources are often used for process development and control [159]. Cobalt-60 gamma sources are normally used for hardness assurance testing. For example, the present MIL-STD-883, Method 1019 test guideline used for qualifying devices for space applications requires devices to be irradiated using moderate-dose-rate ⁶⁰Co sources [178]. Some work has been performed comparing the differences in total dose degradation for X-ray and ⁶⁰Co irradiations. In some cases good correlation between ⁶⁰Co and X-ray radiation-induced degradation was observed [182]; however, in other cases large differences were observed [183,184]. These re-

sults indicate that for some technologies, ⁶⁰Co and X-ray irradiations may produce considerably different results.

The justification for using ⁶⁰Co gamma sources for hardness assurance testing is based primarily on historical practice rather than on technical grounds. This leads to an obvious question: For technologies where X-ray and ⁶⁰Co irradiations cause different amounts of device degradation, which radiation source is best suited for simulating energetic electrons or protons? Work in 2001 [185] comparing the radiation-induced response of pMOSFET dosimeters showed that the radiation-induced response for high-energy protons (60–200 MeV) was only 65–85% of the ⁶⁰Co radiation-induced response. This result raises concern that ⁶⁰Co radiation sources may not be the best radiation source for simulating device response in proton-rich space environments. In this section, we will concentrate on differences between ⁶⁰Co and low-energy X-ray radiation sources, the two most popular types of laboratory radiation sources for characterizing the radiation hardness of ICs for space environments.

Figure 28 shows the ratio of the backgate transistor threshold voltage shift for X-ray and proton irradiations and the ratio for ⁶⁰Co gamma and proton irradiations for transistors irradiated in the 0 V and transmission gate (or pass gate) (TG) bias configurations [184]. The X-ray and proton data were taken at a dose rate of 270 rad(SiO₂)/s, and the ⁶⁰Co gamma data were taken at a dose rate of 50 rad(SiO₂)/s. X-ray data taken at 270 and 50 rad(SiO₂)/s showed no noticeable differences in backgate threshold voltage shift for the different dose rates for devices irradiated to total doses up to 500 krad(SiO₂). Hence, the fact that the data were taken at somewhat different dose rates should not affect the conclusions. Within experimental uncertainties, the X-ray and proton radiation-induced backgate threshold voltage shifts are nearly equal for all total dose levels and bias conditions examined. However, the ratio of ⁶⁰Co gamma and proton backgate threshold shifts varies widely, especially for low total doses. The fact that there is agreement in the backgate threshold voltage shifts at high total doses is not surprising. At this point, the threshold voltage shift is significant and therefore the

Figure 28. Ratio of X-ray to 41.4-MeV proton and ⁶⁰Co gamma to 41.4-MeV proton radiation-induced backgate threshold voltage shifts as a function of total dose for SOI transistors. Transistors were irradiated with either a 0-V or TG bias configuration [184]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

internal field in the oxide is also significant. Thus, a low-field condition in the oxide is no longer satisfied. Note that this is due to the size of the threshold voltage shift, not the total dose. Devices that shift more or less with dose will therefore reach this point at different dose levels. Thus, for this proton energy, total dose levels, and devices, X-ray irradiations much better simulate proton radiation-induced degradation than do ^{60}Co gamma irradiations. Good correlation between X-ray and proton-radiation-induced degradation has been observed for proton energies between 20 and 200 MeV and in the radiation-induced degradation of field oxides in bulk silicon technologies [184]. As a result, for SOI and bulk silicon transistors, laboratory X-ray irradiations may more closely simulate proton-rich environments such as low-Earth orbits (at least in the energy range of 20–200 MeV) than do laboratory ^{60}Co gamma irradiations. This contradicts the commonly accepted tenet that ^{60}Co gamma sources should be used for all hardness assurance qualification. The better match between X-ray and proton-radiation-induced damage was suggested to be a closer match of the initial charge yield between 10-keV X-rays and protons at low electric fields [184]. This does not preclude the use of ^{60}Co gamma radiation sources for device qualification in proton-rich environments. Cobalt 60 gamma radiation sources may overestimate the total-dose degradation and, therefore, are a more conservative radiation source.

Because the charge yield for ^{60}Co gamma rays more closely matches the charge yield for electrons with energies relevant to the space environment, ^{60}Co gamma irradiation better simulates the radiation-induced degradation of SOI devices in electron-rich space environments than does X-ray irradiation [186]. Thus, to simulate total-dose degradation in electron-rich environments such as geosynchronous orbits, ^{60}Co gamma sources are probably still the optimum laboratory radiation source for device qualification.

4. TOTAL-DOSE IONIZATION EFFECTS: BIPOLAR AND III-V DEVICES

4.1. Bipolar Devices: Enhanced Low-Dose-Rate Sensitivity

Since the early 1990s, it has been known that some types of bipolar devices exhibit enhanced low-dose-rate sensitivity (ELDRS) at low electric fields [187–193]. This means that the amount of total-dose degradation in bipolar transistors and ICs that is observed at a given total dose is greater at low dose rates than high dose rates. In general, the degradation results from the buildup of radiation induced charge in the field oxides used to isolate the base and emitter contacts and recombination centers that are created at the Si/SiO₂ interface. ELDRS in n-p-n transistors has been attributed primarily to increased positive oxide trap charge buildup in the isolation oxide overlying the base-emitter junction [193,194]. This charge enhances the surface recombination rate in the p-base region. On the other hand, lateral and substrate p-n-p transistors are primarily affected by increased interface trap charge buildup in the thick isolation oxide over the emitter-base region [192,195]. In most cases, ELDRS effects have

been shown to be more important for lateral or substrate p-n-p transistors than for n-p-n transistors [190]. In fact, Johnston and coworkers [190] showed that the relative damage at low dose rates ($< 0.01 \text{ rad}(\text{SiO}_2)/\text{s}$) for junction-isolated linear processes could be greater than a factor of 2 larger in linear bipolar circuits dominated by p-n-p transistor response than in those dominated by n-p-n transistor response. A data compendium of bipolar linear circuits that exhibit ELDRS can be found in Ref. 196.

ELDRS is illustrated in Fig. 29, which is a plot of the input bias current for LM111 voltage comparators versus total dose for dose rates of 50, 0.1, and 0.01 $\text{rad}(\text{SiO}_2)/\text{s}$ [197]. The voltage comparators were irradiated with all pins short-circuited. As observed in Fig. 29, voltage comparators irradiated at low dose rates have a much larger increase in input bias current than voltage comparators irradiated at high dose rates. This ELDRS effect can cause failure of ICs in satellite environments not observed in standard laboratory testing. As such, ELDRS severely complicates hardness assurance testing for space environments.

Developing an accelerated hardness assurance test method to estimate the “true” low-dose-rate effects in bipolar devices remains a very challenging issue facing the radiation effects community [198,199]. Unfortunately, high-dose-rate irradiation followed by room-temperature annealing, which can accurately estimate the radiation response of CMOS devices at low dose rates [200,201], does not accurately estimate the low-dose-rate response of many types of bipolar devices [187,191]. In MOS devices this is referred to as *time-dependent effects*, not a “true” low-dose-rate effect. Time dependent effects also exist in bipolar devices and must not be confused with a “true” low-dose-rate effect. This has made it difficult to develop a quick and accurate total-dose hardness assurance test method for predicting the radiation response of bipolar devices with the potential to exhibit ELDRS effects. Currently, the most promising rapid screen involves the use of an elevated temperature irradiation at relatively low dose rates ($\leq 1 \text{ rad}(\text{SiO}_2)/\text{s}$) [202,203]. However, the optimum irradiation temperature for this procedure varies from

Figure 29. Input bias current versus dose for LM111 voltage comparators irradiated at dose rates of 50, 0.1, and 0.01 $\text{rad}(\text{SiO}_2)/\text{s}$ [197].

technology to technology [196,203], and does not always bound the low-dose-rate response, and the required dose rate is significantly lower than the current dose rate range [50–300 rad(SiO₂)/s] used for qualifying CMOS technologies. As a result, manufacturers do not have a reliable laboratory test guideline for timely assessment of the radiation hardness of their bipolar technologies. Nevertheless, test procedures have been added to the MIL-STD-883, Test Method 1019 for testing bipolar linear devices that require the use of either low dose rate or elevated-temperature irradiations [204].

On a positive note, researchers have shown that final chip passivation layers can have a major impact on the total-dose hardness of bipolar linear technologies [205]. It is found that devices fabricated without passivation layers do not exhibit ELDRS or preirradiation elevated temperature stress (PETS) sensitivity, while devices from the same production lot fabricated with either oxide/nitride or doped-glass passivation layers are sensitive to ELDRS and PETS. It was also shown that removing the passivation layers on devices that exhibit ELDRS could mitigate ELDRS and PETS effects. While this is obviously not a practical solution to the ELDRS and PETS problems for ICs to be used in space systems, it does appear to indicate that ELDRS and PETS effects are probably not intrinsic to many bipolar process technologies prior to deposition of the final passivation layer. In addition, ELDRS and PETS effects do not appear to be inherently related to circuit design or layout, but are related to mechanical stress effects, hydrogen in the device, or a combination of the two. It appears that mechanical stress induced by the passivation layers might play a critical role in determining the radiation response of bipolar linear ICs. Passivation layers can easily alter mechanical stress in the die. The introduction of thermal cycles and moisture after fabrication has been shown to further impact the film stress [206,207]. These two facts are consistent with both changes in radiation response between unpassivated and passivated devices at high dose rates, and the observation of PETS sensitivity in passivated devices. These results suggest that proper engineering of the final chip passivation layer might eliminate ELDRS and PETS effects in bipolar integrated circuits.

4.2. III–V Devices

These devices are inherently hard to ionizing irradiation. Previous works have shown that GaAs devices can be irradiated with gamma rays to levels in excess of 100 Mrad (GaAs) without significant degradation [208,209]. III–V devices have also been shown to very hard to proton irradiation [210]. Protons interact through ionization effects and can cause displacement damage. Displacement damage can reduce the lifetime of minority carriers and can cause carrier removal. Because GaAs devices are predominantly majority-carrier devices, and the channel regions have relatively high dopant concentrations, neither of these mechanisms cause significant degradation of GaAs devices.

5. SUMMARY AND CONCLUSIONS

The harsh environment of space and manmade systems can cause significant degradation to electronics, which can lead to system failure. The types of degradation range from permanent failure due to total-dose ionizing irradiation and single-event hard errors to temporary loss of information due to single-event upsets. The mechanisms for degradation and failure levels are dependent on many factors, including device type, system design and application, and radiation environment.

As IC technologies continue to advance, they are becoming more susceptible to terrestrial-radiation-induced effects. Terrestrial irradiation can cause single-event upsets in advanced IC technologies, reducing IC reliability. Methods for hardening ICs to single-event effects have been known for a long time. However, most of these techniques require the implementation of circuit and/or device changes that degrade IC electrical performance and/or yield and are not suitable for high-performance commercial devices. Thus, new techniques or other IC technologies (e.g., SOI) will be required to reduce the effects of terrestrial irradiation on IC reliability.

IC response to ionizing radiation has a complex time dependence. The time dependence of oxide-trapped charge buildup and neutralization and the buildup of interface traps makes it difficult to ensure device hardness in space environments based on laboratory measurements. Considerable work has been performed to improve radiation hardness assurance test guidelines, and test guidelines are now available that take into account time-dependent radiation-induced charge buildup. Still, more work needs to be performed to better understand the mechanisms for charge buildup and device degradation to further improve hardness assurance test guidelines, especially for device types that may exhibit nonstandard MOS radiation-induced behavior (e.g., bipolar devices).

With the nuclear age came a need to monitor radiation levels for the protection of workers and the population, and monitoring instruments to fill this need were first developed for projects in government and university laboratories.

Early radiation monitors built in the 1950s were based on vacuum-tube electronics, which were then modified to use industrialized components that would withstand the environment of nuclear power plants. The cumbersome vacuum-tube instruments generated a lot of heat and required large, forced-air-cooled cabinets for housing readouts in the reactor control room.

During the late 1950s and early 1960s, vacuum tube-based electronics were replaced with transistor-based,

solid-state electronics that reduced the required space for the control-room instruments. Each radiation detector had its own channel of electronics, including signal-conditioning circuitry, control-room readout, and associated power supplies. For a typical channel, the detector with a small amount of signal-conditioning electronics was located at the point of detection and the balance of the channel was mounted in or near the reactor control room. These analog-based, radiation-monitoring systems required a separate indicating system for each detection channel in the control room, and they had separate signal, high-voltage, low-voltage, and control-logic cables for each channel between the control room and the detector. This resulted in miles of multiconductor and shielded cabling in a typical plant to provide the required radiation indication at the control room.

In the late 1970s and early 1980s distributed microprocessors were developed, replacing the early analog systems with digital logic. These new microprocessor-based monitoring systems replaced the miles of multiconductor cables with single twisted-pair cables in a loop or star interconnecting configuration and replaced analog indicating instruments with a computer display.

Radiation is always around us and we are constantly being bombarded by radiation of subatomic particles and electromagnetic rays. Sources of the radiation from above us include our sun and solar system as well as the rest of the vast universe of space; and sources of radiation surrounding us include the soil and rocks in the earth and plants, animals, and people that are near us, as well as materials derived from those. Radiation includes both *ionizing* radiation in the form of X rays, gamma rays, alpha particles, beta particles, neutrons, protons, cosmic rays, and so on, and *nonionizing* radiation in the form of the lower-energy portion of the electromagnetic spectrum, including electrical power in our homes, radio and video waves broadcast via cable or transmitted by air, visible light, and infrared energy emitted by bodies according to their temperature.

Radiation monitoring is concerned with measuring and monitoring ionizing radiation. Little is known about the harmful effects of ionizing radiation at levels that are typically encountered in our environment (natural background levels). Effects of high doses of ionizing radiation have been documented as result of such incidents as the atomic bombs dropped on Japan, the atomic accident at Chernobyl, and observation of the effects of therapeutic uses of radiation. It is generally assumed that all radiation is harmful and that people should receive the minimum radiation exposure for what needs to be accomplished. Naturally occurring radiation at historically typical background levels serves as the reference from which allowable additional radiation-exposure limits are set. Medical diagnostic radiation is the primary source of increased radiation over background for most people.

Radiation dose levels that cause death immediately or within a few weeks are well established. Radiation induced malignant tumors have been noted since the earliest use of X rays and other forms of ionizing radiation. Hypothetical increased risks forecasts for low-level radiation doses are based on linear or quadratic extrapolation of

 Individual Consultants

With the nuclear age came a need to monitor radiation levels for the protection of workers and the population, and monitoring instruments to fill this need were first developed for projects in government and university laboratories.

Early radiation monitors built in the 1950s were based on vacuum-tube electronics, which were then modified to use industrialized components that would withstand the environment of nuclear power plants. The cumbersome vacuum-tube instruments generated a lot of heat and required large, forced-air-cooled cabinets for housing readouts in the reactor control room.

During the late 1950s and early 1960s, vacuum tube-based electronics were replaced with transistor-based,

solid-state electronics that reduced the required space for the control-room instruments. Each radiation detector had its own channel of electronics, including signal-conditioning circuitry, control-room readout, and associated power supplies. For a typical channel, the detector with a small amount of signal-conditioning electronics was located at the point of detection and the balance of the channel was mounted in or near the reactor control room. These analog-based, radiation-monitoring systems required a separate indicating system for each detection channel in the control room, and they had separate signal, high-voltage, low-voltage, and control-logic cables for each channel between the control room and the detector. This resulted in miles of multiconductor and shielded cabling in a typical plant to provide the required radiation indication at the control room.

In the late 1970s and early 1980s distributed microprocessors were developed, replacing the early analog systems with digital logic. These new microprocessor-based monitoring systems replaced the miles of multiconductor cables with single twisted-pair cables in a loop or star interconnecting configuration and replaced analog indicating instruments with a computer display.

Radiation is always around us and we are constantly being bombarded by radiation of subatomic particles and electromagnetic rays. Sources of the radiation from above us include our sun and solar system as well as the rest of the vast universe of space; and sources of radiation surrounding us include the soil and rocks in the earth and plants, animals, and people that are near us, as well as materials derived from those. Radiation includes both *ionizing* radiation in the form of X rays, gamma rays, alpha particles, beta particles, neutrons, protons, cosmic rays, and so on, and *nonionizing* radiation in the form of the lower-energy portion of the electromagnetic spectrum, including electrical power in our homes, radio and video waves broadcast via cable or transmitted by air, visible light, and infrared energy emitted by bodies according to their temperature.

Radiation monitoring is concerned with measuring and monitoring ionizing radiation. Little is known about the harmful effects of ionizing radiation at levels that are typically encountered in our environment (natural background levels). Effects of high doses of ionizing radiation have been documented as result of such incidents as the atomic bombs dropped on Japan, the atomic accident at Chernobyl, and observation of the effects of therapeutic uses of radiation. It is generally assumed that all radiation is harmful and that people should receive the minimum radiation exposure for what needs to be accomplished. Naturally occurring radiation at historically typical background levels serves as the reference from which allowable additional radiation-exposure limits are set. Medical diagnostic radiation is the primary source of increased radiation over background for most people.

Radiation dose levels that cause death immediately or within a few weeks are well established. Radiation induced malignant tumors have been noted since the earliest use of X rays and other forms of ionizing radiation. Hypothetical increased risks forecasts for low-level radiation doses are based on linear or quadratic extrapolation of

limited data where relatively large populations received very high doses. However, studies have not yet validated those models, and risk from low-level radiation may be lower than is generally postulated.

Background radiation levels are different at different places on Earth, due to elevation, the makeup of the soil, and related factors. For example, background radiation in Denver, Colorado is about twice that of San Diego, due primarily to the higher elevation with less air mass to absorb radiation from space, such as cosmic rays. People are typically exposed to higher background radiation in masonry buildings than in wood structures because of naturally occurring radioactivity in the materials in cement, brick, or rock. The human body contains radioactivity in the form of naturally occurring potassium-40, carbon-14, and other radioactive isotopes. According to current government regulations, if a laboratory animal were injected with the amount of radioactivity in an average person's body, it would be considered radioactive (see Further Reading list).

Commonly encountered radioactive objects include glow-in-the-dark radium watch dials made during the first half of the twentieth century, thorium oxide coated gas-lamp mantles, smoke detectors containing about 1 microcurie of americium-241, fluorescent lamp starters containing a minute amount of krypton-85, porcelain tooth caps colored with metal oxides that contain uranium to give an improved reflective appearance, radon gas in tightly built homes over radium-containing soil or rock and in water supplies, and potassium-containing fertilizers. Although these may give off ionizing radiation at levels that would require careful accountability in a laboratory or industrial environment under state or federal regulations, they are seldom considered hazardous and are not required to be monitored.

In today's society there are areas where the use of ionizing radiation that must be monitored according to state or federal government regulations to ensure that radiation does not pose a hazard to personnel or to the environment: areas include radiation for instructional use in schools and universities, medicine, industrial gauging, sterilization of medical supplies or food, mining and milling of radioactive ores, steel mills, space flights, fusion facilities, and nuclear reactors.

The use of radiation sources at schools and universities may range from simple isotopic sources for demonstration purposes that are small enough to be exempt from regulations to fully operational nuclear test reactors where reactor physics is taught and isotopic sources are produced.

The use of ionizing radiation in medicine includes electron beams, X-ray sources, and gamma-ray sources for transmission imaging or for therapy and gamma-ray sources tagged to pharmaceuticals and injected into the patient for determining organ function in nuclear medicine. The types of sources include isotopic sources, X-ray tubes, and linear accelerators. X-ray tubes and linear accelerators generate ionizing radiation only when power is properly applied; however, isotopic sources always emit radiation as a result of the natural decay of the radioactive isotope. The physicians or medical technologists are responsible for properly administering radiation to patients;

they use radiation monitoring devices to ensure that source strengths and photo energies are proper. Those who handle the isotopic sources should not be exposed inadvertently and receive doses above allowable limits.

Many industries use radiation sources for making routine measurements, such as material density, fill height of beverage containers, or material thickness. Radiation is also used to sterilize some medical supplies after the packaging is sealed. A typical radiation source is cobalt-60 with a half-life of just over 5.3 years and a photon energy of just over a million electronvolts; a typical sterilization dose is a million rads. Some foods are also exposed to gamma radiation to kill bacteria and prevent spoilage. Some seeds or bulbs are irradiated with lower doses to enhance growth and increase production. Some gemstones are irradiated to enhance color and brilliance. These industries and radiation facilities use radiation monitoring to calibrate and control exposure doses and to monitor personnel exposure.

Increased incidence of lung cancer among underground miners exposed to radon and radon daughters in their occupations has been demonstrated in epidemiological studies of the inhalation of radon gas and its effects on the lung epithelium. Efficient control of radon and radon daughters in underground mines has been difficult. It is the role of radiation monitoring to identify radiation exposure and assist in its control in underground mines (both uranium mines and non-uranium mines) where radon gases may be present.

The need for radiation monitoring in steelmills is fairly recent and is the result of 49 known incidents since 1973 where companies have inadvertently melted shielded radioactive sources, typically cobalt-60 or cesium-137. These incidents have not caused worker injuries but have resulted in economic harm to the companies with costs typically ranging from \$5 million to \$25 million per accidental melt of a radioactive source. These costs include loss of the melt, facility decontamination, and shutdown of steel production. The sources, generally, had been lost from licensees that had used them for industrial applications. It is also important to identify radioactively contaminated scrap, such as metal activated in a nuclear facility or contaminated in a melt from a lost source. To find a shielded source in a carload or truckload of scrap poses is very difficult.

Radiation monitors and detectors are placed on spacecraft for several purposes. Measuring secondary emissions, induced by the absorption of protons or neutrons, from the surface of planets or moons can identify the elements on the surface of the planets or moons. Monitoring the levels of radiation impinging on the spacecraft can provide information for predicting effects on the materials in the spacecraft and can be used to turn off sensitive electronic components during times of unexpectedly high-radiation exposure where radiation damage occurs when the components are powered.

Atomic fusion is another source of radiation; fusion combines light elements to create elements of greater atomic weight, neutrons, and excess energy, neutrons are eventually absorbed by the surrounding materials, typically resulting in radioactive isotopes. Radiation monitoring is required to measure levels of radiation during

facility operation as well as radiation levels from neutron activation.

In the fission process in nuclear test reactors and nuclear power reactors, heavy atoms, such as uranium-235, absorb a neutron and split into fission products that include gamma rays, neutrons, alpha particles, beta particles, and lighter elements that are typically radioactive. Radioactive materials result from the fission process, as well as from activation from absorption of neutrons or other atomic particles. Radiation monitoring in nuclear power plants is discussed in detail later in this article.

Any of the facilities discussed prior that has one or more licensable radiation sources must have instruments that can measure the radiation from the source(s) and must provide personnel monitoring devices, such as film badges, ring badges, or thermoluminescent dosimeters (TLDs), to monitor the dose that personnel receive who work where they may be exposed to radiation from the source(s) that exceeds 10% of federally established limits. A personnel dosimeter badge is worn only by the individual to whom it is issued and, when not being worn, it is stored where it will not be exposed to radiation. This badge provides a record of radiation exposure for evaluating potential adverse effects and for ensuring that no worker exceeds established limits, such as the annual total body effective dose equivalent limit of 5 rem. Federally established limits in the United States of America can be found in the US Code of Federal Regulations, 10 CFR 20.

1. RADIATION MONITORING IN NUCLEAR POWER PLANTS

Radiation-monitoring (RM) systems are installed in nuclear power plants to satisfy U.S. Nuclear Regulatory Commission (USNRC) regulations and plant operating license requirements. The objective of those requirements is to protect both personnel and the environment from the effects of ionizing radiation. An installed system measures, displays, and records the presence and level of radiation and alerts plant personnel to excessive levels of radioactivity, and control actions are initiated automatically for required functions when levels exceed their limits.

Monitoring radiation in nuclear power plants is often divided into categories according to application. Typical categories include area monitoring [1] for determining radiation levels in areas where personnel may be working or may have a need to enter; process monitoring [2,3] for determining radiation levels in processes in the plant; effluent monitoring [4] for determining amounts of radiation leaving the plant through any pathway; and perimeter monitoring for identifying any increase in radiation level at the perimeter of a plant. Both process monitors and effluent monitors can be further separated in two categories according to whether they monitor a gaseous stream or a liquid stream. The instruments can be grouped according to the design as area γ -ray monitors, liquid monitors, and atmospheric gaseous, particulate, or iodine monitors.

A typical radiation-monitoring instrument has many functions to perform: it may detect, display, and record levels of radiation in the plant and provide alarms when

selected radiation levels are exceeded; it may monitor process flow lines for detecting radioactive leakage; it may monitor effluent for recording radioactivity levels and inhibiting excessive releases from the plant; it may provide signals for control functions in other systems; it may provide samples for analysis for complying with USNRC Regulatory Guide 1.21; and it may provide postaccident monitoring in accordance with the requirements of NUREG 0737.

Electrical equipment in nuclear power plants is separated into safety categories according to the functions performed in order to establish quality requirements for procurement, installation, operation, and maintenance. The typical categories are *safety-related* and *non-safety-related*. The safety-related category implies that the equipment is essential to ensure the integrity of the reactor-coolant pressure boundary, the capability to shut down the reactor and maintain it in a safe shutdown condition, or the capability to prevent or mitigate the consequences of accidents that could result in potentially major offsite exposures to the public. Safety-related equipment has the highest quality requirements and must not cease to perform its functions when any single credible failure occurs with the equipment. Other categories are introduced for postaccident monitoring equipment that must operate following a design basis accident. (The *design basis accident* for a nuclear power plant is the worst credible accident postulated for the plant for the purpose of evaluating risks and potential hazards associated with siting the plant.)

Most radiation-monitoring instrumentation is typically classed as nonsafety related, with some specific instruments identified either as safety-related or as postaccident monitors [5] that may have quality requirements similar to safety-related equipment. Requirements for safety-related equipment typically include demonstrated performance under normal and extreme service conditions and installation of redundant channels that are powered from redundant, safety-related power sources. Each channel may also be required to have demonstrated capability of performing its function under design basis service conditions following a design basis earthquake.

The USNRC has established the Standard Review Plan (SRP) [6] as a guide for reviewing designs of nuclear power plants against requirements, including a review of radiation-monitoring systems. An owner of a nuclear power plant provides a safety analysis review to respond to all points of the SRP. The installed RM system must meet the commitments made in the final safety analysis review and the requirements of documents referenced therein.

2. SYSTEM OVERVIEW

A nuclear power plant must have radiation monitors installed at strategic locations throughout the plant for monitoring radiation levels in order to meet regulatory requirements. In addition, laboratory instruments are used for analyzing collected samples of liquids or gases, and portable or handheld instruments are used for making surveys. Chemistry or health physics group members typically observe and record continuous radiation-monitor

channels, but they typically rely on collecting and analyzing samples of effluents for final determination of the off-site dose, and likewise they rely on portable instruments for confirming radiation levels where people are working. Effluent samples are analyzed in laboratory instruments that measure ionizing radiation with excellent energy resolution for identifying the radioactive isotopes contained in the samples. These analyzers typically employ cryogenically cooled germanium detectors.

The descriptions of radiation-monitoring instruments contained herein relate to instruments installed in nuclear power plants for continuous monitoring and do not include laboratory or handheld instruments. The installed systems typically monitor magnitudes of radiation and initiate alarms when radiation levels approach established setpoints; however, because of the need to operate continuously in the plant environment, the energy resolution of the detectors is much poorer than what is available with laboratory instruments.

Analog RM systems usually have a detector installed at each location where radiation levels are to be monitored with a small amount of signal-conditioning electronics, and the detectors are connected by long instrumentation cables to a cabinet at the reactor control room in which are installed signal-conditioning electronics, alarms, readout devices, and power supplies associated with each detector.

Digital RM systems are typically distributed computer systems that include a microcomputer and required power supplies located at or near each detector location, and a communication cable connects that location to a central computer at the control room and at a health physics office or other location where the information is to be used. The communication cable is usually a simple twisted-shielded pair cable.

Typical locations in a pressurized-water reactor (PWR) nuclear power plant where area monitors may be installed include the control room, radiochemical laboratory, hot machine shop, sampling room, reactor-building personnel access, refueling bridge, in-core instrumentation area, fuel storage area, auxiliary-building-demineralizer area, waste-gas-decay-tank area, drumming area, waste-hold-up-tank area, charging-pump area, turbine-building area, and main steam lines.

Typical monitoring points for gaseous process monitors include reactor-building-containment area for airborne gaseous and particulate monitoring, radioactive-waste-disposal-area vent, waste-gas header, fuel-handling-area vent, and control room for airborne gaseous and particulate monitoring. Monitoring points for liquid process monitors may include chemical- and volume-control-system-letdown line, radioactive-waste-condensate return, component cooling water, normal-sample-laboratory isolation, and main steam lines.

Gaseous effluent monitoring may be performed in the plant vent stack, in the condenser air ejector, and in the containment purge stack. Liquid-effluent monitors are typically installed in the radioactive-waste discharge line, in the neutralization sump discharge line, in the turbine plant area sump, and in the steam-generator blowdown. The locations listed above are typical for a PWR plant but may be different in each plant.

3. SOURCES OF RADIOACTIVE MATERIAL

The primary sources of radioactive material in light-water-cooled nuclear power plants are the fission process in the reactor core and neutron activation. The fission process, the splitting of uranium atoms, emits neutrons, γ rays, and β particles directly and creates radioactive elements in the fuel-pellet regions. Those radioactive materials then decay primarily by emission of γ and β radiation.

Neutron activation occurs whenever any atom absorbs one of the neutrons that is emitted from a splitting uranium atom. The absorbing atom gains atomic weight, thus becoming a new isotope of the same element, which may be unstable or radioactive and decay to a more stable state by emitting radiation. Neutron activation creates radioactive material in the fuel-pellet region; in the reactor-coolant region; in support structures, reactor vessel, and piping; and in the regions surrounding the reactor vessel, including the air in that vicinity. In addition to neutron activation, some atoms may be activated by particle radiation emitted from fission products or from neutron-activated elements.

The plant is designed to keep radioactive material contained; however, if systems become unsealed, some radioactive material may leak into the coolant through the fuel cladding, then from the reactor coolant through the pressure boundary or from coolant purification and radioactive-waste processing systems into secondary systems. It is this leakage that radiation-monitoring systems are expected to detect during normal reactor operation. γ rays and β particles are the forms of radiation that are most readily detected.

The concentration and quantities of radioactive material in various regions of the plant depend on the balance among production, leakage, and removal of individual isotopes. In the fuel-pellet region, production processes include fission-product production directly from fissioning uranium atoms, parent-fission-product decay, and neutron activation. Removal processes include decay, neutron activation, and leakage through cladding defects into the coolant. In the coolant region, production processes include (1) leakage of fission and activation products from the fuel-pellet region and from fuel cladding and core structures, (2) parent decay in the coolant, and (3) neutron activation in the coolant materials. Removal is by decay, by coolant purification, by feed and bleed operations, and by leakage. The most abundant isotopes in the coolant are radioactive noble gases (^{85}Kr , ^{133}Xe , and ^{135}Xe during normal operation) and radioactive halogens (in particular ^{131}I).

Neutron activation leads to two isotopes of particular interest, ^{16}N and ^{14}C . ^{16}N is produced by a neutron-proton reaction with ^{16}O and decays by higher-energy γ -ray decay with decay energies of 6.1 and 7.1 MeV. The half-life of ^{16}N is 7.3 s. While there is substantial decay of ^{16}N as it exits from the core and passes through the turbine, it must still be considered in the design of the turbine shielding for boiling-water reactors (BWRs). The detection of ^{16}N in the secondary side of PWRs may be used to monitor changes in steam generator leakage. ^{14}C is produced by neutron activation of ^{17}O and ^{14}N .

The principal generation of tritium (^3H) is from fission and neutron interaction with boron, lithium, and deuterium. The main leakage source is fission tritium released through fuel-cladding defects. Tritium produced in the coolant contributes directly to the tritium inventory, while tritium produced in control element assemblies contributes only by leakage and corrosion.

Activation and corrosion of reactor core support structures produce corrosion products, forming a radioactive material commonly referred to as *radioactive crud*. Corrosion product constituents are typically ^{60}Co , ^{58}Co , ^{54}Mn , ^{51}Cr , ^{59}Fe , and ^{95}Zr .

3.1. Leakage Sources

Any system containing radioactive materials in liquid form is a potential source of radioactive leakage, and radioactive leakage into the reactor-containment area comes from the reactor-coolant system and coolant purification systems. Leakage from systems containing potentially radioactive liquids is collected and processed by liquid radioactive-waste systems. Noble gases that are dissolved in liquid leakage may go out of solution and into the local atmosphere.

Radioactive material can be released into effluents from secondary systems due to leakage. For PWRs, the amount of release depends on reactor-coolant radioactive material concentrations, reactor-coolant leakage rate, primary to secondary leakage rate, steam-generator blowdown rate, and secondary-system leakage rates. Abnormal leakage from the fuel region to the reactor coolant is commonly detected by monitoring the reactor-coolant-system (RCS) letdown stream, either continuously or on a sampling basis.

In PWRs, reactor coolant remains liquid under pressurization in a primary coolant loop and transfers its heat through a heat exchanger to a secondary coolant loop that is converted to steam in the steam generator. The secondary system is typically monitored on steam generator blowdown, component-cooling-water, and liquid-radioactive-waste-processing systems to check for leakage from primary to secondary coolant loops.

In BWRs, reactor coolant is converted directly to steam for use in the steam turbine. γ radiation levels external to the main steam lines are monitored to detect increased levels of radiation in the reactor coolant that may indicate problems such as significant fuel-cladding failure. A fuel-cladding failure would allow fission products, particularly noble gases, to be transported to the steam lines, which could cause the radiation level external to the steam lines to be well above normal background levels.

In both PWRs and BWRs, condenser exhaust is monitored.

3.2. Reactor-Coolant-System Leakage Detection

An increase in reactor-coolant-system leakage rate in a nuclear power plant of 1 gal/min must be identifiable within 1 h. USNRC Regulatory Guide 1.45, *Reactor Coolant Pressure Boundary Leakage Detection System*, outlines the means required for monitoring RCS leakage and indicates that this function must be provided also following

a design basis earthquake. Three required means of monitoring leakage rate are (1) sump level and flow monitoring, (2) airborne-particulate radioactivity monitoring, and (3) either monitoring condensate flow rate from air coolers or monitoring airborne-gaseous radioactivity.

The sump flow rate and airborne-particulate channels are found to be capable of indicating an increase in RCS leakage of 1 gal/min within 1 h under most operating conditions. However, airborne-gaseous monitoring was found to have a much longer response time. This shortcoming was identified generically in a USNRC staff memorandum and is mainly due to the long half-life of ^{133}Xe , the major noble gas in the RCS, and the background radiation level from ^{41}Ar , which is created by neutron activation of air around the reactor vessel. Most RM systems use gross energy measurement methods for RCS leakage detection. Potential leakage-detection improvements using spectral capabilities of new γ -ray sensitive detectors for particulate and gaseous monitoring have been predicted, which might allow specific isotopes to be measured and separated from background radiation.

3.3. Liquid Effluent

Liquid-waste systems in a nuclear power plant collect and process radioactive liquid wastes generated during plant operation and reduce their radioactivity and chemical concentrations to levels of clean water acceptable for being discharged to the environment or recycled in the plant. Radioactivity removed from the liquids is concentrated in filters, ion exchange resins, and evaporator bottoms, and these concentrated wastes are sent to a radioactive-waste solidification system for packaging and eventual shipment to an approved offsite disposal location. If the water is to be recycled to the reactor-coolant system, it must meet the water-purity requirements for reactor coolant. If the liquid is to be discharged, the activity level must be consistent with the discharge criteria of the U.S. *Code of Federal Regulations*, 10CFR20. These liquids normally pass through liquid radiation monitors prior to being recycled or discharged.

4. UNITS OF MEASURE IMPORTANT TO RADIATION MONITORING

Becquerel	The becquerel (Bq) was adopted in 1975 as unit of measure of activity, which is the measure of the rate of decay of a radioisotopic source. 1 Bq is one disintegration per second.
Curie	The curie (Ci) is a measure of the activity or number of disintegrations per second of a radioactive source. It was originally an estimate of the activity of 1 g of pure radium-226. 1 Ci is 3.7×10^{10} disintegrations per second (Bq).
Gray	The gray (Gy) is a measure of absorbed dose. 1 Gy is 1 joule per kilogram, or 100 rad.
Rad	The rad is a measure of absorbed dose in units of energy per unit mass of the absorbing material. 1 rad is 100 ergs per gram. The magnitude of dose will depend on material

properties as well as on the radiation source. Air is typically used as the basis of measurement. When water is substituted for air, the absorbed dose is nearly the same because the atomic number of water is nearly the same as for air.

Rem	The rem is used to measure the effect of radiation on living organisms and was derived from the words <i>radiation equivalent in man</i> and is equal to the absorbed dose times a quality factor, Q . For γ rays and β particles, $Q=1$ and 1 rem is equal to 1 rad. For charged particles, Q is much larger than 1.
Roentgen	The roentgen (R) is a measure of γ -ray exposure in terms of the charge due to ionization by the exposing radiation in a unit of mass of the material. 1 roentgen is 1 electrostatic unit of charge in 1 cubic centimeter of air at standard temperature and pressure.
Sievert	The sievert (Sv) is a measure of the effect of radiation on living organisms and is equal to 100 rem.

5. TYPICAL DETECTORS AND MONITOR TYPES

5.1. Area Radiation Monitors

Area radiation monitors continuously measure radiation levels at various locations within nuclear power plants including reactor-containment-building work areas and fuel-storage facilities for ensuring personnel safety. Area monitors have historically used Geiger-Muller (GM) tubes, ionization chambers, or scintillation crystals coupled to photomultiplier (PM) tubes, depending on the manufacturer and the sensitivity or range requirements. A block diagram of a typical GM-tube-based area monitor is shown in Fig. 1.

In a GM tube [7] an avalanche breakdown occurs in the gas in the tube each time ionizing radiation is detected and then self-extinguishes. The magnitude of the resulting signal (an electronic pulse) is independent of the number of original ion pairs that initiated the process and therefore independent of the energy of the detected ionizing radiation. The electronics in a GM-tube-based area monitor senses these pulses and converts them to a signal that is proportional to their rate of occurrence. However, present-day GM-tube monitoring systems use energy-compensated GM tubes for which the number of counts detected is nearly proportional to the total energy absorbed.

Thin-walled GM tubes used for area monitors are normally energy compensated for a linear response or $\pm 20\%$ or better for γ -ray energies of 60 keV–1.25 MeV. The filter is designed to attenuate the lower-energy γ rays below approximately 100 keV and to increase the responses of higher-energy γ rays by the effect of the high- Z material used for the filter. This energy-compensation effect is due to the complex contribution of primary photon transmission or attenuation and secondary-particle production or attenuation at various depths in the GM-tube wall or outer energy filter [8].

In an ionization chamber [9] ionizing radiation is absorbed in the gas in the chamber, and the number of electron-ion pairs thus created is proportional to the energy of the absorbed radiation. The bias voltage on the ionization chamber sweeps the charge carriers to the electrodes, causing an electrical current to flow, and external circuitry typically measures the magnitude of the current from this ionization process. The current output signal from an ionization-chamber-based area monitor is proportional to the energy of the radiation absorbed in the gas in the chamber in the γ -ray flux field. These area radiation monitors are often calibrated in units of R/h.

When ionizing radiation is absorbed in a scintillator, a light pulse is produced. In turn the light pulse is converted into an electrical pulse in a PM tube that is optically coupled to the scintillator. Over a broad range of energies, the amplitude of the electrical pulse is proportional to the energy of the absorbed radiation. In a scintillator-based area monitor the output signal is proportional to the number of absorbed-radiation events in the detector and independent of energy if the electronics just counts events and provides a count-rate output signal. If the current from the PM tube is measured, the signal will be proportional to the energy of the absorbed radiation.

A typical pulse-counting area monitoring may have a range from 1 to 100,000 counts per minute. A typical ionization-chamber-based area monitor may have a range from 10^{-10} to 10^{-3} A, corresponding to a range from 1 to 10,000,000 rad/h. This high range may be used for applications such as postaccident monitoring inside containment.

5.2. Process Monitors

Process monitors provide information about radiation levels within the nuclear power plant's liquid, steam, and gaseous processing and storage systems. Liquid monitors may have the detectors mounted in the liquid or steam line or may have them mounted offline with a sample

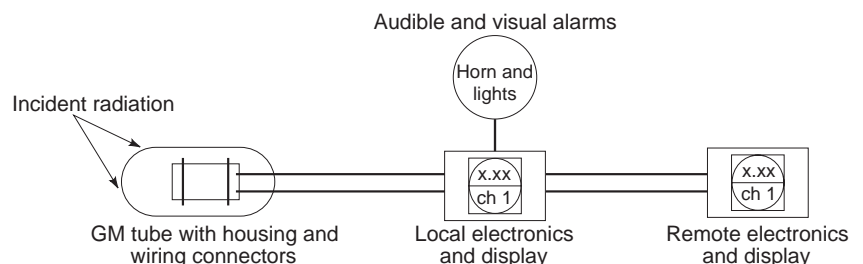

Figure 1. Typical block diagram of an area radiation monitor.

stream taken from the main line and flowing through the detector sample chamber. Gaseous monitors too can have the detectors mounted in the stream or in a sample chamber. If the monitor is in a sample chamber, the gas to be monitored, which could be from a duct or from an open area such as the control room, passes through that sample chamber.

Process monitors typically measure radiation levels that are far below normal background levels, and, as a result, the detectors must be shielded from all external sources of radiation.

5.3. Effluent Monitors

Effluent monitors are similar to process monitors except that they monitor liquid or gaseous streams that leave the nuclear power plant boundary and may transport radioactivity.

The monitors described below are applicable to both process and effluent monitors according to the application to which they are dedicated.

5.3.1. Airborne Monitors

5.3.1.1. Off-Line Particulate and Noble-Gas β -Particle Scintillation Detectors. The β -particle sensitive particulate and noble-gas monitors incorporate plastic scintillators coupled to PM tubes. The gas-detector assemblies are of similar construction. These detectors use similar entrance windows, plastic scintillators, light pipes, and PM tubes. A typical particulate detector is built up from a plastic scintillator coupled to a PM tube and a 0.001-in.-thick aluminum entrance window used for β -particle detectors.

During original prototype evaluation, detectors are tested with solid β -particle sources to obtain a high signal-to-noise ratio when setting the discrimination level. Without changing the detector's alignment, responses are then obtained for calibrated solid or gaseous β -particle sources. The solid alignment sources are serialized and kept for future use. These sources are used for aligning production detectors and prototype detectors prior to isotopic calibration. After alignment of a production monitor to the same counting efficiency as the prototype detector that uses the same solid source, the production and prototype monitors have nearly identical responses to radioactive gases in the sample chamber or to activity on the filter.

After a monitor has been calibrated at a factory and shipped to a customer, corrections to the calibration may be required to account for atmospheric pressure affects because the response of the detector to β -particle radiation in the sample chamber is determined, not only by the total activity in the sample chamber, but also by self-absorption in the sample gas, which changes with gas pressure.

5.3.1.2. High-Temperature, Inline, Noble-Gas, β -Particle Scintillation Detectors. These detectors are designed to operate at high temperatures and to be installed directly into an airduct. The detector assemblies are similar to the off-line β -particle scintillation detectors with the following exceptions.

A thin (0.007-in.-thick) CaF_2 (Eu) crystal or a high-temperature plastic scintillator (0.010 in. thick) and a quartz light pipe are used in place of the plastic scintillator with a Lucite light pipe, and a high-temperature PM tube is used. These detectors use the same 0.001-in.-thick aluminum entrance window as do the other β -particle detectors. Prototype detectors are aligned using the same methods described for the offline β -particle scintillator. After alignment, a prototype detector is installed into a test fixture to simulate the geometry of the intended installation.

5.3.1.3. Iodine Detectors. Detectors used for the iodine channels normally consist of a 2-in.-diameter by 2-in.-long sodium iodide crystal with a 2-in.-diameter photomultiplier tube. The detectors are typically specified to have a maximum resolution of 8% for a 662 keV cesium-137 photopeak and may be supplied with an americium-241 pulser for pulse height stabilization.

The electronics associated with a typical iodine channel has an energy-window discriminator with adjustable lower and upper thresholds. When the amplitude of a pulse signal from the detector lies between the lower and upper thresholds, the signal is counted as a valid event. The typical output is the number of events per unit time that fall within the energy window.

Since each detector has its own resolution and the system is operating as a single-channel analyzer, each detector's response will be unique. The response from a calibrated simulated iodine-131 source (barium-133) for each detector may be used when calculating the individual detector's expected responses for iodine-131. Upon completing the alignment of the iodine channel as a single-channel analyzer on the 356 keV photons of barium-133, the window will need to be readjusted to be centered on the 364 keV photons of iodine-131.

A typical pulse height stabilizer consists of a small sodium iodide crystal. The doped crystal provides a constant source of γ -ray equivalent energy (GEE) in the form of light pulses. The light pulses are detected by the PM tube and converted to an electrical pulse by the PM tube and the preamplifier. The GEE is produced from an americium-241 5 MEV α -particle decay in the pulser crystal. These high-energy light pulsers are attenuated to an equivalent light energy of a 3 MEV γ -ray decay at the time the pulser crystal is imbedded into the mother crystal.

A typical preamplifier may contain three window circuits as shown in Fig. 1. One window is used to monitor the americium-241 stabilization signal from the detector, one is used to monitor the iodine peak, and one is used to monitor the background level at energies just above the iodine window. By monitoring the known stabilization source, compensation can be made for instabilities, such as from temperature variations in the gain of the PM tube and preamplifier. The background window can be used for active background subtraction.

5.3.1.4. Particulate, Iodine, and Noble-Gas Monitor. Often the measurement of airborne-particulate radiation, radioactive iodine, and radioactive noble gas is combined

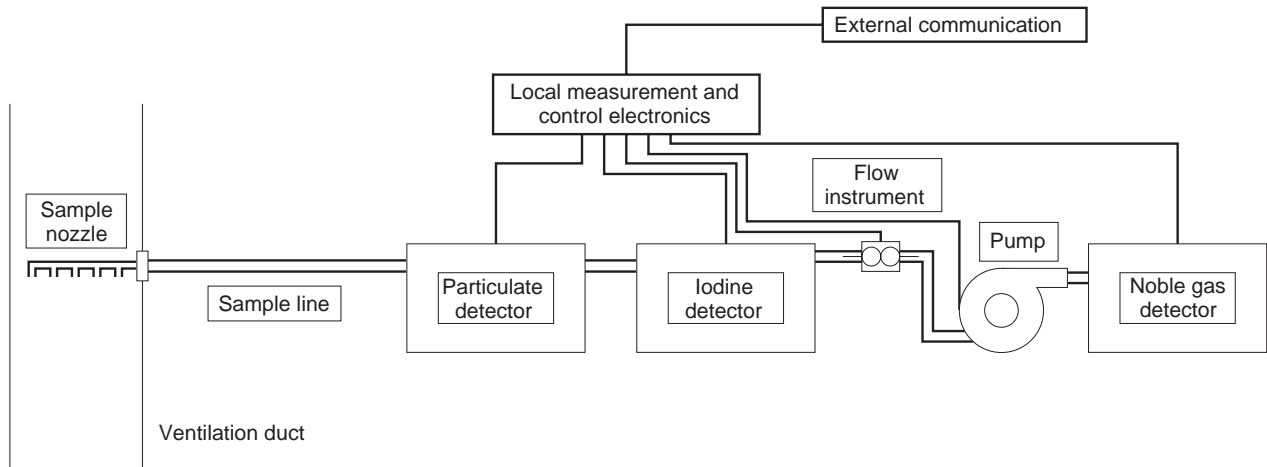

Figure 2. Block diagram of an airborne-particulate, iodine, and noble-gas monitor.

into a single instrument for such applications as airborne containment-building or vent-stack monitoring. A typical block diagram for such an instrument is shown in Fig. 2.

5.3.1.5. Typical Postaccident-Effluent, Wide-Range, Gas Monitor. A stack gas monitor typically is mounted near the nuclear power plant vent stack and receives a sample of the gas in the stack, which has been collected with isokinetic nozzles mounted in the stack. A normal-range monitor would be constructed as described previously and may cover a range of about five decades. A wide-range gas monitor may cover a range of about 12 decades through the use of multiple detectors.

An isokinetic nozzle is used to sample the air in the stack because, by keeping the velocity of the air entering the nozzle the same as the velocity of the gas bypassing the nozzle, a more representative sample of gas should be obtained for analysis in the monitor.

The low-range detector may be a β -particle scintillator and the preceding description applies. The mid- and high-range detectors may be solid-state detectors of a material such as cadmium telluride.

5.4. Liquid Monitors

Liquid monitors typically employ a sodium iodide scintillator coupled to a PM tube to measure γ radiation in the liquid stream. The liquid monitor may be mounted in-line with the stream to be monitored, or a sample stream may be extracted from the main stream and routed through a sample chamber into which the detector of the offline liquid monitor is mounted.

An in-line liquid monitor typically is bolted directly into the liquid line with flanges on each end of the section of pipe that passes through the monitor. The monitor consists of a section of inline pipe, a detector mounted adjacent to the pipe, and lead shielding surrounding the pipe and detector to prevent radiation from the surrounding area from entering the detector.

An off-line liquid monitor typically has a sample chamber into which the detector is inserted, and liquid enters and leaves the sample chamber through small-diameter

pipes. Lead shielding surrounds the sample chamber and detector to prevent radiation from the area around the monitor from entering the detector.

The volume of water near the detector in a liquid monitor causes Compton scattering of the radioactivity in the liquid so that the signal seen by the detector includes not only the primary γ -ray energies but even more lower-energy signals from scattering of the primary photons. Therefore, there is typically no effort to distinguish specific energies of radiation in a liquid monitor.

5.5. Perimeter Monitors

Many nuclear power plants put radiation monitors around the perimeter of the plant site to measure dose levels at the site boundary. Communication with these monitors is often achieved by telephone lines or radio transmission. Perimeter monitors are typically high-sensitivity area monitors. At least one vendor has provided large-diameter, high-pressure ionization chambers and another vendor offers energy-compensated GM tubes. Typically requirements include an on-scale reading at normal background levels, a wide range for detecting significant radiation releases, and battery backup to avoid loss of data during a power outage.

6. MONITOR-PERFORMANCE PARAMETERS

In order for the monitors in the RM system to perform their required functions, they must operate within specific bounds of range, sensitivity, accuracy, and response time. The range is usually described in terms of the smallest and greatest magnitudes of activity or concentration for which the output signal is a valid representation and the radiation energies that may be included in the measurement. Sensitivity is a statement of how the output signal responds to a change in the measured variable. Accuracy is a measure of the uncertainty in the output signal. And response time is a measure of the length of time required for the output signal to change as a result of a change in the measured variable.

6.1. Range and Sensitivity

The range of an instrument may be limited on the low end by noise or by instrument precision and accuracy or it may be established by the scale and levels set for the output signal. The upper end of the range may be limited by the linearity or saturation characteristics of the detector or instrument.

The scales of most radiation monitors are logarithmic, and the span of an individual radiation channel is typically 5 decades. A decade is a factor of 10, so that a scale from 1 to 100,000 is 5 decades. The American National Standards Institute (ANSI) Standard N42.18 Section 5.4.2 recommends that the span be at least four decades above the minimum detectable level (MDL). Spans of more than six decades often require the use of multiple channels with overlapping ranges. Guidance for selecting the ranges for specific monitors is provided in ANSI N42.18 and ANSI/ANS-6.8.2 for effluent monitors, in ANSI/ANS-6.8.1 for area monitors, and in Regulatory Guide 1.97 for postaccident monitors.

For monitors that measure the concentration of radioactivity in gases or liquids, range and sensitivity are normally specified for a certain isotope or a distribution of isotopes as opposed to being specified over an interval of radiation energies. For monitors that measure dose rate, range, and sensitivity are normally specified over an interval of radiation energies.

Sensitivity is normally determined by the characteristics of the detector. For monitors that measure dose rate, the sensitivity is often given as the ratio of the change in output signal to the change in radiation level that caused the signal to change, for example, for an ionization chamber, sensitivity is normally given in units of (A)/(R/h) or for a GM-tube-based area monitor, the sensitivity is usually given in units of (cpm)/(R/h), where cpm is counts per minute. For monitors that measure concentrations of radioactivity, the sensitivity is normally stated as the minimum detectable signal, which is a function of the detector characteristics, the effectiveness of radiation shielding, and the magnitude of background radiation.

6.1.1. Direct Measuring Instruments. A radioactive material concentration estimate A for a direct measurement is given by

$$A = \frac{y - \text{Bkg}}{R_d}$$

where y is the detector response to the concentration A plus the background, Bkg is the detector response to background, and R_d is the detector response per unit of concentration. A direct measurement is, for example, measurement of a gas or liquid volume in a fixed geometry. Typical units for y and Bkg are counts per minute, and typical units for R_d are counts per minute per $\mu\text{Ci}/\text{cm}^3$.

The uncertainty in the concentration estimate due to counting statistics alone depends on the magnitudes of the total count and of the background count during some fixed time. The uncertainty due to counting statistics is then

translated into an uncertainty in the concentration estimate by dividing by detector response.

The maximum sensitivity represents the lowest concentration of a specific radionuclide that can be measured at a given confidence level in a stated time (at a given flowrate, where applicable) under specific background radiation conditions (see ANSI 42.18, Section 5.3.1.4). The maximum sensitivity is commonly termed *minimum detectable level* (MDL) and is defined in terms of the uncertainty in interferences (termed *background* in radiation detection) and the response of the radiation detector:

$$\text{MDL} = \frac{C_L s_b}{R_d}$$

where C_L is the confidence level desired in the measurement (unitless) and s_b is the background uncertainty in units of the detector output (e.g., counts per minute).

A MDL that is termed *minimum detectable concentration* (MDC) is based on ANSI N42.18:

$$\text{MDC} = \frac{2s_b}{R_d}$$

Another MDL is termed *lower limit of detection* (LLD) [10].

$$\text{LLD} = \frac{4.66s_b}{R_d}$$

6.1.2. Indirect Measuring Instruments. Radiation monitors that view a medium through which a sample has been drawn (e.g., particulate channels that monitor the radiation buildup on a filter) have additional characteristics for the establishment of range.

Detector response is stated in terms of output per unit of activity deposited on the filter medium. The quantity of activity on the filter for isotopes with half-lives much longer than the sample collection time is the product of concentration A times sample flowrate f times the sample collection time T . Then the concentration estimate becomes

$$A = \frac{y - \text{Bkg}}{R_i f T}$$

where R_i is the detector output per unit activity on the filter [e.g., (counts per minute)/ μCi]. Then

$$\text{MDC} = \frac{2s_b}{R_i f T}$$

and

$$\text{LLD} = \frac{4.66s_b}{R_i f T}$$

A specification of sensitivity also establishes the level above which the setpoint value should be established. Set points should be well above MDLs in order to avoid spurious alarm/trip outputs due to statistical fluctuations in the measurement. See ANSI/ANS-HPSSC-6.8.2, Section 4.4.8.

Ambient background radiation is specified in order to determine the quantity of shielding required around the radiation detector, and this specified ambient level should be greater than the levels expected during plant operation. Detector-assembly performance can be stated in terms of detector response per unit background radiation for a specified isotope.

6.1.3. β -Particle Detectors for Airborne-Radiation Monitoring. Airborne effluent is frequently monitored by drawing a sample from the effluent stream into a lead-shielded sample chamber. The sample chamber is viewed by a detector with a thin (around 0.010 in.), predominantly β -particle-sensitive detector, since nearly all noble gases emit 1 β particle per disintegration.

β particles that are in excess of several hundred keV will lose about 100 keV for entrance normal to the detector face. The lower discriminator must be set above noise in the detection system. The upper discriminator needs to be open ended or set above 500 keV due to the high-energy tail of the energy distribution deposited by the β particles. This energy straggling for β particles results from infrequent, large-angle scattering by which the β particle can lose up to one half of its initial energy [11].

The decays per disintegration are the first factor in determining the response of a detector. The isotopic distribution of radioactive elements during normal reactor operation is significantly different from that postulated for accident releases. The use of a β -particle-sensitive detector has the advantage that the number of β particles per disintegration changes little from normal operation releases to the release postulated under accident conditions. γ -ray-sensitive detectors are at a disadvantage because the number of γ rays released per disintegration rises dramatically from normal operation to postulated initial-accident conditions and drops as noble gases decay. The element seen in normal operation is predominately ^{133}Xe , which undergoes γ -ray decay about 35% of the time. Initial-accident noble gas yields around 2 γ rays per disintegration.

6.2. Over-Range Condition

An RM instrument should operate over its range within the required accuracy, and when radiation levels are significantly above the range (above full scale), the instrument must survive and continue to present an appropriate readout. When an instrument is in an over-range condition, it is important that the instrument output not fall below full scale with input levels up to 100 times greater than full scale.

Count-rate circuits are typically limited in their maximum counting rates by the resolving time required to distinguish two consecutive input pulses. That resolving time is sometimes referred to as *deadtime*, and if a second pulse occurs during the deadtime, it is missed and not counted. This is sometimes referred to as count-rate loss due to pulse pileup. If count-rate loss gets so severe that the output actually decreases while the input is still increasing, the condition is called *foldover*. Radiation emission from radioactive atoms is a random process and has a

Poisson statistical distribution. The resolving time of most count-rise instruments is equal to or greater than the width of the incoming pulse. As the input rate increases, the count-rate loss will increase until the output goes into saturation or even foldover. In some instruments, very high input rates have been able to freeze the circuit and cause the output rate to go toward zero. Such instruments are sometimes referred to as “paralyzable” and those that overcome this failing as “nonparalyzable.”

The instrument output count rate n can be calculated, as shown by Evans [12], from the input rate N and the instrument dead time p , during which the circuitry cannot respond to a second input pulse, by the equation

$$n = Ne^{-Np}$$

A useful method for estimating count-rate loss for a system that obeys Poisson statistics is to use the following approximation: when the output count rate is $A\%$ (any value below 10%) of the frequency represented by the inverse of the dead time, $1/p$, the instrument has a count-rate loss of approximately $A\%$.

Many design methods have been used to eliminate or reduce the effects of foldover and prevent the output of an instrument from going below full scale when the input levels are above full scale.

6.3. Accuracy

The definition of accuracy from ANSI Standard N42.18 is “The degree of agreement [of the observed value] with the true [or correct] value of the quantity being measured.” Accuracy cannot be adjusted nor otherwise affected by calibration. It is a performance specification against which a channel is tested. For channels with multiple components, the individual accuracies are combined as part of the overall accuracy.

Accuracies, for monitors measuring concentration-related quantities, are normally specified for a certain isotope or a distribution of isotopes as opposed to radiation energies. Accuracies for monitors measuring dose rate are normally specified over an interval of radiation energies.

ANSI Standard N42.18, Section 5.4.4, provides a guideline that the instrument error for effluent monitors should not exceed $\pm 20\%$ of reading over the upper 80% of its dynamic range.

6.4. Response Time

For safety-related equipment, system response times used in safety analyses include the response times of the individual subsystems performing the protective function. This typically consists of instrument response time and mechanical system response time. The system response time must be allocated among the subsystems.

For a radiation monitoring channel, the response time depends on the initial radiation levels, the increase in radiation level as a function of time, and the channel setpoint.

ANSI Standard N42.18 recommends that radiation-monitoring-channel response time be inversely proportional to the final count or exposure rate. This characteristic

RADIO BROADCAST STUDIO EQUIPMENT

WALT LOWERY
Symetrix, Inc.

comes naturally with analog count-rate circuits. The time constant is typically established by a resistance and a capacitance in the feedback path of an operational amplifier, and for logarithmic circuits the resistance is typically the forward resistance of a diode at its current operating point. A factor of 10 increase in count rate will typically make the time response a factor of 10 faster. And, in these type circuits, if the change in input activity is a step function, the time response will be strictly a function of the end point and will not be affected by the starting point. Digital circuits, including software algorithms, are typically designed to emulate the time response of their analog counterparts. Thus fast response times can be provided at high radiation levels and longer response times at lower levels. Both types of circuits usually offer the ability to adjust the time constant to match requirements of the application.

Slow response times are needed to provide stable, smoothed outputs at the low end of the range. ANSI Standard N18.42 recommends that response times at low radiation levels should be long enough to maintain background readings within the required accuracy.

The quality of a broadcast station's only distributed product, its sound, is determined by the events taking place in the studio. The best source material and the best air talent will produce only marginal results when burdened by inadequate equipment. Even in television, audio can no longer be treated as a secondary technology. State-of-the-art equipment, properly used in the studio, equates to ratings and translates to revenue for the station.

This article describes the equipment and operation of audio facilities used in radio and television studios. First is an overview of typical studio layout and a discussion of the major components used in an audio facility. This article provides the novice engineer with guidance for the design and construction of a studio suited for the station's needs. We also make the leap to digital audio equipment and investigate the new terms and standards destined to change studio operations forever.

Broadcast studios now take advantage of digital audio source material, digital audio processing equipment, and now digital consoles. A major manufacturer recently introduced a digital studio-transmitter link (STL) system that operates without data compression. Just as compact disks (CDs) killed vinyl disks as the standard source material for radio broadcasters over an alarmingly short period of time, digital broadcast equipment is poised to eclipse analog studio systems. We have the potential to reduce the radio studio to a touch-screen computer operation, but the trend in the industry remains loyal to familiar function and feel. Broadcasters prefer their digital equipment to emulate the friendly analog devices that they have used for decades.

1. TYPICAL RADIO STUDIO LAYOUTS

Many stations in active markets have suffered as a result of changes in formats and managers and engineers who have left a crazy quilt of analog and digital equipment. The results have handicapped each station's ability to survive in a competitive market. Programming needs, available space, and creativity of former engineers often dictated the design of a studio. Design du jour, accompanied by galloping changes in technology, leaves many studios ripe for redesign and rebuilding.

The station's current format should dictate the main design parameters. The operational concepts will be much different for a music format than for a news/talk operation. It is possible to catalog radio station studios under a few general categories.

1.1. Music Formats

Studios built for music formats remain the most common, particularly in smaller markets. The basic configuration consists of an audio console, two or more CD players, and multiple cart players all arranged on a U- or L-shaped desk. Other associated equipment might include audio

routing, transmitter remote control, and telephone interface equipment. Careful design places all equipment within arm's reach of the operator. This configuration handles the rather simple programming needs nicely. The announcer on duty mixes and switches audio, reads announcements, plays music from CD players, plays commercials from digital cart players, and switches news and network programming from a satellite receiver.

Some stations transfer music from CD to analog, or digital, cart, making the studio an all-cart operation. In this situation the studio contains four to six cart playback decks and no CD players. Having all program material on cart makes the operation more "idiotproof." The operator needs only to talk, push plastic boxes into slots, and push-buttons.

Going one step further, some stations retrieve their program material from digital audio storage systems. Commercials and music are stored digitally on a hard drive, retrieved when required, converted back to analog audio, and fed to the console. This eliminates the physical handling of any audio storage medium. The operator controls each audio event with keyboard and mouse.

Music formats require positions for one operator and possibly an announcement booth for the newscaster. With the popularity of the zoo format, many large-market stations designed their studios for two or three on-air personalities. One member of the team operates the console, one juggles phone calls and pulls music and spots, and the third handles news. The studio layout varies with the duties handled by each member of the team.

1.2. News/Talk Formats

All-news stations serve up information from live in-studio talent and short-duration feeds from a large number of sources. Here the board operator functions as an engineer rather than on-air talent. Small studios orbit the central control room allowing eye contact between the board operator and on-air talent. The console provides more of a switching function than audio mixing. Live news or talk programs dictate a larger number of console inputs than the typical disk-jockey operation. Digital audio storage systems help this format flow smoothly because the operator is busy enough without the mechanics of handling carts.

Technology now allows replacement of the audio console with a computerized audio switching system. Hard-disk audio storage systems use multiple computers linked to a central network server through a local-area network (LAN). Each studio retains access to all stored program material. The operator sees the log displayed on the screen and can shift events around, control audio source equipment, adjust levels, and even read copy and tags directly from the screen.

Talk formats require a studio for the show host and the on-air guests. A large round table with the microphone booms mounted in the center allows the host and any guests working room plus affords eye contact between them. The show producer operates the mixing console and telephone hybrids in the control room. If not located

in an adjacent room, the show's call screener also shares the space in the control room.

Large-market budgets afford lots of labor power and first-class equipment. A visit to a small-market talk show may reveal the show host running all the control room equipment while talking with callers. The station's telephone receptionist works frantically screening calls and shuttling caller names on yellow sticky notes to the frenzied show host.

1.3. The Production Studio

A separate studio provides an area for commercial production work and transfer of music to a cart or a digital audio storage system. The production studio provides access to CD players, a digital audio workstation, cart recorders, equalization, patch panels, reel-to-reel recorders, and possibly turntables. The production studio provides more flexibility and handles a wider variety of audio media than the on-air studio.

The 4-, 8-, and 16-track consoles and multitrack recorders found in major market production facilities often intimidate the typical disk jockey accustomed only to segueing music and commercials. These consoles feature submaster mixing busses, allowing the mix down of multiple tracks of music, voice tracks, and sound effects, producing complex spots and promos. Special effects and equalization, not needed in the main studios, remain standard fare in production.

Production directors are enthusiastic about digital workstations because they allow editing without razor blades and splicing tape. Digital workstations bring to audio production the speed and versatility that word processing brought to typing. Workstations allow editing of individual tracks, a feat impossible with multitrack reel-to-reel tape editing.

Because all material produced in this studio will eventually be played on the air, the quality of the equipment should be equal to, if not better than, that used in the main studio. Smaller-market stations erroneously tend to scrimp on equipment for the production room. Using hand-me-down and cast-off equipment in the production studio hampers the potential success of the station.

2. TYPICAL TELEVISION STUDIO LAYOUT

Audio for television stations can be challenging because of the need for many types of audio mixes. Multichannel TV sound (MTS) requires a stereo program feed to the transmitter, on-camera talent needs a monitor mix, programs with a studio audience require a mono public address (PA) mix, and talk and news programs must have a mix-minus for telephone hybrids and possibly a mix in a different language for a second audio program (SAP) channel.

The Grand Alliance advanced television (ATV) threatens to make life even more interesting. As the motion picture format 5.1-channel comes to television, the audio engineer must deal with left channel, center channel, right channel, two surround channels, and a low-frequency effects (LFE) channel. The first five audio channels offer full 20 kHz bandwidth. The LFE channel provides

response from 3 to 125 Hz. All this arrives as digitally compressed audio in the Dolby AC-3 format.

Audio monitoring of the preview channel is accomplished through the mixer solo function. If a remote truck is involved, an interruptible foldback (IFB) system requires a program audio feed plus audio cues to the talent at the truck. The console to handle all this requires a design specifically for these complex tasks. The TV audio operator mixes audio and nothing else.

An audio routing switcher tied to the video switcher assumes some of the workload. The audio switcher operates in sync with the video source, leaving level correction adjustments to the station's audio processing chain.

3. STUDIO PLANNING

3.1. Technical Basics

Analog audio signals consist of complex mixtures of altering currents of different frequencies at different powers. In broadcasting, the decibel (dB) serves as one unit for measuring audio power. We measure the power with VU (volume units) meters, marked in decibels, on our equipment. What is a decibel? The decibel is one-tenth of the logarithm of the ratio of two powers.

The VU meter shows a "0" reading, but it is not on the left end of the scale; it's to the right of center. On a VU meter, "0" does not mean zero or none. These volume units are referenced to the 1 mW of power produced by a 1 kHz audio tone across a 600 Ω load. This combination of audio power (1 mW) and load value (600 Ω) creates 0.775 V of audio and is represented by the "0" on the VU meter.

The designation dBm identifies all readings referenced above or below this power level. A signal of -3 dBm contains half of the energy of a signal measured at 0 dBm. A signal of +3 dBm is twice as loud as the 0 dBm signal. A signal of +10 dBm is 100 times as powerful.

Decibel values identified as dBu (decibels-unterminated) indicate an audio voltage of 0.775 V across an open circuit. Decibels measured in dBv (decibels-volts) are also measured across an open circuit but are referenced to 1.0 V. Because the circuit lacks the traditional 600 Ω load, these are simple measurements of an audio voltage, not power. Modern analog equipment no longer uses 600 Ω impedance-matching circuits; most references to decibels now carry the dBu or dBv notation.

Occasionally the 0 dBm output level on a console drives the input meter on a recorder to +4 dBm. 0 dBm still equals 0 dBm, but equipment manufacturers often calibrate their equipment to provide an output level of +4 dBm, or +8 dBm, when the output VU meter indicates 0 dBm. Engineers always standardize operating levels of all equipment in the station. This allows them to patch any output into any input without operating level problems.

Signal levels of 0, +4, and +8 dBm are all valid operating levels. Each station may use a different level, but an engineer will calibrate all the equipment in the station to one of these three "standard" operating levels. Someone bringing in equipment from outside the facility may find it necessary to recalibrate to the signal level used

throughout the facility. Digital audio equipment presents another level-matching challenge. Headroom meters, not VU meters, monitor digital inputs. A headroom meter indicates how close the input signal comes to clipping the analog-to-digital converter circuit. A 0 dBm signal fed to a digital recorder with 18 dB of headroom will appear on the headroom meter at -18 dB. You will find headroom meters referencing a decibel value identified as dBfs (decibels referenced to full scale).

3.2. Analog Equipment

An analog VU meter operates like the speedometer in a car, which directly shows the speed at which the car is traveling as a stated value. A headroom speedometer would show how much faster the car can go in relation to the speed limit. In this example, we will assume a speed limit of 60 mph (37 km/h). When the headroom speedometer shows -10 mph (-6 km/h), a conventional speedometer would show a speed of 50 mph (31 km/h). The headroom speedometer displays that there are 10 mph (6 km/h) to go before reaching the 60 mph (37 km/h) speed limit.

Analog circuits tolerate operation with the levels driven in the red above 0 dBm on their VU meters. 0 dBm is not the clip point. An analog circuit clips when the audio signal exceeds the voltage potential of the power supply. A sine wave then flattens on the peaks when the input signal reaches a level higher than the power supply voltage. This condition results in audio distortion.

Typically analog audio equipment clips around +24 dBu. If the manufacturer calibrated the VU meter to an output of +4 dBu ("0" on the meters equals an output of +4 dBu), the equipment is said to have 20 dB of headroom. Input audio reading an average value of 0 dB could contain audio peaks 20 dB higher without clipping and distorting as it passes through the equipment. It is easy to understand why analog equipment with 20 dB of headroom forgives trespasses into the red above 0 dB on the VU meter.

3.3. Digital Equipment

Digital equipment inputs demand closer attention. When a digital recorder, with a headroom meter, is driven above "0," the digital audio clips and the recording will contain irreparable distortion, clicks, or pops. Digital audio clips at the analog-to-digital converter (ADC). Digital clipping occurs when the analog input signal drives the ADC past its maximum output capability. The converter is outputting all 1s and can no longer digitally reproduce the rising analog input. Good digital recording practice maintains peaks of -6 dBfs.

3.4. Balancing Input and Output

Professional analog broadcast equipment features balanced inputs and outputs. A balanced audio output consists of two wires that carry the analog audio voltage to the next device. Neither of these wires connect to ground. Only the cable shield, which protects the audio from electrical noise and hum, is grounded. A balanced circuit can

be run over properly shielded audio cables several hundred feet long.

The 230 V electrical circuit to an electric stove is similar. Two wires carry 230 V between them. Anyone who connects either wire to ground, may not live to tell about the resulting sparks. Although the low voltages associated with balanced audio do not represent any danger, grounding either side will short-circuit half the audio voltage to ground. Balanced outputs should not be directly connected to unbalanced audio inputs.

When wiring balanced analog audio, care should be taken to connect the high, or plus (+), terminals. Connect the low, or negative (-), terminals only to similarly marked terminals. If 3-pin XLR connectors are used, pin 2 is always high (+). Pin 3 is always low (-). Pin 1 of an XLR connector is ground. When $\frac{1}{4}$ -in. tip-ring-sleeve (TRS) plugs are used, the tip is high (+), the ring is low (-), and the sleeve is ground. Failure to follow the rules of polarity will result in out-of-phase audio. Stereo audio, wired out of phase, results in an audio dead spot centered in front of the speakers. Listeners with monaural radios hear only the difference between left channel and right channel if out-of-phase audio is fed to the transmitter.

In 1984, a Baltimore, Maryland, FM station once operated for 2 days with its audio out of phase. It went unnoticed by those listening in stereo; no one at the station detected anything wrong. But a bedside monaural clock radio reproduced nothing but a left minus right signal. Mono listeners assumed that the station was off the air; they heard only high-frequency spitting noises and muffled mumbling.

An unbalanced audio circuit consists of a single conductor and grounded shield. Consumer electronic equipment uses unbalanced audio circuits easily identified by the single-pin, RCA phono plugs found on the connecting cables. An unbalanced circuit carries half the power of a balanced circuit. It is more subject to hum and noise. Unbalanced circuits cannot support long runs of cable for this reason.

An unbalanced circuit is similar to the 115-V wiring in a house. One wire delivers 115-V to the lights, the second wire in the lamp cord is ground. It can carry only half the voltage of a balanced, 230-V circuit. Connecting an unbalanced output directly to a balanced input will not damage the equipment, but the input level will be too low. A matching interface box is needed to convert the unbalanced output to a balanced one and boost the signal level.

Bridging audio input circuits present no load to the source audio. Bridging inputs abandon the traditional 600- Ω , power-matching input circuits found on older equipment. Without a load, no power transfer takes place. These bridging circuits simply transfer an audio voltage from output to input. A bridging input handles a wider variety of input sources than possible when everything terminated with a 600 Ω load. If an output requires a 600 Ω termination, a 620 Ω resistor tied across the input terminals provides a perfect match.

In the days of tube equipment, both inputs and outputs used transformers. Tubes could not drive 600 Ω loads directly; solid state equipment could. Audio equipment manufacturers slandered the transformer with rumors of poor

performance as they removed them during the transition to solid-state design. Good transformers are expensive; manufacturers looked for ways to cut their costs and the audio transformer became a casualty.

Some applications still require the physical isolation that only a transformer can provide. Any time that audio equipment connects to a phone line, a transformer blocks the 48 V “telco battery” from entering the equipment. Unusually long audio cable runs operate best, with lower noise, when a transformer isolates the equipment on each end. The audio transformer provides best common-mode rejection (CMMR) of electrical noise included into long cable runs. Transformers still provide input termination on many high-end microphone preamplifiers. The transformer provides the required 150 Ω load for the microphone and isolates the preamp from the phantom voltage required to power condenser microphones. Common mode rejection of noise becomes even more important when dealing with the extremely low-level output signals of dynamic microphones.

3.5. Where to Begin (Step 1)

Planning a new studio, or rebuilding an old one, begins with a layout on paper or computer screen of all the required audio sources and feeds. The console inputs offer a good place to start. Working from a list of all possible sources, the engineer assigns them priorities according to how often and how quickly the operator must put them on the air. This determines the number of mixing channels needed and how many switched inputs each mixer requires.

All frequently used audio sources should be assigned to individual console mixers. Keeping input switching and patching required of the operator to a minimum avoids errors and dead air. A console with two or three more inputs and mixers than absolutely necessary provides insurance against obsolescence and frequent studio rewiring jobs.

Accepted engineering practice runs all line-level inputs through patch panels on their way to console inputs. This allows the engineer to reroute special program audio and patching around any problems that may develop. The exception to the rule is microphone-level audio. Directly wiring microphone outputs to the console input terminals remains the best option. Microphone input positions seldom change, and the extra wiring through patch panel jacks invites noise problems. A possible exception is the television studio where the program must allow transfer from set to set.

Part of proper planning for a new console ensures that levels from all sources will be compatible with the input levels required by the console. If not properly matched, the operating positions of the potentiometers will be different for each mixer, making it difficult for the operator to run the board properly. The operator may open the pot a fraction of a turn and drive the meters to the pin or may not get enough gain even with the control fully open. Either situation results in a poor audio mix with possible distortion and noise problems. Normal operation sets rotary attenuators at the 2 o'clock position and slider attenuators at a 70% position.

Figure 1. The H-pad resistive network reduces levels and matches impedances in balanced analog audio circuits.

All studio sources should be adjusted to operate within their normal output range. Interface amplifiers (matching boxes) should be used to boost low-level audio sources to the +4 dB levels required for most consoles. If the source signal overloads the console input, an H-pad will drop it to gain a proper match.

An H-pad is a simple network of five resistors arranged in the shape of an H laid on its side. The resistors convert some of the audio energy into heat, which drops the audio level by a predictable amount. At the same time, the H-pad maintains the impedance of the circuit. Pads of 10 dB or greater also correct impedance mismatches. Figure 1 illustrates the schematic of the resistive H-pad.

Pads are essential when connecting two audio transformers directly together. If an output transformer directly feeds an input transformer, the output transformer sees a changing inductive load. The frequency response of the system suffers. With an H-pad between them, the output transformer sees a linear resistive load. The H-pad may be mounted inside the equipment or at the studio punch blocks. Table 1 shows resistor values for commonly needed 600 Ω H-pads.

The worksheets in Figs. 2 and 3 offer an example of the starting point for designing a studio. Figure 2 illustrates wiring to the console inputs; Fig. 3 designates the wiring path of the console outputs. Preparing customized worksheets for each studio saves false starts and wiring errors. Any computer spreadsheet program accommodates the

Table 1. Typical H-Pad Values

Loss (dB)	R1 (Ω)	R2 (Ω)
1	5100	18
3	1800	51
6	820	100
8	560	130
10	430	160
12	330	180
14	240	200
16	200	220
18	150	240
20	120	240
22	100	270
24	75	270
26	62	270
28	47	270
30	39	270
32	30	300
34	24	300
36	18	300
38	15	300
40	12	300

task easily. Computer drafting programs offer another option for perfecting studio wiring prior to pulling cable.

The studio outlined in these worksheets is one of two in a station. A second studio serves as the production room. Patch panels route all audio. Outputs of both studios appear at the patch panel in the main studio as well as the production studio. If technical problems take the control room offline, the station can originate the program from the production console.

3.6. Buying Equipment

Preparation of a shopping list and cost estimate for new equipment follows the design of the studio on paper. The major components (console, cart players, professional CD players, and furniture) should be chosen early in the planning stage so that budget cuts will not compromise their quality. Price increases, sales tax, and shipping costs should be allowed for, and hidden “handling” or drop-shipment charges should be scrutinized.

Each engineer should maintain a working relationship with a reputable broadcast equipment dealer. Absolute bottom-dollar may not be the best deal. There is no saving in paying \$15 less for a CD player that fails to arrive in time to make the on-air date for the new studio. Experienced broadcast equipment salespeople offer their best deals and service to customers with whom they do regular business.

The shopping list should arrive at the dealer at least a week before the cost estimate is needed in order to allow the dealer time to research and work up a quotation. Engineers who demand quotations on short notice seldom get serious attention by dealers. Competition in the broadcast supply business ensures that pricing between reputable dealers will vary by only a few percentage points.

Competitive bids should be limited to two. Time is more valuable than chasing nickels and dimes. If the regular dealer does not offer an item required for the project, ask for a recommendation for a source. A salesperson will know all good suppliers and sometimes offer to get equipment not in the suppliers’ normal line for the best customers. This extra service can be worth a lot more than a few dollars when considering the big picture.

4. AUDIO CONSOLES

4.1. Radio Consoles

Centered in the radio studio, in front of the disk jockey, sits the on-air audio console. An 8–12 mixer analog console typifies this unit. Smaller mixing consoles find their way into news editing rooms and production studios.

The number of mixing channels limits the number of audio events that can occur simultaneously or in rapid succession. The station format dictates its requirements. Although an operator-assisted easy listening or satellite-based format may be able to use a four or five channel console, it would be out of the question for a fast-paced contemporary or rock program. These smaller consoles may not offer an audition bus or switchable inputs. The lack of multiple switched inputs requires one mixer for

Studio Wiring Plan			
Audio Source	Input Jacks, Patch Panel #1	Output Jacks, Patch Panel #1	Console Inputs
Microphone #1			Mixer 1
Microphone #2			Mixer 2

Figure 3. This example of studio wiring of the console shows the versatility afforded by patch panels. Should the main console fail, patch cords can feed the production studio to the on-air processing and the transmitter.

each audio source. External switchers can provide extra flexibility when required.

The console found in most control rooms offers 10 or more mixers. The most common variety features rotary attenuators. Heavy on-air use begs for step attenuators because they require only occasional cleaning in order to maintain silent operation. These attenuators use make-before-break switches to move through a series of resistive pads. The step between the contacts results in uniform 2 or 3 dB steps throughout the entire range of 20 or more steps. Their rugged construction offers smooth, quiet, dependable operation, but with large size and rotary design as limiting factors. Program audio passes directly through the attenuator, but a switch routes the audio into the console cue bus as the attenuator reaches its fully counter-clockwise position.

Wear and buildup of dirt plague attenuators that depend on sliding a contact over a resistive element. The resistive element consists of either carbon, conductive plastic, or metal film. Normal wear changes the element's resistance, and buildup of worn-off carbon may cause erratic resistive changes in the contact between the slider and the element. Noise and uneven tracking between stereo channels results with age.

Noisy pots present a major problem when the program audio routes directly through the potentiometer. In the case of a voltage-controlled amplifier (VCA) design, audio does not pass through the control. With the VCA design, only a sample DC control voltage passes through the potentiometer. This voltage controls the gain of an amplifier, which carries the program audio. Figure 4 offers a schematic of a VCA control circuit.

VCA console design solves the problem of audible noise from defective attenuators, but the noisy attenuator will affect the accuracy of the control voltage. The audio passing through the VCA-controlled circuit will become erratic and nonlinear as the noisy control moves through its range. Replacement of the defective attenuator prevents clumsy-sounding crossfades and stereo channel dropouts. This console design allows for the use of cheaper rotary or straight-line (slider) attenuators. As with any amplifier with VCA introduces some thermal noise and distortion. A good console has an overall distortion figure of 0.05% or less. The noise floor should be less than -90 dBm.

Figure 4. The VCA allows gain control via an adjustable DC voltage. This circuit is typical of those found in VCA-controlled audio mixers.

Modular design consoles offer the engineer major advantages. Removing and swapping modules make troubleshooting easy. The layout of the console allows easy changes to keep up with station format undulations. The positioning of blank panels created dividers, neatly grouping sources together. Custom panels accommodate special functions such as reel-to-reel recorder control or telephone line selection. Extra space left in the main rack offers expansion with additional mixers as the station's needs grow. These benefits justify the extra investment in a modular console.

For on-air use, a cue channel allows the operator to receive cue audio from remotes and networks and to preview program material. Even if carts deliver all program material, a cue channel is essential. It serves as a valuable troubleshooting tool for the station engineer.

In the early days of radio, all program material was live, and the audition channel served as the cue channel. Levels were set, and program material was previewed using the audition channel. Today the audition channel records network feeds for later use while the program audio travels the program channels. The audition channel can monitor the audio quality and set levels of remote feeds using the studio monitor system.

Some consoles allow audio from the mixers to feed the program and audition channels simultaneously. This allows recording of on-air programming using the audition channel. In talk formats using fixed-time-delay systems, the audition channel mixes the real-time program audio and feeds it to the delay. The output of the delay is brought back into the console on the program channel, which then feeds the delayed program to the transmitter.

4.2. Television Audio Consoles

The requirements of TV audio are compounded because more live audio sources come into play (as opposed to radio, where most program material is recorded). In television installations, additional monitoring requirements mean multiple output mixes. Television consoles include mono input modules for microphones, telephone hybrids, and other mono sources. The inputs offer a gain control or switch to allow stepping between microphone and line-level input. These modules include a pan pot to allow left-right positioning of the apparent audio source. A mode switch may replace the pan pot, enabling selection of normal stereo, left channel only, right channel only, a mono mix, or reversed channels. A cue channel feed plus a solo button permit stereo monitoring of a single audio source in the control-room monitors. Audio sweetening requirements make equalization on each module a popular option.

The ability to create multiple audio feeds by using sub-master mixing buses represents the major departure from radio consoles. The operator assigns mixer outputs to sub-master buses, and these submasters in turn create the master mix. This allows us to create several mix-minus feeds for special monitoring requirements.

4.3. Console Features and Options

A growing list of optional equipment available on audio consoles serve both radio and television audio mixing.

These make them more user-friendly. Clocks and timers put timing functions in the immediate field of vision of the board operator. The timer resets to zero anytime that a new channel is selected so the operator will know how long a CD or cart has been running.

A mix-minus, program audio minus the caller's voice, feeds console to the telephone hybrid and then down the line to the caller. If program audio, including the caller's voice, were fed to the phone hybrid, a feedback path would exist. Figure 5 illustrates a block diagram of a mix-minus circuit for telephone hybrid. This example demonstrates that not all console inputs must route to the mix-minus bus. Note that only input 1 and input 2 (announcer microphones) connect to program, audition, and mix-minus circuits.

If the studio contains multiple phone hybrids, a mix-minus feed for each hybrid is required so that callers will be able to hear each other's comments. In a television studio, a mix-minus feed provides on-air monitoring for talent on a live set. This feed includes program audio minus the talent's microphone preventing acoustic feedback while allowing the talent to hear program material and cues.

Consoles designed for radio production and television contain prefader processing patch points. These route the audio source compressors, equalizers, or other signal-processing devices before arriving at the mixing bus. These processing loops provide convenient connection points for microphone processing units.

Monitor amplifiers may be external or built into the console. Power and space limitations restrict built-in monitor amps to less than 10 W. Many engineers prefer to drive studio monitors with external, higher-power amplifiers. The stereo monitor system should contain a stereo/mono switch. This allows the operator to check out-of-phase program material and misaligned tapes. A single-pole, single-throw switch wired between left and right

channels at the monitor gain control accomplishes this function. At some stations, the control room monitors routinely operate in the mono mode. This immediately alerts station personnel to out-of-phase conditions.

A well-designed console offers switchable input levels and impedance matching on each input module. This handy feature allows easy transfer of input sources to different mixers, allowing for future changes in the studio. An input amplifier could then be used for either microphone or line-level audio. A second best system would have interchangeable mixer input amplifiers, which an engineer could shuffle between positions in the console mainframe.

Going one step further, some consoles offer programmable presets for input configuration. The engineer first stores pre-programmed console input settings in memory, then tells the console which program is planned for use. All the input sources automatically switch to the proper mixer. Fast and accurate setups result.

Professional consoles feature balanced, bridging inputs. Bridging audio input circuits used in modern consoles handle a wider variety of input sources than possible when everything was designed with 600Ω, +4 dBm terminations. A bridging input provides a 10 kΩ or greater termination impedance, which provides no load to the source equipment. If an output requires a 600Ω termination, a 620Ω resistor tied across the input provides proper matching.

Remote start contacts for cart machines and other program sources became standard equipment in the 1980s. They allow the operator to start the equipment by simply turning on the appropriate channel. Some console manufacturers provide more flexibility by using logic circuits, which allow the mixer to be turned on by pushing the Start button on the cart player. When the cart machine recues, the mixer automatically turns off. Automatic disabling of this logic when the input selector is switched to another input source eliminates the annoyance of having a cart machine start when the mixer is turned on for an auxiliary function.

Console manufacturers offer consoles with a choice of conventional analog VU meters or light-emitting diode (LED) bar-graph metering. LED metering provides multiple color visual monitoring of root-mean square (RMS) audio voltage plus peak values. One model shows left, right and peaks on a single display. LED displays may make operators less likely to run a board with the meters buried in the red.

Multitrack recorders and digital workstations in the broadcast production environment require consoles with more than a single pair of left and right outputs. Four and eight channel consoles assist in producing award-winning production. Channel assignment switches route the audio to the proper bus. Pan pots then shift it between left and right. Equalizers on each mixer allow adjustments to each audio source. Such production consoles resemble those once found only in recording studios.

Alert engineers realize that digital technology arrived to the audio console industry in the mid-1990s. The basic operating rules still apply to these new boards. The only exception is that they pass along a digital signal rather

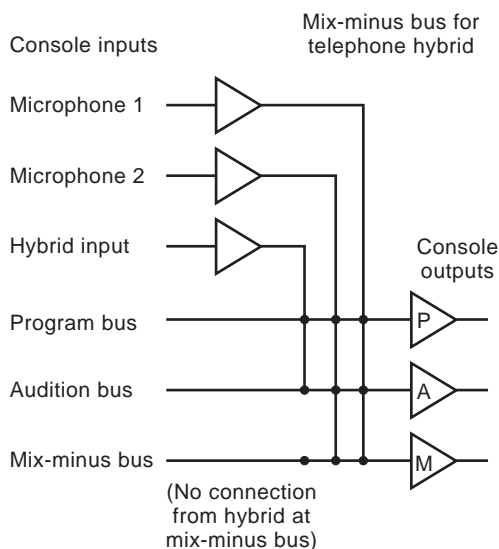

Figure 5. Broadcast consoles used with telephone hybrids require a mix-minus bus to feed the send input of the telephone hybrid. The mix-minus allows the caller to hear the talk show host's voice (microphone 1 and microphone 2) but prevents the caller's audio from being fed back into the hybrid.

than analog. As of this writing, many digital consoles remain in the prototype stage.

5. AUDIO DISTRIBUTION AND ROUTING

5.1. Patch Panels

There are three basic types of patch panels, or jack fields. The tip/sleeve $\frac{1}{4}$ -in. jack size is the oldest type, consisting of one conductor and one shield. This obsolete design dates back to the early days of radio. The tip/sleeve patch panel requires four single-plug cords to patch a balanced stereo connection.

The tip/ring/sleeve $\frac{1}{4}$ -in. panel remains the most popular patch panel for radio. It offers two shielded conductors per cable. A pair of single-plug cords will complete a stereo circuit. Dual-plug cable assemblies allow the convenience of patching a stereo source with a single cable.

The most useful $\frac{1}{4}$ -in. patch panel design includes dual rows of 24 jacks. This configuration allows stereo pair spacing. These panels usually group their jacks in pairs with wider spacing between stereo pairs. This spacing technique, when used with a dual-plug patch cord, makes it impossible to cross-patch an audio source. Cross-patching occurs when the user inserts the first single patch cord in one audio feed and the second patch cord in the adjacent audio feed on the patch panel. The dual plug will align only in paired jacks; cross-patching becomes impossible with these types of patch panels and dual plug cords.

Patch panel jack numbering uses the following convention: the jack in the top, left corner is identified as jack 1. Counting across and to the right, the last jack on the top row becomes jack 24. Jack 25 falls below jack 1 and is the first jack on the bottom row, starting on the left. Jack 48 is located on the bottom row at the right end and below jack 24. Although patch panels may contain more, or fewer, than 48 jacks, this numbering system remains the standard for identifying individual jacks.

The $\frac{1}{4}$ -in. patch panels also come in single rows of 26 jacks or dual rows of 52 jacks. These panels have standard spacing between all jacks and allow an additional stereo circuit on the 26-jack version and two additional stereo circuits on the 52 jack, dual-row model.

Special configurations of the $\frac{1}{4}$ -in. jack field can create very useful designs. One version offers three rows of 26 jacks for a total of 78 jacks on the panel. The wiring scheme of the two lower rows create a conventional dual-row patch panel. Wiring the top row directly to the circuits of the middle row of jacks allows monitoring these equipment output circuits by patching between the top row jacks and the monitor amplifier inputs. Inserting a plug into the top-row jacks does not interrupt the normal audio path through the patch panel.

Another custom item is a patch panel with special jacks that not only switch the conductors but also the shield when a patch cord is inserted. The patching of microphone circuits requires this seldom-used configuration.

One arrangement features patch panels built into a 19-in. (48-cm) rack mount chassis. The entire assembly mounts into the equipment rack just like the equipment that it connects. The jacks appear on the front of the rack,

and the rear termination points on the rear offer easy access to equipment wiring from the back of the rack. There remains a misconception that this design provides protection from radiofrequency interference (RFI). However, the phenolic bay fronts provide no shielding of the jacks, and some manufacturers even wire these designs with unshielded wire.

Rapidly making its way out of the recording studio and into broadcasting is the bantam or tiny-telephone jack field. These 0.175-in.-diameter plugs and jacks feature the tip/ring/sleeve configuration. The bantam patch panel consumes about half the space that a similar $\frac{1}{4}$ -in. jack panel would require in an equipment rack. The 96 jacks fit in a $1\frac{3}{4} \times 19$ -in. (4.45 \times 48-cm) rack space. Television facilities discovered bantam jack fields years ago.

5.1.1. Patch Panel Wiring and Termination. The jacks used in an audio patch panel have, for each circuit, a set of contacts that make contact when no plug is inserted in the jack. The circuit connection opens when the user inserts a plug. This allows for “normaling.” An audio source wired to a pair of these jacks passes automatically to the pair of jacks associated with an input that it normally feeds. Proper procedure wires all outputs to the top row of jacks in a dual-row patch panel, and the “normals” connect them to the bottom row of jacks. When not interrupted by the insertion of a patch cord, outputs feed to the proper inputs directly below, which are their normal connections. Figure 6 illustrates several methods of wiring patch panel normals.

Short jumpers between the rows usually make the connection for the normals between upper and lower rows of jacks. The jumpers can be brought rear terminations. If the normals route through a termination, the engineer can determine whether the circuit is normaled. Changes in normaling then can be made without removing the patch panel and unsoldering the jumpers.

When situations require the board operator to reroute the output of a cart player normaled to console input 3 to input 6, the operator first inserts a pair of cords in the top row of jacks associated with the cart machine’s output. This interrupts the audio path going to mixer input 3 by breaking the normal circuit. The operator then inserts the other ends of the patch cords in the jacks on the lower row associated with inputs for mixer 6. This breaks the normal circuit from the audio device normally feeding mixer 6 and puts the output audio from the cart player into the console input for mixer 6. Inserting a plug into a patch panel with conventional normal wiring breaks the circuit.

If the engineer wants the ability to monitor equipment outputs at the patch panel, half-normaling or top-row bridging wiring design meets the need. Half-normaling wiring connects the jumpers of the top row of jacks directly to their jack arms. The normaling contacts of the top-row jacks are not connected. This means that the circuit between the top-row jacks and the bottom-row jacks is broken only by inserting a plug into the lower-row jacks. This allows high-impedance monitoring, or metering, across the circuits without interrupting the audio connection.

Experienced engineers never connect patch panel jacks directly to equipment inputs and outputs. Termination

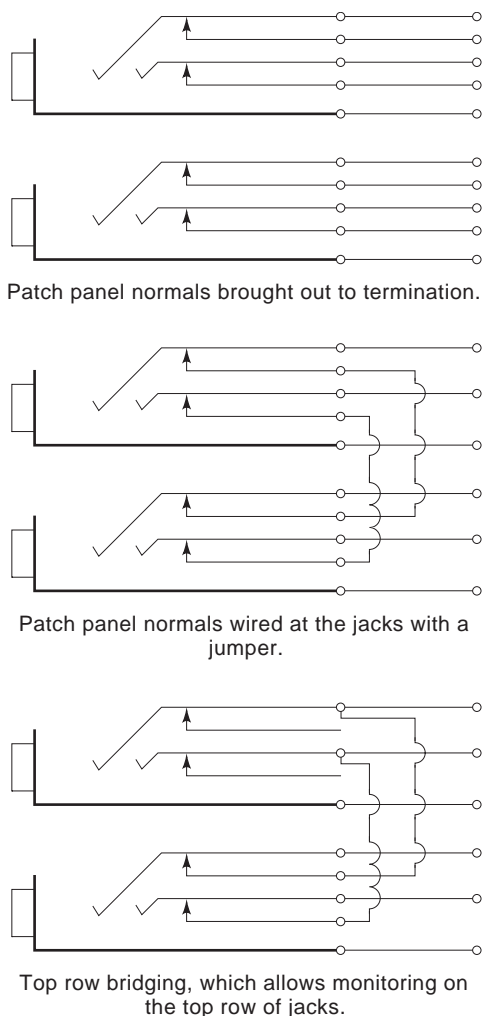

Figure 6. Audio patch panels are wired with either (1) all connections brought out to punch blocks, (2) the normals connected by jumpers at the jacks, or (3) the top jacks bridged to allow monitoring of the audio outputs wired to the top row of jacks.

blocks speed patch panel installation and offer flexibility when making wiring changes. Accepted practice mounts patch panel termination blocks in individual equipment racks, in a group in each studio, or in a central point in the engineering area. Short jumpers between connections on the termination blocks complete the links between inputs and outputs. This allows wiring changes at a convenient, easy-to-reach location without pulling new wire between equipment. Terminations used including solder-type “Christmas trees,” wire wrap, type 66 telephone punch blocks, or the newer types of punch blocks designed for stranded copper wire.

Christmas trees remain popular with engineers who trust only solder connections. They still serve well in remote trucks because of vibration concerns. Otherwise, they are obsolete.

Most engineers have switched to punch-type terminations. A specifically designed tool “punches” insulated wire into a slotted connector. The wire insulation strips away as the wire pinches into the connection. The process

eliminates the soldering task associated with Christmas tree blocks. The “66” block accommodates 22-gauge solid wire used in telephone service. Using only solid 22 wire ensures dependable connections. Stranded wire generally works although the strands may flatten out, preventing dependable removal of the insulation. Some strands may also break in the punchdown process. Solid conductor wire should be used for best results.

5.2. Audio Routing Switchers

The audio routing switcher offers an alternative to patch panels. This unit accomplishes the same function by switching the audio with relays or solid state switches rather than by plugs and jacks.

The system eliminates patch cords, can often be operated by remote control, and may often route audio to more than one feed at a time. Some of the more elaborate systems feature computer control. The increased flexibility of a routing switcher provides the only practical solution when many audio sources must be switched frequently such as in a busy TV control room.

Failure of the relays or cross-point switches in routing switchers adds some cause for concern. What happens when there is a power interruption? Latching-type relays hold their connections if power fails. Powering the routing switcher through an uninterruptible power supply presents another choice for fail-safe operation.

Size determines the cost of a routing switcher. A stereo switcher with 12 inputs and 12 outputs contains 288 cross-points (12 inputs × 12 outputs × 2 audio channels = 288). If the switcher is visualized as two side-by-side matrices of 12 horizontal lines (inputs) intersected by 12 vertical lines (outputs), each intersection becomes a possible connection point. One matrix represents left-channel audio; the other represents the right channel.

In a television station, engineers must decide whether individual switchers handle left, right, mono, SAP, or if one large system routes all signals and audio. With the larger system approach, mono sources connect directly into left and right channels. The switcher may correct channel reversals and create mono mixes. A switcher with sufficient cross-points to handle all switching tasks requires a larger investment than several smaller ones assigned to individual channels. The station considering the new ATV format is looking at a major investment in routing for the system’s six channels of audio.

5.3. Distribution Amplifiers

When distributing audio to a number of locations on a continuous basis (without switching), a distribution amplifier (DA) proves invaluable. Sending a console’s output to several recorder and other studios or routing a satellite receiver’s feed to all studios ensure the distribution amplifier an important role in audio routing. A DA eliminates the need for constant patching and switching of various pieces of equipment. A DA becomes the only practical solution when audio must be fed in multiple directions on a constant basis.

The typical DA provides six to eight stereo outputs for each channel. Although there may be no input level

adjustment, economical units should provide individual output trim pots. Modular distribution systems offer more versatility and avoid wasted, unused outputs. One model offers four stereo inputs, which can be assignable to any of its 14 stereo outputs by the use of jumpers. Popular DA options include metering, input level adjustment, audio compression, loss-of-signal alarms, and redundant power supplies.

6. STUDIO MONITORS

The control room audio monitoring system provides the first line of defense in spotting equipment failures and problems. For that reason, professional monitor speakers should be selected.

In choosing monitors, room size dictates cabinet size. In a large studio, invest in monitors with 12-in. woofers, 5-in. (13-cm) midrange cones and horn or dome tweeters. Size limits small studios to a model with 5- or 6-in. (13- or 15-cm) woofers. Current speaker technology offers amazingly good sound quality from small cabinets. The designer should look for low distortion and flat response.

A meticulous studio designer will consider background noise sources, reverberation time of the room, interaction from walls and ceiling, and room equalization. Doing this properly means testing the control room with a real-time analyzer and positioning the monitors for best results. This is seldom practical.

When mounting the monitors on walls, suspension mounts, preferably with vibration-isolating components, should be used. Each monitor should be positioned an equal distance from the operator's normal position. Sound-proofing material should be used on as much of the flat wall surfaces in the room as possible.

In small studios, "near-field" monitoring provides the best solution. The monitors should be positioned in a triangular arrangement with equal distances between the monitors and the ears of the operator. Near-field monitoring ensures that the monitors will be close enough to the listener that the direct audio from the speakers will overpower reflections and any undesirable acoustics of the room. Mounting solutions include a shelf, or wall brackets, above the console, suspension from the ceiling, or floor stands behind the console but directly in front of the operator. Near-field monitors should be positioned at, or just above, ear level.

The power amplifier becomes another vital consideration. Space and power requirements limit audio console internal monitor amplifiers to 10 W or less. Noise and distortion specifications may not be as good as those of stand-alone amplifiers.

Matching the power amplifier with the requirements of the monitors means another task in studio design. Pushing a low-power amplifier to provide adequate listening levels can cause audio waveform clipping with distortion on peaks. Operating in this manner could damage the speakers. A better choice would be to operate a more powerful amplifier in a conservative manner.

To prevent DJs from blowing the speaker voice coils with too much power, fast-blowing fuses should be in-

stalled in the lines. The engineer needs to experiment with fuse values and listening levels to find the proper combination.

Just as important as amplifier power is the wiring between amplifier and monitors. At least 16 AWG, should be used for low-power amplifier and speaker combinations. Heavier wire, up to 12 AWG should be used for combinations above 100 W or long runs of speaker wire. The cables from the amplifier, out of the rack, across the ceiling, and then down to the monitors may eat up 50 ft (15 m) of wire even in a small studio. Audio purists insist that the wire-length for both speakers remain equal.

7. AUDIO SOURCES

7.1. Compact-Disk Players

The CD player commonly provides the audio source of choice in radio. CD technology encodes audio as digital bits recorded as etched holes on the surface of the disk. A transparent plastic coating protects the surface so that only an accumulation of dirt or scratches affect the playback quality. The bits are read by a laser beam focused on the spinning disk. Because nothing but the laser beam touches the disk, there is no wear.

Selecting the best equipment that the station can afford represents the most cost-effective choice. Several manufacturers build CD players designed specifically for broadcast and professional use. If the station that must use semiprofessional players should remember that they were designed for use in a living room a few hours a week. These consumer-grade machines will not last indefinitely when run in a radio station 24 hours a day.

A station using semiprofessional players should keep two spare (meaning new, unopened, in the box) players in the station for quick replacement of a failed machine. No attempt should be made to repair a failed consumer-grade machine. They can be replaced with less trouble and expense than making repairs.

The output level and impedance of semiprofessional CD players are not the same as broadcast quality ones. If the console inputs require +4 dB levels and present 600 Ω loads, a matching interface should be used. These matching boxes convert the -20 dB, high-impedance, unbalanced output of the consumer-grade CD player to a +4 dB, 600 Ω , balanced source. Consumer-grade equipment can be difficult to cue and slow to start; the engineer should evaluate units carefully before committing to purchasing a quantity.

7.2. Turntables

Turntables still find work in some radio stations, but their importance has greatly diminished. Some unique source material remains available only on vinyl; the owner of one broadcast equipment manufacturing firm still sells 40 to 50 phono preamplifiers a month.

Turntables come in two flavors: the idler wheel design and direct drive. The once-common broadcast turntable used a motor which turned at 1800 rpm driving an idler wheel. The idler wheel in turn drove a large hub at the

center of the platter. This design minimized wow and flutter caused by fluctuations in motor speed. The use of a heavy platter achieved further speed stability. Rapid starts necessary for tight cueing required a heavy, powerful motor.

The direct-drive turntable became more popular because of its reduced noise, wow, and flutter. There is no idler wheel to replace or bearings to lubricate; the platter is the rotor of these slow-turning electronic motors. The speed control circuits of direct-drive turntables constantly monitor and adjust their speed, keeping it more accurate than if left to line voltage and frequency. Further contributing to the demise of the rim-drive tables, the speed control function made precise speed enhancement of music possible. Circuit repairs may be a problem because of the minimal documentation provided with most direct-drive turntables.

No real broadcast tone arms remain; all current models are designed for consumer use. They track well and adjust easily but some prove difficult to cue and are not very rugged. A professional tone arm can be adjusted once and then left alone except for occasional testing. When installing a tone arm, the template from the turntable manufacturer should be used and the instructions supplied with the arm followed. The tracking weight is specified by the cartridge manufacturer.

The choice of the phono cartridge depends on the audio quality required. Rugged, less-expensive models give the longest life in on-air use. Moving up to more expensive but less rugged models gains better separation and high-frequency response. Consumer-grade phono cartridges should be avoided.

The turntable's preamplifier is easily neglected because it is never seen after installation. The important specifications of noise, frequency response, and separation need consideration. More expensive models offer filtering, high-frequency cut or boost, and adjustable cartridge loading.

Another pressing concern for the engineer is the pre-amp's resistance to radio frequency interference if the studio is co-located with the transmitter. The RF easily makes itself known in these high-gain amplifiers.

7.3. Microphones

No serious program director ever leaves the choice of the studio microphone to chance. Dynamic microphones remain the most popular for studio use. They are rugged, dependable, and affordable.

Condenser microphones crept out of the recording studios into FM stations during the 1970s and 1980s. Condensers yield flatter frequency response but cost more. Ribbon microphones were the industry standard in the 1960s years ago but are traded only by collectors today.

Wireless microphones provide the advantage of mobility at radio remotes and for television use. The wireless systems use either a miniature lavalier mike and belt-pack transmitter or a handheld design with the transmitter in the microphone case. Television news crews value the extra directional characteristics of shotgun microphones in situations when the sound professional cannot get close to the on-camera person. TV studio sets use

the shotgun mike on a boom to keep the microphone off-camera.

7.4. Audio Cart Machines

Since the 1950s, continuous-loop tape cartridge (cart machines) have proved invaluable for playing commercials, jingles, and music. Even stations that rely on digital audio storage system keep a few cart machines around as a backup system.

A mono machine uses two tracks, the upper track for program material and the lower for cueing. Stereo versions use three audio tracks on the endless loop of tape. Two of the tracks record stereo audio: the third carries cue tones. Trading recorded carts between mono and stereo players will not work because the tracks do not line up.

A brief 1000 Hz tone is recorded on the cue track at the beginning of the cart recording process. When the cart recorder is in the record mode, pushing the Start button generates the 1000 Hz "stop" tone and begins the recording process. After the tape loop cycles through the cart and returns to the starting point, the playback head detects the 1000 Hz stop tone and stops the tape at the beginning of the recorded program material.

Deluxe machines offer secondary and tertiary tones for cueing and starting the next tape. The secondary, or aux tone, is at 150 Hz tone and customarily triggers the next event in the program sequence of automation systems. The tertiary tone is a 8 kHz tone and triggers a cue light to warn air talent as the program material nears its end. The operator manually inserts the secondary and tertiary tones while recording the cart.

Although still a dependable and reasonably good storage medium for commercials and music, digital audio storage systems bulldozed the cart machine out of the radio business. In addition, while cart machines ruled the studio, their manufacturers failed to standardize on a single type of motor. As a result, when sales volumes fell, the price of all those custom motors rose at a logarithmic rate. Cart machine prices rocketed as the price of hard drives fell.

7.5. Reel-to-Reel Tape Recorders

The reel-to-reel recorder still remains a workhorse in some stations because of its simplicity and durability. Tape also provides an economical means for storing longer program material without filling the hard drive of the station's digital audio storage system.

Reel-to-reel recorders operate by mixing the incoming audio with a high-frequency AC bias signal of fixed level and frequency. This combined signal magnetizes the tiny ferric oxide particles attached to the plastic tape as it moves past the record head. During playback, the play head converts the magnetic fields stored on the recorded tape to an audio voltage sonically equal to the signal originally recorded.

The bias signal ensures that the record head creates a magnetic field sufficient to penetrate the ferric oxide portion of the audio tape fully. The frequency of the bias signal must be supersonic and typically is at least 5 times the frequency of the highest audiofrequency recorded on the

tape. The bias signal may be optimized for a particular audiotape by adjusting the bias level to produce minimum harmonic distortion when recording and reproducing a sine wave at a frequency in the range of 2–3 kHz. The operator’s manual for the reel-to-reel recorder will contain instruction for optimization of the bias signal.

During playback, an equalization curve applied in the playback preamplifier ensures that the reproduced audio produces a mirror image of the audio previously recorded. The equalization curve corrects inaccuracies related to the electrical characteristics of the record head, playback head, and speed of the tape as it moves past the heads. Both low-frequency and high-frequency compensation perfect the playback process.

Alignment of both the record and playback heads provide job security for the station engineer. Both heads must remain exactly perpendicular to the tape as it moves past the heads. Incorrect azimuth (side-to-side) alignment causes poor high-frequency reproduction. Stereo recorders exhibit a loss of stereo separation when allowed to drift out of perfect 90° azimuth alignment. Improper zenith (front-to-back tilt) also contributes to the high-frequency reproduction problem.

Professional machines include a third head in the tape recording process. An erase head uses the bias signal to clear any previously recorded audio from the tape during the recording process. If damaged, or not properly aligned, the erase head will leave remnants of audio beneath the new recording. In extreme cases, the old recording makes itself heard during silent, or low-level, portions of the new recording.

In the radio station control room, the reel-to-reel records news feeds from networks and reporters in the field. FM stations record music requests and contests winners on a reel-to-reel for delayed playback. Some program material arrives in the station on reel-to-reel tape. A two-track stereo deck with speeds of 7½ IPS (inches per second) and 15 IPS fills the requirements of most control rooms.

Tape reels constantly turn in the typical production studio. Tape edit points, marked with a grease pencil, are cut with a razor blade and edited in a splicing block. Tape containing unwanted audio is discarded, and the two edit points are then spliced together. Words can be cut out and loose cues tightened using this methods. This works well with mono or two-track stereo formats. When editing with a multitrack machine, the operator should remember that all tracks are cut on the tape as the audio is edited.

When producing commercials with multitrack machines, the operator records elements of the production on different tracks and then mixes all tracks to a single stereo mix as the finished product records to cart. A multitrack recorder makes adding tags or reading copy into “doughnut” tapes much easier. The stereo music bed or agency tape is recorded on two tracks, and a third track contains the local copy. If the announcer makes a mistake, only the voice track must be recorded.

Multitrack recorders have a selective synchronization feature that switches the record heads of the tracks not in the record mode to the playback amplifier in order to synchronize playback with recording. Without this feature the timing between playback and the recorded audio on

different tracks will be off by an amount equal to the distance between the record head and the playback head.

The favorite tape speeds for production work are 15 IPS = 38.1 cm/s and 30 IPS = 76.2 cm/s. Faster tape speeds generate the widest possible bandwidth and best audio quality. Faster speeds make cut and splice editing easier because the audio spreads over a greater distance on the tape.

7.6. Telephone Hybrids

During the 1990s, talk radio and TV talk shows moved to a position as a dominant format leader. This challenged station engineers to get the caller’s voice from the telephone to the transmitter. The clash between old and new technologies made the job difficult.

The telephone system between the telephone company’s central office and the home, or business, remains largely the same as it was at the turn of the century. We still depend on a pair of copper wires to transfer voices from one place to another. This part of the dialup telephone network still operates as a two-wire system.

Both the voice being transmitted and the voice being received mingle back and forth on the same pair of wires. A telephone hybrid converts the two-wire system into a four-wire system which separates the caller’s voice from that of the talk show host. Figure 7 shows the theory behind a telephone hybrid.

In this example, the core of the hybrid consists of two transformers, each having a single primary winding and two secondary windings. The talk show host’s voice, the transmit audio, feeds to the phone line from the primary of T1 and through secondary 1 of T1. The caller’s voice, the

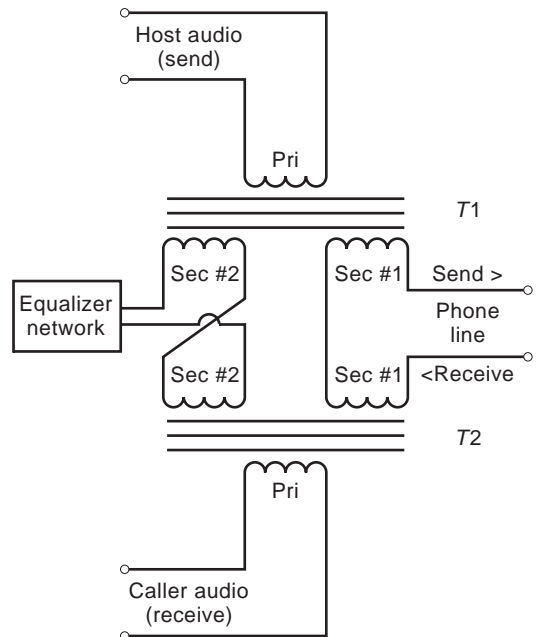

Figure 7. The telephone hybrid circuit converts the two-wire telephone line into a four-wire circuit. The hybrid creates individual send and receive audio connections separating the caller’s voice from that of the host.

receive audio, travels from the phone line through secondary 1 of T2, then to the primary winding of T2. Note that the transmit audio also passes, in series, through secondary 1 of T2. This means that the transmit audio appears in T2.

Note what is happening with secondary 2 on both T1 and T2; they are wired out-of-phase in relation to the first secondary windings. Although the transmit audio is introduced into T2 because secondaries 1 of both transformers are wired in series, the transmit audio is canceled out by the out-of-phase wiring of secondaries 2. This leaves, in theory, only the receive audio, the caller's voice, on the primary of T2.

If the phoneline exhibited a perfect 900 Ω resistive load, a 900 Ω resistor at the location of the equalization network would produce a perfect match. Telephone lines do not represent a perfect world. Capacitance creeps into the mix because the phone company uses miles of 22-gauge twisted pair to connect to its central office. That much twisted wire forms a nice capacitor. The resistance of the circuit varies with the length of all that 22-gauge wire running back to the phone company. Loading coils, used in the telephone circuits to flatten frequency response, add the inductance.

We connect our hybrid to what amounts to an *RCL* network when we plug into the phoneline. The null created by the out-of-phase circuit created by the 2 secondaries no longer matches the amount of transmit audio induced into T2 through its 1 secondary. A tunable equalization network wired between the 2 secondaries compensates for the electrical characteristics of the phone line circuit. When improperly tuned, audible amounts of out-of-phase host audio mixes with the caller's voice making the host sound "hollow," as if the show were taking place at the bottom of a large metal trash can. Our hybrid circuit may cascade into feedback in extreme cases of mismatch.

An analog phone hybrid requires tuning for best performance on each phone line to which it will connect. The process involves transmitting pink noise during a call to an outside phone number and then tuning the equalization network for a minimum level of pink noise at the hybrid's caller output. Digital phone hybrids accomplish this task with a short pink noise burst at the beginning of each phonecall. The result is perfect separation of host and caller audio with excellent-sounding talk show audio.

Integrated hybrid systems include multiple hybrids and call switching functions in a single unit. This approach removes the challenge of building a talk show phone system from scratch with equipment from different manufacturers. The multiple hybrid system also handles the requirement of multiple mix-minus feeds. The installation time saved justifies any additional cost of the combined phone hybrid and call handling system.

7.7. Broadcast Delay Units

Radio talk shows can be hazardous to a station's liability insurance. The spontaneity of a good talk show ensure that callers can, and will, say anything. This prompts the need for a system that allows time to "pull the plug"

before certain words, or accusations, pass through the transmitter.

Before digital technology accomplished this task with no moving parts, there was tape. Tape delay systems employed a special cart machine with an erase head. A 10-s cart was inserted in the recorder. Real-time audio was recorded on the tape. It took the 10 s for the tape to loop through the cart before reaching the playback head. The output audio emerged from the recorder 10 s after it was recorded, allowing time for the talk show producer to interrupt the delayed audio containing profanity.

Simple digital delays perform this task without the worries of moving parts and broken tape. The device simply converts audio to a digital signal, records it in memory, and then plays it back 10 s later. The talk show producer mixes the program in the console's audition channel, which feeds the input of the digital delay. The output of the delay routes to the program channel of the console and to the transmitter.

If things go wrong, the producer turns off the mixer carrying the delayed audio to the program channel and inserts fill music and has the option of switching the show host from the audition channel to the program channel after dropping the caller. The host then resumes the program in real time.

Both tape delay and fixed-time digital delays pose the problem of transition in and out of delay. If the show host simply starts talking at the beginning of the program, words won't exit the delay system until 10 s later. Meanwhile, the audience is treated to 10 s of silence. Most stations overcome this by playing a 10 s recorded introduction to the show on the program channel as the show host begins talking on the audition channel. The host's voice exits the delay precisely as the recorded message ends. If timed properly, the transition is seamless.

A better approach to the problem of keeping talk show audio respectable is the digital delay unit that gradually builds the delay at the start of the program. This delay digitally records the real-time audio into memory. While it is building the delay time, it plays back the program audio slightly more slowly than it is being recorded. This process gradually fills the memory until the delay time reaches the maximum. After the memory fills, this delay operates just like the fixed-time delay; the audio appears at the output 10 s after it is received at the input.

If a caller says something offensive, the host pushes a dump button that erases all, or part, of the audio in memory. Because the profanity is stored in memory, it disappears when the dump button is pushed. The program now is on the air in real time and the delay begins the process of rebuilding the delay time again. After about a minute the host has enough delay in memory to begin taking callers on the air again.

This type of delay allows easy return to real time at the end of talk program. A few minutes before the show ends, the producer puts the delay in the exit mode. Now the delay records the program, but it plays back slightly faster than it is recording. This eventually depletes the audio stored in memory and the program returns to real time. The best of these delays features a relay bypass that takes the delay off-line when it is not in delay, or if it fails.

7.8. Audio Remote Systems

One of the most profitable activities for a radio station is the commercial remote. This consists of packing off one or two of the on-air staff with a van full of prizes, amps, speakers, and a microphone to a remote location. The primary concern is to transmit the voices of the talent from the site back to the radio station with reasonable quality. The dialup telephone network provides a cheap and easy solution.

The output of a simple microphone mixer, or small audio console, connected to a telephone line coupler provides the basis for the most elementary remote system. The person doing the remote calls the station, is connected to the control room console via the station's telephone hybrid, and monitors the off-air signal for his cues. This system is easy to set up and operate, but the dialup phone system limits the audio quality. Our telephone system, designed only to transmit voice from one telephone to another, limits the bandwidth to a range of 300–3200 Hz. The talent at the remote site *sounds* as if they are on the telephone.

7.9. Telephone Frequency Extenders

The problem with using the dial-up telephone system for delivering broadcast audio is the limited frequency response. The fact that the telephone system rolls off all audio below 300 Hz costs 2.5 octaves of audio on the low end (50–300 Hz). This tends to product the “tinny” characteristic that makes unprocessed, dialup telephone remotes sound bad when compared with the full-spectrum audio of regular programming. There is a solution.

Analog telephone frequency extenders trick the telephone system into passing audio with a bandwidth of 50–2900 Hz. An encoder–decoder process shifts audio frequencies upward by 250 Hz, sends the up-shifted audio over the phone line, and then returns the audio to its normal frequencies on the receive end. The encoder travels to the location of the remote broadcast and serves the double duty of shifting the audio up by 250 Hz plus connecting the remote mixer to the dial-up telephone network. Most include telephone touchpads for dialing.

The encoder converts 50 Hz audio upward by 250 Hz to a frequency of 300 Hz. Audio at its natural frequency of 2950 Hz exits the encoder at a frequency of 3200 Hz, which barely squeezes through the limited bandwidth of the phone system. The output of the frequency extender encoder sounds quite strange. Even the lowest baritone voice sounds very high-pitched. Obviously, reverse treatment is required on the receiving end.

The frequency extender system's decoder shifts the audio, which it receives down by 250 Hz, restoring it to the original frequencies. The analog frequency extension process delivers an audio bandwidth of 50–2950 Hz. The result is very pleasing voice transmission over a dialup telephone circuit. The process sacrifices one-seventh of an octave between 2950 and 3200 Hz, but it restores 2.5 octaves between 50 and 300 Hz.

The system suffers from two disadvantages. Analog frequency extension is a one-way system. When the remote is out of the range of the broadcast station's signal, a second

telephone line is required for talk-back and cueing. Compatible equipment is required on each end. A station in New York cannot send frequency-extended audio to a station in Los Angeles unless both have identical equipment.

7.10. Digital Audio Codecs

The computer age brings another means of transferring high-fidelity audio from one point to another. We can now digitize the source audio, apply data compression techniques, and send the audio over telephone lines via modems. Because computer modems operate bidirectionally, we also pick up the benefit of two-way audio communication over a single phone line.

In a nutshell, these digital audio codecs (coder/decoder) consist of a computer sound card, a modem, and data compression software bundled into a single package. The modem is designed for Switched 56, integrated services digital network (ISDN), or dialup lines. Switched 56 service provides data transfer at a rate of 56 kilobits per second (kbps). ISDN doubles the speed to 128 kbps.

Dialup lines limit data transfer to less than 53 kbps and will vary from line to line with weather and with telephone traffic conditions. A 28.8 kbps computer modem does not always connect at a speed of 28.8 kbps. Switched 56 and ISDN service are consistent. The tradeoff for less audio bandwidth brings the ease of connection to any existing telephone line without extra line charges and construction delays. For a 4-h commercial remote, the use of a dialup line is a moot point. Coverage of a week-long special event may justify the expense of an ISDN line.

Systems designed for Switched 56 lines provide a 7.0 kHz, bidirectional audio circuit. ISDN service doubles the bandwidth to 15 kHz or allows stereo 7.5 kHz audio transmission. Improvements in modem speed and technology now challenge these premium services with bidirectional audio bandwidth of up to 10 kHz over dialup telephone lines. The program audio bandwidth capability depends not only on the bandwidth of the telephone circuit, but on the data compression algorithm used in the codec.

The audio compression (data reduction) algorithms most frequently employed with Switched 56 and ISDN lines include ISO MPEG Layer II [International Standards Organization (ISO), Moving Pictures Experts Group (MPEG)], ISO MPEG Layer III, apt-X, Musicam USA, or the international telephone standard ITU G.722 (formerly CCITT G.722). The rules of compatibility dictate that the codec on each end of the telephone line use the same algorithm. MPEG Layer III will operate with a Layer II device, but performance is limited to Layer II levels. MPEG is not compatible with ITU G.722. Likewise, apt-X talks only with apt-X. Musicam USA will converse with MPEG Layer II.

G.722 introduces a minimal delay, making it the most popular algorithm for talk shows and live remotes. Stations often find themselves using their top-of-the-line codecs in the “plain-vanilla” G.722 mode. A further discussion on audio compression algorithms is contained in Section 8.

7.11. POTS Codecs

The compression algorithms discussed above were designed for use on Switched 56 or ISDN lines, which have a guaranteed data rate of 56 kbps or 64/128 kbps. Standard analog telephone lines (POTS, or plain old telephone service) provide varying data rates depending on line quality. Telephone modems, such as the one in your computer, are designed to scale the transmitted and received data rate accordingly. This sliding data rate makes it very difficult to use compression algorithms, which were designed for specific transmission speeds.

New technologies have emerged that permit the transmission of compressed audio over POTS, thus delivering a bandwidth much higher than the normal 3 kHz signal normally available. POTS codecs use high-speed modems (33.6 kbps as of this writing) and compression rates in the 12:1 range to deliver audio bandwidths varying from 5 to 10 kHz, depending on the connection speed of the modems.

There is an important difference between audio sent by POTS codecs and audio sent via computer or the Internet. Computers use asynchronous modems, which means that they send a packet of information, wait for confirmation that the packet was received, then go on to the next packet. For one-way delivery of audio that has been stored at a site, this method of transmission is not a problem. However, asynchronous modems must use a buffer to reconstruct the audio. This creates a delay large enough that two-way communication with the studio is simply not possible over the single telephone line used for the remote. For “real-time” bidirectional remotes, most POTS codecs use synchronous modems. With a synchronous modem, a bit is transmitted, and without waiting for verification of receipt, the modem goes on to the next bit. This constant data stream in both directions results in audio that is delayed only by the compression algorithm used. The modems go through a complex “handshaking” process to determine the best data rate for transmission in order to minimize errors caused by lost bits.

There are four companies producing POTS codecs, and each company uses a different approach to audio compression. One company uses ITU G.728 compression, also known as code excited linear prediction (CELP). Two other manufacturers use modifications of the MPEG Layer III algorithm; however, their systems are not compatible with one another. The fourth uses a proprietary compression algorithm designed specifically for the slower connect speed of POTS. All four companies’ codecs are designed to scale transmit speeds and bandwidths according to line quality; however, the range of connection speeds varies with the manufacturer. Before buying a POTS codec, the designer should try to get a pair of demonstration units to determine whether they will work for the station’s application. Remember, two codecs are needed, both from the same manufacturer.

8. DIGITAL AUDIO SYSTEMS

8.1. The Standards

The Audio Engineering Society and European Broadcasting Union (AES/EBU) standards provide a benchmark for

digital inputs and outputs. Fortunately, these standards provide a common denominator found on all professional equipment. AES/EBU, also known as AES3, created a balanced system that can transmit digital stereo audio up to 100 m over a single shielded, twisted-pair wire.

AES/EBU calls for internal transformer coupling, with DC blocking capacitors, on both input and output circuits. The circuit is designed for shielded audio cable with an impedance of 110 Ω. The digital input protocol must match the digital output of the source. AES3 ensures that any two pieces of equipment using this standard will work together. Copies of AES3—1992 are available, for a fee, from the Audio Engineering Society in New York; the phone number is (212) 661-8528.

The AES3—1992 standard specifies a nominal signal voltage between 2 and 7 V measured across a 110 Ω terminating resistor. An earlier standard (1985) allowed a 2–10 V range. No compatibility problems exist between the 1985 and 1992 standards.

AES3 specifies connections using the familiar XLR three-pin audio connectors. Pins 2 and 3 carry the digital signal. Pin 1 is ground. This convention is exactly the same as used in wiring XLR connectors for microphone or balanced line-level audio. The connectors remain the same but the wire does not.

Miniature broadcast audio cable (Belden 8451 or West Penn 291) does not meet the impedance specification. Digital audio is actually computer data that run at a rate of 64 Hz times the sample rate. Digital audio, sampling at a rate of 48 kHz, becomes a data stream running at 3.072 Mbps (64 Hz × 48 kHz = 3.072 MHz). Cable capacitance can rapidly degrade the 3 MHz signal. Low-capacitance digital audio cable will do a satisfactory job of transferring the digital audio signal for the AES3-specified distance of 100 m (328 ft).

The need to transport digital audio farther than 100 m (328 ft) resulted in a new standard using unbalanced coaxial cable. AES-3id—1995 allows transmission of a 1 V digital audio signal up to 1000 m (3280 ft). Considering the 3 MHz frequency of digital audio, 75 Ω coaxial cable make a lot of sense. No knowledgeable engineer would suggest conducting a 3 MHz RF signal over twisted-pair audio cable. AES-3id calls for RG6A/U, or RG59B/U, cable and BNC connectors.

Television and video production facilities rapidly embraced this new standard. AES-3id not only allows for longer cable lengths, but also permits them to use 75 Ω cable, terminated with BNC connectors, for both video and digital audio signals. Copies of AES-3id—1995 are available for a fee from the Audio Engineering Society in New York. The Society’s phone number is (212) 661-8528.

Sony and Phillips developed a standard for consumer-grade equipment. S/P DIF (Sony/Phillips Digital Interface Format) defines an unbalanced digital connection. S/P DIF and AES3 signals do not mix in all cases. An AES/EBU input will accept a S/P DIF output, but a S/P DIF input will not accept an AES/EBU output without an interface to correct the differences in the data formats and wiring. Only equipment with AES3 inputs and outputs should be used.

S/P DIF specifies the old RCA phono pin connector; 75 Ω coax works well as the conductor. The problem of yet another connector and cable type in the studio proves reason enough to standardize on AES3 digital equipment in the station.

The AES/EBU (AES3) standard supports 16, 20, or 24 bit quantization formats. The 20 bit audio sounds better than 16 bit; 24 bit offers improved performance over a 20 bit digital signal. When audio is digitized, sine waves are changed into vertical samples based on time. They also get sampled horizontally based on amplitude. Amplitude resolution is determined by the quantization format, the bit rate. Each bit communicates 6 dB of amplitude information.

In theory, the 16 bit audio of a CD can communicate up to 96 dB of amplitude change (6 dB × 16 bits = 96 dB). The 24 bit digital audio can reproduce a theoretical dynamic range of 144 dB (6 dB × 24 bits = 144 dB). In the real world, digital audio equipment achieves performance less than theoretically possible. The 16 bit audio typically renders 90 dB of dynamic range due to the limitations of the analog-to-digital converters and digital-to-analog converters.

An increase in dynamic range means a lower noise floor. Note the 48 dB reduction in the noise floor when comparing 16 bit digital audio with a 24 bit signal. Assuming a clip level of +24 dBu, 16 bit digital audio equipment can theoretically reproduce a minimum signal level of -72 dBu. Twenty bit digital audio has the potential of reproducing a minimum signal of -120 dBu. Figure 8 illustrates the difference in possible dynamic range between 24, 20, and 16 bit digital audio.

AES3 standardizes sample rates of 32.0, 44.1, and 48.0 kHz. The digital recording process limits the maxi-

imum recordable audio frequency to one-half the sample rate. Each cycle of a sine wave must be sampled at least twice during a cycle. If not sampled once during its positive peak and once on its negative peak, the sound cannot be accurately sampled and converted to digital audio.

A sample rate of 44.1 kHz permits audio bandwidth up to 22 kHz. The sample rate of 48.0 kHz pushes the upper limit to 24 kHz. Equipment using a 32 kHz sample rate chokes off the audio at 16 kHz but consumes less bandwidth and/or hard-disk space.

Today the existence of three sample rates hinders digital broadcasting. Compact disks came out of the gate with the sample rate of 44.1 kHz. This single-standard sample rate crossed all brand names and entrenched itself as *the* sample rate for CD work. Recording studios adopted the sample rate of 48.0 kHz in an effort to achieve better fidelity. Digital audio workstation and digital audio storage equipment manufacturers shifted downward to 32.0 kHz to conserve disk space because FM radio passes only 15 kHz of audio bandwidth.

No manufacturers of digital broadcast equipment currently exhibit any interest in trying to develop a standard sample rate frequency. They support all three sample rates, driving up the cost of digital equipment. The issue of sample rate frequency remains as another roadblock slowing the progress of the digital output of a CD player from directly reaching the FM digital exciter.

As digital audio consoles approach the threshold of the control room, the engineer wishing to “go digital” in the studio has a problem. The digital audio of different sample rates cannot be combined even though all the sources adhere to the AES/EBU standard. Somewhere in the studio system sample rate conversion must take place. The 44.1 kHz sample rate of the CD must switch to the 48.0 kHz sample rate of the console, which must convert to the 32 kHz sample rate of the digital STL.

One console manufacturer offers input modules that match the sample rate of input audio to that of the console. Its solution to the problem is sample rate conversion on each input. A standard sample rate for all broadcast applications offers a better solution, but that has not yet happened. Careful planning during equipment selection remains the best defense for minimizing potential problems.

Even after the sample rate problem has been addressed, one more problem surfaces when a digital console arrives in the on-air studio. When mixing two digital audio sources of the same sample rate, their clocks must be synchronized. If one digital audio source runs at 48,000.00 Hz and is mixed with a second signal running at 48,000.02 Hz, and the internal clocks run separately, digital “train wrecks” occur.

The results pollute the combined audio with clicks and pops. A digital master clock provides a workable solution. A single timing signal connected to all digital audio equipment in the station synchronizes everything in frequency as well as phase.

This plan works when all digital equipment in the studio offers clock input connections. However, not all digital equipment is designed with this feature. Older digital equipment featured a “word clock,” which ran at the

Figure 8. Higher quantization rates (bit rates) result in a wider dynamic range for digital audio. 24 bit audio provides a theoretical dynamic range of 144 dB for a 48 dB lower noise floor over 16 bit audio. This also means a 48 dB lower noise floor.

sample rate. Newer equipment locks internal clocks together with the AES standard digital audio reference signal (DARS), which is an AES3 digital signal without audio. The digital equipment manuals must be checked to verify which systems will operate in a facility.

Three more pieces of the AES/EBU puzzle remain. The first bit of the digital signal indicates whether the output signal originates from consumer-grade equipment or professional gear. If the first bit of the first 8 bit word is a 0, the source audio is from consumer equipment. Professional equipment identifies itself as such with a 1. Many professional recorders will not accept a signal from semi-professional equipment.

Digital audio may also include a consumer copyright protection bit. The serial copy management system (SCMS) prevents illegal digital copying. Digital audio also includes a parity checksum for the channel status data. The cyclic redundancy check (CRC) error light on the recorder may indicate a problem with the recording configuration.

Unfortunately the engineer will need a digital audio analyzer to identify these situations correctly. The fixes require a means of real-time editing of the channel status bits or reprogramming of the equipment.

System designers greatly increase the storage capacity of hard disks by using the bit rate reduction techniques of ISO MPEG, Audio Processing Technology's apt-X, Musicam, the international telephone ITU G.722 standard, Dolby's AC-2 or AC-3. Without bit rate reduction, 1 min of stereo audio consumes about 10 MB (megabytes) of hard-drive space. With a 4:1 bit rate reduction the same 10 MB could store 4 minutes of audio.

Early algorithms accomplished bit rate reduction by transmitting only the difference between samples. These systems gained a 2:1 reduction in digital data, but were nondestructive. The algorithm restored the original audio signal when decoded.

Lossy bit rate reduction discards bits not needed because the human ear would not hear the sound reproduced by the bit when played back. The sound would be either too low in volume to be heard, or covered up by a louder sound. The data-compressed information reproduces an audio signal almost indistinguishable from the original to the critical ear. This destructive process changes the source audio forever. After the data are compressed, the exact original audio can never be recovered. Huge gains in storage space and transmission bandwidth requirements justify the use of these algorithms.

The MPEG compression algorithm is the audio portion of a video compression system standardized by the ISO. The facts that (1) it is accepted worldwide and (2) it is attached to a video compression scheme ensure that it will be here for a long time. MPEG offers three levels of signal quality identified as Audio Layers I, II, and III. The complexity of the system, including hardware, rises and the quality of the audio improves with each advancing layer. Audio Layer I provides transparent 20 kHz audio quality at a compression ratio of 4:1. Audio Layer II achieves the same results but at a ratio of 6:1. Audio Layer III operates as high as 24:1.

Musicam USA's compression system is compatible with MPEG Audio Layer II. Musicam chops the 20 kHz audio

spectrum into bands of 750 kHz. It then discards any unnecessary bits in each band. The Musicam system represents a compromise between transparent re-creation of compressed audio and complexity of the processing algorithm. Processing delays increase with complexity of any system's algorithm.

Bit rate reduction serves to allow digitized audio transmission over limited bandwidth media. Early digital STL systems use bit rate reduction to squeeze two channels of 15 kHz audio and remote control data into the 500 kHz bandwidths of the 950 MHz spectrum. Remember that bit rate reduction algorithms throw away part of the digitized audio, preventing further audio processing. All audio compression and limiting must happen before the program audio passes through a digital STL that uses bit rate reduction. Two digital STL systems that do not use audio compression algorithms were introduced in 1997. These solve the problem of bit rate reduction and should become the systems of choice.

T1 digital telephone systems offer enough bandwidth to allow uncompressed audio to reach the transmitter. A T1 STL system offers flexibility in the location of audio processors. Multiband compression may be applied at the studio, and final limiting accomplished at the transmitter site. T1 systems also solve the problem of the congested 950 MHz spectrum.

Technology changes rapidly. An engineer should carefully study current technology as applied to the products available before making an investment in digital equipment.

8.2. Digital Audio Storage Systems

Digital audio storage offers the most rapidly developing technology in the broadcast audio field. Its acceptance by the industry became apparent in 1995; both Ampex and 3M announced their exit from the magnetic tape business. The magnitude of this development becomes evident after considering that Ampex pioneered magnetic tape recording in the United States. Working with development money provided by Bing Crosby, it perfected the process that was first used on Crosby's radio show. Digital recording media now include magnetic tape, hard drives, high-density floppy disks and magneto-optical (MO) disks.

Designed for the consumer market, the rotating head digital audio tape (DAT) machine became widely accepted by broadcasters. This format uses a rotating head much like a videocassette recorder (VCR), and records on a cartridge tape. DAT cartridges offer recording times of 60, 90, and 120 minutes. The cartridge design prevents razor blade editing. Professional models feature fast cueing, instant starts, remote control, and time-code compatibility. DAT machines offer broadcasters the ability to record live events, concerts, and network feeds in the digital domain without increasing noise and sacrificing dynamic range.

Stations using multitrack consoles for production work may take advantage of eight-track DAT recorders. Like their smaller cousins, the eight-track models use a rotating head but record on VHS videotape cartridges. These DAT recorders excel in recording live concerts and storing multitrack production work.

Smaller facilities may opt for the digital cart machines coming on the market. These record to super-high-density floppy disks, minidisks, or MO disks. They offer the advantages of low-noise digital audio reproduction and the elimination of head alignment woes and maintenance associated with analog cart machines. But it leaves the disk jockey still sorting and slamming plastic devices into slots and pushing start buttons.

Note, however, that there is still a need for human intervention for trouble shooting and problem solving.

If a station is planning a transition to “digital,” why handle the storage medium at all? Digital audio storage systems using hard drives as the storage medium threaten to oust cart machines and carts of all types from the control room. Hard-drive systems now offer the capability to store and play all the station’s commercial library plus its program material. Multiple hard drives provide the necessary “crash protection.” The systems can automatically record network feeds for delayed broadcast, eliminating the need for reel-to-reel recorders. One large system offers simultaneous access to program audio by seven studios.

8.3. Digital Editing and Workstations

The digital audio workstation benefits the broadcast station with faster and more creative production, using a process quite similar to the way word processors edit written text. Digital workstation systems store multiple audio tracks on hard disk and allow editing in random access memory (RAM). Two or more analog input channels (through A/D converters) and direct digital inputs receive the incoming audio. Options allow analog or digital outputs. They allow editing tracks individually and produce a finished product by using keyboard and scrub wheel rather than grease pencil and razor blade. The audio waveform of each track crawls across a screen allowing visual as well as audible cueing and editing.

To produce a spot with a digital audio workstation, the operator records the audio tracks and music beds in the system memory, commands the workstation to move component sounds, adjusts timing, edits tracks, and finally completes a stereo mix. Unlike razor-blade editing with analog tape, the software process preserves the original material. Correcting mistakes and editing experiments become child’s play with the Undo key found on most editors.

Workstation editors most closely emulating the operation of a reel-to-reel recorder get production work flowing quickly with minimal training time. An accurate scrub wheel operation speeds the work of a producer tightening loose voice tracks and other tricky edits. Scrub audio sounds exactly like that heard when manually rocking tape back and forth across the playback head of an analog tape deck.

A good display shows the audio waveform of all tracks on the screen simultaneously. Most editors show a vertical cursor line that moves across a stationary audio waveform as the editor reproduces the audio. This display mode consumes fewer computer resources than a system that shows the audio waveform crawling across a stationary cursor

because the screen is not continually requiring refreshment. Some audio producers favor a display that depicts the waveform moving across a stationary cursor as the screen more accurately represents the operation of a reel-to-reel machine where the tape travels left to right across the stationary playback head.

Creative engineers can assemble a two-track audio workstation with a Pentium PC, a good sound card, and editing software. The system should include as large a hard drive as possible; the source material plus overhead consumes about 12 MB/min for stereo audio. A 1-MB drive handles most two-track production tasks. The more elaborate systems include mixing capabilities providing an all-in-one approach for production work.

9. AUDIO PROCESSING EQUIPMENT

9.1. Compressors

All the hype whirling about concerning the on-air processing market simply clouds the central issue of reducing dynamic range of the source material. The difference between the loudest sound and the quietest equals the dynamic range. Audio compressors take large, rapidly rising audio voltages and make medium-sized, slowly rising audio voltages. The goal remains simple: reducing the dynamic range and increase the average modulation level of the transmitter.

The industry complicated matters when, in the 1960s, one engineer found a way to crank the average modulation level up 3 dB higher than the station across town. The resulting “modulation wars” in the AM band trashed audio quality and drove listeners to FM. Then Mike Dorrrough showed us how to crunch FM audio without sounding quite as bad. Bob Orban next combined the stereo generator with Dorrrough’s multiband limiter and other than doing all this digitally, not much has happened since.

If the output of a CD player were connected directly to the audio inputs of a transmitter, the wide dynamic range would prevent the average modulation from reaching more than 50–60%. The station would disappear from the band among those processing their audio by today’s aggressive standards. An AM station operating this way would sacrifice a part of its coverage area. An audio compressor reduces the dynamic range to a more practical spread and holds the modulation level at a much higher value.

Here is how it works. A threshold control defines the point where the compressor starts to attack a rising audio voltage. If the compressor’s threshold control instructs it to attack a voltage at -20 dB, the compressor will attempt to hold down a rising audio signal after it rises above the -20 dB level. A signal below -20 dB will pass through the compressor unscathed.

After the audio passes the threshold (-20 dB), the ratio control instructs the compressor how serious it is about restricting the level of the audio voltage. A 5 : 1 ratio limits an audio signal that has risen 5 dB to an increase of only 1 dB at the compressor output. Using this example, an input signal of -20 dB would appear at the compressor output at -20 dB; no compression would take place. An input

signal of -15 dB (5 dB higher) would show up at the output at a level of -19 dB (1 dB higher).

Low ratios induce less compression for any given input above the threshold. When the user increases the ratio, the compressor aggressively attacks the dynamic range of the source material. The threshold presents more of a “brickwall” to the incoming audio as the operator dials in ratios of 10:1 and higher. Premium-quality compressors offer two thresholds with an independent ratio control attached to each threshold.

This type of compressor moderately squeezes a rising signal of low level as it crosses the first threshold level. Should the signal continue to rise above the second threshold, more aggressive compression attacks the signal. A compression ratio of 20:1 used above the second threshold provides the peak-limiting required to properly modulate a transmitter.

The compressor’s “knee” is the point where the incoming audio signal rises above the threshold and the compression action begins. A “hard-knee” compressor engages the compression precisely at the exact threshold value with the exact ratio. A good ear hears the full amount of processing kick in as the signal rises above the threshold. If the compressor smoothes the transition with a gradual, rounded transition point at the threshold, the processing action engages slowly over about a 6 dB range. The transition into processing is less apparent as the compressor begins to act on the rising audio signal. This describes a “soft-knee” compressor. The old tube-type compressors, the UREI LA-2 for example, remain popular because of the smooth transition through their soft knee.

Release time determines how quickly the compressor releases the compression when a falling voltage drops below the threshold. A slow release time may measure 2.5 s or longer. A fast release time, measured in milliseconds, will release as each low-frequency waveform decays. A high compression ratio coupled with fast release time may result in too much of a good thing.

When more aggressive compression hammers the dynamic range, the normal soft passages in music disappear and the normal voice migrates to a stream of shouted commands. Overcompressed audio becomes irritating over a period of time. Some musical notes can actually be lost. If guitar notes and the beats of a kick drum arrive at the input of a compressor at the same time, the compression required to tame the kick drum will drop the level of the guitar so much that some notes will not be heard.

In the AM modulation wars of the 1960s, Mike Dorrrough recognized this deficiency and split the audio spectrum into three bands. In the discriminate audio processor, the Dorrrough DAP, Dorrrough assigned each band its own compressor. The combined outputs of the compressors reassembled the complete audio spectrum while gaining independent compression for each band. Now the kick drum’s compressor could be stomping 12 dB of compression while the guitar’s band may only receive 3 dB of compression. The listeners no longer missed the rhythm guitar. Thus was born multiband compression.

This all sounds easy. Figuring out the frequencies included in each band made things more complicated. The proper crossover frequencies, the points on the audio

spectrum where bass becomes midrange and midrange becomes treble were elusive and depended on the program material. The crossover frequencies for the relatively narrow AM spectrum were not correct for the 15 kHz FM spectrum.

Also, that each band required different attack and release times. The much shorter waveforms of high frequencies require faster attack than the long waveforms of bass frequencies. Improper attack and release times for adjacent bands results in inconsistent processing in each of the three bands. Release times set too short for the low band will overcompress the bass notes. When the release time for the high-frequency band is set too long, the highs disappear and the station will sound “muddy.”

9.2. Limiters

A peak limiter fits in the program chain just ahead of the transmitter, the stereo generator for FM. The limiter provides a brick wall for any overshoots that the compressor misses. Its sole purpose is to prevent overmodulation of the transmitter.

Limiters used for U.S. FM broadcast include the 75 μ s preemphasis curve that boosts the high frequencies. Other countries may use different preemphasis curves; check the government’s broadcast specifications. FM limiters operate symmetrically; positive and negative peaks receive equal limiting. AM limiters operate asymmetrically. They clamp their negative peaks at 100% modulation while allowing positive peaks to shoot upward to 125%. This maximizes the modulation and output power of the AM transmitter. AM limiters also include the National Radio Standards Committee (NRSC) preemphasis curve and 10 kHz lowpass filter. C-QUAM, AM stereo processing, usually requires an optional circuit board.

Most engineers locate the peak limiter at the transmitter site, feeding its input from the STL output. They leave the multiband compressor at the studio. Leaving the compressor at the studio end also enhances the modulation of a 950 mHz radiolink.

9.3. AGC/Levelers

A novice may confuse an automatic gain control (AGC) amplifier with a compressor. The AGC/leveler is not an audio-processing device. It will not reduce the dynamic range or limit loud audio peaks. The AGC amplifier ensures that the compressor and limiter receive constant input levels.

The AGC operates similarly to a compressor when a signal above its target output range appears at the input. In this case, the AGC amplifier gently pulls the signal level down to the target output level. It is operating like a compressor set with a 2:1 ratio and a slow, 2 min release time.

The AGC amplifier reacts differently when the input signal falls below the target output level. Now it turns up the gain of the low-level signal, bringing it slowly up to the target output range. Compressors cannot accomplish this level correction function.

Changing input levels to a compressor or limiter subjects the program audio to varying amounts of

compression. Audio from a loud source may receive too much compression, creating distortion. If the output of a low-level source is not corrected, it receives little or no compression and sounds weak and thin. Sudden changes in the station’s audio processing irritate listeners.

AGC/levelers provide a safety net for sloppy board operation, the times when the meters remain buried in the red for minutes at a time. Stations employing walkaway operations, where no one sits at the console correcting levels as the automation system switches between sources, benefit greatly from the processing consistency created by an AGC amplifier.

9.4. Equalization

Engineers work nights in anguish maintaining audiofrequency response as “flat” or linear as possible. Program directors toil overtime in anguish producing a “signature” sound for the station. The two professionals butt heads at the equalizer. In the audio processing chain, creative use of an equalizer gives character to the station’s audio. In production, an equalizer routinely cleans hum and hiss from noisy tapes. The production director also creates special effects and unique voice tracks with the help of his or her equalizer.

Low frequencies can be boosted to produce a heavy “thumping” bass and the upper mid-range can be boosted to add brightness. Enhancement of the highs and lows with an equalizer satisfies the desire to make a station sound better to the average nontechnical listener than the competition. Table 2 matches the audio ranges and qualities with the knobs on the equalizer.

Equalizers come in two types. The best known, the graphic equalizer, divides the audio spectrum into a series of bands represented by rotary or slider controls on the front panel. The operator adjusts the controls to affect gain in each particular band. The graphic equalizer with slider controls creates a visual picture of the frequency response curve that is being produced. Nontechnical people find it easy to use because of this design. Nine out of ten program directors prefer a graphic equalizer in the station’s processing chain to tailor the on-air sound.

The parametric equalizer provides more versatility in the hands of a trained operator. A specific frequency can be dialed in with a parametric equalizer for elimination or boosting. A graphic equalizer does not allow this frequency-specific accuracy. The parametric equalizer also allows the adjustment of filter bandwidth or selectivity. A narrow bandwidth can “notch out” a hum or buzz. A wide band-

width produces broad curve to boost or cut an entire band of frequencies. The typical parametric equalizer offers three or four sections covering the entire audio spectrum. Parametrics are considered valuable tools in the production studio.

9.5. Microphone Processors

Stations spend thousands of dollars for processing equipment to compress and equalize their music program material. The studio microphone often suffers from processing neglect although it deserves major attention. Compression, equalization, and “de-essing” of the studio microphone give the on-air talent a chance of competing with the professionally produced program material played on the air. A good microphone processor elevates the local disk jockey closer to the voice quality level of professional voice talent.

Compression reduces the dynamic range of the natural voice, providing more power and punch by raising its average energy; it becomes louder. The added power prevents the voice from being buried by song introductions and music beds. The equalizer provides a means of boosting regions of the voice spectrum that lack natural presence. Male DJs always want a generous boost of low-frequency energy. A “muddy” voice benefits from a boost in “brightness” from the equalizer’s upper midrange (around 2.5 kHz). The de-esser reduces annoying, lisping, spitting “s” sounds. Sibillance problems show up at frequencies between 6 and 7 kHz. The de-esser monitors the energy level in this range and kicks in additional compression to reduce sibillance problems. When adjusted properly, the de-esser will take the edge off a sibillance problem without punishment to the high-end frequency response. A de-esser circuit requires fast attack and release timing and a narrow (less than 0.5 octave) bandwidth.

The properly adjusted combination of 3 dB of compression, a one-octave, 6 dB boost at 125 Hz, and a two-octave, 3 dB boost at around 2.5 kHz from the equalizer can convert any voice to an acceptable quality. Table 3 provides some direction for equalizer adjustments.

Without voice processing on the studio microphone, the station may find itself overprocessing its music while stretching to achieve a suitable amount of processing for the on-air voices. The addition of a microphone processor provides a more balanced processing mix from on-air voices and produced program material. Suddenly the local announcers no longer sound “wimpy” compared with network announcers and production studio voices.

9.6. Noise Reduction Systems

Noise reduction systems minimize source noise from analog audio tape, vinyl records, and remote program unit (RPU) radio links. Dolby and dual-ended systems record encoded audio on tape and decode it to reproduce the original audio with a lower level of system noise.

Audio “companding” (compression/expanding) systems provide another option. During the recording process, the dynamic range of the program material is severely compressed, keeping it further above the noise floor of the recording medium. The process reverses during playback

Table 2. Audio Qualities and their Frequencies

Quality	Audio Frequency Range (Hz)
Subbass	15–65
Bass	65–256
Voice	256–2,048
Upper vocal	2,048–3,750
Presence	3,750–5,000
Sibillance	6,000–7,000
Brilliance	6,500–15,000

Table 3. Vocal Qualities and Frequencies

Audio Frequency Range	Descriptive Quality
75–200 Hz	Rumble, heaviness
200–300 Hz	Bassiness, bigness
400–600 Hz	Warmth, chesty
600–1,000 Hz	Volume, loudness
2–4 kHz	Clarity
3 kHz	Presence, nasal
5–8 kHz	Enunciation, brightness
6–7 kHz	Sibilance
10 kHz +	Mouth and air noise

when the recorded audio is expanded restoring the normal dynamic range. These dual-ended systems provide benefit in audio tape recording but require identical equipment on each end of the record/reproduce process.

Dolby and companding noise reduction systems hide noise. Single-ended systems provide freedom from the encode/decode process by “painting over” noise. These frequency-sensitive gating devices eliminate all audio in certain bands when the signal falls below a fixed threshold. The theory of operation assumes that anything below the threshold must be noise and should be eliminated. Single-ended systems offer a better solution than cutting the frequencies associated with tape hiss with an equalizer. The equalizer also eliminates desirable program material in that spectrum. The noise reduction unit attenuates a part of the audio spectrum only when no significant program material appears in that band.

9.7. Effects Generators

Digital effects generators enable production directors to produce the special effects of phasing, flanging, and echo for creative production. Several effects devices allow easy pitch changes of voice and music for special effects and to compensate for speed adjustments made to time tapes perfectly to 30 or 60 s. When tape speed varies more than 2% or 3%, pitch correction restores normal tone to the voice.

When using reverberation in program material, the amount mixed in should be 20 dB down from normal program level. Otherwise, the effect will be too distracting. When used with compression or limiting, it should be mixed back into the audio chain at the limiter output. This prevents the percentage of the mix from varying with the operation of the compressor/limiter.

10. SUMMARY

This article attempts to describe the state of the art in equipment and standards of engineering practice. A review of previous work on the subject of studio audio for the National Association of Broadcasters, starkly depicted the vast changes in the hardware realm in just 5 short years. Broadcasting technology now provides a digital signal path from the audio source to the transmitter.

The standards, which have served well since the infancy of broadcasting, now fall to new technology.

Digital AES/EBU (AES-3) interface supersedes the “standard” 600 Ω , +4 dB connection between audio equipment. Long-familiar hardware—punch blocks, screw barrier strips, and XLR connectors—make way for DB25s, fiber optic cable, and ISDN.

The broadcast engineer can now build a studio using source material from digital audio storage devices mixed on a totally digital console. The console could become a touch-screen controlled computer. The all-digital processing system has arrived. Some stations have already replaced their 950-mHz STLs with T1 carrier systems. A digital STL that uses no data compression was introduced in 1997. Equalized program telephone lines are on the way out, and 111C repeat coils are obsolete. Digital stereo generators arrived several years ago; an engineer can now buy a digital FM exciter.

Retooling to provide the new technology in hardware challenges the equipment industry. New names are emerging and some of the industry leaders are fading from vogue as they fall behind the pace of changing technology. Pressure will be on broadcast engineers also to educate themselves in order to provide competitive product to their listeners and viewers.

RADIO DIRECTION FINDING

RICHARD L. JOHNSON
 JACKIE E. HIPP
 WILLIAM M. SHERRILL
 Southwest Research Institute
 San Antonio, Texas

Radio direction finding is the technique of measuring radiowave angle of arrival (AoA), as illustrated in Fig. 1. A transmitting antenna radiates radio energy toward the direction finding site. At distances greater than several wavelengths from the transmitting antenna, the radiowave can be represented as a plane wave, with linear contours of constant phase perpendicular to the direction of propagation. Ideally, the radiated energy propagates along the most direct path from the transmitter to the receiver. The receiving system is conventionally called a *direction finder* (DF). Figure 1 shows AoA expressed in terms of an *azimuth* component in the horizontal (x-y) plane and an *elevation* component measured in the vertical plane, relative to the horizon.

A direction finder employs one or more antennas in a DF array, used to detect the incoming radiowave. The out-

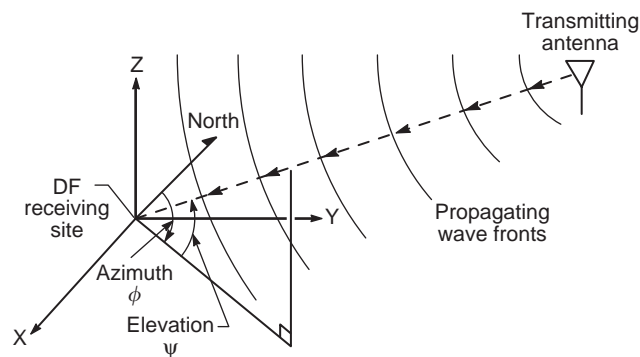

Figure 1. Radiowave received at a direction-finding site. Contours of constant amplitude propagate radially from the transmitting antenna, and the angle of arrival is characterized by azimuth and elevation.

put of each antenna is applied to a radio receiver, and this signal is sampled and supplied to a DF computer processor for determining AoA. The DF processor may either (1) determine the direction of energy flow toward the direction finder, (2) measure the direction of maximum rate of phase change across the DF array, or (3) estimate the velocity vector, normal to the plane-wave fronts. A well-known example of a simple DF system, which is still in use, is a rotatable loop antenna connected to a radio receiver as shown in Fig. 2. AoA is measured by determining the direction of energy flow toward the DF antenna. This is accomplished by rotating the loop for minimum audible output as indicated by the headphones, and thereby placing the null response of the loop on the AoA of the received signal. Thus, the direction to the transmitter is indicated by the broadside angle of the loop. The loop also has a null response on the reciprocal bearing, 180° from the true AoA. This problem of ambiguity can be resolved with an auxiliary "sense antenna."

The advent of radiocommunication in the late 1890s launched the development of DF techniques for navigation and radio transmitter location. Radio navigation and radio location are complementary technologies exploiting a common methodology. For example, signals received at sea from known shore-based radio beacons are used for navigation by *triangulation* to fix the position of a ship (Fig. 3a). Conversely, a network of two or more direction finders at known locations can be used to locate a radio transmitter by triangulation as shown in Fig. 3b.

For location applications, the DF network result is the observed *line of bearing* (LoB) or *bearing* to the transmitter. A LoB is expressed either as the *true bearing*, specifically, an angle measured clockwise from true north, or as a *relative bearing*, which is measured clockwise from a reference direction such as the heading of a mobile DF platform (ship, aircraft, vehicle). True bearings are generally used to locate a radio transmitter on a map.

A major factor affecting DF system performance is the process of *confirming* that each reported bearing is associated with the correct signal. Since there may be many signals on the air with overlapping frequencies, confirmation is sometimes a very difficult task. Often the achievable accuracy of a DF network is determined by the

Figure 2. Rotating simple loop antenna direction-finding system. The headphones are used to detect when the AoA is broadside to the loop and the received signal is minimum.

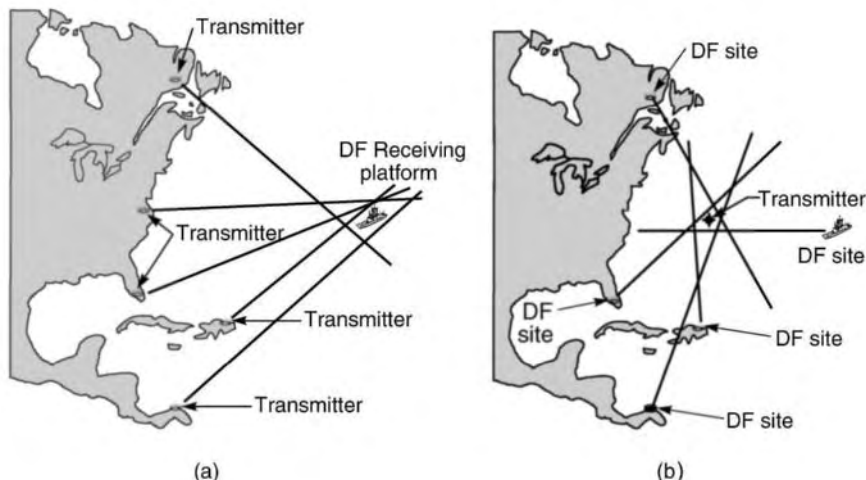

Figure 3. Similarities between radio navigation and DF radio location technology: (a) shipboard navigation technique using five radio beacons for position fixing; (b) radio transmitter location technique with five DF sites.

reliability with which each bearing is confirmed to be associated with the correct signal.

Operational DF measurements are always subject to error, and minimizing DF error is a major consideration in direction finder system design. DF error may be divided into three categories:

1. *Site error* is caused by reradiating structures and ground-plane characteristics at the DF antenna site that distort the arriving wavefronts into nonplanar configurations. Under these conditions the estimated AoA will vary depending on the location of the DF antenna array in the wavefield.
2. *Measurement error* may be caused by imperfections in the DF system instrumentation but is more frequently dominated by perturbed conditions in the received wavefield. Multipath propagation and co-channel interference create a multicomponent wavefield and are common sources of error in DF algorithms that are based on a single-plane-wave model. Multipath occurs when the signal arrives at the DF site via two or more propagation paths. Co-channel interference is caused by other on-the-air signals transmitted at frequencies that overlap the signal of interest.

3. *Propagation error*, the most fundamental source of error, is introduced by the propagation medium, which may deviate the radiowave off the most direct path to the DF receiver. At best, the DF system accurately measures AoA as received at the DF site, and the estimated bearing may not indicate the “true” direction to the transmitter. Propagation error, which is beyond the control of the DF system engineer, imposes a fundamental limit to achievable DF accuracy.

Conventional shipboard DF operations in the high frequency band (2–30 MHz) illustrate all of these DF errors in a single situation (Fig. 4). Signals experience multipath propagation through the ionosphere. Also, the ionosphere introduces propagation error by deviating each of the arriving propagation modes out of the great-circle plane. A conventional single-plane-wave DF algorithm produces DF error by treating the superimposed ionospheric modes as a single plane wave. Finally, the ship’s superstructure introduces additional site error by reradiating the incident waves into the DF array, thus creating a second and more complex source of multipath.

This brief introduction has provided an overview of the science and technology of radio direction finding. For a

Figure 4. Shipboard direction-finding scenario illustrating sources of bearing errors. An error will result because the radio wave is not traveling on a direct path from the transmitter. The presence of multiple signal paths will induce a measurement error due to wave interference, and the metallic structure of the ship will cause errors due to reflections near the receiving antenna.

more thorough overview of the field, the interested reader is referred to Refs. 1–3. An extensive bibliography of direction finding literature is provided in Ref. 4. The following sections discuss various approaches to DF system design. Conventional DF design techniques based on the assumption of a single incident plane-wave signal are considered. The impact of operational conditions on conventional DF system performance is emphasized along with important methods for mitigating site error. Also, modern design techniques are described that are based on the decomposition of multicomponent wavefields. These latter DF techniques are generally referred to as *superresolution methods*. Finally, current trends in DF research are surveyed and performance benefits are assessed.

1. APPLIED DIRECTION-FINDING TECHNOLOGY

A radio direction finding system performs both time and spatial sampling of the field distribution and processes the samples to estimate AoA. A DF system acquires spatial samples through a combination of individual antenna placements and/or antenna patterns. The local description of any spatial field distribution may be estimated from either a set of spatially separated samples or a set of spatial derivatives at a single point in space.

A local description of a field at an arbitrary point \mathbf{r} in a Cartesian coordinate system may be developed by considering a monochromatic plane wave propagating in free space as

$$x(t, \mathbf{r}) = B \exp[j2\pi(f_0 t + \mathbf{k}_0 \cdot \mathbf{r}) + \gamma] \quad (1)$$

where $\mathbf{r} = (r_x, r_y, r_z)$ is the spatial coordinate, B is signal amplitude, f_0 is the frequency of the wave, $\mathbf{k}_0 = \mathbf{v}f_0/|\mathbf{v}|^2$ is the wavenumber that is a function of the scalar frequency and \mathbf{v} is the vector velocity of propagation (typically assumed to be the speed of light in free space), and γ is a random phase that is uniformly distributed over $[0, 2\pi]$. The AoA information is contained in the $2\pi\mathbf{k}_0 \cdot \mathbf{r}$ phase term and is given as

$$\begin{aligned} 2\pi\mathbf{k}_0 \cdot \mathbf{r} &= \beta(r_x \cos \varphi \cos \psi + r_y \sin \varphi \cos \psi + r_z \sin \psi) \\ \beta &= 2\pi|\mathbf{k}_0| = 2\pi/\lambda_0 \\ \lambda_0 &= \text{wavelength} \\ \varphi &= \text{azimuth AoA} \\ \psi &= \text{elevation AoA} \end{aligned} \quad (2)$$

If it is assumed that there are M antennas in the array, then a simultaneous sampling of the output at each antenna may be expressed as a column vector $\mathbf{X}(t, \mathbf{r}) = [x_1, \dots, x_M]^T$, where the superscript T denotes the transpose operation. The vector \mathbf{X} is known as an *array snapshot*. If the AoA term in Eq. (1) is separated, then the array snapshot for a single incident signal may be characterized as

$$\mathbf{X}(t, \mathbf{r}) = \mathbf{A}(\mathbf{r})s(t) + \mathbf{N}(t) \quad (3)$$

where $s(t) = B \exp(j2\pi f_0 t + \gamma)$ is the time-varying part of the signal, and the thermal noise in each of the M receiving channels is represented by $\mathbf{N}(t) = [n_1, \dots, n_M]^T$. $\mathbf{A}(\mathbf{r})$ is an $M \times 1$ column vector that represents the antenna array response for a signal arriving from an arbitrary direction (φ, ψ) as

$$\begin{aligned} \mathbf{A}(\mathbf{r}) &= [a_1, \dots, a_M]^T \\ a_i &= \exp(j2\pi\mathbf{k}_0 \cdot \mathbf{r}_i) \end{aligned} \quad (4)$$

for an array of isotropic antennas. The column vector given by Eq. (4) is referred to as the *array-steering vector*. The collection of all array steering vectors as a function of AoA, polarization, and frequency is referred to as the *array manifold*.

Two examples of wavefield sampling are shown in Fig. 5. Figure 5a illustrates an aerial view looking down on the surface of Earth at a single plane wave propagating across a circular array of eight antennas. In this case, the amplitude term B in Eq. (1) is constant throughout the space. The phase term $2\pi(f_0 t + \mathbf{k}_0 \cdot \mathbf{r}) + \gamma$ is illustrated for constant contours of $n\pi$ as a function of \mathbf{r} . The contours plot as parallel straight lines, and AoA is orthogonal to the contours of constant phase. In the example plot of Fig. 5b, it is assumed that four signals are propagating across an interferometer array of seven antennas. Signals of equal amplitude are assumed to be arriving from azimuth and elevation AoAs of $(45^\circ, 15^\circ)$, $(50^\circ, 30^\circ)$, $(60^\circ, 45^\circ)$, and $(45^\circ, 50^\circ)$, respectively. In this case, the amplitude of the composite signal is not constant but varies with \mathbf{r} . The dark contours illustrate those regions where the composite amplitude exceeds a normalized threshold of 0.95 units. The thin lines are contours of constant phase showing a somewhat distorted pattern. Clearly, the antenna array is not able to adequately sample all the features of the spatial interference pattern, and a plane-wave solution will incur multipath error; decomposing the wavefield into its individual components is required for a complete DF solution.

The processing objective of radio direction finding is to determine a unique AoA that is consistent with the set of data measured on the array. The key to this process is a knowledge of the array manifold *that includes site effects of the operational environment*. In the most general form, the bearing estimation process requires an iterative comparison between the observed data and the array manifold for every possible combination of polarization and AoA.

The remainder of this section describes DF techniques that progress from simple closed-form solutions (where stringent constraints apply to the antenna patterns, array geometry, local scattering environment, and number of simultaneous signals), to more general calibration-based DF processing algorithms, and finally to DF methods that decompose multisignal wavefields.

1.1. Single-Plane-Wave Direction Finding

1.1.1. Direction Finding in the Absence of Site Effects. Traditional DF techniques assume a single uniform plane wave incident on the DF antenna array. These DF techniques require noninvasive electromagnetic field measurements across a region in space in which the wavefront must maintain its properties as a uniform plane wave.

Figure 5. Contrasting single and multiple plane-wave fields incident on DF arrays: (a) single plane wave incident on a circular array of antennas—amplitude is everywhere constant and contours of constant phase are parallel straight lines; (b) multiple plane waves incident on orthogonal baseline interferometer array—contours of constant amplitude and phase are distorted. (Contour plot provided by D. N. Travers.)

This requirement imposes stringent constraints on the installation site, on the selection of the antenna elements, on the array geometry, and in some cases on the class of signals against which the system can operate. The requirement that the system be noninvasive demands that (1) no antenna element within the array perturbs the response characteristics of any other antenna element (i.e., mutual coupling must be negligible) and (2) the array of antennas must be installed in a region that is sufficiently separated from structures that would disturb the planarity property of the propagating wave. The selection of array geometry, choice of antenna elements, and site selection are all design factors that influence the simplicity of the DF process and system performance for various signal conditions [signal-to-noise ratio (SNR), polarization, elevation, etc.].

If the noninvasive constraints are satisfied and simple antenna elements are deployed in a favorable array geometry, then the characteristic response of the system (array manifold) may be analytically predicted as a function of AoA and polarization. In this case, AOA may be calculated by closed-form analytic solution, thus avoiding the more general requirement for an iterative search. For example, solution of Eq. (2) for phase measurements made among identical elements in a circularly disposed antenna array (CDAA) produces an estimate of AoA using a closed-form arctangent solution. Many CDAA closed-form processing techniques relax the mutual coupling constraint among the antenna elements, provided array rotational symmetry is preserved.

Table 1 lists eleven examples of traditional DF systems that are based on the assumption of a single uniform plane wave incident on the antenna array. The table summarizes antenna array configuration, basis for AoA determination, and primary advantages and disadvantages, and

provides literature references to more detailed descriptions. Table 2 illustrates the corresponding antenna array geometries and analytic processing algorithms associated with the eleven examples of Table 1. DF results are derived from solutions of Eqs. (1) and (2) with appropriate modifications to account for antenna patterns and array geometry.

Under more general conditions, it may not be possible or desirable to impose the restrictive design constraints that are essential for traditional DF techniques. Under more general installation conditions, arbitrary and diverse antenna elements that experience mutual coupling are installed in irregular array geometries (sometimes dictated by the site) on a location that distorts the characteristics of the incident uniform plane wave. Under these conditions, the DF process must be generalized to determine AoA by performing an iterative comparison between the observed response vector and the array manifold. Further, calibration measurements to determine installed antenna response patterns are required to characterize the array manifold as a function of AoA, frequency, and polarization. DF calibration and its application to iterative DF processing are discussed in the next section.

1.1.2. DF under Conditions of Site Interaction. The previous discussion focused on DF systems that were isolated from electrically conducting structures, and each antenna element within the array was excited by a single, uniform plane wave. However, an incident wave induces currents on conducting structures in the vicinity of the array, and these induced currents become sources of secondary radiation that also couple into the DF antennas. In the presence of conducting structures, DF antennas experience phase and amplitude perturbations that distort their ideal

Table 1. Examples of Traditional DF Systems

DF System	Typical Array Description ^a	Basis of Operation	Primary Advantages	Primary Limitations	Ref.
Rotatable loop	Single, rotatable loop	Determines orientation of horizontal component of curl of electric field vector	Simple processing, small antenna size	Polarization error	5
Crossed loops	Orthogonal pair of fixed, horizontal-axis loops				
Rotatable H-Adcock	Pair of identical, vertical electric dipoles, differentially connected	Responds to horizontal spatial derivatives of vertical electric field vector	Avoids polarization error by responding only to vertical polarization	Reduced sensitivity over loop	6
Four-element Adcock array	Four element, mast-mounted array of vertical electric dipoles, differential connection of diametrically opposite element pairs				
Spinning spaced loop	Coaxial pair of identical loops, differentially connected	Responds to horizontal spatial derivatives of horizontal magnetic field vector	Responsive to all polarizations, without polarization error	Reduced sensitivity over loop	7,8
Fixed, crossed spaced loop	Four, cross-spaced loops				
Phase-sampled linear interferometer	Two linear arrays of identical antenna elements	Measures phase gradient	Reduced noise-induced DF error	Requires large, clear site	9
Phase-sampled pseudo-doppler	CDAA of linear monopoles or dipoles		Phase-only process	Sensitive to phase errors	10
Willenweber	CDAA of multiple vertical elements in presence of cylindrical reflecting screen	Develops high-gain, rotating-beam pattern	High sensitivity, good interference rejection	Requires large, clear site.	11
Amplitude mode	CDAA of identical antenna elements	Develops various orders of spatial derivatives in horizontal plane	Higher-order patterns tend to be less sensitive to site interaction	Higher-order patterns are less sensitive to low-level signals	12
Phase mode	CDAA of identical antenna elements	Develops various orders of spatial derivatives in horizontal plane	DF processing reduces to measuring a phase difference	Directly sensitive to phase errors	12

^aSee Table 2 for array geometry.

patterns. If one assumes ideal array patterns, these distortions result in erroneous DF estimates. To the extent that the structures remain stationary, the distorted antenna patterns and the erroneous DF estimates are repeatable functions of the incident signal AoA, polarization, and frequency. This repeatable characteristic provides the basis for using calibration measurements to improve DF performance under conditions of stationary site interaction.

Calibration measurements to accommodate site interaction can be performed at either of two levels: (1) measurement of AoA error correction values or (2) measurement of installed antenna response patterns. The application and effectiveness of these two basic approach-

es for DF operation in the presence of site interaction are the focus of the following paragraphs. Under either scenario, the basic procedure for performing the calibration is to record the appropriate measurement from the *installed* DF system while exposing it to a controlled (calibration) incident plane wave under every appropriate combination of signal parameter (i.e., azimuth, elevation, polarization, and/or frequency).

1.1.2.1. Calibration for AoA Error Correction. For a low degree of residual site interaction with the DF antennas, moderate pattern distortion and moderate DF error exist. In this case, calibration for AoA error correction is effective. One conventional approach for reducing AoA er-

Table 2. Traditional DF Array Geometries and Algorithms

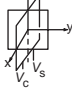

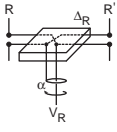

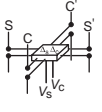

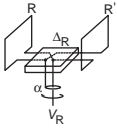

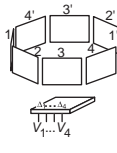

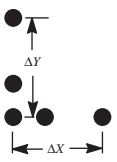

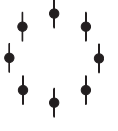

DF System	Typical Array Configuration	DF Algorithm (ϕ = Azimuth AoA, Ψ = Elevation AoA)
Rotatable loop		Operator monitors both the loop response V_R and the loop orientation α while rotating the loop to identify the response null from a vertical polarization response pattern described by $V_R(\alpha) \propto \sin(\phi - \alpha)$
Crossed simple-loops		$\phi = \tan^{-1} \frac{V_S}{V_C}$
Rotatable H-Adcock		Operator monitors both the H-Adcock response V_R and the azimuth orientation α of the H-Adcock array while rotating the array to identify the response null from a response pattern described by $V_R(\alpha) \propto \sin(\phi - \alpha)$
Four-element Adcock array		$\phi = \tan^{-1} \frac{V_S}{V_C}$
Spinning spaced loop		Operator monitors both the spaced-loop response V_R and the orientation α of the spaced-loop array while rotating the array to identify the stable response null from a response pattern described by $V_R(\alpha) \propto [E_H \sin \Psi \sin(\phi - \alpha) - E_V \cos(\phi - \alpha)] \cos \Psi \sin(\phi - \alpha)$ where E_V and E_H are respectively the vertically and horizontally polarized components of the incident electric field
Fixed, cross-spaced loop (four-spaced loops illustrated)		$A_0 = (V_1 + V_2 + V_3 + V_4)/4$ $A_2 = (V_1 - V_3)/2$ $B_2 = (V_2 - V_4)/2$ $D = \pm(A_2^2 + B_2^2 - A_0^2)^{1/2}$ $S_2 = (A_2 D + B_2 A_0)/(A_0^2 + D^2)$ $C_2 = -(A_2 A_0 - B_2 D)/(A_0^2 + D^2)$ $\phi = 1/2 \tan^{-1}(S_2/C_2)$
Phase-sampled linear interferometer		Use unambiguous phase measurements from short baselines to resolve the ambiguities in the phases $\Delta\Phi_x$ and $\Delta\Phi_y$ measured across the two long baselines ΔX and ΔY ; use the resolved phase measurements $\Delta\Phi_x$ and $\Delta\Phi_y$ to estimate the azimuth and elevation AoA
Phase-sampled pseudodoppler		Resolve the ambiguous phase measurements to assure that phase differences between adjacent elements remain less than 180° in magnitude; compute the Fourier series coefficients A_1 and B_1 for the first harmonic of the resolved phase progression around the circle; solve for the azimuth AoA: $\phi = \tan^{-1}(B_1/A_1)$
Wullenweber		Develop a pair of rotating high-gain beams to produce (1) a rotating-beam pattern having a deep pattern null in the steering direction and (2) a rotating-beam pattern having a high-gain pattern maximum in the steering direction
Amplitude mode		Combine every individual response v_n from CDAA element located at orientation α_n to develop responses proportional to the sine/cosine Fourier series coefficients A_m and B_m for the m th harmonic of the directional response around the array:

Table 2. (Continued).

DF System	Typical Array Configuration	DF Algorithm (ϕ = Azimuth AoA, Ψ = Elevation AoA)
Phase mode		$A_m = \sum v_n \cos(m\alpha_n)$ $B_m = \sum v_n \sin(m\alpha_n)$ <p>Calculate the unambiguous azimuth AoA using two adjacent modes:</p> $\phi = \tan^{-1} \left(\frac{B_{m+1}}{A_{m+1}} \right) - \tan^{-1} \left(\frac{B_m}{A_m} \right) \text{ for } m \geq 0$ <p>In the absence of intrinsic polarization error, an ambiguous AoA may be calculated from a single mode as</p> $\phi = \frac{1}{m} \tan^{-1} \left(\frac{B_m}{A_m} \right) + \frac{\pi}{m}, \quad i = 0, 1, \dots, m \text{ for } m > 0.$ <p>Develop response proportional to the exponential Fourier series coefficients a_m for the mth harmonic of the directional response around the array:</p> $a_m = \sum v_n e^{-jm\alpha_n}$ <p>The azimuth AoA is estimated as the phase difference between the responses of two adjacent phase mode responses:</p> $\phi = \Phi(a_m) - \Phi(a_{m-1})$

rors in DF performance is to start with a carefully controlled site in which the DF array is removed as far as practical from perturbing structures. To the extent that this objective can be achieved, AoA errors due to site interaction are minimized. In this situation, a reasonably good AoA approximation is obtained using the single plane wave assumption, and residual AoA error due to site interaction is reduced through a calibration correction curve.

A primary criterion for AoA error correction to be effective is that the curve of corrected bearing versus observed bearing (i.e., the uncorrected AoA estimated by the DF system) is single valued. Figure 6 shows two calibration correction curves illustrating both moderate and severe AoA error. The calibration curve of Fig. 6a shows a moderate case of site interaction and a corresponding single valued AoA correction curve. The calibration curve of Fig. 6b illustrates the impact of severe site interaction and displays reentrant regions. There are two intervals in which one value of observed bearing estimated by the DF system is associated with more than one corrected bearing. Calibration for AoA errors is not effective in reentrant regions, and DF based on an experimentally determined array manifold is generally necessary.

1.1.2.2. Calibration of Antenna Responses. DF is a process that requires a priori knowledge of the installed array steering-vectors. Conventional DF system development assumes a carefully controlled array of antennas having response patterns that are closely approximated by ideal predictions. When the DF array is installed on an adverse

site, antenna patterns can suffer severe distortion from nearby conducting structures. In such cases, required knowledge of the installed array steering vectors must be obtained by measuring antenna responses and storing this information in an array manifold consisting of antenna patterns versus frequency, AoA, and polarization. For ship and aircraft platforms, the installed array steering-vectors may be measured by repeatedly turning the platform in circles to expose the antennas to all possible AoAs from a far-field calibration station transmitting a wide range of signal frequencies. As an alternative, array manifolds have been obtained by performing calibrationlike measurements of antenna responses from scale-model arrays installed on highly detailed miniature models of the platform.

1.1.2.3. Iterative Search DF Techniques. The essential process of any iterative search DF technique is to select the AoA of the calibrated array steering-vector that *best* agrees with the measured array response to the unknown signal. The primary difference between DF iterative search schemes is the criterion for obtaining *best* agreement. A commonly used procedure for iteratively comparing observed array response to the calibrated array response vectors is a beamsteering process that acts as an equivalent bank of matched filters. In this case, *best* agreement is defined in a least-mean-squared error sense.

A digital beamformer may be viewed as a matched filter that processes the observed antenna response to produce a single (scalar) response that is maximum when the preferred direction of the beamformer *best* agrees with

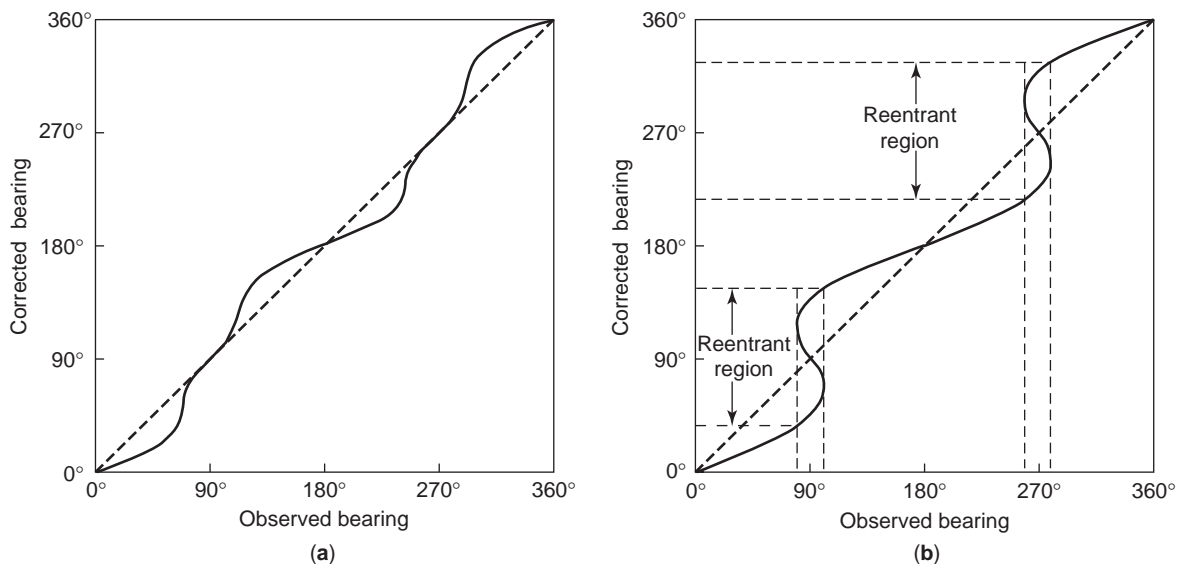

Figure 6. Moderate and severe site interaction AoA calibration curves: (a) moderate site interaction having AoA errors that are correctable; (b) severe site interaction having reentrant regions in which AoA error correction is ambiguous.

the AoA of the signal. Beamsteering DF iteratively processes an observed response vector through a progression of matched filters (viz., array steering vectors), each of which represents a different AoA. Under the constraint of a normalized input vector (i.e., unit norm), the output level of the filter is maximum when excited by a vector that matches the filter parameters. Or, stated another way, maximum output is obtained from the filter whose steering vector AoA *best* agrees with the bearing of the observed signal. In this manner, the process scans (or steers) a simulated beam over all possible AoAs, searching for the steering direction that maximizes the beamformer response.

The beam steered iterative process may be characterized mathematically by considering an array manifold of L steering vectors for a particular frequency. The array manifold is the set of array steering vectors \mathbf{A}_i for $i = 1, L$. This implies that the DF system was calibrated at L bearings in the interval $[0^\circ, 360^\circ]$. If $\hat{\mathbf{X}}$ denotes the observed array response vector for a signal of interest, then the output y_i of each matched filter is given as

$$y_i = |\mathbf{A}_i^H \hat{\mathbf{X}}|, \quad i = 1, L \tag{5}$$

where H denotes the Hermitian or conjugate transpose operation. The *best* AoA estimate is obtained when y_i is a maximum. A typical plot of y is shown in Fig. 7. In this illustration, $L = 25$, and the AoA estimate is 195° corresponding to the maximum value associated with the array steering vector at y_{14} . This process results in an AoA estimate that is *best* in a least squared (vector match) error sense.

Three areas of particular importance that impact the performance of DF systems which are based on iterative search techniques are (1) antenna array design, (2) adequacy of calibration, and (3) polarization effects. Antenna

array design critically influences the pattern of the steerable beam. The characteristics of the steerable beam are determined by the geometry of the array, the intrinsic element patterns, and the number of antennas in the array. Of primary concern in the design of the steerable beam pattern is the beamwidth of the mainlobe and relative level of the sidelobes.

Beamsteering DF system performance is also controlled by the accuracy and completeness of the calibration process used to characterize the array manifold. To obtain robust maxima in the matched-filtering process, the array manifold should be acquired at high SNR to

Figure 7. Beamsteered iterative search indicating a maximum when steering angle matches AoA of arriving signal.

minimize the possibility of contaminated data. The calibration data must be measured in AoA increments that permit accurate interpolation.

The array manifold varies not only with AoA but also with signal polarization. Under arbitrary polarization conditions, the steering vector must be adjusted to match the polarization *and* the AoA of the incident signal. For arbitrary polarization applications, the array manifold at each steering direction must consist of a *pair* of steering vectors for two different polarizations, for instance, $\mathbf{A}_V(\varphi, \psi)$ and $\mathbf{A}_H(\varphi, \psi)$ for vertical and horizontal polarization. The additional maximization step required by the polarization extension of beamsteering DF at each bearing is to maximize the beamformer response over all possible linear combinations of $\mathbf{A}_V(\varphi, \psi)$ and $\mathbf{A}_H(\varphi, \psi)$. The matched filter thus becomes a digital beamformer that processes the observed antenna response producing a single (scalar) response that is maximum when the steered direction of the beamformer matches the AoA of the received signal.

1.2. DF Error Mitigation

There are a number of sources of error in radio direction finding, and an exhaustive discussion is well beyond the scope of this survey; however, there are three categories common to all DF systems: (1) site errors, (2) measurement errors, and (3) propagation errors. These are considered in the following discussion.

1.2.1. Site Errors. The antenna array is generally designed to operate on a site that is clear of obstructions and reradiating structures. As discussed in the previous section, array calibration is generally used to mitigate site error in those cases where the DF antenna must operate in a cluttered environment. The concern in this section is selecting a site that least perturbs the incident signal.

Generally, DF systems are deployed on level, unobstructed terrain where the ground dielectric constant and conductivity are reasonably uniform within 10–20 wavelengths of the antenna array. Abrupt discontinuities in the electrical properties of the terrain such as nearby rivers, lakes, or coastlines should be avoided. Also, DF sites in the vicinity of rock or mineral outcroppings are undesirable. Abrupt changes in terrain topology such as nearby mountains, high cliffs, or deep ravines should be avoided.

In addition to selection of natural features, proximity to manmade reradiating structures should also be considered. The DF site should be clear of aboveground conductors such as utility lines and wire fences. The site should not have buried conductors beneath the antenna array such as pipelines or utility distribution lines. The site should be clear of tall structures such as buildings, bridges, or water towers.

It is rarely possible to achieve all of these conditions at a DF site. Generally, there are a number of other antennas deployed at a DF site, as well as buildings and facilities that support other signal intelligence-gathering activities. In practice, the DF system engineer attempts to locate the antenna array on a site that contains the *fewest* perturbing factors.

1.2.2. Measurement Errors. Leaving aside instrumental accuracy and resolution determined by SNR, significant DF measurement errors are caused by multipath and co-channel wave interference, which corrupt the planarity of an incident wavefront. Two approaches for mitigating measurement errors are (1) acquire data under favorable conditions and exclude corrupted data, and (2) extract the desired signal from the interference.

The first class of techniques includes wavefront tests that determine whether a single plane wave is present or if the wavefield is corrupted by interference. A test that has been used in CDAA systems is to compare the array scan of amplitude versus azimuth with an ideal sum or difference array response [1]. In the case of the sumbeam response, one tests for a symmetric mainlobe having an expected width depending on frequency. When this condition is satisfied, it is assumed that a single plane wave is present and the bearing data are accepted; otherwise, the bearing data are rejected. Another test which has been used successfully in interferometer systems is that of a linear phase progression across the array [12]. If the wavefield consists of a single planewave, then the relative phase between separated antennas is linearly dependent on distance. In the presence of wave interference, this condition is seldom satisfied.

The second class of techniques includes Fourier analysis [fast Fourier transform (FFT)] methods that decompose the received signal into highly resolved spectral bins. In many cases, interference due to other on-the-air signals may be separated from the desired signal through a difference in spectral occupancy. In this situation, accurate DF results may be obtained by DF processing each spectral bin occupied by the signal of interest and ignoring the spectral bins corrupted by the interfering signal. Another approach is to use the superresolution techniques described in the next section. These techniques decompose the wavefield into its constituent components and permit accurate DF for each component of the wavefield.

1.2.3. Propagation Errors. DF error caused by propagation off the great-circle path is essentially beyond the control of the system designer. In this case, the signal arrives at the antenna array from a direction that is not on the direct path to the transmitter. An example is a cellular telephone signal, propagating in a dense urban environment, received after reflection from several buildings. The received AoA may be considerably different from the true bearing to the transmitter. Another example is the refractive error introduced by the ionosphere on HF ionospheric paths [3].

The essential approach to minimize the effect of off-path DF errors is to perform DF on the first arriving signal. One method for implementing this technique is to acquire data on the leading edge of the waveform after a signal OFF-to-ON transition and before the multipath components arrive. Another alternative is to decompose the complex wavefield and identify the first arriving signal through cepstral delay analysis [13]. In both implementations, the intent is to estimate AoA for the first arriving signal on the premise that it will most nearly represent the true bearing to the transmitter.

A technique that has been developed to mitigate off-path errors for HF skywave signals is that of elevation angle discrimination. This technique is based on the premise that signals arriving at higher elevation angles spend more time in the ionosphere and are therefore more prone to off-path refraction than are signals arriving at lower elevation angles. In those cases where multipath propagation is present, the mode arriving at the lower elevation angle produces an azimuth estimate closer to the great circle bearing than a higher angle mode. This situation is almost always true in practice. The limiting case is a surface wave with a simultaneous skywave component over a path at sea. The surface wave invariably produces a more accurate bearing estimate.

1.3. Superresolution Direction-Finding Methods

DF techniques described in the previous section were concerned primarily with system response to a single-component wavefield. In contrast, the problem considered in this section is that of decomposing a multicomponent wavefield. Superresolution methods are particularly attractive for solving the multicomponent problem since the wavefield is generally undersampled in the spatial domain; that is, the dimensions of the antenna array are small relative to the scale of the spatial interference pattern.

An important building block used in superresolution spectrum analysis is the spatial covariance matrix. If the vector \mathbf{X} denotes an array snapshot at time t_0 , then $\mathbf{X}(t_0, \mathbf{r}) = [x(t_0, \mathbf{r}_1), x(t_0, \mathbf{r}_2), \dots, x(t_0, \mathbf{r}_M)]^T$ and for M antennas, the spatial covariance matrix is given as

$$\mathbf{R} = \begin{bmatrix} R(\mathbf{r}_1, \mathbf{r}_1) & R(\mathbf{r}_1, \mathbf{r}_2) & \cdots & R(\mathbf{r}_1, \mathbf{r}_M) \\ R(\mathbf{r}_2, \mathbf{r}_1) & R(\mathbf{r}_2, \mathbf{r}_2) & \cdots & R(\mathbf{r}_2, \mathbf{r}_M) \\ \vdots & \vdots & \ddots & \vdots \\ R(\mathbf{r}_M, \mathbf{r}_1) & R(\mathbf{r}_M, \mathbf{r}_2) & \cdots & R(\mathbf{r}_M, \mathbf{r}_M) \end{bmatrix} \quad (6)$$

$$= E\{\mathbf{X}(t, \mathbf{r})\mathbf{X}^H(t, \mathbf{r})\}$$

where \mathbf{H} is the Hermitian operator and $E\{\cdot\}$ denotes statistical expectation. Each matrix element $R(\mathbf{r}_i, \mathbf{r}_j)$ is the averaged product of the output of the antenna located at point \mathbf{r}_i times the conjugated output of the antenna located at point \mathbf{r}_j .

1.3.1. Subspace-Based Superresolution. A large volume of work has been presented since the early 1980s on superresolution techniques that are based on an eigendecomposition of the spatial covariance matrix. Many modern algorithms have their origin in the early work of Pisarenko [14], which was revived and expanded by Schmidt [15]. Schmidt's *multiple-signal classification* (MUSIC) algorithm is the most widely cited superresolution technique in the present day literature. It has been the springboard for a seemingly endless flow of methods that are variations of the original approach. In this treatise, the original MUSIC algorithm is considered; however, for

an extensive survey of MUSIC-related techniques, the reader is referred to Krim and Viberg [16].

The initial step in the MUSIC algorithm is to solve the following eigenequation

$$\mathbf{R}\mathbf{E} = \lambda\mathbf{E} \quad (7)$$

where \mathbf{R} is the $M \times M$ spatial covariance matrix, λ is an arbitrary eigenvalue, and \mathbf{E} is an arbitrary eigenvector. This formulation implicitly assumes that the noise background is uncorrelated white Gaussian noise. The M eigenvalues may be ordered such that $\lambda_M \geq \lambda_{M-1} \geq \dots \geq \lambda_1$. The corresponding eigenvectors are arranged to form the matrix \mathbf{R}_E :

$$\mathbf{R}_E = [\mathbf{E}_M, \mathbf{E}_{M-1}, \dots, \mathbf{E}_1] \quad (8)$$

A threshold value is determined such that the eigenvalues greater than the threshold are assumed to be associated with eigenvectors residing in the signal subspace. Likewise, eigenvalues that are smaller than the threshold produce eigenvectors that are assumed to be in the noise subspace. If the spatial covariance matrix were $M \times M$ and there were d signals in the wavefield, then the resulting eigenvector matrix would be partitioned such that the first d columns are vectors spanning the signal subspace, and the rightmost $p = (M - d)$ columns are vectors spanning the noise subspace. If the matrix partition corresponding to noise were denoted \mathbf{R}_p , then the MUSIC spectrum would be given by

$$P = (\mathbf{A}^H \mathbf{R}_p \mathbf{R}_p^H \mathbf{A})^{-1} \quad (9)$$

where \mathbf{A} is the $M \times 1$ array-steering vector defined in the previous section. AoA is determined using an approach similar to the technique described in Section 1.1.2.3. A scalar value P is computed using Eq. (9) for each array steering vector \mathbf{A} , and AoA is given by the array steering vector that maximizes P . If multiple signals were present in the incident wavefield, then the MUSIC spectrum would exhibit multiple peaks. This is illustrated in the next section.

1.3.2. Multisignal DF Example. The MUSIC algorithm is capable of simultaneous DF on multiple incident signals. To illustrate the capability, a linear antenna array geometry is considered with two interfering signals incident on the array [17]. The antennas were deployed in a nine-element minimum redundancy array configuration and this provided an equivalent 30-element filled array measurement. The plot of Fig. 8 shows the results obtained for one signal on array endfire at 180° and a second signal at 61° off array boresight at 151° . The signal at 151° also produced a peak at 209° due to the inherent bearing ambiguity present in a linear array. The effect of the end fire grating lobe of the antenna array is evidenced by the relatively broad peak about 180° . The signal arriving at a bearing removed from the endfire condition produced the more robust peaks observed at 151° and 209° . Although the MUSIC algorithm was able to provide DF results for

Figure 8. Two signals incident on a linear antenna array resolved using the MUSIC superresolution algorithm. The signals are received from azimuths of 151° and 180° , and the peak at 209° is an ambiguity. The peak at 180° is somewhat smeared because the AoA of the signal is aligned with the longitudinal axis of the array (or endfire).

both signals, these data clearly indicated that angular resolution becomes poorer for signals arriving from directions near array endfire.

A situation in which the MUSIC algorithm was unable to correctly resolve the two signals is shown in Fig. 9. In this case, the AoA separation of the two signals was 4° , and the AoAs were near array endfire, 160° and 164° respectively. The image solutions were evident at 196° and 200° azimuth. Because the AoAs were close together and near array endfire, the MUSIC algorithm as not able to

Figure 9. Two unresolved signals arriving from azimuths of 160° and 164° on a linear antenna array. The peaks at 196° and 200° are due to ambiguities in the array. In this case the effective aperture of the array was too small to resolve an AoA separation of 4° . A possible solution would be to lengthen the array by adding more antennas.

resolve the two signals. Two peaks were evident in the MUSIC spectrum; however, neither one indicated an AoA correctly associated with an arriving signal. Improved AoA resolution can be realized for signals arriving on or near the boresight of the array (i.e., orthogonal to the array).

1.3.3. Superresolution Implementation Issues. One of the primary difficulties encountered in the implementation of the superresolution techniques is the requirement for a precise characterization of the antenna array response (viz., array manifold). In general, the array manifold must be known for all frequencies, polarizations, and AoAs. In practice, an array deployed on highly conducting soil and on a site free of interacting structures, may be characterized mathematically using ideal antenna responses [17]. However, for antenna arrays deployed on shipboard, airborne, satellite, or other cluttered sites, a mathematical characterization is generally not possible and the array manifold must be determined by calibration using a transmitter at known locations. Because of the highly robust nature of the superresolution techniques, the array calibration must be done in sufficiently close increments of AoA, frequency, polarization, and elevation as to avoid significant interpolation error. These issues were discussed in the previous section relating to array calibration.

Another source of difficulty is detecting the number of signals in the wavefield. One rule of thumb is based on the relative magnitudes of the eigenvalues. Larger eigenvalues are associated with signals and smaller eigenvalues are associated with noise. This process works reasonably well in high-SNR situations, but it is unreliable for low SNR. It has been shown that underestimation of the number of signals results in poor AoA performance [18], and for this reason, system designers generally try to overestimate the number of signals; however, overestimation may be a problem in low-SNR situations because the eigenbased techniques tend to produce extraneous peaks corresponding to the number of estimated signals. A number of techniques for signal detection have been developed and one which continues to be used as a baseline for performance comparisons is the minimum-description-length (MDL) criterion developed by Wax and Kailath [19].

Coherent signal interference causes a difficulty in the application of superresolution technology. The spatial covariance analysis proceeds on the assumption that the matrix elements are a function of the separation between antennas and are not dependent on the location of the antennas within the wavefield. If the signals are incoherent, then the spatial interference pattern will move relative to the antenna array, and the elements of the spatial covariance matrix will depend only on the relative separation between antennas. However, if the signals are coherent, then the spatial interference pattern will be fixed in space and the elements of the spatial covariance matrix will depend on both separation and location of the antennas. In this case, the analysis will fail. To overcome the difficulty caused by coherent interference, Shan et al. [20] have proposed a technique of *spatial smoothing*, which partitions the antenna array into identical subsets and averages

several covariance matrices of reduced size. This effectively moves the array relative to the interference pattern.

In general, the eigendecomposition part of the computation is not a significant burden, but the search for the AoA solution may be computationally intense. In particular, one must perform the matrix multiplication within Eq. (9) for each array steering vector leading to a solution. For an azimuth-only solution, the task is greatly simplified and the computational burden generally depends on the number of antennas in the array. In the case of 2D azimuth-and-elevation AoA solutions, a number of numerical search techniques have been applied, and they all encounter the well-known difficulties of dependence on starting point, convergence to local maxima, and other variables.

It should also be noted that the superresolution techniques require a separate radio receiver connected to each antenna to permit simultaneous sampling of the array. For this reason, superresolution implementations are frequently called N -channel systems. Multiple matched receiver channels are a major cost driver in the implementation of superresolution methods. Generally, the system designer must evaluate hardware cost versus the expected performance improvement as compared with a more conventional DF architecture consisting of a reference receiver connected to one antenna and another receiver that sequences through all the antennas in the array.

2. TRENDS IN DF RESEARCH

Two primary areas of research in the science and technology of radio direction finding are (1) efforts to improve DF system performance in the presence of reradiating structures and (2) investigations to improve the performance of the superresolution wavefield decomposition techniques. The discussion in this section focuses on a representative subset of the many important research efforts under way.

2.1. Ongoing Developments in Array Calibration Technology

Array manifold errors arise from differences between the overall system response (including site interactions, antenna elements, interfacing networks, cabling, characteristic impedances vs. frequency, etc.) and the model from which the array manifold was derived. Errors in the array manifold generally cause DF performance degradation that equals or exceeds degradations caused by measurement errors. Array manifolds are frequently based on the model of ideal array geometry, perfect channel amplitude/phase match, complete interelement isolation, and absence of site interaction. To the extent that these assumptions are valid, the array manifold can usually be generated analytically. When these simplifying assumptions do not apply, a conventional procedure has been to generate the array manifold through exhaustive calibration measurements with the installed array responding to cooperative transmitters, a procedure that can be expensive and/or impractical.

Because DF performance is critically dependent on the array manifold, the development of efficient methods for

accurately and completely characterizing the array manifold is a topic of active investigation. These investigations typically begin with an initial estimate of the array manifold and an assumed underlying relationship between the installed responses of the array and the initial array manifold characterization. The objective is to minimize the quantity and difficulty of controlled measurements required to accurately characterize the *installed* patterns as a function of azimuth, elevation, polarization, and/or frequency of interest. The initial array manifold characterization is analytically estimated and is assumed to be correct except for discrete, unknown factors that account for (1) antenna mutual coupling, as was done by Friedlander and Weiss [21], (2) directionally independent amplitude and phase errors, and (3) perturbations in the location of each antenna element, as proposed by Weiss and Friedlander [22].

Many research efforts seek to use a bootstrapping technique to develop a *calibrated* array manifold. In this approach, system responses are measured using signals of opportunity, and the initial estimate of the array manifold is adaptively modified to agree with the measured data. These developments usually exploit various constraints on array geometry, nature of modeling error for generating the initial array manifold estimate, knowledge and distribution of AoAs, the statistical nature of the incident signal temporal characteristics, and other factors. Constraints on knowledge of *calibration* signal AoA range from requiring complete knowledge to a complete lack of knowledge, in which case the signal AoA and the array manifold correction factors must be jointly estimated from multiple measurements of responses to the unknown signals. In a related approach, Gustafsson et al. [23] characterize the statistical distribution of the random differences between the initial model and the installed system response, and use this information as a basis for developing linear transformations (through weighting factors) to estimate system responses and reduce modeling errors.

2.2. Research in Superresolution Direction-Finding Techniques

2.2.1. Detection of the Number of Signals. Since eigen DF processing is dependent on an accurate estimate of the number of signals present, research is continuing to define more effective estimation techniques. Two techniques of hypothesis testing for signal detection using eigenvalues were developed by Wax and Kailath [19] and are called the Akaike information criterion (AIC) and MDL methods. One of the difficulties encountered in the application of these two techniques is that performance tends to degrade rapidly as the noise background departs from the white Gaussian assumption. In a more recent work, Chen et al. [24] have proposed a technique called the *canonical correlation test* (CCT) method, which is designed to work well in unknown colored noise and does not require a subjective threshold setting. Also, Wu and Wong [25] have developed an algorithm called *parametric detection* (PARADE), and they contend that the performance of their method is better than that of the CCT approach, particularly in the presence of correlated signals.

It has been observed that the performance of the AIC and MDL criteria tends to degrade in the presence of coherent or highly correlated signals. Ma and Teng [26] report a technique to detect the number of coherent signals through the use of a modified spatial smoothing scheme called *weighted subspace smoothing* (WSS). The authors suggest that the WSS technique provides significant performance improvement over the conventional MDL method in the presence of highly correlated or coherent signals.

Another difficulty in the application of the AIC and MDL criteria is that the performance tends to degrade significantly for short data records or in the small-sample case. This problem has been considered recently by Shah and Tufts [27], who propose a nonparametric procedure designed to improve performance for short data records with moderate-to-high SNRs. The authors contend that the AIC and MDL criteria do not provide flexible control over the false-alarm rate while their method permits a choice of false-alarm rate and corresponding probability of error. In a related work, Zhu et al. [28] develop two new criteria based on information theoretic and eigendecomposition methods and an assumed noise covariance structure. The development results in modified AIC and MDL criteria which the authors claim to show significant performance improvement over the conventional AIC and MDL methods in the case of small-sample populations.

2.2.1.1. Real-Time Subspace-Based Implementations.

Two difficulties routinely encountered in a DF operational scenario are (1) tracking radio transmitters that are in motion and (2) the continual appearance and disappearance of radio transmissions. In both cases, there is a difficulty in realizing real-time adaptive responses with the eigenbased techniques since the averaging operation is used to estimate the spatial covariance matrix. Averaging is necessary to obtain wide-sense stationarity and to achieve statistical stability. In a real-time signal environment, it is highly desirable to update the estimate of the number of signals present and corresponding AoAs with each new snapshot of array data.

A class of fast subspace-tracking (FST) algorithms has been recently developed by Rabideau [29]. The techniques require on the order of $O(Md)$ operations per update (where M is the number of antennas and d is the number of estimated signals). This is contrasted with the $O(M^2d)$ operations required in eigendecomposition methods. The author also implements a rank-adaptive version of the approach called RAFST which tracks changes in the number of signals present in the wavefield.

Another tracking technique, developed by MacInnes and Vaccaro [30], requires $O(M^2)$ operations per update. The authors also propose a scheme for detecting a change in the number of signal sources using each new array snapshot. The authors contend that the new algorithm is capable of tracking rapidly changing AoAs, and that the response is virtually identical to that obtained through the use of a complete eigendecomposition at each timestep. Moreover, the technique is able to accurately track appearing and disappearing sources.

Zha [31] has proposed the use of newly developed fast subspace decomposition methods that exploit the redundancy in large antenna arrays to reduce the computational burden of estimating AoA. The computational complexity is $O(Md) + O(d^3)$ per data vector update.

Another technique proposed to achieve real-time implementation has been developed by performing only linear operations on the data. It is called *subspace method without eigendecomposition* (SWEDE). The technique was developed by Eriksson et al. [32] and is computationally simpler than the exact implementations of the eigenbased methods and is also more robust to assumptions regarding noise spatial correlation. The authors assert that the approach is computationally more efficient than the approximate fast eigendecomposition algorithms, and that the computational complexity of the method is $O(Md^2)$.

2.2.1.2. Coherent Signal Analysis. The problem of correlated signals has been attacked primarily through the application of spatial smoothing as suggested by Shan et al. [20]. In the presence of coherent signals, the primary difficulty arises from the fact that the spatial covariance matrix is not statistically stationary in the wide sense; that is, the terms in the matrix depend on antenna *location* as well as *spatial separation*. Spatial smoothing is a process whereby the array is partitioned into smaller subarrays, and the resulting covariance matrices from the subarrays are averaged. The resulting averaged covariance matrix effectively *decorrelates* the coherent signals. There are a number of research efforts in progress designed to improve on the spatial smoothing approach.

A technique has been proposed by Li et al. [33] to estimate AoA for coherent signal components without the use of spatial smoothing and eigendecomposition. The authors have developed a new method for 2D spatial spectrum estimation of coherent signals using a rectangular planar array, and the method works in the presence of unknown noise environments. The authors claim that the performance of the proposed technique is similar to that of spatial smoothing in the presence of spatially white noise and provides improved performance in spatially colored noise environments.

In another approach, Delis and Papadopoulos [34] propose an enhanced forward/backward spatial filtering method that provides improved performance over spatial smoothing techniques. The authors contend that their enhanced spatial filtering approach requires the same number of antenna elements as the spatial smoothing methods, and it achieves improved performance.

An improved spatial smoothing technique has been proposed by Du and Kirilin [35]. Two problems with the spatial smoothing method are that it reduces the effective aperture of the array and does not take into account the cross-correlation between the subarrays. The authors propose an averaging technique that utilizes the correlations between the subarrays to produce a more statistically stable estimate of the averaged covariance matrix. The authors suggest that the technique provides improved performance when the subarrays are small compared to the size of the overall array.

3. OPERATIONAL ISSUES

All direction-finding operations proceed on the axiomatic assumption that the bearing measured is confirmed on the signal of interest. The advance of DF technology has produced DF systems with the *potential* for excellent operational performance. Experience shows that this potential may never be realized in practice unless equal consideration is given to explicit *confirmation* that the AoA reported is on the signal of interest. Traditionally, DF confirmation has been the responsibility of the DF operator, while DF system engineers have concentrated on bearing accuracy, sensitivity, and response time. The growing speed and complexity of communications signals plus the need to control DF operating costs strongly favor automatic, unmanned DF operations where automatic DF confirmation then becomes crucial for success. A review of DF confirmation techniques is beyond the scope of this article. However, DF confirmation processing is rapidly becoming an integral and indispensable part of DF system engineering. As a result, DF processing choices are increasingly concerned with the acquisition of signal parameter data *directly tied to the corresponding DF measurement* to confirm that the bearing is associated with the signal of interest.

RADIO-FREQUENCY IDENTIFICATION SYSTEMS (RFID)

HITOSHI HAYASHI
Nippon Telegraph and
Telephone Corporation
Yokosuka, Kanagawa, Japan

1. INTRODUCTION

There has been increased use of automatic identification–data collection (AIDC) systems for a variety of applications in many industrial and commercial fields. These technologies include [1]

- Barcodes (including two-dimensional symbols)
- Magnetic stripes
- Optical character recognition (OCR)
- Biometrics
- Smart cards
- Radiofrequency identification (RFID)

RFID technologies have become increasingly popular for use in AIDC systems. *Radiofrequency identification* (RFID) is the commonly used term for equipment that transmits and receives its unique identification data through wireless radiofrequency channels [2]. Although the most widely recognized AIDC applications are barcodes (designed in the 1970s), RFID has additional characteristics that are impossible to achieve with barcodes.

Table 1 compares the characteristics of RFIDs and barcodes. The most significant advantage of RFIDs is the noncontact, non-line-of-sight characteristics, where barcode technologies would be useless. This has made RFIDs indispensable for a wide range of AIDC applications that would not be possible otherwise.

Table 1. Characteristics of RFIDs Compared to Barcodes.

Characteristics	Explanation
Noncontact and non-line-of-sight data transfer	RFID tags can be read by noncontact and non-line-of-sight data transfer using wireless communications
Omnidirectional	They are relatively omnidirectional and readable from almost all directions
Potentially greater amount of data	Potentially greater amount of data can be carried.
Unique identification codes for individual items	Unique identification codes are allocated for individual items
Stable operation even in harsh environments	They work even in various environmental conditions, such as snow, fog, ice, or dust, by adaptively using packages.
Potentially rewritable	Data are rewritable during the product manufacturing stages or lifetime, if read/write type memory is used
Readable even when RFID tags are moving	High-speed read processing can be done even when they are in motion
Relatively long communication range ^a	They can provide long-range communications, especially when active tags are used.
Secured	Encryption can be applied to achieve high-level security
Good anticollision	Multiple tag reading can be done simultaneously
Copies/reproductions	Illegal copies or reproductions are difficult
Longlived/reusable	RFID tags are long-lived and reusable under normal conditions.

^aThey are sensitive to regulatory and environmental constraints.

2. RFID TAGS

Generally, an RFID system is composed of RFID readers and tags. Every object to be identified, such as people and animals, in the RFID system is physically labeled with an RFID tag. The tag carries a unique identification code, and the RFID reader reads and writes the identification codes stored by the RFID tags, which are also called IC tags or RF tags. The working of RFID systems and their features depend mainly on the type of RFID tags used. These tags can be classified in several ways, as shown in Fig. 1.

2.1. IC Chip

One optional characteristic of RFID tags is whether they contain an integrated circuit (IC) chip [3]. Chip type tags contain an IC chip, whereas chipless tags do not. Chipless tags are less expensive to make and are adequate for use in antitheft systems in retail stores. However, to enable an RFID reader to identify manufactured items from around the world, the RFID tags must have sufficient memory to contain an identification code large enough to identify a massive number of objects.

An electronic product code (EPC) concept was proposed by EPC Global Inc., which is the organization that sets the standards for RFID [4]. The EPC is a unique number that identifies a specific item in the supply chain. Each tag can store 96 bits of data, which is sufficient to include the manufacturer's name, the product name, and a tremendous number of unique identification codes that can be assigned to each product.

There are three components in IC chips:

1. RF analog front-end circuits
2. Digital circuits for data processing
3. Memory for data storage

The RF analog front end provides an interface between the antenna and the other functional blocks of the RFID tag

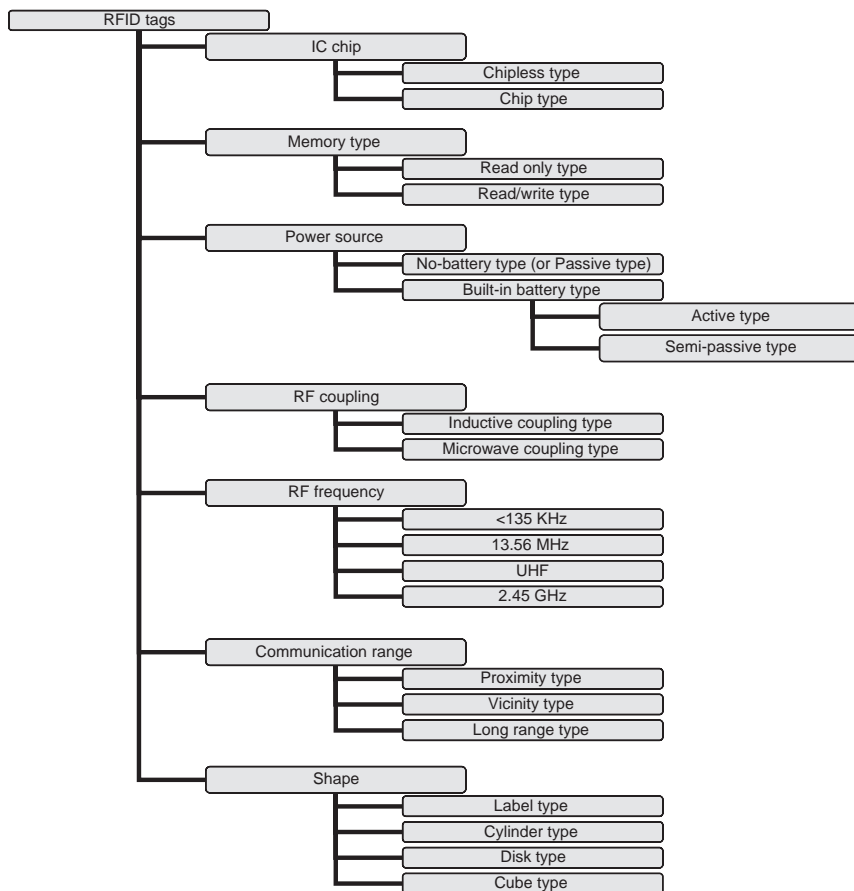

Figure 1. Classification of RFID tags.

such as the power supply, biasing, clock recovery, and data processing. We generally use flip-chip mounting technology to combine the IC chip with the antenna.

Alien Technology, a manufacturer of EPC tags, has developed a new chipmaking technology called *fluidic self-assembly* (FSA) to make miniaturized IC chips [5]. This process allows us to package ICs for assembly into EPC tags at extremely high speeds, which is important for the economical production of EPC tags.

For next-generation ultraminiaturized IC chips, Usami et al. unveiled a prototype called a “μ chip” [6]. The chip is only 0.3 mm² and can hold 128 bits of data. This has also

been authorized by the Ubiquitous ID Center, the organization that sets the standards for RFIDs in Asia [7].

2.2. Memory Type

Another classification of RFID tag is based on its memory type: read-only or read/write. Every RFID tag has an electronically programmed memory with a unique identification code. A “read only” tag has a read-only memory that stores an identification code recorded at the time of manufacturing or when allocated to an object. This is very promising for low cost applications, and can essentially

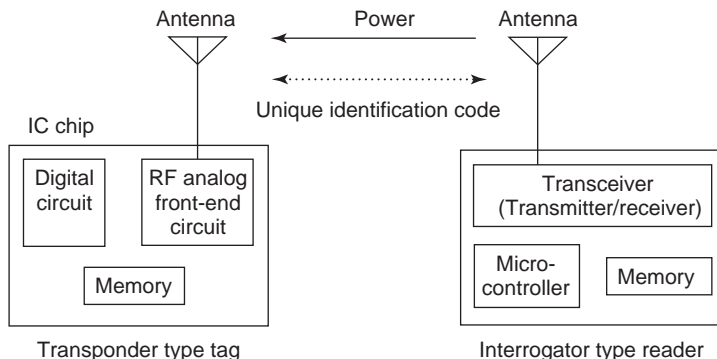

Figure 2. RFID system using transponder-type tags.

Table 2. Comparison between Passive and Active Tags

	Passive Type	Active Type
Communication range ^a	Short	Long
Function	Single	Multiple (adaptive with sensors)
Cost	Low	High
Reliability	Medium	High
Size	Small	Medium
Lifetime	Unlimited	Limited

^aSubject to regulatory and environmental constraints.

provide the same functions as read/write type tags in combination with well-designed networked distributed databases. Auto-ID Labs is currently studying a network infrastructure that will support the efficient and robust collection and delivery of information stored by RFID tags [8]. Read/write tags can have their memories changed or written over many times, and can therefore offer more functions than read only type tags.

2.3. Power Source

Most distinguished classifications of RFID tags are of either the passive, semipassive, or active type [3]. The difference between passive, semipassive, and active-type tags is in the power source and the transmitter. Passive tags have no on-tag power source and no active transmitter. Semipassive tags have an on-tag power source, but no active transmitter. Active tags have both an on-tag power source and an active transmitter. At present, passive tags are the most common.

2.3.1. Passive Tags. Typical RFID systems that use passive tags are made up of a transponder (transmitter/re-sponder)-type tag and an interrogator-type reader.

Figure 2 shows an RFID system using transponder type tags. The interrogator-type reader typically contains a transceiver (transmitter/receiver), a microcontroller, a memory, and a coupling element to connect with the transponder type tag (antenna). The transponder type tag is activated only when it is within the interrogation zone of an interrogator-type reader. The power required to activate the tag is supplied to it from a reader through an antenna.

Passive-type tags are widely used because they are small and very cheap. For example, they are extensively used in applications such as the automatic verification of tickets and gate management. Passive tags are attached to retail merchandise, particularly items that are small,

light, and expensive, such as game software and DVDs, to discourage shoplifting. If the item has not been paid for, an alarm sensor-activated will ring when the object passes through the entrance/exit gate.

2.3.2. Active Tags. Typical RFID systems that use active tags are made up of a transmitter-type tag and a receiver-type reader, or a transponder-type tag, and an interrogator-type reader.

Transmitter-type tags have transmitters only. They do not have receivers, and can periodically transmit their unique identification code, which is dependent on the presence of a receiver-type reader.

Transponder-type tags are activated only when they are within the interrogation zone of an interrogator-type reader. When compared to transmitter-type tags, the transponder-type tag has good anticollision or multiple-reading performance.

The most popular uses for active-type tags are in remote keyless entry systems. Identification of active-type tags is rapid and reliable, and is preferred for these applications. The long-communication-distance capability of active-type tags has made them attractive for locating applications as well.

2.3.3. Comparison between Passive and Active Tags.

Table 2 compares passive and active tags.

Passive-type tags are much lighter, less expensive, and durable than active tags, offering a virtually unlimited operational lifetime. The tradeoff is that they have shorter communication ranges than do active tags.

2.4. RF Coupling and RF Frequency

RFID tags are roughly classified by inductive or microwave coupling between antennas. In general, the configuration and size of the antenna depend on the RF frequency and desired gain, which determine the communication range.

Loop antennas or coils are used mainly for inductive coupling for near-field antennas. On the other hand, dipole antennas and microstrip patch antennas are used mainly as microwave coupling for far-field antennas. Microstrip patch antennas are fabricated on dielectrics with a conductive ground plane underneath. These are typically made using etched thin metal plates or printed conductive lines.

Active integrated antenna (AIA) technology, in which the passive and active components are integrated with the antennas to enable a variety of electrical functions, is also a promising future technology for RFID tags [9,10].

Table 3. General Electrical Characteristics of RFID Tags, Based on Representative RF Frequencies

RF Frequency	RF Coupling	Electromagnetic Interference	Influence of Water or Moisture	Communication Range ^a
<135 kHz	Inductive coupling	High	Very low	Short
13.56 MHz	Inductive coupling	Low	Low	Medium
UHF	Microwave coupling	Low	Medium	Long
2.45 GHz	Microwave coupling	Medium	High	Long

^aSubject to regulatory and environmental constraints.

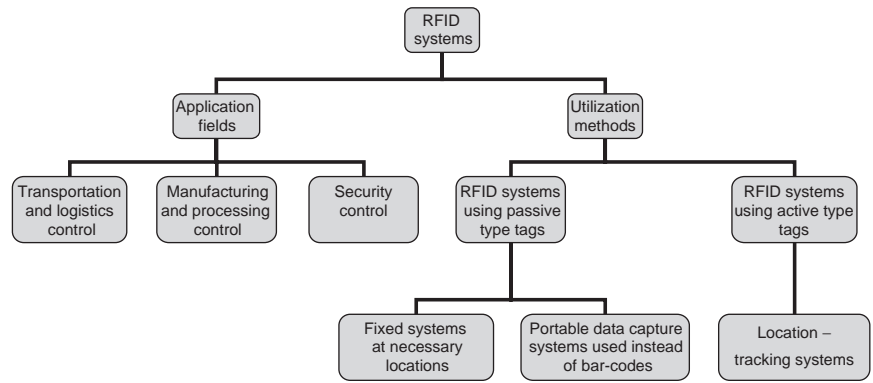

Figure 3. Classifications of RFID systems.

Table 3 shows the general electrical characteristics of RFID tags, based on representative RF frequencies. The allocated frequency and limited power, which influence the communication range, are set by the radio regulations of each country. We have to select an RF frequency that considers the radio regulations and the RFID applications.

2.5. Communication Range

An RFID tag is also classified by its communication range: proximity type, vicinity type, or long-range type. The communication range of proximity type tags is less than several centimeters, while the communication range of long-range tags is more than one meter.

2.6. Shape

RFID tags come in a wide variety of sizes and shapes, such as the label type, cylinder type, disk type, and cube type. We also have to select encapsulating materials within various environmental constraints and with consideration of RFID applications.

3. RFID SYSTEMS

We can roughly classify RFID systems as shown in Fig. 3.

3.1. Application Fields

RFID systems can be a common and useful tool for transportation and logistics, manufacturing and processing, and security control. Figure 4 shows the various applications for these systems.

3.2. Utilization Methods

RFID systems can roughly be grouped into three categories, using the utilization methods:

- Fixed systems at necessary locations (e.g., entrances/exits to detect theft in retail stores)
- Portable data capture systems used instead of bar-codes
- Location-tracking systems

In general, passive tags are used for fixed systems and portable data capture systems, while active tags are used for location-tracking systems.

Location-tracking systems generally rely on triangulation from the time of arrival (ToA) or received signal strength (RSS) [11,12].

3.2.1. ToA Location-Tracking Systems. The best known example of a location-tracking system that uses ToA is the global positioning system (GPS) [13,14]. Current GPSs have been miniaturized to such an extent that they can be

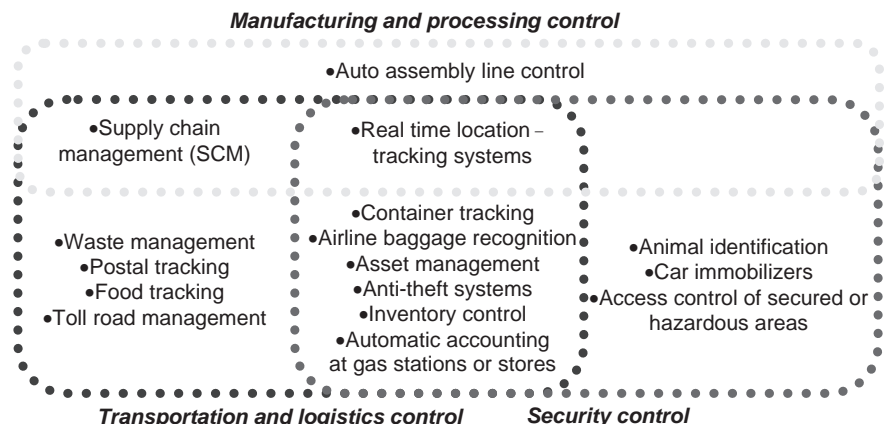

Figure 4. Various applications for RFID systems.

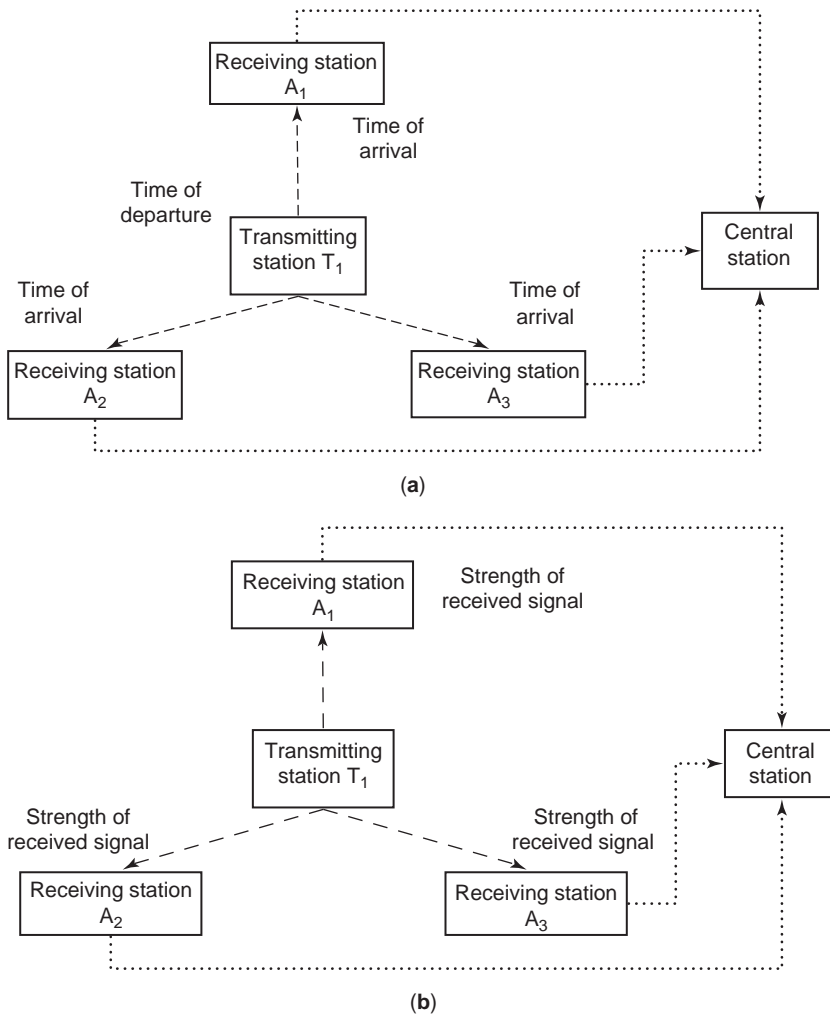

Figure 5. ToA (a) and RSS (b) location-tracking systems.

installed in watches or cellular phones. A ToA location-tracking system is shown in Fig. 5a. It includes a transmitting station T_1 , three or more receiving stations A_1 – A_3 , and a central station that communicates with the receiving stations. The transmitting station transmits a signal, containing its identification code and the current time (i.e., departure time) at predetermined time intervals, using radiowaves. Every time a receiving station receives a signal from a transmitting station, the received signal and the ToA with its identification code are transmitted to a central station. The central station calculates the distance between the transmitting station and each receiving station, based on information provided by the receiving stations, and then estimates the position of the transmitting station. More precisely, the central station determines the signal propagation time from the departure time and the ToA, and calculates the distance between the transmitting station and each receiving station by multiplying the propagation time by the propagation speed of the radiowaves. Then, the central station can estimate the position of the transmitting station by triangulation, relative to the receiving stations.

3.2.2. RSS Location-Tracking Systems. Figure 5b shows an RSS location-tracking system. This system includes a

transmitting station T_1 and three or more receiving stations A_1 – A_3 . The transmitting station generates and transmits radio signals during the positioning operation. Each receiving station reports the measured RSS to the central station. The central station calculates the distance between the transmitting station and each receiving station from the RSS, and then estimates the position of the transmitting station, based on its relative position to each receiving station.

3.2.3. Indoor Location-Tracking Systems. Although GPSs may be effective outdoors, they are unsuitable indoors. In GPSs, while it is possible to request an object's position by measuring the arrival time of the signal from a reference point over a wide outdoor area, large positioning errors can be expected in indoor environments. Even if a position is estimated using RSS information, in many cases the relationship between the distance and RSS does not follow the Friis transmission formula, expressed by

$$L = 20 \times \log_{10} \left(\frac{4\pi d}{\lambda} \right) \quad (1)$$

where L denotes the propagation loss, d the distance, and λ the wavelength [15,16].

The Friis transmission formula does not work for indoor propagation because the receiving station may be blocked from line-of-sight transmission, or local fluctuations in RSS may occur as a result of the influence of reflected waves.

Shimizu et al. proposed a location-tracking system that introduces a corrected Friis transmission formula that takes the environmental influences into consideration [2,12,17]. They also developed a prototype asset management system using active-type tags, in which an RMS position estimation error of 2.3 m was obtained in the test room ($\sim 200 \text{ m}^2$).

4. CONCLUSION

In the near future, every object will likely be connected to the Internet by unique identification codes, through RFID systems. Furthermore, the integration of sensing and actuating technology could also provide new ubiquitous applications. However, to increase the popularity of RFIDs, the following three problems must be solved:

- *Reduction in Cost of RFID Tags.* At present, RFID tags are much more expensive than barcodes. Therefore, we must reduce their cost.
- *Differences in Radio Regulations between Countries.* Radio regulations for RFID applications are different for each country, and this interferes with worldwide (global) use.
- *Protection of individual privacy.* Since RFID systems can be used to track and identify individuals after they have purchased items with RFID tags, there are profound privacy implications to be considered. One possible solution for this problem is to use "kill" technology. All EPC RFID tag specifications include a requirement that the tag will be deactivated when it receives a "kill command" [18]. This would allow a company to render the RFID tag useless after the sale and help assuage some of the privacy concerns related to the use of RFID systems.

1. INTRODUCTION

For many years III–V semiconductors were essential to realize monolithic microwave integrated circuits (MMICs). The late 1990s, however, saw a dramatic change of emphasis with silicon becoming the material of choice for microwave wireless transceivers because of the importance of analogue-digital integration and low cost [1]. The 1990s have been dubbed “the silicon radio decade” [2]. The vast majority of consumer wireless application are in the sub-6 GHz range, including cellular mobile systems, GPS, wireless LANs, RFID, and Bluetooth™ systems. Silicon technology is able to satisfy the noise figure requirements for these applications, and in many cases the power and efficiency requirements as well. These silicon RF integrated circuits are widely referred to as RFICs, and the historic distinction between “RF” and “microwave” has been lost. In the sub 6 GHz region, GaAs technology has been relegated to a few niche areas such as switches and high efficiency power amplifiers. Silicon technology offers much higher levels of integration, including mixed-mode and digital circuitry on the same chip. This latter requirement has led to the development of advanced BiCMOS processes, which produce RF bipolar and low power digital CMOS devices on the same chip, and to widespread interest in RF CMOS, which has less process steps and less mask levels, meaning lower costs.

Even at higher frequencies, Silicon heterojunction devices have started to challenge the dominance of GaAs. However, whereas GaAs provides a semi-insulating substrate ideal for microwave interconnects, silicon does not, and both the designer and process engineer have to address major difficulties at such high frequencies. High-

resistivity substrates, “3D” MMICs [3] and micromachining [4] are just some of the approaches that can be used to combat the substrate loss problem.

The design of an RFIC transceiver is very different from established RF design for a number of reasons:

1. The high level of integration means that interconnects are short and “50 Ω ” design concepts are mostly used only at the LNA input and PA output.
2. The substrate loss and coupling mean that layout techniques such as matching, guard rings, and isolation trenches have to be employed. Cross-chip coupling is a major issue and difficult to simulate, sometimes making it necessary to go through several design iterations.
3. The close integration of digital and analog functions, and techniques such as zero or near-zero IF architectures, mean that a wide range of CAD tools must be integrated into a single design environment.

The RF design, at transistor level and with much layout interaction, may be concurrent with digital design using hardware description languages such as Verilog™ and VHDL. In between, high-speed digital-analogue converters need detailed mixed-signal design. All these parts of the transceiver end up on the same mask, and the CAD environment must provide a seamless integration of the design. The design of fully integrated RFIC transceivers is so complex, and the design cycle so short, that intellectual property (IP) transfer and partnerships between design houses, foundries and consumer product manufacturing companies have become an important business strategy.

2. DEVICE TECHNOLOGY

2.1. Bipolar Transistors

For many years the bipolar device was the only available microwave device in silicon. In virtually all silicon technologies a planar device, fabricated by ion implantation, is used. To optimize the high-frequency performance the device structure must highly advanced, as exemplified by the double polysilicon device shown in Fig. 1. This structure gives higher transition frequencies, higher power gain, lower noise operation, better heat dissipation, simpler matching, and higher integration levels [5].

Figure 1. Double-polysilicon npn transistor in cross section.

Often, base resistance is high in bipolar devices, which means that their noise figure is higher than FETs and the f_{max} is reduced. With careful device design, this problem can be overcome to some extent. However, generally, the BJT has a number of parameters that eventually conflict when trying to optimize the device for high performance. Advanced silicon BJT technology, such as that in the Philips QUBiC4 BiCMOS process, is typically capable of $f_t \sim 40$ GHz and f_{max} of 90 GHz [5]. To improve the device much beyond that, it is necessary to change the structure and employ a heterojunction.

2.2. SiGe HBTs

Like the III–V HBTs, the SiGe HBT is based on having a wider bandgap in the emitter than in the base, as shown in Fig. 2. SiGe has a lower bandgap than does silicon, but Ge and Si have different lattice constants, so there is a limit to the maximum concentration of Ge that can be used. Up to that limit, the strain can be accommodated in the layer. The current gain increases dramatically with the difference in barrier height for electrons and holes, but this is traded off with other device parameters in order to achieve an optimum device. The following advantages are provided by the difference in bandgaps:

1. Improved emitter injection efficiency
2. Reduced base transit time
3. Higher output resistance
4. Reduced charge storage in the emitter

Broadly speaking, a key advantage is that the base can be much more highly doped than a standard BJT, and this means a thin base (5–10 nm) can be used without the penalty of a high base resistance. The thin base then leads to a much shorter transit time. The Philips QUBiC4G process (the SiGe equivalent of QUBiC4) achieves 75 GHz f_t and 110 GHz f_{max} . Experimental results have shown that f_t and f_{max} of >160 GHz can be achieved with quite modest lithography. Good noise figures and power efficiencies have also been reported, but it should be remembered that these good results may not be available from the same device structure as a result of the various tradeoffs.

Figure 2. Basic SiGe HBT band diagram.

2.3. RF CMOS

CMOS technology is the foundation of the computer technology revolution. In logic gates the devices have much lower power consumption than do other technologies, and so microprocessors and memory use CMOS exclusively. For a system-on-chip radio solution there has been much interest in BiCMOS, with RF/analog functions in bipolar technology and DSP and other techniques, in CMOS.

However, the process complexity is high, and very many mask levels are needed. For lower cost it is preferable to realize the RF functions in CMOS and dispense with the need for bipolar devices. Already the Pentium™ can clock at >3 GHz and contains more than 50 million transistors.

To integrate RF electronics with these computing components is the ideal way to realize a single-chip communication transceiver. Techniques such as software radio and direct-conversion architectures have assisted with this. To fabricate the LNA, power amplifier, and oscillator on chip requires high-performance microwave devices; performance cannot be compromised. “RF CMOS” is the technology optimized for this combination of RF and base-band circuitry. It seems to dominate all applications in the low-GHz range. Figure 3 shows the photograph and Fig. 4 the layout of an Intel RFIC transceiver on 0.18 μm TSMC (Taiwan Semiconductor Manufacturing Corporation) CMOS technology. This IEEE 802.11a (5 GHz band) transceiver employs a direct-conversion architecture and includes an internal synthesizer. This is Intel’s first RFIC used in a WLAN product.

The outlook for RF CMOS is extremely promising. CMOS processes have become very advanced, with deep submicrometer devices and multiple levels of interconnect metals and dielectrics, as shown in the SEM photograph of the interconnect stack in Fig. 5 [6]. Functional blocks such

an ALU (arithmetic logic unit) have been demonstrated at >10 GHz, and yet transistor scaling will continue for some years; Fig. 6 shows a cross section of the Intel TeraHertz transistor [7]. Intel's predictions are for > 1 billion

Figure 5. Interconnect stack in the Intel 130-nm P860 technology [6]. (Courtesy of and copyright Intel Corporation.)

Figure 6. Intel TeraHertz transistor [7]. (Courtesy of and copyright Intel Corporation.)

transistors per chip and 45-nm technology by 2007, as illustrated in Fig. 7. This fantastic technological feat is the product of huge investment in research and development right across the range of process steps, guided by the industry roadmap for silicon [8]. EUV (extreme ultraviolet) lithography is a cornerstone in achieving 10 nm feature size. Power consumption, and therefore heat, is seen as the limiting factor.

There are three classes of the RF CMOS process:

1. Bulk CMOS
2. Bulk CMOS with RF technology enhancements
3. Silicon on Insulator (SOI)

“Bulk” CMOS is standard CMOS, as used in digital circuits, where the device is formed in the surface of the semiconductor wafer by implantation. This technology has been developed worldwide at massive cost to produce <0.1 μm feature size on 300-mm wafers. Even at the 0.18-μm technology node, CMOS can achieve 150 GHz f_{max} [9] with careful layout optimization. The F_{min} of the NMOS device is typically 1 dB at 2.45 GHz. This is poor compared to GaAs devices and SiGe ones, but is adequate for most wireless applications. Since the selling price of a complete Bluetooth transceiver is expected to be \$3 in 2005, bulk CMOS is preferred as it is the lowest-cost solution. The problem with standard bulk CMOS is that the substrate is not insulating; passive components have

Figure 7. CMOS technology development [7]. (Courtesy of and copyright Intel Corporation.)

very poor performance, and coupling through the substrate can be serious. Techniques such as guard-rings and deep-trench isolation around individual building blocks are needed.

The RF technology enhancements used in some RF CMOS processes include extrathick metals, MIM capacitors, and a higher substrate resistivity. These enhancements ease some of the design challenges but lead to extra mask levels and more process steps. The added cost may not be acceptable for the \$3 radio transceiver.

SOI technology uses either a bonded-wafer approach or a thin silicon implanted oxide (SIMOX) technology to fabricate transistors that are isolated from the substrate. This greatly eases the coupling problems and improves the transistor performance by reducing key parasitic elements. Again, the added process complexity must be considered.

2.4. Silicon Heterojunction Field-Effect Devices

As in GaAs HEMTs, in silicon the field-effect device can be improved by using a heterostructure to create a thin channel of carriers that are separated from their donor/acceptor atoms. The SiGe HFET uses this approach, with either a Schottky gate junction or a gate oxide—the HMOST (heterojunction MOS transistor) device. “HCMOS” (Heterojunction CMOS) technology produces both NMOS and PMOS devices. HCMOS is necessary to realize low-power-consumption digital circuits.

For a given feature size, the SiGe device has approximately 2.5 times the f_v/f_{\max} of a standard silicon device. In the research lab, values over 100 GHz have been achieved, and predictions of >400 GHz have been made from simulations. The enhanced performance can be used to relax the fabrication requirements as well (e.g., use a 0.35- μm SiGe device that has approximately the same performance as a 0.13- μm standard device but much lower mask costs).

3. PASSIVE COMPONENTS

3.1. Resistors

There are numerous ways to implement a resistor in silicon technology. The resistors in integrated circuit technology deviate significantly from the ideal resistor. It is the parasitic capacitance, mainly from the substrate capacitance, which is the key parasitic element that restricts the maximum operating frequency of the resistor. Furthermore, linearity in the resistor and its temperature and process variations are other important factors that affect the design.

Among the techniques to realize resistors in silicon technology, the diffusion resistor is commonly used in standard bipolar technology and can be found in MOS technology. The resistors are formed by diffusing p^+ into an n well, or vice versa. Silicide technology can be used in this technique to reduce the sheet resistivity. Since the resistor structure fundamentally consists of n- and p-type material forming a diode junction, so the resistor’s voltage coefficient is relatively large [10].

Polysilicon resistors are extensively used in digital and analogue CMOS technology nowadays and are highly suitable for RF applications as they have low parasitic capacitance leading to higher frequency of operation. There are two types of polysilicon resistors: salicided and non-salicided structures. Compared with the salicided resistor, the nonsalicided resistor needs an additional mask to prevent a silicide layer forming during the salicidation process. The salicided resistor has a lower resistivity (5–10 Ω/square) than the nonsalicided one (100 Ω/square). Both resistors are commonly used in integrated circuit design because of their small temperature and voltage coefficients. Typically, the temperature coefficients of p^+ - and n^+ -doped resistors, depending on the technology used, are within $\pm 0.1\%/^\circ\text{C}$ and their variations to process are usually within $\pm 20\%$ [11].

The n-well resistor, however, offers the highest resistivity value and hence helps achieve a small die design, but its large temperature and voltage dependence limit it to certain applications, such as in pullup or pulldown resistors. For applications that need high precision and very small resistance values, a metal sheet can be deposited for the resistors. The desired resistance of such resistors can be calculated using the metal sheet resistivity. Alternatively, a small resistor can be obtained using the p^+ and n^+ source–drain region (3–5 Ω/square).

A given resistor type is typically defined by its sheet resistivity in ohms per square (Ω/square). We can determine the value of a resistor from its layout by counting the number of squares of the resistor and multiplying this with the Ω/square value. When the resistor has to be meandered for some specific layout, it has been suggested [12] that the squares at the corners contribute to the area by a factor of only 0.56. The resistor width should also be carefully chosen, especially in high-power and high-frequency applications, since this will relate to the maximum power handling and maximum operating frequency.

3.2. Capacitors

There are several roles for capacitors in RFIC design, including coupling AC signals, bypassing the low-frequency signals to ground, and controlling the operating frequency. Most silicon -based RFIC designs typically implement capacitors in the form of a parallel-plate capacitor. This structure is composed of two separated electrodes of area A , sandwiching a thin dielectric material of dielectric constant ϵ . The two electrodes are separated by a distance d . The capacitance value of this plate capacitor depending on the dielectric in use is given by $C = \epsilon A/d$. In standard silicon technology, there are several forms of the parallel-plate capacitor; for instance, poly–poly capacitor, polydiffusion capacitor and metal–insulator–metal (MIM) capacitor. Other techniques, such as the MOS capacitor, or an active-device-based voltage-dependent capacitor are also sometimes used.

The poly–poly capacitor is a parallel-plate structure in which polysilicon plates form both electrodes and a thin oxide is grown between them. A nitride layer can be used to obtain higher capacitance values. A metal–poly capacitor uses a metal plate as the top plate rather than the

Figure 8. MOS capacitor.

polysilicon. The benefit of this change is that it minimizes the series parasitic resistance resulting from the electrode. For a polydiffusion capacitor, a highly-doped n^+ implant is applied at the specified area and then the gate oxide layer is grown on top. The fabrication of polydiffusion capacitors uses only the standard process steps. For RF circuit designs that mostly require low-parasitic capacitors, the metal–insulator–metal (MIM) capacitor with a well-controlled thin dielectric is best. However, they are only provided by some commercial foundries.

The MOS capacitor, shown in Fig. 8, is perhaps the most commonly used monolithic capacitor. The top plate is a heavily doped p^+ polysilicon layer; the dielectric layer is formed from silicon oxide, and the bottom plate is the n -type silicon. Here, the top- and the bottom-plate electrodes are referred to as the *gate* (G) and the *body* (B), respectively. The capacitance of the MOS structure depends on the voltage dropped across these two terminals (v_{GB}). According to the bias voltage, the MOS capacitance operates in three regimes: (1) accumulation, (2) depletion, and (3) inversion. Nikenejad has described its operation in more detail [13].

The MOS transistor can be used as a capacitor by connecting the source to the drain terminal for one plate and the gate terminal for the other plate. This capacitor can be used as a varactor in a voltage-controlled oscillator by changing from a low capacitance at low junction voltage to a high capacitance as the voltage exceeds the threshold voltage (v_{th}).

3.3. Inductors

The need for a single-chip solution, ease of system integration, and a low-cost design inevitably require an RFIC chip that needs a minimum number of off-chip components. Realizing a high-performance on-chip inductor is, however, one of the biggest challenges for RF engineers [14–16]. Apart from the main inductor design target, which is its inductance value L , two more parameters of the inductor critically affect the design of RFICs: the quality factor (Q) and the self-resonant frequency (f_{sr}), which are figures of merit defining how close it is to an ideal inductor. The Q factor represents the loss mechanisms in the

on-chip inductor, while the self-resonant frequency defines the inductor’s maximum useful operating frequency. Although there are other parameters, such as maximum power handling, Q and f_{sr} are the most important two parameters discussed here.

RFIC designers using a monolithic inductor struggle with low substrate resistivity in silicon, which is usually less than $20 \Omega \cdot \text{cm}$. As the single-chip solution with a high level of integration is demanded for future wireless communication, a standard heavily doped silicon substrate leading to low substrate resistivity is needed for easing the interface with low-frequency circuitry. The low substrate resistivity means that current is electrically and magnetically induced beneath the circuit and this limits the Q and f_{sr} of the inductor. This notoriously well-known conflict is unavoidable for Si-based RFICs unless some special techniques for enhancing the performance such as MEMS technology [17] or silicon-on-insulator (SOI) [18] are used with an increased cost. The details of these improved inductor technologies will be described later.

Figure 9 shows a simplified electrical model relating to the physical form of a square-type spiral on-chip inductor. This model is applicable not only to the square geometry but also other geometries such as circular and octagonal. The self-inductance of this spiral inductor is denoted by L . The series resistor R represents the loss mechanisms in the inductor. These are metallization, skin effect, and the eddy-current loss. The inductor Q at low frequency is limited mainly by the series resistance, which can be reduced by using stacked metals or increased metal thickness, by employing some smoother shapes such as octagonal or circular shapes rather than square, or by choosing a high-conductivity metal such as copper. In Fig. 9, C_p represents the capacitive element between the spiral turns and C_{ox} and C_{sub} are the oxide and substrate capacitances, respectively. These three capacitances contribute to f_{sr} and Q . Note that R_{sub} is the substrate resistance contribution, which also limits both Q and f_{sr} .

Many techniques are used to enhance planar spiral inductors. However, some of the techniques proposed in GaAs technology, for example, multilevel metallization, using copper, do not significantly enhance Si-based

Figure 9. A first-order lumped model of a planar spiral inductor.

inductor performance since the substrate conductivity is the key contribution to degradation of the inductor. The achievable Q of spiral on-chip inductors in standard silicon processes is usually less than 15. Reducing the substrate loss can be achieved by short-circuiting or isolating the low-resistivity substrate from the circuit. Short-circuiting the substrate current is achieved using the patterned ground-shield technique [19], which is shown in Fig. 10a. The slots in the ground-shield plane are designed such that the induced loop ground current is reduced. The inductor Q at 1–2 GHz is increased by up to 33%, but f_{sr} is decreased due to the substrate capacitance increase. A high- Q inductor isolated from the substrate can be achieved by inserting a high-resistivity substrate such as sapphire material between the circuit and the low-resistivity substrate. A 5.5-nH spiral inductor, with a Q of 25 was realized in this way [18] with the drawback of increased process complexity. MEMS technology has been extensively used for improved inductors, including applying a bulk micromachining technique to remove the

underlying silicon substrate, surfacing micromachining, or using an electromechanical process. Note that these techniques need some special processing, and hence the cost of fabrication will increase. An inductor using this special technology to realize a suspended form is shown in Fig. 10b. The peak Q of this fully CMOS-compatible MEMS-based 1.32-nH inductor is 70 at 6 GHz [17]. “Self-assembly” techniques have been investigated by a number of researchers in order to realize inductors that are lifted up off the substrate [20,21].

3.4. Other Passive Components

Many passive components apart from the aforementioned components can be implemented for RFICs [22–24]. Resonators are used in many circuit blocks, such as voltage-controlled oscillators and RF bandpass filters, and can be realized in many forms. The simplest form is a tank circuit consisting of a parallel inductor and a capacitor. The capacitor is often a parasitic component in an active device. Transformers have been used on Si-based RFICs and applied to low-noise amplifier design and other circuit blocks. Other passive components, such as a balun and hybrid combiner, are also readily used and have shown feasibility in certain applications. Since these component topologies rely on a spiral inductor form, the key factor limiting their performance is, however, still the high substrate loss in silicon.

4. CAD

This section reviews the different CAD packages that are available and describes how they are used in conjunction with various models in the RFIC design process. A wide range of different component models can be used; the choice depends on the level of component characterization that has been carried out and on the specific CAD package that is available. For RFIC design a fully integrated CAD workstation that has an integrated layout library is essential. The key companies in the RFIC CAD business are listed in Table 1. A wide range of software is available. When mixed-signal design and DSP is integrated with RF circuitry for a single-chip radio solution, the design framework will have to integrate everything from VHDL (very high speed integrated circuit hardware description language) synthesis to transistor-level RF design tools.

4.1. System Block Diagram Simulation

Such is the complexity of many designs that individual circuits have to be treated as blackboxes with some kind of describing function. This enables complex subsystems, such as complete transmitters and receivers, to be designed at a high level. Since systems are becoming increasingly complex, and as digital signal processing becomes closely integrated with RF/microwave hardware, system-level and mixed-signal simulation is becoming more important and is receiving a great deal of attention. Note that where pseudorandom baseband signals and high-frequency carriers are present simultaneously, there may be *huge* numbers of sample points to be calculated; the “modulation domain” analysis in ADSTM addresses this problem.

4.2. Simulator Customization

Fierce competition requires that designs work first time to reduce time to market. Since successful RFIC design relies heavily on the accuracy of the available models for active and passive components, it is vital that manufacturers offer extensive model libraries and design information. The extent to which a process has been characterized and carefully developed into a fixed production process is often more important to a customer than the ultimate performance achievable. The characterization and process definition task, from the first RFOV (RF on water) testing of a new device up to the official release of a model library and design manual, may take many man-years. The model library is the fruit of a great deal of labor, and while it represents only a small part of the manufacturer's modeling and design information, the model library is the basis of all the customer's design work.

In a fully integrated CAD package there is seamless integration of the schematic (e.g., see Fig. 11) and parameterized layout. In order to achieve this level of design integration for ICs, the simulator must be customized to the foundry with suitable technology files, models, and parameterized layout library elements. In this way the layout and schematic can be linked together; a change made in the layout window will automatically result in a change of the parameters in the schematic. For example, if you edit the length of a track in the layout editor and then pass the new length information to the schematic, the simulation can be rerun directly. This transfer of information directly between the layout and the schematic/simulation is called backannotation. It should be noted, however, that despite all the apparent sophistication of such a CAD suite, it is as important as ever that the designer be aware of the nature and limitations of the models that he/she is using.

5. AMPLIFIERS

5.1. Low-Noise Amplifiers

The low-noise amplifier (LNA) is, perhaps, the most essential building block for a modern wireless receiver

since it must be able to receive an extremely small incoming signal from the front-end antenna from within a hostile atmosphere (both noise and interference signals) and, subsequently, boost the received signal while maintaining the signal quality. In order to achieve this, a good LNA must amplify the amplitude of an input signal while, ideally, no extra unwanted noise is added to the output signal of the LNA. The figure of merit most often used is the noise figure (NF). Besides NF, gain, and linearity, RF designers must consider the input and output impedances to ensure that no unnecessary mismatch loss occurs at the antenna-LNA interface. Furthermore, with the demand for low-cost, high-performance, and small-size portable communication terminals, various low-complexity receiver architectures, such as a homodyne receiver and a low-IF receiver, have been proposed to fulfill these design goals. However, new problems of these architectures have emerged. Hence, the subsystems supporting these proposed architectures must have enhanced features to counteract these new problems, such as LO and DC offset leakage in a homodyne receiver. Therefore, apart from an LNA's aforementioned conventional design parameters such as gain or NF, the LNA designer must be concerned with other design parameters, such as high reverse isolation of the LNA to prevent leakage of LO power from the mixer back to the antenna [25,26].

Designing LNAs in silicon technology is more problematic than in GaAs technology because of the low-resistivity substrate material, which contributes to substrate loss, eddy-current loss, and substrate capacitance. As discussed in Section 3, realization of high- Q and high-self-resonant frequency inductors on a standard silicon technology requires a laborious effort to achieve success. A low- Q inductor creates more dissipation loss and, hence, directly degrades the noise performance of the LNA. The substrate noise and coupling are other major problems in silicon technology. To suppress these, the differential topology is commonly used rather than the single-ended design because of its high common-mode noise rejection, although there are power consumption and circuit size tradeoffs [27].

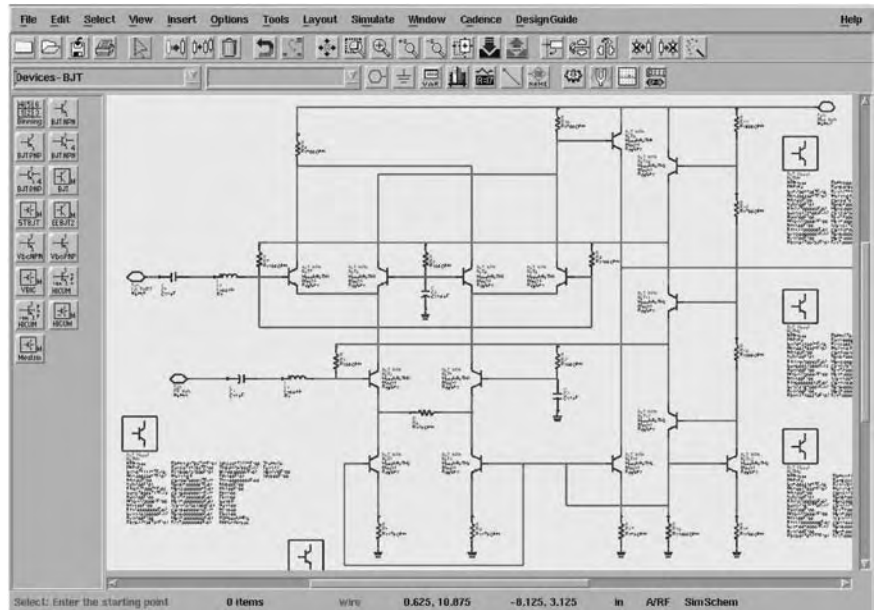

Figure 11. Gilbert cell mixer schematic in ADS™.

Among the numerous techniques used to implement the LNA for wireless applications nowadays with standard silicon technology, the common-emitter (for bipolar transistor) or common-source (for field-effect transistor) devices with inductive series feedback, as shown in Fig. 12a, are typically used to achieve a high gain, low noise, and simple design [28]. The topology comprises the operational bandwidth; the series feedback inductor L_E increases the input resistance by the amount of $R_i = \omega_T L_E$, where ω_T is the unity-gain frequency. This equation shows that the input impedance on the Smith chart of this common-source or common-emitter inductive series feedback topology can move to the 50-Ω region without the noise tradeoff, leading to simultaneous noise and power matching. Also, the input reactance, mostly in capacitive form, can be canceled by using a series inductor to resonate it out. This will simplify the design task efficiently. Nevertheless, the designed LNA has narrow bandwidth due to the input matching structure. Furthermore, in practice, the noise figure of the LNA is increased because of the finite Q inductor. The advantage of using this feedback is high linearity and good temperature dependence of gain

and input impedance so that the bias of this topology need not be accurate. Input-output isolation performance is a problem for this topology as the feedback capacitance and Miller capacitance dominate, especially at high frequency.

Figure 12b shows the emerging LNA architecture for Si-based application, namely, the “transformer feedback LNA” [29]. In this technique a portion of power from the drain terminal is magnetically coupled to the source terminal, which gives negative feedback. The amount of feedback is determined by the transformer’s coupling factor k , where the invert wiring arrangement mainly determines the mechanism of negative feedback. This feedback neutralizes the transistor by canceling the Miller capacitance, which, in turn, improves the reverse isolation. The minimum noise figure of this transformer feedback LNA is theoretically equal to the minimum noise figure of the device due to its inherent source degeneration property (L_{11}). Since a single transistor is required, this LNA topology is suitable for low-voltage applications. The right-hand side of Fig. 13 shows a chip microphotograph of a 5-GHz transformer feedback LNA designed on 0.18-μm CMOS technology [29].

Figure 12. Three LNA topologies suited for silicon RFICs: (a) source degeneration; (b) transformer feedback; (c) cascode.

Figure 13. A 0.18- μm CMOS chip microphotograph of a 1-V 5-GHz transformer feedback LNA [29] (Copyright IEEE, used with permission.)

As shown in Fig. 12c, the cascode LNA architecture uses a series connection of a common-emitter (CE)/common-base (CB) or common-source (CS)/common-gate (CG) transistor pair. It eliminates the Miller multiplication of the feedback parasitic capacitance of the CE (CS) transistor. Then, the cascode LNA is almost unilateral; that is, low reverse transmission coefficient (S_{12}) is achieved, and this will simplify the amplifier design task for input-output matching. Although noise can be added from the CB (CG) stage, the noise figure of the cascode LNA is not significantly higher than the source/emitter degeneration transistor if the front-end CE (CS) of the cascode has sufficiently high gain. Since the front end is CE (CS), the source/emitter degeneration technique can also usually be applied to obtain simultaneous noise-power matching. There is, seemingly, a need for more headroom voltage for the cascode design due to the extra CB (CG) stage. Oscillation can possibly occur, especially at the second stage if the gate of the second stage is not small-signal-grounded. The microphotograph of a 5-GHz cascode LNA on 0.18- μm CMOS technology is shown in the left half of Fig. 13.

5.2. Power Amplifiers

The power amplifier (PA) is one of the most crucial RF front-end parts of a wireless transceiver. The PA's main function is to boost the signal power up to a specific power level that can transmit to the receiver at a desired distance. Small size, low cost, low voltage, and long battery life are needed for portable terminals; hence, a high-efficiency, high-power, and low-voltage-operated PA using a cheap IC technology such as silicon technology is required. In addition, a high-linearity PA is increasingly important to support multichannel and multiuser wireless communication technologies, for example, wideband code-division multiple-access (WCDMA) standards. PA design with cheap silicon technology seems to face the same problem as the LNA does. It is the poor passive component performance that is the main bottleneck. Loss in Si-based passive components used for matching networks or bias chokes causes low achievable power, low power gain, and increased power consumption, and ultimately, reduces the

power efficiency significantly. Sometimes, the off-chip component solution, particularly for the output matching network, is used to realize a high-performance PA, but this is not as desirable as the low-cost single-chip concept. Another problem in a fully integrated PA design, especially in CMOS technology, is the low breakdown voltages, source-drain, drain-gate, and drain-substrate, resulting in a low-power device. Higher output power can be achieved using an impedance transformer, but the low-performance passive components in standard silicon technology pose a challenge. Chip-level combining of small devices to achieve high power faces the notorious problem of low substrate resistivity. Fortunately, there is one promising technique worthy of mention, namely, the distributed active transformer (DAT). The DAT uses magnetic coupling of the output power from each push-pull transistor cell. Fig. 14 shows the microphotograph of a DAT-based >1-W PA chip using standard CMOS technology [30,31].

As mentioned before, silicon technology is preferred for wireless technology nowadays because of its relatively low cost compared with GaAs. However, silicon RFIC designers have to struggle with the low substrate resistivity,

Figure 14. Chip microphotograph of DAT-based 1-W fully integrated PA on CMOS [30]. (Copyright IEEE, used with permission.)

giving many problems to solve. However, silicon has excellent thermal conductivity, 3 times that of GaAs. This makes the silicon-based PA more suitable for high-power application. Besides PA output power, the other crucial PA performance properties (linearity and efficiency) and enhancement techniques will be briefly discussed.

Efficiency is the most important PA design issue. Traditionally, the approaches to improve PA efficiency are achieved by controlling the DC biasing point, for instance, classes A, AB, B, and C. Among these, the most classical approach, class A, is the amplifier that provides the lowest maximum power efficiency but highest linearity [32]. As mentioned above, the derivative techniques of class A, such as classes B, AB, C, use a smaller bias current so that average biasing current is decreased. The power efficiency of these amplifier classes is significantly improved, but the distortion increases since the active devices are not conducting throughout the cycle. Therefore, these PA classes inevitably require an RF bandpass filter at the transistor output to eliminate the nonlinear generated harmonic distortion.

The class E PA [33] is intentionally designed such that the transistor is operated like a switch. The switch waveform and its duty cycle are controlled by the drive level and the biasing point at the transistor input. The output voltage and the output current waveform timings are designed such that no DC power dissipation occurs in the device. The PA is highly nonlinear since the output waveform is square-wave-like, and, as in classes B and C, a bandpass filter is needed to eliminate the harmonic distortion. Class F PA design [33] allows an increase in power efficiency by adding odd harmonics to flatten the output voltage waveform. This will allow more peak output power and then the efficiency increases.

The Doherty amplifier is very suitable for modern wireless applications, such as in multiuser multi-channel communication systems that need a power control scheme or in a high-capacity communication system that needs a high linearity transmitter—for example, orthogonal frequency-division multiplex (OFDM) systems. This technique tunes the output impedance of the main amplifier actively by employing a high-efficiency auxiliary amplifier. The feasibility of the CMOS-based Doherty amplifier was demonstrated [34] using a lumped-element approach to reduce loss and minimize the die area, and therefore the fabrication cost.

So far, all the aforementioned techniques to boost power efficiency trade off the PA linearity. There are various emerging wireless communication standards such as CDMA that transmit the information via the carrier envelopes. These standards impose very strict specifications on PA linearity. In order to meet these, linearization techniques are applied to the PA designs [35]. There are many proposed PA linearization techniques but only a few that are suitable for on-chip integration. Feedforward, although offering high performance in terms of intermodulation distortion and wide bandwidth, seems to be inappropriate for IC applications. The main reasons are its complexity and the sensitivity of the distortion reduction performance. The feedback technique has been used for ICs but has many disadvantages, such as narrow

bandwidth, potential instability, lower gain, and lower power, and hence is not so attractive for PA applications. Perhaps, the most successful linearization technique nowadays is the predistortion technique. The input signal is predistorted such that the predistorted input signal will cancel out the distortion generated from the nonlinear mechanisms in PA active devices. The predistortion technique is the most frequently used linearization technique especially in portable communication units because of its simplicity, compact size, low power consumption, good distortion reduction performance, and low cost. The simplest predistortion block is realized by using a diode, which is a standard device in silicon technology. Increasingly, the predistortion block is implemented at baseband using digital signal processing, which is widely used in wireless communication nowadays. The technology solution for a high-efficiency and high-linearity RFIC PA seems to be a high-efficiency PA with the digital predistortion technique [36].

The “linear amplification using nonlinear components” (LINC) technique is another technique that is gaining in popularity as the need for linear transmitters increases with the introduction of wideband systems using advanced modulation schemes. The LINC concept is based on the fact that a highly nonlinear amplifier can still deal with phase modulation. The amplitude modulation of the signal is replaced with a pair of constant-amplitude phase-modulated signals that are then independently amplified by two high-efficiency amplifiers, such as class C ones. The outputs are power combined to reconstruct the original input signal waveform. The LINC concept needs a signal processing part to generate the phase-modulated waveform pair, this being referred to as the signal component separator (SCS). In practice, the efficiency is reduced by combining loss and phase/gain mismatch has a significant impact on the nonlinear distortion reduction performance. Adaptive signal processing needs to be employed to eliminate this phase-gain mismatch. Figure 15 shows the microphotograph of a BiCMOS SCS chip with integrated mismatch control circuitry [37].

Figure 15. A chip microphotograph of BiCMOS SCS chip for 200-MHz IF LINC transmitter [37]. (Copyright IEEE, used with permission.)

6. OSCILLATORS

The oscillator is an essential component for all RF transmitters and receivers. Virtually all modern applications employ frequency synthesis in order to achieve good frequency stability and low phase noise. The voltage-controlled oscillator (VCO) is the key RF component in a phase-locked loop (PLL) frequency synthesizer. There are two classes of oscillator circuit, namely, feedback and negative-resistance oscillators. A feedback oscillator consists of an amplifier and a resonant circuit that couples the output signal back into the input. A negative-resistance oscillator consists of a negative-resistance circuit coupled to a resonator. In fact, the two types are quite similar because feedback is used to create the negative resistance, anyway. The ring oscillator is clearly a feedback oscillator, but since it does not use a high-*Q* resonator (e.g., LC type), its phase noise is fairly poor.

There are various kinds of resonators in general use at RF, including *LC* tuned circuits, cavity resonators, dielectric resonators, YIG resonators, and superconductive resonators. Few of them, however, can be integrated onto RFICs. A varactor-tuned oscillator can easily be realized using a resonator consisting of a varactor diode and an inductor or transmission line. The low-*Q* factor of such a resonator means that the phase noise is poor, and this approach is used only for noncritical applications or for externally phase-locked oscillators. For better phase noise performance the most common technique is to employ an off-chip resonator, a bond-wire inductor [38,39], or MEMS technology [40,41].

While the classic Colpitts oscillator is widely used in hybrid RF circuits, most RFIC oscillators are based on a differential pair, cross-coupled to provide positive feedback. This topology is simple and gives reliable startup. The differential oscillator rejects unwanted common-mode signals such as substrate and PSU (power supply unit) rail noise. The tank circuit consists of a pair of inductors with the capacitor *C* as shown in the NMOS-only version in Fig. 16a, realized with a pair of varactor diodes connected cathode to cathode with the tuning bias applied at the cathodes. For increased tuning range, additional switchable capacitors might be incorporated for band selection. It is widely known that the tank energy must be maximized to improve phase noise. A detailed analysis and procedures for optimum design of these *LC* VCOs has been presented by Ham and Hajimiri [42]. The complementary version of Fig. 16b gives some improvement in phase noise; however, the novel noise-shifting differential Colpitts VCO in Fig. 16c, designed with careful consideration of the optimum waveforms, gives the best performance [43]. For image rejection and direct conversion applications, a pair of quadrature outputs can be generated by coupling two such circuits together via the tank circuits [43,44].

6.1. Negative-Resistance Oscillators

Most microwave oscillator designs employ the negative resistance approach. Consider the circuit shown in Fig. 17, where Γ_R and Γ_T are the reflection coefficients of the resonator and the transistor, respectively. The oscillation

Figure 16. VCO circuits: (a) NMOS-only; (b) complementary; (c) differential Colpitts, [43]. (Copyright IEEE, used with permission.)

condition of a negative resistance oscillator can be stated as $\Gamma_R \Gamma_T = 1$. This expression implies that, at the frequency of oscillation, the return loss of the resonator has to be equal to the return gain of the active block, and the sum of the arguments of Γ_T and Γ_R has to be an integral multiple of 360° . A return gain means that a negative resistance must be present at the input terminal of the active device. Note that the oscillation frequency is not necessarily the same value as the resonant frequency of the resonator, provided the criterion above is satisfied. For oscillations to begin, the magnitude of the negative resistance must be bigger than the value determined from this small-signal condition. Because of the excess negative resistance in the circuit, the oscillation will grow in amplitude until the negative resistance is reduced in value, by nonlinear effects, to a steady-state value. In practice, the negative resistance is created by applying feedback to transistors.

In the case of the bipolar transistor (BJT or HBT), the device is often connected in common-base configuration with an inductive feedback element, as shown in Fig. 18a, and the negative resistance is developed at the emitter terminal. In the case of the FET the device can be in common-gate configuration with an inductive feedback element or in common-source configuration with a capacitive feedback element, as shown in Figs. 18b–d. The circuits provide feedback by circulating the output current

Figure 17. Negative-resistance oscillator.

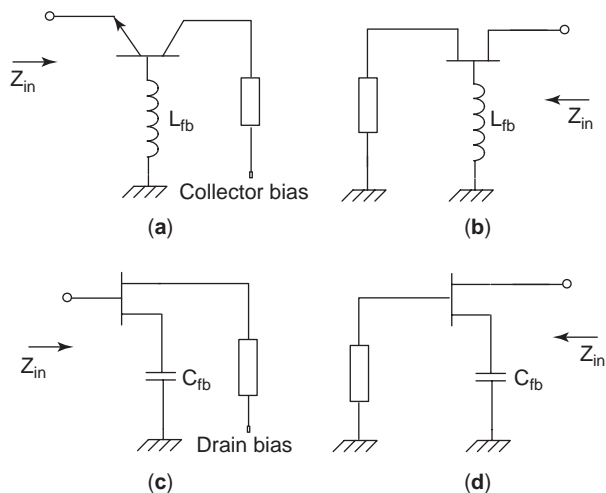

Figure 18. Negative-resistance oscillator topologies: (a) bipolar transistor in common-base FET; (b) common-gate FET (c); common-source FET (d).

through the feedback element in such a way that the voltage developed across the feedback element becomes part of the input signal.

6.2. Phase Noise

The various device technologies cannot be compared thoroughly without discussing phase noise. In active devices, low-frequency noise is dominated by trapping effects from defects in the bulk, at junctions, and at the surface. This contribution is known as flicker noise. The power spectral density (PSD) of flicker noise is inversely proportional to frequency, and meets the thermal (Johnson) and shot noise “floor” at a frequency called the “ $1/f$ corner frequency.” Above the $1/f$ corner frequency, thermal noise and shot noise dominate.

Flicker noise is particularly serious in nonlinear circuits, because the low-frequency noise can be upconverted to RF via the nonlinear mechanisms. In an oscillator, the noise will appear as sidebands on the RF, and these sidebands will interfere with the information signal(s). It should be noted, however, that this flicker noise limit is approached only when a very high factor is used in the oscillator, or when frequency synthesis is used.

FET devices have much higher $1/f$ corner frequencies than do bipolar devices, because current flow is lateral, in the plane of the interfaces that cause flicker noise. Typically FETs (including silicon) have corner frequencies >10 MHz, whereas bipolar devices have corner frequencies <1 kHz. For wireless applications—especially direct-conversion transceivers—low-phase-noise synthesized oscillators are of absolutely key importance, giving yet more challenges to the RF CMOS designer. More recent results have indicated that CMOS devices incorporating SiGe and with a buried channel have improved phase noise.

Relatively recently it has been shown that the waveform within the oscillator circuit has a dramatic effect on the phase noise, and the impulse sensitivity function (ISF) has been introduced to quantify this phenomenon [45].

6.3. Frequency Synthesis

Frequency synthesizers are one of the most challenging and crucial subsystems for a wireless system, especially for 3G, W-CDMA, WLAN, and future generations of wireless networks. The main challenges in the design of a frequency synthesizer are to achieve low phase noise with high frequency resolution, fast switching speed, low power consumption, small size, and low cost. The frequency synthesizer includes three main components: the reference oscillator, the VCO, and the phase-locked loop (PLL). Since the early 1990s PLLs and VCOs have begun to be integrated with the rest of the wireless system on the same silicon IC for reduced cost, size, and improved reproducibility of design.

Because of the increasing number of wireless users using the same band, and operating at progressively higher data rates, both interference and signal-to-noise-ratio have become key considerations in system design. Phase noise and spurious emissions contribute significantly to both of these issues and are largely dependent on PLL performance. Minimizing phase noise and spurs of the frequency synthesizer while staying within power consumption, size, and cost constraints is one of the main challenges for RF design engineers. Because of all these challenges and requirements, several different techniques are used to implement the PLL section of a transceiver. This section describes the existing PLL technologies and how emerging PLL technologies are making this challenge more manageable.

6.3.1. Direct Digital Synthesis. Direct digital synthesis, as shown in Fig. 19, uses a lookup table to store the sine wave values, and an accumulator driven by a clock simply steps continuously through the values. The signal is converted by a DAC, and filtered to reduce spurious signals resulting from the quantization. It is a very powerful technique with many advantages; for example, very fast phase-continuous frequency switching is possible. Commercial products have become extremely sophisticated, incorporating tremendous programmability and additional functions such as modulation. However, although DDS is moving into the RF range, generally a PLL solution will have lower chip area and power consumption. A DDS source can be integrated into a PLL as a hybrid solution offering many advantages.

6.3.2. Direct Synthesis. For completeness, direct synthesis should not be forgotten; in this method a plethora of signals is created from a single-crystal reference, and then these are multiplied together (with mixers) and divided into various combinations to generate other frequencies. The required frequency is set by using switches to select the desired combination for multiplication and division. However, the multiplicity of sources, mixers, and dividers means that this approach requires large chip space and high DC power consumption, so it has a limited applicability to RFICs.

6.3.3. Integer- N Synthesis. Integer- N or divide-by- N synthesis is the classic form of a digital PLL. A number

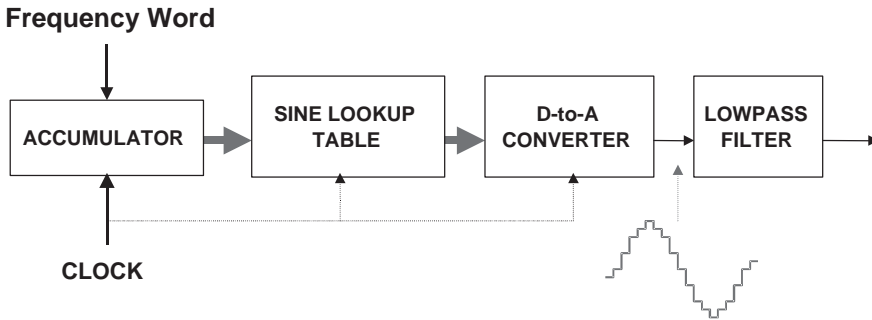

Figure 19. Simplified direct digital synthesizer block diagram.

of well-known texts describe their principles and optimum design procedures [46–48]. Referring to Fig. 20, the basic building blocks are as follows:

- Reference counter ($\div R$)
- Phase detector
- Loop filter
- Prescaler and programmable counter ($\div N$)
- VCO

6.3.3.1. Reference Counter. The most stable frequency references are usually high-frequency sources using crystal resonators, which operate in the MHz regime. However, in the basic PLL the reference frequency applied to the phase detector determines the minimum-frequency step-size. Thus, in order to provide reasonable frequency resolution, the crystal reference is first divided down by the reference counter; $F_r F_x / R$. With the basic PLL, with integer division in the feedback loop, F_r is the smallest frequency step that can be achieved at the output—it determines the frequency resolution. However, using a very small F_r is not a practical proposition, because then the reference signal is effectively multiplied up many, many times in frequency, degrading phase noise considerably; for a division ratio of N , the reference signal phase noise is in principle increased by $20 \log N$. For a 10-MHz crystal, divided by 1000 to give a 10 kHz resolution, the degradation is a whopping 60 dB.

6.3.3.2. Phase Detector. The phase detector compares the reference frequency signal to the divided VCO feedback, and generates an error signal that is passed through the loop filter and controls the VCO. For a high reference

frequency, a mixer might be used to multiply the two signals—the output is then a DC level when the two signals are the same frequency but out of phase. More often, digital circuits are used such as the J–K flip-flop, the exclusive-OR gate and the digital phase frequency detector. The phase frequency detector (PFD) is most widely used since it gives a monotonic output when the phase difference exceeds $\pm 2\pi$ —namely, when the frequencies are different. This means that it can pull the VCO into lock more effectively when switching frequency.

6.3.3.3. Loop Filter. The loop filter is required to filter noise from transitions at the phase detector output. However, if its bandwidth is too low (a large time constant), then the PLL will take a long time to switch from one frequency to another. Many systems use schemes such as dynamic channel allocation and frequency hopping, and fast switching is required. However, if the loop bandwidth is too large, there will be overshoot and problems with spurious signals. In general, when determining the bandwidth of the loop filter, the PLL designer must achieve a tradeoff between phase noise, switching speed, and spurious signal suppression. The loop filter can be active or passive. Passive filters are mainly resistor–capacitor networks that connect directly between the phase detector and VCO, but are mostly suitable only for narrowband applications. Active loops allow the synthesizer to generate large tuning voltage levels and are more suitable for wideband applications since a wide VCO tuning voltage range is needed.

6.3.3.4. Prescaler and Feedback Counter. A programmable counter (frequency divider) is required in order to vary the output frequency. However, programmable counters

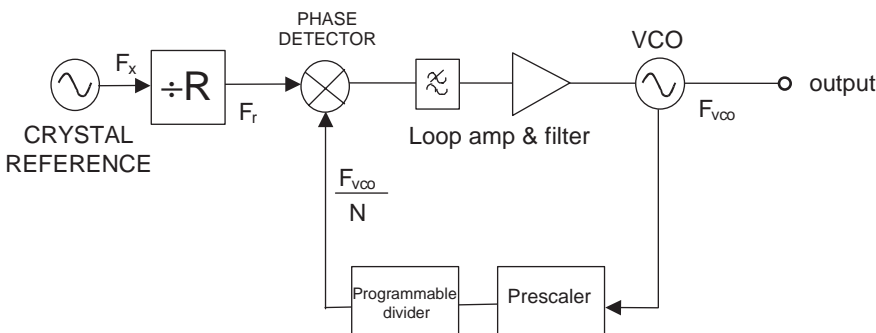

Figure 20. Integer- N PLL block diagram.

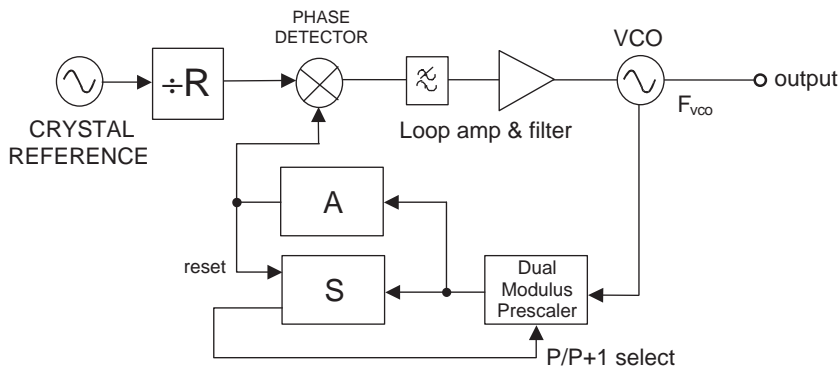

Figure 21. Dual-modulus PLL.

are fairly complex circuits, and cannot operate at very high frequency. A prescaler is a simpler circuit giving a fixed division ratio but able to operate at GHz frequencies. However, a simple prescaler ($\div P$) increases the minimum frequency step to $P \times F_R$. A dual-modulus prescaler can ease this problem at the expense of added complexity. As shown in Fig. 21, with the dual-modulus prescaler the feedback counter alternately divides by P and $P + 1$. This is achieved using the combination of a programmable counter (A) and a second counter, often called the swallow counter (S). At first the prescaler is set to $P + 1$; the swallow counter counts up to S and then sets the prescaler to P . Throughout, the programmable counter is counting and, when it reaches the value A , it resets the swallow counter. This means that the prescaler divides by $P + 1$ for S pulses, and by P for $(A - S)$ pulses, giving an aggregate division ratio (N) of $A \times P + S$. Dual-modulus prescalers and also multimodulus prescalers, have been widely adopted.

A dual-modulus system can be used as single modulus by simply setting the S value to 0. Most PLLs have two pairs of moduli, which can be statically selected via the programming interface. For example, the prescaler might be configurable as either 32/33 or 64/65. In a product, the various counters would have wide programming ranges to enable use in a wide variety of applications.

6.3.3.5. Speedup Mechanisms. In most cases, the loop filter must be designed to meet certain phase noise and spurious signal specifications, and this does not provide sufficient switching speed. Various speedup mechanisms can be used. One such method is to “pretune” the VCO to the desired new frequency. This puts the VCO close to the required frequency and the system near to locking. Other methods include various schemes to “tweak” the loop filter—for example, switch elements in or out temporarily, or charge up capacitors actively.

6.3.4. Fractional- N Synthesis. Integer PLLs, like that in Fig. 20, were the first digital implementation of frequency synthesis, and this traditional technique is still widely used in wireless applications. One of the main limitations of integer- N PLLs is that the VCO frequency cannot be varied in steps smaller than that of the divided reference (F_r). Integer- N is restricting when small frequency step size and low phase noise are required. Demand for faster

switching and lower phase noise in the local oscillator (LO) of wireless communication systems has led to dramatically increased interest in fractional- N synthesis. This was originally developed in the early 1970s by Hewlett-Packard and Racal, and was then known as the “digi-phase” technique. The fractional- N architecture allows frequency resolution that is a fractional (not integer) proportion of the reference frequency F_r . Therefore F_r can be higher than the stepsize and N can be reduced to improve phase noise.

The fractional- N architecture is shown in simplified form in Fig. 22. The dual-modulus prescaler PLL and fractional- N synthesizer look very similar at first sight—the difference becomes clear when looking at the signals in the time domain. In the dual-modulus prescaler, the switching between $N/N + 1$ takes place within a *single period* of F_r ; there is no phase error between the divided VCO signal and the reference, and the VCO output is rock-steady in the locked state. Therefore, everything is well behaved, but the division is integer and the frequency resolution is equal to F_r .

In the fractional- N PLL, for every group of F periods of F_r , the divider is set to N for a certain number of cycles, and $N + 1$ for the other K cycles. This gives an average division ratio of $N + K/F$ [47]. With programmable counters, a variable *fractional* divisor is achieved. The key is the *phase accumulation register* or *fractional accumulator*, which counts up to a set number F of F_r cycles in steps of K . This can only hold numbers from 0 to $F - 1$; every time the counter overflows, the divide number is changed for that F_r cycle to $N + 1$ (sometimes people refer to this as a *pulse removal process*—the result is the same). After the total of F pulses, everything is reset to the beginning. This is illustrated in Fig. 22b for $N = 3$, $F = 9$, and $K = 5$, giving a division ratio of $3\frac{5}{9}$. The upper trace is the F_r signal, for nine cycles, with the accumulator value indicated above it. The middle trace is the VCO signal, which has 32 pulses for the nine F_r pulses because the average divisor is $3\frac{5}{9} = \frac{32}{9}$. The lower trace is the signal from the counter that feeds the PFD. As can be seen, the average phase error is zero, but there are dynamic errors between the divided VCO signal and F_r . This leads to high levels of unwanted spurs called *fractional spurs*, which can be very large. To correct this, one method, as shown in Fig. 22a, is for the phase accumulation register to feed a DAC that generates an equal but opposite error signal and injects it

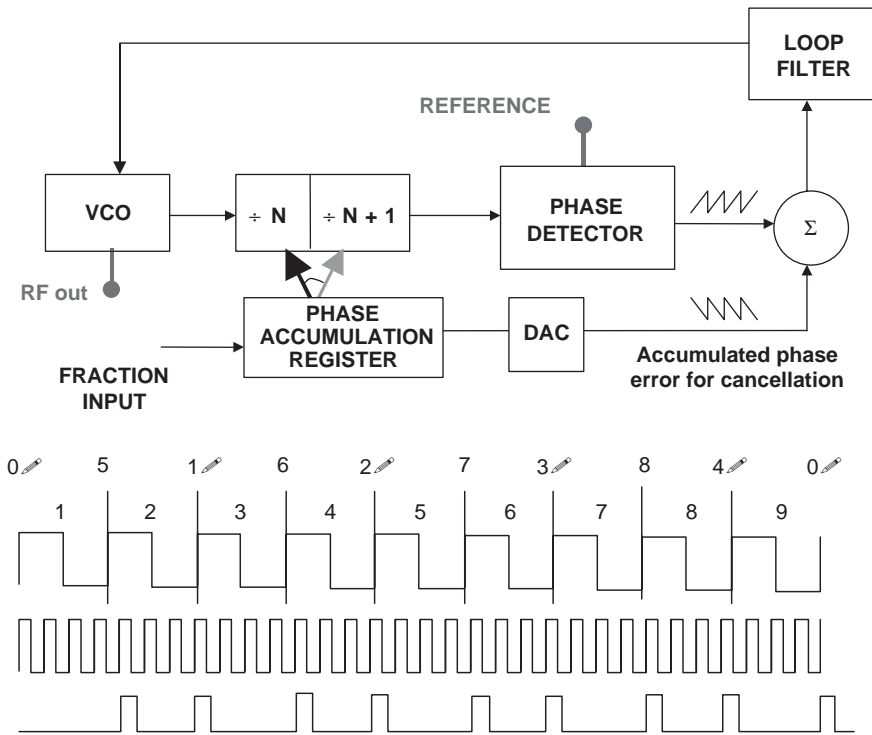

Figure 22. Fractional- N synthesis: (a) block diagram; (b) division process for $N = 3$, $F = 9$, $K = 5$.

at the PFD output. A very important technique is the use of a high-order sigma-delta modulator [49], which effectively dithers the $N/N + 1$ switching process so that the spurs spread out considerably and look like harmless high-frequency noise that is removed by the loop filter.

6.3.5. Summary. Integer- N synthesis is still popular despite some challenges. Most importantly, a small frequency stepsize requires a large division ratio, which compromises phase noise. Furthermore, if F_r is set equal to the desired channel spacing, reference spurs will occur exactly in band in the nearby channels. Integer- N requires the use of complex multiloop designs to achieve fine resolution without using a large division ratio with its associated high phase noise. Fractional- N synthesis is gaining in popularity as it offers significant potential improvement in phase noise performance due to the reduction in division ratio (N). The reference frequency can be set higher, and then the loop bandwidth increased for fast switching speed. Relatively new techniques, such as the use of sigma-delta modulators, can reduce the unwanted spurs to acceptable levels. Combinations of techniques, (i.e., hybrid approaches) and new techniques such as the antijitter circuit [50] are likely to be of increased interest as a way of improving performance even further.

7. MIXERS AND MODULATORS

Mixers and modulators on RFICs are almost always based on the Gilbert cell [51,52], shown in Fig. 23 for bipolar technology. T_1 to T_4 form the double-balanced mixer core; these four devices provide the commutating action, switching the RF input through four paths in current

mode. The double-balanced core ensures high port isolations and cancellation of even-order spurious products. T_5 and T_6 are the RF input gain stage and perform a voltage-to-current conversion. This stage may be linearized using either series feedback, for example, emitter degeneration, by adding an auxiliary feedback device in parallel, or by employing multi- \tanh cells or the micromixer [53–56]. The LO and RF signals are both fed into the mixer with balanced drive; the RF preamplifier can provide single-ended to balanced conversion, with low output impedance emitter follower output stages to drive the mixer. The balanced LO signal can be directly generated with a suitable push-pull oscillator. In CMOS form, especially for low-IF and

Figure 23. BJT Gilbert cell mixer.

Figure 24. Hartley-type mixer.

direct-conversion receivers, phase noise is crucial problem, and must be optimized by careful design [57].

7.1. Resistive FET Mixers

High-linearity CMOS mixers with low $1/f$ noise can be realized using the time-varying channel resistance in an unbiased FET fed with an LO signal at the gate. Without drain bias, the channel resistance acts as a very linear time-varying resistor and the devices do not conduct any LO current component. This results in a mixer with low intermodulation and flicker noise. Other advantages of this mixer include low DC power consumption and natural separation of LO and RF/IF ports. Both single-balanced and double-balanced resistive mixers have been demonstrated [58,59]. The disadvantage is that the insertion loss, compared to the gain of the active mixer, requires high LNA gain in the receiver, which may cause stability problems and increase DC power consumption.

7.2. Image Rejection Mixers and Single-Sideband Upconverters

Rejection of the image signal is a major challenge in integrated superheterodyne receivers. Using off-chip filtering is possible but greatly complicates the packaging of the chip. The phasing-type image rejection mixer introduced by Hartley is widely used. It consists of a pair of mixers that are fed with identical RF input signals but a phase quadrature LO, as shown in Fig. 24. The upper or lower sideband is canceled by quadrature combining the two IF signals. To achieve the required wideband 90° phase difference at high IFs, polyphase RC filters are widely employed. Adaptive tuning of the amplitude and phase balance can be used for optimum image rejection. Often, the Weaver architecture is used in order to simplify the

design of the 90° phase shift circuitry. For low-IF frequencies, for example, for voice or low-data-rate systems, the 90° combining can be performed digitally after A-to-D conversion; however, the A-to-D converters must then have enough dynamic range to preserve the wanted signal information in the presence of a strong image signal. In many current systems this is impractical, when the image is perhaps 50 dB above the wanted signal in the extreme case. The direct-conversion receiver discussed in Section 9 is a better solution since there is no image; the mixer is then a demodulator, converting the input RF directly to baseband. Quadrature mixing is required in order to preserve the baseband information when modulation schemes such as QPSK and m -QAM are used because the information in the upper and lower sidebands is not identical. In direct-conversion receivers second-order intermodulation can be a major issue, and the even-harmonic quadrature mixer using antiparallel Schottky diodes has been proposed as a solution [60].

For image rejection upconverters, the principle is the same, but the circuit is usually called a *phasing-type single-sideband modulator*. The RF input signals and the modulating signals are fed in phase quadrature while the mixer outputs are combined with an in-phase combiner as shown in Fig. 25. As shown, the single-sideband modulator produces only the lower sideband. If the modulating frequency's 0 and 90° signals are switched, then the upper sideband is produced. For digital modulation, the SSB upconverter becomes the IQ modulator and the IF signals are at baseband. The IQ (vector) modulator is a powerful technique for generating an RF signal with a range of complex modulation schemes, such as QPSK, m -QAM, OFDM, and CDMA. Significant digital processing power and fast D-to-A converters are required in order to incorporate functions such as frequency shifting, linearization, and spectral shaping.

8. FILTERS

The RF filter is one of the key building blocks in wireless communication transceivers. The function of the RF filter is to eliminate undesired signals, including thermal noise, interference, image signals, harmonic distortion, and signal leakage. The background theory for the synthesis of RF filters is well established, but the realization of on-chip Si-based RF filters is still a research topic. Numerous RF designers involved in developing fully-integrated

Figure 25. Single-sideband modulator block diagram.

transceiver chips become frustrated when trying to design a high-performance on-chip RF filter; passive components simply do not have sufficiently high enough Q factor, and active filters pose other problems. Often the problem is avoided by adopting other solutions, for example, by employing an image rejection mixer to reject image channels rather than attempting to realize an image filter.

There are, at present, three main approaches for on-chip RF filter design based on silicon technology. Their pros and cons will be briefly discussed in the following subsections.

8.1. Purely Passive Filters

The frequency response of passive filters is determined by the quality of the passive components that are used. The on-chip capacitor is not too problematic, but designing a low-loss on-chip inductor with standard silicon technology is difficult, as has been discussed already. The low- Q factor inductor significantly increases the passband insertion loss and also degrades the sharpness of the cutoff. The increased loss at the front-end receiver chain means increased receiver noise and hence degraded BER, while poor response sharpness limits the capability to reject the out-of-band unwanted signals and ultimately degrades the BER or robustness of the system. Usually, the achievable Q of spiral inductors on standard silicon technology is less than 15. Applying a lightly doped substrate, using insulator material, or MEMS technology effectively enhances the filter's Q , but fabrication is more expensive and may cause integration problems. Using bondwire inductors [61] to substitute planar spiral inductors is another solution but has not yet been proved practical in mass production. Consequently, purely passive RF bandpass filters seem to be an unattractive solution for silicon technology.

8.2. Inductorless Active Filters

Because of the large size and low Q of planar on-chip spiral inductors, active inductors realized by using two transistors with a feedback network have been widely studied. Figure 26 shows some topologies for single-ended active inductors in a CMOS process [62] using n- and p-type

Figure 26. Some examples of single-ended CMOS active inductor.

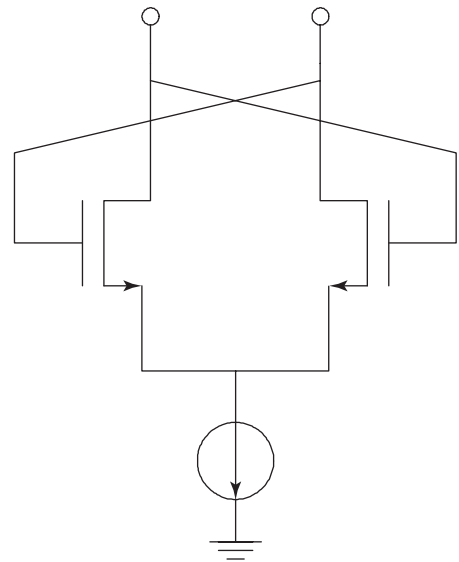

Figure 27. Differential CMOS active inductor.

transistors. To deal with substrate noise and coupling interference, these active inductors are usually realized in a differential form. The operating frequency of active inductors of the type shown in Fig. 26 increases as the unity-gain frequency of M_1 and M_2 increases. This can be accomplished by choosing small devices or applying larger bias current I_b . Of course, this leads to a dynamic range and power consumption degradation. The Q factor of such active inductors is usually less than unity, so for active filters some Q -enhancing schemes are necessary. The effect of low quality factor can be modeled as a series resistance; therefore, a negative series resistance is simply added to this positive resistance in the active inductor, contributing to a net zero resistance, which, in turn, increases Q dramatically [63,64]. Figure 27 shows a technique for synthesis of the negative resistance in differential form, which is often used [65]. One distinct benefit obtained from this inductorless active filter is the compact size since no planar inductors are used. Despite this, the inductorless active filter is still in doubt for its feasibility in RFIC applications. There are lots of disadvantages in this approach, and the major concern is its spurious-free dynamic range quantified by noise and intermodulation distortion, which is too poor for real-life wireless applications. The development of inductorless active filter techniques for Si-based RF applications is still in its infancy.

8.3. Active LC Filters

This technique was proposed as a compromise between circuit size and obtained dynamic range [65–68]. To achieve high dynamic range, a planar spiral inductor is used, rather than an active inductor in the previous subsection. The Q of the spiral inductor is enhanced by applying a Q -enhancement scheme such as a negative-resistance circuit. Another Q -enhancement technique [69], shown in Fig. 28, uses the negative mutual resistance, which negates the inherent parasitic resistance in the spiral inductor.

Figure 28. *Q*-enhanced resonator using mutual resistor scheme [69]. (Copyright IEEE, used with permission.)

The frequency response of this type of filter is affected by the frequency dependence of the synthetic negative resistance. Hence, this filter topology is limited to narrow-band applications. A balanced structure is preferred to a single-ended design, especially in silicon technology, since it has more immunity to the substrate coupling, substrate bounce, and noise from the supply lines, which are major problems. In addition, the balanced topology yields a high linearity since all even-order distortion is theoretically eliminated [70]. Automatic frequency and *Q* tuning techniques are essential for this active *LC* filter [68] because of the effects of tolerance, environmental variation, and the interacting effect of *Q* and frequency. Consequently, the power consumption, noise, and linearity of this filter are also determined by this automatic tuning circuit. The spurious free dynamic range is usually insufficient for wireless receivers but suits some wireless transmitter applications [68].

9. TRANSCEIVERS

The wireless market is highly competitive, and a single-chip solution [71–81] using Si technology is essential in order to achieve lowest possible cost. Unfortunately, it is highly challenging to design an integrated single-chip transceiver on silicon. It is well known that the digital CMOS process uses a heavily doped substrate to minimize the problem of latchup and substrate coupling, but this heavily doped substrate is not desirable for high-performance RF circuits. This conflict seems to be more problematic in a wireless receiver design since the sensitivity of the receiver must be sufficient to pick up extremely small received signals. In addition, to support multifunction applications, a multiband multimode wireless transceiver is needed to reduce cost [81]. The chip microphotograph in Fig. 29, which is a highly integrated quadband wireless transceiver designed on BiCMOS technology, exemplifies modern transceiver design. A wireless transceiver is composed of two main parts: a transmitter

Figure 29. A chip microphotograph of BiCMOS-based quadband homodyne transceiver [81]. (Copyright IEEE, used with permission.)

and a receiver. These two subsystems will now be discussed individually in detail.

9.1. Transmitters

Figure 30(a) shows a double-conversion superheterodyne transmitter. The topology has two mixer stages and needs an IF filter to suppress the in-band noise from the IF gain block. The dynamic range and power control of the transmitter can be determined by controlling a variable-gain amplifier at the IF or RF stage. This leads to a high dynamic range but high design complexity due to the additional passive and active components needed. Compared with its companion, a direct-conversion transmitter, the finished design has a large chip area, leading to high chip cost, which is unacceptable for low-cost applications.

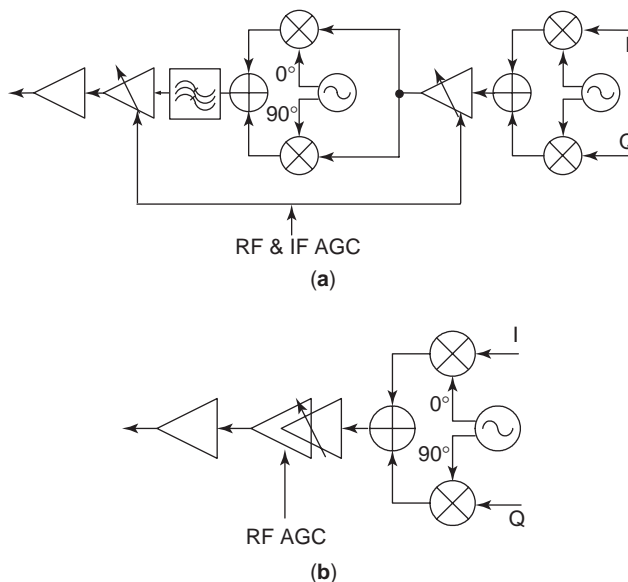

Figure 30. Wireless transmitter architectures: (a) double conversion; (b) direct conversion.

The most suitable single-chip and highly integrated solution for a wireless transmitter is perhaps the direct-carrier modulation or direct-conversion transmitter architecture, which is shown in Fig. 30b. Compared with its companion, the double-conversion transmitter, it evidently needs less circuit components by directly modulating baseband signals onto the RF carrier. Another benefit obtained is an increase in the versatility of the transmitter since the advances in high-speed digital technology and software radio techniques support the possibility of a multimode transmitter. Furthermore, numerous techniques for improving the transmitter performance, such as efficiency enhancement, linearization, and adaptive modulation, are highly feasible in the digital domain. However, care should be taken especially with I/Q phase and gain mismatch, VCO pulling, remodulation, and the dynamic range of the design [71].

The mismatch in phase and gain causes degradation in the transmitted signal quality, usually quantified in terms of error vector magnitude (EVM). Large EVM results in more spreading of the transmitted spectrum and degrades the signal-to-noise ratio. The VCO pulling and remodulation increase phase noise in the VCO and hence degrade the transmitted signal quality. Designing a VCO operating at double or quadruple of the LO is one of the solutions to eliminate this impairment. The high dynamic range of this transmitter is achieved only by adding amplifier gain stages at RF since there is no IF circuitry. For silicon technology, where the substrate loss is substantial, this may result in high power consumption being required for the direct-conversion transmitter, which is not suitable for specific applications that need high-dynamic-range transmitters.

Transmitters for wireless standards that use constant envelope modulation schemes [e.g., Gaussian minimum-shift keying (GMSK)] do not need such stringent dynamic range and linearity performance. The translation loop transmitter [71] is a candidate that is suitable for low-complexity transmitter designs as it has no need for the expensive SAW IF filter. The operation of this transmitter is similar to that of a standard PLL. Low complexity designs can be realized, but this architecture is limited to constant envelope modulation schemes only.

9.2. Receivers

Although various receiver architectures have been implemented for an integrated solution, none of them is the definitive approach for a particular wireless communication standard. The designers must reach a compromise based on cost, system complexity, and their own experience. In addition, all the existing receiver architectures have their advantages and disadvantages for a specific application. Therefore, in this subsection, each individual receiver architecture is discussed briefly.

The heterodyne receiver, shown in Fig 31a, has a long history in wireless communication systems, ranging from HF (high-frequency) to millimeter-wave bands and has been successfully used in various forms, whether with discrete components, hybrid circuits, or integrated circuits. The system downconverts the received RF signal to a low-frequency band, namely, the IF (intermediate frequency),

and the signal is then filtered and subsequently demodulated with low-frequency circuitry. The desired communication channel is selected by the frequency synthesizer (LO_1) such that the down-converting signal is fixed at a single IF. The key to the success of this architecture basically stems from its excellent selectivity by using a very high- Q IF filter to select channels. This high- Q IF filter offers the capability to eliminate nearby and out-of-band interference, and a high-selectivity and high-sensitivity receiver is achievable. Nevertheless, a Si-based single-chip solution for a heterodyne receiver has been hindered by the need for a high- Q filter. The design and realization of a high- Q IF filter on standard silicon ICs is still a research challenge. The simple approach to solve this is to employ an off-chip high- Q filter, normally a SAW filter. However, these are expensive, and furthermore the impedance interface of the on-chip mixer and IF amplifier must be set to $50\ \Omega$ for the SAW filter, and increased power consumption is inevitable. Consequently, this configuration seems unsuitable for applications that need low cost, low DC power, and small size, which are the major RFIC research issues nowadays.

The homodyne receiver, presently more often called the *zero-IF* or *direct-conversion receiver*, was, in fact, invented before its derivative, the heterodyne receiver. The homodyne structure is depicted in Fig. 31b. It is evident that this architecture has less components than the first since the received signal from the antenna is directly downconverted to baseband. The image problem is also eliminated as the IF is zero. However, it suffers other problems as a result of downconverting the received signal to DC. Because of the limited reverse-isolation performance of the LNA, LO leakage through the RF port of the mixer can be radiated to the atmosphere. Also, this LO leakage power can be reflected back into the receiver and then mixes with itself to produce an undesirable DC offset due to the mismatch of the antenna. Another homodyne receiver impairment is the second-order harmonic distortion effect from the second-order nonlinearity of the mixer. This problem seems to be more severe than the DC offset from LO leakage, which is static, since the modulating received signal is demodulated to DC via the second-order nonlinearity and then produces a time-varying DC offset. Furthermore, some channel conditions such as multipath fading and handset mobility can produce this dynamic DC offset. Consequently, the demodulated I/Q constellation is dynamically perturbed by this DC offset, and hence the receiver's BER will be considerably deteriorated unless the modulation signal is not sensitive to DC offsets. The flicker noise in active devices, especially in CMOS, also creates a DC offset by the down conversion mechanism.

Numerous techniques are used to control the DC offset problem. Cancellation of a static DC offset can be achieved by measuring the offset during the idle time intervals, but this is usable solely for time-division duplex systems, not for the frequency-division duplex mode. A time-varying DC offset is alleviated by choosing the subharmonic diode mixer with the drawback of high conversion loss. With careful design techniques, the homodyne receiver is well suited for wireless applications in which the low cost and long battery life are main targets.

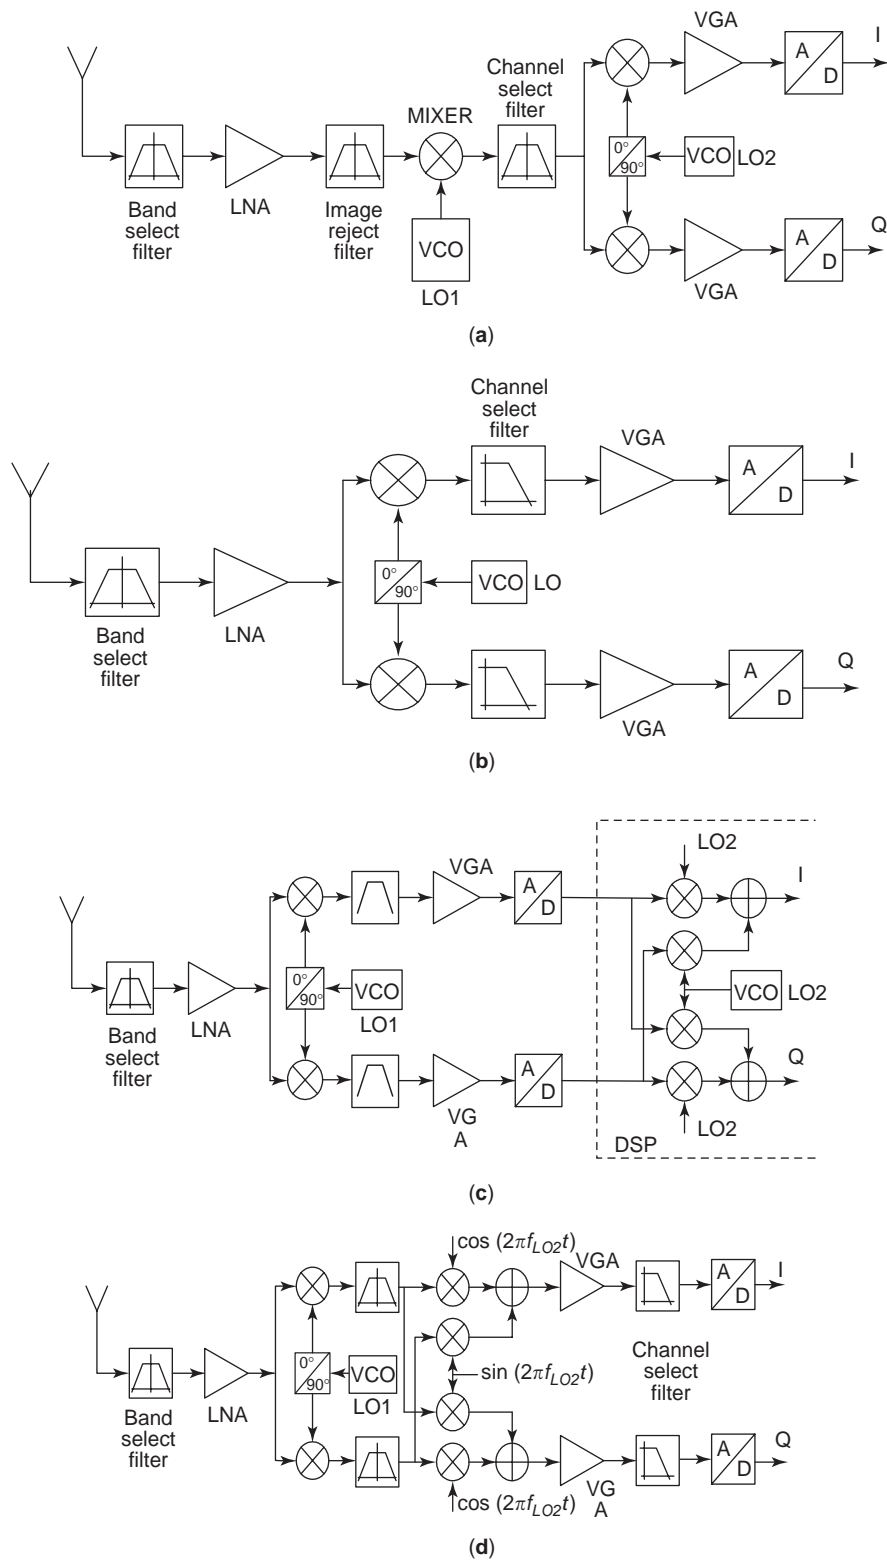

Figure 31. Some wireless receiver architectures: (a) heterodyne; (b) homodyne; (c) low IF; (d) wideband IF.

With the advance of digital CMOS technology, the low-IF receiver architecture, as shown in Fig. 31c, has been proposed. By selecting the IF low enough, the second downconversion can be performed in the digital domain. The IF must be chosen to be low in order to relax the ADC requirement. The advantage over the conventional het-

erodyne receiver is the low complexity, and the DC offset problem of the homodyne receiver does not exist. In principle, it achieves an integrated solution with minimal off-chip components. The digital (often software) downconversion step can incorporate techniques to achieve near-perfect quadrature for image rejection using a

Weaver-type topology. The phase and gain mismatch between the *I* and *Q* channel mixers can be adaptively tuned with complex algorithms [80]. However, the image signal is still present in the ADCs, and so the receiver topology is not suited when the image signal is much stronger than the desired RF signal, because of the ADC dynamic range problem.

Figure 31d shows the wideband IF receiver with double conversion. The LNA is followed by a quadrature down-conversion mixer to an IF, and this quadrature mixer will also suppress the image channels. However, the image rejection capability relies again on the *I-Q* phase/gain mismatch. There is no problem of LO leakage or DC offset unlike the homodyne receiver.

With the emerging digital technology leading to the development of high-speed digital circuitry, the second downconversion and the following filters can be implemented in the digital domain. The main disadvantage of this system is the large power consumption of the high-speed analog-to-digital converters (ADCs) and digital processing circuitry. So, there are trade offs, but this architecture inevitably finds application in wideband wireless communication, such as the 3G (third-generation) mobile systems.

10. CHIP-PACKAGE INTEGRATION

Virtually all RFICs require off-chip components, especially for power supply decoupling, and often components from a mix of semiconductor technologies must be combined in order to realize a product with the desired functionality and performance. Many microwave and millimeter-wave applications require certain key GaAs or InP components in order to achieve low noise, high power efficiency, and so on. Thus the chip(s) and package must be designed in a

coherent fashion for optimum results, and the system-in/on-package (SoP or SiP) approach has been widely adopted. Here, various ICs and high-*Q* passive components can be integrated, as shown conceptually in Fig. 32. Three main technologies are used for these multichip modules: MCM-L (laminate); MCM-C (ceramic), and MCM-D (deposited).

MCM-L technology uses copper on large fiberglass-reinforced or PTFE-based boards. In mass production, 18 × 24 in. panel sizes are common and costs per circuit are very low. Multilayer boards are produced by laminating different layers together. Vias can be produced by mechanical punching or laser machining. Using PTFE-based materials, this technology has been used to over 60 GHz.

In MCM-C technology, ceramic materials in tape or paste form are used to build up a multilayer substrate and metal pastes are deposited using screen printing. LTCC (low temperature cofired ceramic) technology has the advantage over MCM-L that SMT (surface mount technology) resistors and capacitors are already manufactured using the same sort of process. Therefore, embedded passive components can be fabricated in the module, which reduces component count and costs. Also, LTCC substrates offer a stable mechanical base for chip-on-board (CoB) assembly and offer better thermal properties than the organic materials of MCM-L technology.

MCM-D technology uses sputtering and evaporation of metals and spin coating of dielectrics. The metal deposition equipment used is relatively expensive, and the substrate must be in a vacuum. In mass production, the need to wait for the chamber pressure to drop down, and the limited substrate size, are significant drawbacks. However, thin-film technology gives the best pattern definition and the highest performance if suitable materials are used.

Figure 32. Conceptual system-in-package using a multilayer substrate [82].

Acknowledgments

Professor Robertson would like to acknowledge the support of the Engineering and Physical Sciences Research Council (EPSRC) as part of the *Continuing Education in Electronic Systems Integration*. Master's Training Package (Grant nr GR/N31122/01). See www.ceesi.ac.uk for details of the scheme and the academic partners.

M. Chongcheawchamnan would like to acknowledge the assistance of his project students and his colleague Sarayut Srisathit for their help in preparing this manuscript.

Figure 1. Geometric relationship of different radio navigation schemes.

RADIO NAVIGATION

GERALD BENDIXEN
Rockwell Collins, Inc.

A key function of navigation is the estimation of current position of a vessel. The reception of radio signals from transmitters whose location is known is a common means of implementing the position estimation functions. Several different schemes have been developed. They can be classified according to the means of determining a position from radio signals. Figure 1 provides the geometric relationships for the different schemes.

A theta–theta system determines the position by the vessel's bearing with respect to two transmitters. This scheme is not common in aviation due to its low accuracy when compared with other available systems.

Rho–theta system use radio signals to determine distance and bearing with respect to the transmitter. This scheme has been in common use in aviation for many years. Most of the airspace can be flown using this basic means of navigation. Errors in bearing measurement will result in position errors that depend on the distance from the station.

Rho–rho systems are based on distance measuring equipment (DME) that determines the position of an aircraft using two or more distance values. When only two distance values are available, there is potentially an ambiguity of position. This ambiguity is usually resolved by using the last computed position to determine the most reasonable position. The position accuracy of the rho–rho solution is dependent upon the accuracy of the measured

distance and the bearing angles to the stations. If the aircraft is close to the line through two stations, the error in the position solution using only those two stations becomes large.

Hyperbolic systems measure the time delay of signals simultaneously transmitted from three or more stations. The locus of all points that have a constant delay of signals from two stations is hyperbolic in shape and is called a line of position (LoP). The intersection of two LOP determine a unique position.

The accuracy of each navigation scheme is dependent on the particular implementation. The following sections describe the characteristics of the different equipment.

1. DME CHARACTERISTICS

Distance measuring equipment (DME) is a transponder system combining both airborne and ground equipment to provide distance information. The distance information may be used by other equipment or provided on an indicator to the pilot. In addition, the DME may provide ground speed information. Data from DME is used for both rho–rho and rho–theta navigation systems (see Fig. 2).

The major units of the airborne DME equipment are a receiver–transmitter together with an antenna. In addition, a control unit and distance display may be provided in the airborne equipment. The ground-based equipment is a transponder consisting of a receiver–transmitter and an antenna.

Figure 2. DME operation.

The DME ground-based facility is usually part of a VOR/DME, ILS/DME, VORTAC, or TACAN facility. A VOR/DME station is a VHF omnidirectional station combined with the DME. An ILS/DME facility is an instrument landing system with DME. TACAN is a military navigation system providing both azimuth and distance information. A VORTAC is a VOR facility together with TACAN equipment.

DME ground stations are capable of handling approximately 100 aircraft simultaneously. If more than 100 aircraft interrogate the ground station, the ground station reduces its sensitivity and replies to the 100 strongest interrogations. Most airborne DME units will operate down to a 50% reply efficiency, so operation is continued even when the ground stations does not respond to all interrogations.

The ground station continually transmits a 2700 pulse pair per second squitter signal. At 30s intervals, the ground station transmits a 1350 pulse pair per second signal that encodes the station identifier in Morse code. When interrogated by an airborne DME pulse pair, the ground station replaces the squitter pulse pair with a pulse pair 50 μs after interrogation.

The airborne equipment operates in two modes, search and track. In the search mode, the airborne equipment transmits 90 or more pulse pairs per second. The transmission rate is randomly shifted to prevent possible confusion effects due to another airborne DME transmitter. After each pulse pair is transmitted, the receiver equipment waits for a reply pulse pair that arrives with a consistent delay after the transmission. If such a reply is found, the airborne DME switches to the track mode and tracks the regular delays of the replies. In the track mode the airborne equipment reduces the interrogation rate to 20 or fewer pulse pairs per second. The reduction in the interrogation rate allows more airborne units to be serviced by the ground-based DME facility.

The airborne equipment converts the time duration between the transmission of the interrogation pulse pair and the reception of the reply pulse pair into distance. Because the speed of the radio signal is a known constant, the distance from the DME facility can be determined. To be more precise

Distance in nm

$$= (\text{Time duration in microseconds} - 50 \text{ ms}) / 12.359 \text{ ms/nm}$$

The airborne DME unit has memory that handles the situation when the reception of the DME reply is momentarily interrupted. The equipment uses the memory to

remain in the track mode and provide distance data during the reply interruption. The memory allows the DME to provide distance information for up to 10s after loss of reception.

It is common for airborne DME units to handle up to five DME ground facilities simultaneously by multiplexing the receiver-transmitter circuits. This allows the equipment to simultaneously provide distance information for up to five DME nav aids.

The airborne DME transmits and receives on one of 252 channels. There are 126 X and 126 Y channels. The transmit and receive frequencies of any one channel are separated by 63MHz. In the first 63 X channels, the ground-to-air frequency is 63MHz below the air-to-ground frequency. For X channels 64 through 126, the ground-to-air frequency is 63MHz above the air-to-ground frequency. For Y channels the situation is reversed. The ground-to-air frequency of the first 63 Y channels is 63MHz above the air-to-ground frequency. Channels 64Y to 126Y, the ground-to-air frequency is 63MHz below the air-to-ground frequency. The 252 ground-to-air frequencies are each whole MHz frequencies from 962 to 1213 MHz. The air-to-ground frequencies are each whole MHz frequencies from 1025 to 1150 MHz.

The duration between each pulse of the pulse pair transmitted by the airborne equipment and that of the ground equipment is different for X and Y channels. The table below shows the pulse spacing.

	Air-to-ground	Ground-to-air	
X-channel		12 μs	12 μs
Y-channel		36 μs	30 μs

Most DME channels are paired with a VHF frequency allocated to VOR or ILS. That is, for each VOR or ILS frequency there is an assigned DME channel for use when DME equipment is part of the nav aid facility. The X channels are paired with VHF frequencies in 100kHz increments (108.00, 108.10, 108.20, etc.). The Y channels are paired with VHF frequencies in 100kHz increments but offset by 50 kHz (108.05, 108.15, 108.25, etc.). The table below shows the DME channel pairing with VHF frequencies.

DME Channels	Assignment	VHF Frequencies
1–16	Unpaired	134.4–135.9 MHz
17–56		
Even channels with ILS	ILS and VOR	108.00–112.00 MHz
Odd channels with VOR		
60–69	Unpaired	133.3–134.2 MHz
57–59, 70–126	VOR	112.00–117.9 MHz

DME operation requires that the aircraft and the ground facility be in a direct line-of-sight connection. Terrain and the curvature of the earth limit the range. The formula below provides an approximate limit on the

range of DME equipment due to earth curvature with an assumption that the ground station antenna is about 16 ft. above the surface.

$$\text{DME range limit (nm)} = 1.23\sqrt{\text{aircraft altitude (ft)} + 4}$$

The DME provides the slant range distance from the aircraft to the DME navaid facility. If the DME range is large compared with the aircraft altitude the slant range is essentially the same as the ground distance. Navigation equipment that uses the DME range data can remove the effect of the aircraft altitude by incorporating in the calculation both the measured aircraft altitude and the elevation of the navaid as retrieved from the navigation database.

The accuracy of DME range measurement is dependent on the range, environmental conditions, and the equipment being used. A nominal 95% accuracy is about 0.1 nm at shorter ranges. For longer ranges the accuracy degrades due to atmospheric conditions and lower signal-to-noise ratio.

2. VOR EQUIPMENT CHARACTERISTICS

VHF omnidirectional range (VOR) equipment consists of a ground station (transmitter) and an airborne receiver. The VOR ground station continuously transmits a signal that may be used by all aircraft within reception range of the signal. Using the VOR signal, the receiver determines the bearing from the ground station to the receiver. VOR stations are often colocated with other navigational aids such as DME and TACAN stations. The frequency of VOR stations ranges from 108.00 to 117.95 MHz.

There are two types of VOR transmitters: Doppler VOR and conventional VOR. Doppler VOR has limited usage. The details of conventional VOR follow.

The transmitted signal from the VOR station consists of a VHF carrier and a 9960 Hz subcarrier. The VHF carrier is amplitude modulated by a variable 30 Hz signal whose phase is dependent upon the bearing with respect to the ground station. The 9960 subcarrier is frequency modulated by a 30 Hz reference signal. The subcarrier is modulated between 10440 and 9480 Hz (see Fig. 3).

Figure 4 illustrates the phase-bearing relationship of the two components of the VOR signal. At 0° bearing, the phase of the variable signal is the same as the phase of the reference signal. At 90° bearing from the ground station, the variable signal is 90° out of phase with respect to the reference signal. The phase difference between the two signals is proportional to bearing from the ground station to the receiver.

The phase difference between the variable signal and the reference signal is used by the receiver to determine the bearing from the ground station to the receiver. Essentially, the receiver separates the subcarrier from the VHF carrier, detects the phase of the 30 Hz signal in each and then determines the phase relationship.

In a conical area above the VOR station, the phase difference between the two signals cannot be detected reliably. This area is called the VOR cone of confusion.

Figure 3. Components of VOR signal.

Receivers have monitors that detect this condition and provide alerts to the pilot that the signal is unreliable.

In general, the VOR ground-station antenna is physically aligned so that the VOR signal indicates 0° bearing when the receiver is magnetically north of the ground station. That is, in general, the VOR bearing from the ground station to the receiver is the same as the magnetic bearing to the receiver. However, Earth's magnetic field is constantly changing. In Europe and the United States there are regions where the magnetic north is changing 1° every 7 years. Therefore even if the VOR signal was aligned with magnetic north at one instant in time, after some period of time there can be a significant difference. When the difference becomes too large (2° or so), the VOR antenna is usually realigned.

The accuracy of VOR signals is degraded by range and terrain. Generally, the VOR signal error is less than 1°. As the range from the VOR station is increased, the VOR signal bearing often oscillates around the true bearing. This effect is known as scalloping.

There are several types of VOR indicators that are in common use. Most of the indicators provide bearing as a rotating arrow pointing to the bearing angle on an azimuth card. The azimuth card is slaved to the heading sensor so that the current heading is at the top directly under the lubber line. The indicators often include a distance indication that is connected to the DME.

Figure 4. Phase relationship of VOR signal.

3. ILS CHARACTERISTICS

An instrument landing system (ILS) consists of ground-based transmitters and airborne equipment that provides lateral, along-track, and vertical guidance. The lateral signal is provided by a localizer transmitter and the vertical signal is provided by the glideslope transmitter. The airborne ILS receiver is capable of receiving and processing both the localizer and the glideslope signals. The along-track information is provided by marker beacons (transmitter located along the descent path that provide a narrow vertical radio signal) or distance measuring equipment (DME). The marker beacon receiver can be part of the ILS receiver or it can be a separate receiver (see Fig. 5).

The localizer beam is almost always aligned to guide the aircraft directly over the runway threshold. In certain

situations, only a localizer signal is provided and no electronic glideslope signal is provided. In some localizer-only situations, the localizer signal is not aligned to the runway but instead provides guidance to some location from which the pilot has other means to complete the landing.

In some cases, the ILS DME transponder delay is adjusted so that the sensed DME distance is zero at the runway threshold instead of at the DME antenna. Such DMEs are known as biased DMEs and the bias is indicated on the approach chart. There are two general arrangements of biased DMEs (see Fig. 6). In one case the DME antenna is located at the glideslope antenna and adjusted to read zero at the corresponding runway threshold. In the other case, the DME antenna is located midway between the two runway thresholds at opposite ends of the runway. In this case the single DME will support approaches from either direction and will read zero at both runway thresholds.

The localizer signal is transmitted on assigned frequencies between 108.1 and 111.95 MHz. As shown in Fig. 5, the localizer antenna is usually located past the far end of the runway very near the extended runway centerline. The signal pattern are two main lobes on each side of the centerline. The left lobe is predominantly modulated at

Figure 5. Common layout of ILS facility.

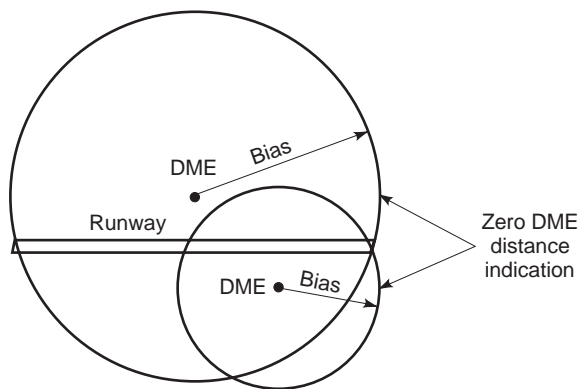

Figure 6. Biased DME antenna situations.

90 Hz and the right lobe is predominately modulated at 150 Hz. Along the center line, the two modulated signals are equal (see Fig. 7).

The localizer signal also extends backwards and is called the back course. This signal can be used for guidance but the modulation convention is reversed. There is no glideslope signal provided on the backcourse region. When flying the backcourse, either the equipment must reverse the localizer indications or the pilot must recognize and fly the reversed indications.

The glideslope signal is transmitted on assigned frequencies between 328.6 and 335.4 MHz. The glideslope antenna is located on the side of the approach end of the runway. The glideslope signal consists of two main lobes on each side of the desired glideslope path. The glideslope descent angle is usually 3°. To provide obstacle clearance or to reduce noise, steeper glideslope paths are used. The upper glideslope lobe is predominantly modulated at 90 Hz and the lower lobe is predominantly modulated at 150 Hz (see Fig. 8).

Marker beacon signals are transmitted at 75 MHz and are modulated at 400, 1300, or 3000 Hz. The transmitters are located along the descent path of to the runway. Figure 9 shows the general arrangement of the beacons. When the aircraft passes over the beacons, the marker beacon receiver detects the signal and provides an indication to the pilot of the passage. The exact location of the marker beacons is given on the approach procedure chart. Inner marker beacons are installed at runways with category II and category III operations.

In typical operation, the pilot maneuvers the aircraft to cross the localizer signal centerline. At this time, the localizer receiver provides an indication that the localizer signal is being received and provides a lateral deviation indication showing the aircraft displacement from the centerline. Using the lateral deviation indication, the

Figure 7. Localizer antenna lobe patterns.

Figure 8. Glideslope antenna lobe patterns.

pilot steers to the localizer centerline until the glideslope receiver indicates reception of the glideslope signal. At that time the pilot has both lateral and vertical indications to guide the aircraft on the desired glideslope path. The marker beacons or DME indications provide along-track indications of the progress of the descent.

4. ADF NAVIGATION

The automatic direction finder (ADF) is the oldest and most widely used radio navigation system. The ADF system consists of a ground-based transmitter and an airborne receiver. The ADF system provides an indication of the bearing of the station from the aircraft centerline. The ADF receiver is capable of receiving AM signals from 190 to 1750 kHz. The transmitter can be either commercial AM broadcast stations or nondirectional beacons (NDB) that are installed expressly for radio navigation.

An omnidirectional antenna is used to receive the signal to aid in tuning the receiver. The ADF receiver determined the bearing of the station using the directional sensitivity of loop antenna. The loop antenna may be physically rotated to determine the bearing to the signal or the bearing may be determined using electronic sensing of the signal strength from more than one loop.

5. LONG-RANGE NAVIGATION (LORAN)

Low-frequency long-range navigation (LORAN) was first developed for military applications during World War II. Since then it has evolved into today's LORAN-C system that is also used for civil applications. Marine applications were the first to appear, followed by aviation applications.

The LORAN system consists of a group or chain of transmitting stations and a receiver. Within each chain there is one master station and several slave stations identified by a single letter. Associated with each chain is a unique group repetition interval (GRI) that identifies

Figure 9. Marker beacon locations.

the chain. A single chain provides navigation coverage for several hundred miles from the master station. The frequencies of transmitted signal are between 90 and 110 kHz. The pulse patterns of the transmitters are different allowing the receiver to separate the received signals.

Within each chain, each station simultaneously transmits a pulse at the specified GRI. Each station has an assigned pulse pattern that allows the receiver to distinguish between the different signals. By determining the time differences between the set of received pulses, the receiver can determine the difference in distance from each transmitting station. If three or more signals are received, the receiver can determine the best estimate of the location of the receiver. The accuracy of the LORAN position estimate depends on the position of the receiver with respect to the location of stations providing signals. The nominal accuracy of the LORAN system is 0.25 nm when within the groundwave range.

To improve accuracy, LORAN receivers compensate for the differences in velocity of the ground wave when the signal is propagating over land rather than water.

6. GLOBAL POSITIONING SYSTEM (GPS)

The space segment of the global positioning system (GPS) consists of a set of orbiting satellite transmitters that provide two L-band, 1575.42 MHz (L1) and 1227.6 MHz (L2) signals. The two frequencies allow the appropriately equipped user to correct for errors due to ionospheric refraction. Civil receivers use only the L1 signal. The basic satellite configuration is a set of 24 satellites in 6 orbital planes.

The signals provided by the satellites are modulated with two pseudo-random-noise (PRN) codes: a coarse/acquisition (C/A) signal and a precise (P) signal. The P code component of the signal allows higher-precision ranging and information necessary to decode the signal that has restricted distribution.

The airborne GPS receiver receives the L1 signal of all satellites in view and by the use of correlation techniques can detect the unique C/A code for each satellite. The C/A code has a chipping rate of 1.023 MHz and a length of 1023 bits so it repeats every millisecond. By use of signals from four or more satellites, the receiver can determine the time reference and the range to each satellite and hence estimate the receiver position.

To deny the accuracy of GPS to unfriendly forces, the satellite signals are intentionally degraded using a concept known as selective availability (SA). This technique degrades to L1 signal characteristics to the extent that navigation accuracy is about 100 m (95%).

7. MICROWAVE LANDING SYSTEM (MLS)

Microwave landing systems consist of an azimuth and elevation microwave transmitters, a conventional DME transponder, and the airborne receivers. The azimuth transmitter provides coverage for 40° to each side of the

centerline. The elevation transmitter provides coverage up to 15° of elevation.

Microwave landing transmitters operate on one of 200 assigned frequencies between 5.031 and 5.1907 GHz. The azimuth transmitter provides a narrowbeam signal that sweeps the azimuth coverage area ($\pm 40^\circ$) at a rapid rate. By detecting the timing between the reception of the microwave signal, the receiver can determine the azimuth angle from the centerline. A preamble microwave signal is transmitted from a broadbeam antenna to indicate the beginning of the azimuth sweep. Various information is digitally encoded in the preamble signal. The elevation function is provided in the same manner as the azimuth function. High sweep rates provide about 40 samples per second for azimuth and elevation.

RADIO NOISE

ROGER DALKE

Institute for Telecommunication
Sciences

Radio noise can be defined as unwanted and unavoidable electromagnetic fluctuations that tend to obscure the information content of a desired radio signal. In a radio receiver, the noise disturbances are fluctuating voltages and currents that alter the desired signal's original frequency, amplitude, or phase in some unpredictable, unwanted manner. In early radios, much of the "noise" stemmed from the quality of the equipment; for example, poor contacts and unreliable connections, sensitivity to mechanical vibrations, and unstable detectors and amplifiers all contributed to the degradation of the radio signal. Over the years, there was steady progress in improving transmitters and receivers and greatly reducing or completely eliminating these and other noise sources. It was soon realized, however, that all sources of noise could not be totally eliminated and that a fundamental residual noise remained as a lower limit. This article focuses on such noise emanating from both natural sources and human activities that affect the performance of *narrowband* radiofrequency (RF) communications systems.

Typically radio noise is divided into two components—internal or *receiver* noise (that is, intrinsic noise generated by the receiving system components) and external or *environmental* radio noise (noise collected by the receiving system antenna). Receiver noise is largely due to natural processes such as *thermal noise*, arising from the motion of thermally agitated free electrons in resistors, and *shot noise*, resulting from current fluctuations superimposed on the steady current flow in both vacuum tubes and solid-state devices. Environmental noise is an intrinsic part of a wireless communications channel and consists of *natural radio noise* (i.e., noise originating from natural sources such as atmospheric noise and sky noise), and *unintentional* RF emissions due to human activity, which are

commonly referred to as *man-made* noise. Atmospheric noise is largely due to lightning and related phenomena, such as precipitation static. *Sky noise* is a generic term used to describe noise from a variety of terrestrial and extraterrestrial sources, such as cosmic noise and absorption of radio waves in Earth's atmosphere due to rain, water vapor, and oxygen. Intentional RF emissions that result in adjacent- and cochannel radio interference, including inter-modulation and jamming, are not covered in this article.

While such noise cannot be completely eliminated, understanding the character of radio noise allows engineers and system designers to evaluate radio system performance and devise means to lessen the adverse effects. The most important design parameter used to characterize noise performance is the predetection signal-to-noise ratio (SNR), and hence, noise power is generally the most significant parameter in relating the interference potential of noise to system performance. Noise power calculations must include noise generated in all components of the receiving system as well as the radio channel. This is usually accomplished by determining a single parameter, the *operating system noise factor*, which is essentially the ratio of the receiving system predetection noise power referenced to the terminals of an equivalent loss-less receiving antenna and the noise power available from a resistor at standard temperature (288 K).

In this article, important sources of receiver noise are described and the concept of receiver noise factor is developed. The noise factor concept is then extended to cover the entire radio receiving system, including the receiving antenna and environmental noise. This is followed by a description of important environmental noise sources.

1. RECEIVER NOISE AND NOISE FACTOR

The two most important receiver noise sources, used as noise standards and for noise characterization, are thermal and shot noise. Thermal noise is characterized as the spontaneous fluctuations in voltage across a resistor due to the random motion of thermally agitated electrons. Thermal noise is always present in any radio system and often establishes the lower limit of signal detection. Shot noise, on the other hand, originates in a flow of discrete charges not in equilibrium where the mean-square noise current is proportional to the product of elementary charge, the average current, and the bandwidth or $2eIb$ [1]. The cathode-to-anode stream of a temperature-saturated thermionic diode is an example of a pure shot noise generator. Shot noise currents in semiconductors such as diodes and transistors are due to the diffusion of charge carriers in p-n junctions.

Since thermal and shot noise may be described as being the sum of a very large number of random, short-lived disturbances, it follows from the central limit theorem that the processes are Gaussian. More precisely, observed voltages are white Gaussian noise. It was shown experimentally by Johnson [2] and theoretically by Nyquist [3] that the mean thermal noise power density available from a resistor is simply kT , where

$k = 1.38 \times 10^{-23} \text{ W Hz}^{-1} \text{ K}^{-1}$ is Boltzmann's constant and T is the absolute temperature of the resistor. The characterization as white noise is an approximation valid for typical narrowband RF communication systems operating at or near the standard ambient temperature $T_0 = 288 \text{ K}$. When quantum mechanical considerations are included, the mean power density kT is replaced by the more accurate expression obtained by Max Planck [4]

$$\frac{h\nu}{e^{h\nu/kT} - 1} \text{ (W/Hz)} \quad (1)$$

where $h = 6.626176 \times 10^{-34} \text{ J/Hz}$ is Planck's constant and ν represents frequency. Clearly, the flat power spectral density approximation is inaccurate when high frequencies are combined with cryogenic temperatures. Such systems are beyond the scope of this article.

Since both thermal and shot noise constitute white Gaussian noise sources, the properties of the noise voltage they deliver to an output circuit are indistinguishable. The significant difference is that thermal noise is proportional to temperature and shot noise is proportional to the average current. Hence, an equivalent noise temperature T_e can be used to characterize the noise of a device with thermal sources at temperature T and shot noise sources with mean power dw_s in an incremental bandwidth $d\nu$ as follows:

$$kT_e = kT + \frac{dw_s}{d\nu} \quad (2)$$

Solid-state shot noise sources such as noise diodes are commonly used in noise measurements. To achieve the required precision in T_e , these devices are calibrated against a primary standard. Noise diodes are commonly characterized in terms of excess noise ratio defined as

$$N_R = 10 \log_{10} \left(\frac{T_e}{T_0} - 1 \right) \text{ (dB)} \quad (3)$$

Thermal noise generated within or passing through a band-limited receiver circuit is colored and perhaps amplified. Since thermal noise power is independent of frequency over the bandwidth of most narrowband RF communication systems, it is useful to define a *noise-equivalent bandwidth* b_0 . When a resistor is attached to the input terminals of a linear receiver with gain $g(\nu)$, the total noise power available to the receiver w_a in the system band can be expressed in terms of the noise equivalent bandwidth as follows:

$$w_a = kT \int_0^\infty \frac{g(\nu)}{g_0} d\nu = kTb_0 \quad (4)$$

where g_0 is the nominal gain in the system bandwidth.

1.1. Statistical Characterization of Narrowband White Gaussian Noise

If the receiver input termination is a resistor, the receiver output noise voltage is a random function of time whose

behavior can only be described statistically. For a typical RF communication system, the signal is narrowband with respect to a central radiofrequency ν_c and the output noise voltage $V(t)$ can be written as

$$V(t) = \text{Re}\{v(t)e^{j2\pi\nu_c t}\} = E(t) \cos(2\pi\nu_c t - \Phi(t)) \quad (5)$$

where $v(t)$ is the complex baseband representation, $E(t)$ is the amplitude, and $\Phi(t)$ is the phase. In this representation, $v(t)$ is a complex random process and the pair $(E(t), \Phi(t))$ are two associated real random processes. When the observed voltages are white Gaussian noise, their baseband representations are 0-mean complex Gaussian processes with a flat power spectral density. This means that the co- and quad phases of v are independent and Gaussian distributed with 0 means and identical variances. It also means that voltages at different times are independent—a statement that must be emended by the fact that the receiver is narrowband, so that the actual observed power spectral density is proportional to the power spectrum of the receiver.

For these complex Gaussian processes, it is also true that the resulting amplitude and phase are independent of each other and that the phase is uniformly distributed over the complete circle. The amplitude is then *Rayleigh distributed*. In terms of the *instantaneous noise power* (which is proportional to the square of the amplitude), the cumulative distribution function (more precisely, the exceedance distribution function) is

$$\Pr\{\text{noise power} > w > 0\} = e^{-w/w_o} \quad (6)$$

where w_o is the average output noise power. This average equals the total area under the power spectral density curve and is equal to the sum of the mean power of the input noise amplified by the receiver and the mean noise power added by the receiver w_r or

$$w_o = g_o k T b_o + w_r \quad (7)$$

where T is the temperature of the resistor connected to the input terminals.

To obtain this result, the receiver noise is assumed to be Gaussian and white, as would be the case when thermal and shot noise are dominant. More generally, Eq. (7) is valid for any random processes. If the receiver noise is not Gaussian, however, the instantaneous power distribution would not be Rayleigh, as given in Eq. (6). The white Gaussian thermal noise assumption is reasonable for most narrowband RF receivers. In general, however, w_r will depend on frequency.

In noise calculations, it is important to define clearly what is meant by gain. There are many possible definitions of gain. Assuming that a signal generator is connected to the receiver input terminals and a power meter is connected to the receiver output terminals, an obvious choice would be to use the ratio of the input and output powers, or so-called *power gain*. Clearly, power gain depends on the impedance of both the signal generator as well as the impedance of the power meter, and hence a

noise characterization based merely on power gain is ambiguous. To circumvent this difficulty, the gain used in noise calculations is usually taken to be the *available power gain* [5], defined as the ratio of the available power from the receiver to the available power from a signal generator connected to the receiver input terminals so that any mismatch losses are included. With this definition, the gain does not depend on the receiver load; however, it does depend on the impedance of the signal generator.

In determining noise performance, the signal generator is often matched to the receiver so that the maximum power is delivered to the receiver. This is a reasonable choice for most RF applications, where signal generators, connecting cables, the loads, and so on are usually 50 Ω devices, or they are matched waveguide interfaces. It should also be noted that when there is a complete match at the input and output, the available gain and the power gain are equal.

1.2. The Receiver Noise Factor

In radio engineering it is desirable to have a simple, yet unambiguous method of characterizing the noise properties of a radio receiver. For this purpose, the concept of noise factor was developed and defined. There are a variety of ways to define noise factor. The basic idea is to relate the available noise power at the input of an active or passive two-port linear network to the noise power available at its output terminals. Assume that a CW signal generator is connected and matched to the input terminals of a receiver. Let w_g be the available signal generator power, w_1 be the signal power available at the load, and w_o be the available noise power at the load; the International Radio Consultative Committee (CCIR) [6] definition of noise factor is given as follows: The noise factor f_r of a radio receiver is defined to be the ratio of the available CW signal-to-reference noise power w_g/kT_0b_o at the terminals of the signal generator to the corresponding total signal-to-noise power ratio w_1/w_o available to the load of the linear portion of the receiver with the CW signal tuned to the maximum response of the receiver bandpass characteristic and with the signal generator output impedance at the reference temperature T_0 :

$$f_r = \frac{w_g/kT_0b_o}{w_1/w_o} = \frac{w_g}{w_1} \frac{w_o}{kT_0b_o} \quad (8)$$

The ratio w_1/w_g is simply the maximum available power gain and hence,

$$f_r = \frac{w_o}{g_o k T_0 b_o} \quad (9)$$

If it is assumed that the receiver bandwidth is very narrow $b_o \rightarrow d\nu$ so that the receiver noise is constant over the bandwidth, Eq. (9) gives the spot noise factor

$$f_s(\nu) = \frac{dw_o}{g(\nu)kT_0} \quad (10)$$

which is essentially a single-frequency value based on a unit bandwidth. It should be noted that the noise factor is simply the available output noise power referred to the input terminals (i.e., divided by the nominal gain) in units of kT_0b (i.e., the noise power available from a resistor at standard temperature).

The spot noise factor as given in Eq. (10) is equivalent to the Institute of Radio Engineers (IRE) definition [7]. In practice, for narrowband linear receivers, the weighted average spot noise factor over the system bandwidth \bar{f} is the quantity commonly used to characterize receiver noise performance

$$\bar{f} = \frac{\int_0^\infty f_s(v)g(v)dv}{\int_0^\infty g(v)dv} = \frac{w_0}{kT_0 \int_0^\infty g(v)dv} = \frac{w_0}{kT_0g_0b_0} \quad (11)$$

which is precisely f_r defined previously.

1.3. Noise Factor for a Passive Two-Port Linear Network

Communications receivers use transmission lines, attenuators, and other devices that can be generally classified as passive two-port linear networks. It is important to consider the effects of such devices operating in tandem with the actual receiver to characterize properly the noise performance of the receiving system.

The spot noise factor of a linear two-port network is obtained by calculating the power density ratio given in Eq. (10) when a resistor at reference temperature T_0 is connected to the input terminals of the network. If the network is at the ambient temperature T_0 , the available output noise power density is just kT_0 . If the network temperature is $T_n \neq T_0$, a correction arising from the temperature difference $T_0 - T_n$ must be included; hence

$$\frac{dw_0}{dv} = kT_n + gk(T_0 - T_n) \quad (12)$$

where g is the available gain. From Eq. (10), the spot noise factor is

$$f_s = 1 + \frac{T_n}{T_0} (1/g - 1) = 1 + \frac{T_n}{T_0} (\ell - 1) \quad (13)$$

where $\ell = 1/g$ is the available loss factor. Note that the spot noise factor depends on the input resistance used to determine the available gain (or loss).

1.4. Noise Factor for Cascaded Linear Networks

The noise factor for a linear receiving system can be calculated from the noise factors for its individual components. Understanding the relationship between the system noise factor and the noise factors for various components is important in system design since it shows which components contribute most significantly to the noise factor.

Assume that two networks are connected together: network a with spot noise factor f_a and gain g_a , and network b

with spot noise factor f_b and gain g_b . Further assume that a resistor is connected to the input of network a and the entire system is at temperature T_0 . The power density available at the output of network b is equal to the sum of the power density available at the input of network b scaled by g_b and the available noise power density due only to network b or

$$\frac{dw_0}{dv} = f_a g_a g_b kT_0 + (f_b - 1)g_b kT_0 \quad (14)$$

Using Eq. (10), the spot noise factor for two cascaded networks is

$$f_{ab} = f_a + \frac{f_b - 1}{g_a} \quad (15)$$

which is the result originally obtained by Friis [8]. Spot noise factors will usually vary somewhat across the band of an actual network and, for a particular system, the effects of nonuniform noise and gain may require additional consideration. As described previously, the weighted average spot noise factor is often used to characterize the receiving system.

This analysis is readily extended to several linear networks in cascade. For example, if network c is connected to the output terminals of network b , the system noise factor is

$$\begin{aligned} f_{abc} &= f_{ab} + (f_c - 1)/g_{ab} \\ &= f_a + (f_b - 1)/g_a + (f_c - 1)/g_a g_b \end{aligned} \quad (16)$$

and so on for additional networks. This result shows that if network a has a high gain, its noise factor will be the most important in determining the overall noise factor for the system. High-gain low-noise amplifiers are often used to reduce the noise factor in receiving systems.

1.5. Noise Factor for the Linear Portion of a Receiving System

In addition to the actual receiver, a typical radio receiving system is composed of an antenna, transmission lines, and other circuits, all of which contribute noise and must be included in the analysis of the system noise performance. Of particular importance for wireless systems is the receiving antenna, which collects environmental noise. By using the results of the previous sections, the noise factor can be extended to characterize any specified portion of an operating system at any specified set of input terminals. For a radio receiving system, the most useful reference point for noise factor calculations is the input to the terminals of an equivalent loss-free receiving antenna [6]. This reference point provides an appropriate and unique measure of the performance of the entire receiving system.

Typically, the linear portion of a receiving system can be divided into a series of cascaded two-port networks, as shown in Fig. 1. The receiving antenna is modeled as an equivalent loss-free antenna connected to an antenna circuit network. A section of transmission line connects the

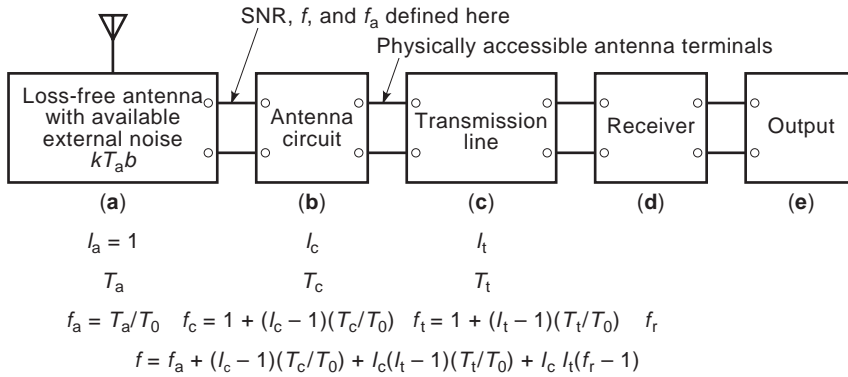

Figure 1. The receiving system and its operating noise factor, f .

antenna to the receiver. Using Eq. (16), the noise factor for the receiving system is

$$f = f_a + \frac{f_c - 1}{g_a} + \frac{f_t - 1}{g_a g_c} + \frac{f_r - 1}{g_a g_c g_t} \quad (17)$$

where f_a , f_c , and f_t are the spot noise factors; and g_a , g_c , and g_t are the gains of the antenna, antenna circuit, and transmission line, respectively; and f_r is the spot noise factor of the receiver.

The external noise power in the band $d\nu$ that is available at the terminals of the loss-free receiving antenna can be expressed as $kT_a d\nu$, where T_a is the noise temperature of the radiation resistance of the receiving antenna at the center frequency of the receiver. The antenna noise factor f_a is equal to the ratio T_a/T_0 . Since the antenna circuit and transmission line are passive two-port networks, the spot noise factor can be expressed as

$$f = T_a/T_0 + (l_c - 1)T_c/T_0 + l_c(l_t - 1)T_t/T_0 + l_c l_t(f_r - 1) \quad (18)$$

where the gains have been replaced by the corresponding loss factors. Strictly speaking, this result is meaningful for narrowband systems where the noise factors do not vary significantly over the operating frequency range. It should be understood that all of the spot noise factors and loss factors are determined with generator impedances that are the same as those in the actual receiving system. Also, the formula for cascaded networks is applicable regardless of the degree of match or mismatch between the output impedance of one network and the input impedance of the following network. The magnitudes of these mismatch losses do influence the values of the spot noise factors and loss factors and will thus affect the noise factor.

The quantity of interest for finite bandwidth systems is the weighted average spot noise factor, which is often referred to as the operating noise factor f_{op} [6]. The operating noise factor can be expressed in terms of the weighted average noise factors of the receiving system components as follows

$$f_{op} = \bar{f}_a + \bar{f}_{ct} - 1 + (b_r/b)(g_r/g_o)(\bar{f}_r - 1) \quad (19)$$

where, denoting the overall system gain at frequency ν as $g(\nu)$, the weighted average antenna noise factor is

$$\bar{f}_a = \frac{\int_0^\infty T_a(\nu)g(\nu) d\nu}{T_0 \int_0^\infty g(\nu) d\nu} \quad (20)$$

\bar{f}_{ct} is the weighted average combined noise factor of the antenna circuit and transmission-line network

$$\bar{f}_{ct} = \frac{\int_0^\infty f_{ct}(\nu)g(\nu) d\nu}{\int_0^\infty g(\nu) d\nu} \quad (21)$$

b is the equivalent bandwidth of the system, b_r is the equivalent bandwidth of the receiver, g_o is the nominal gain of the system, g_r is the maximum gain of the receiver, and \bar{f}_r is the weighted average receiver noise factor, as given in Eq. (11) and using the receiver gain function.

To apply the foregoing results, noise factors for the receiver, related electronic components, and an equivalent loss-less antenna must be determined. Using the definitions given in the previous sections, measurement methods can be readily devised and implemented to calculate accurately noise factors for receivers and other electronic components (see, for example, Ref. 9). The determination of the antenna noise factor is, in general, much more difficult. For RF communication systems, the antenna noise factor is often a nonstationary random process that varies with time, frequency, geographic location, and receiving antenna characteristics. As a consequence, researchers have spent many years measuring and compiling statistics that can be used to estimate the antenna noise factor for various environmental noise sources. In the case of man-made noise, not only is there a fast time dependence over fractions of an hour to days, but there is also a relatively slow time dependence based on advances in technology. Significant changes in the background noise for a particular environment may occur within a few years, and as a consequence published data can become outdated. Antenna noise factors based on published noise statistics are described in the following sections.

So far in this article, lowercase letters have been used to represent noise factors, gains, and bandwidths. In noise

analysis, it is common to express these quantities as decibels and to use uppercase letters to denote that the quantity is in decibels. Also, when given in decibels, the noise factor is usually referred to as *noise figure*; for example, the antenna noise figure is

$$F_a = 10 \log_{10} f_a \text{ (dB)} \quad (22)$$

and in decibels, the notations for gain and bandwidth are

$$G = 10 \log_{10} g \text{ (dB)}; B = 10 \log_{10} b \text{ (dB/Hz)} \quad (23)$$

This notation and terminology is used in the following sections.

2. ENVIRONMENTAL NOISE AND ANTENNA NOISE FIGURE

Environmental noise emanates from both natural and man-made sources and is collected by the receiving system antenna. The determination of noise parameters, such as the antenna noise figure F_a , requires careful measurement programs that must account for temporal, spatial, and frequency variations of the particular noise source. In this section, some of the more important sources of environmental noise are described. The statistical data presented are based on many years of measurements of natural and man-made noise over the entire radio spectrum.

2.1. F_a for Blackbody Radiation

All objects at temperatures above absolute zero radiate energy in the form of electromagnetic waves. A blackbody is a perfect absorber and a perfect radiator of electromagnetic energy. It absorbs all incident radiation at all wavelengths, and the radiation from it is a function of only temperature and wavelength. Although the concept of a blackbody is an idealization, it can be used to estimate the radio noise emitted by a variety of objects. For example, the cosmic background, thought to be the lingering echo of the creation of the universe, is equivalent to radiation from a blackbody at 2.7 K.

The *brightness* β of radiation from a blackbody radiator at temperature T and frequency ν is given by Planck's radiation law [10]:

$$\beta = \frac{2h\nu^3}{c^2(e^{h\nu/kT} - 1)} \text{ (W m}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1}) \quad (24)$$

where $c = 2.99792458 \times 10^8$ (m/s) is the speed of light in free space. For typical radio frequencies and standard temperatures, where, $h\nu \ll kT$, this reduces to the Rayleigh-Jeans approximation

$$\beta \cong \frac{2kT}{\lambda^2} \quad (25)$$

where λ is the free-space wavelength. As in the case of thermal noise in a resistor, the radiation power is directly proportional to temperature.

The power received by an antenna from an incremental blackbody of area dA at temperature T in bandwidth $d\nu$ is

$$dw = \frac{1}{2} \beta \frac{\lambda^2}{4\pi} \gamma(\Omega) d\Omega d\nu \cong \frac{kT}{4\pi} \gamma(\Omega) d\Omega d\nu \quad (26)$$

where $d\Omega$ is the element of solid angle subtended at the receiver by dA and $\gamma(\Omega)$ is the directive gain of the antenna. Note that the antenna only collects half the power since only a single polarization is received. The total power collected when the blackbody radiation at temperature T is received from all directions is

$$w = kT d\nu \left(\frac{1}{4\pi} \int_{4\pi} \gamma(\Omega) d\Omega \right) = kT d\nu \quad (27)$$

which is the same as the total power available from a resistor at temperature T . Hence, the antenna temperature is simply T and $f_a = T/T_0$ independent of the antenna gain.

2.2. F_a for Common Natural and Man-Made Radio Noise Sources

Both natural and man-made radio noise have been measured and carefully studied by many scientists and engineers in the latter half of the twentieth century. The results of these efforts have been published in various journals, conference proceedings, and reports and recommendations of radio engineering organizations, such as the International Telecommunication Union (ITU) [11–14]. In this article, statistical data from these studies are presented for what are considered to be some of the more important environmental radio noise sources. For a more detailed treatment of these and other sources of radio noise, the reader is referred to the references.

The antenna noise figure F_a for background natural radio noise from 1 Hz to 1 THz is illustrated in Fig. 2 [15]. These data show that natural radio noise depends strongly on frequency over the radio spectrum (nominally 3 kHz–300 GHz). In addition, several noise sources are nonstationary in time and space (e.g., atmospheric, sun, rain). Of particular interest for communications systems operating at or below about 30 MHz is atmospheric noise, where F_a is random and is characterized by its statistics. Atmospheric noise is also non-Gaussian. The other noise sources shown in this figure are essentially Gaussian.

For RF systems operating at frequencies of several hundred megahertz and below, man-made noise is an important source of radio noise. Like atmospheric noise, man-made noise is both nonstationary and non-Gaussian. Figure 3 [16] shows the median antenna noise figure F_{am} for man-made noise in four environments and galactic noise as compared with the expected daytime and nighttime levels for atmospheric noise. Man-made noise is strongly dependent on frequency and, in general, the F_{am} curves have a slope of -27.7 dB/decade of frequency.

Figure 4 [15] shows the details of natural radio noise over the frequency range of 100 MHz–100 GHz. The estimated median business-area man-made noise has also been included. The $E(90^\circ)$ curve shows sky noise measured with a narrowbeam antenna at zenith. The water

Figure 2. Natural radio noise (1 Hz-1 THz) [15].

and oxygen absorption bands are clearly visible. The $E(0^\circ)$ curve is sky noise with a narrowbeam antenna directed along Earth’s surface.

It was shown that when an antenna receives blackbody radiation at a uniform temperature from all directions, F_a does not depend on the receiving antenna gain. For most environmental noise sources, however, F_a does depend on the antenna gain and on several other factors. Appropriate corrections must be applied when the radio system-receiving antenna differs significantly from that used to measure the noise.

Curves L_D , L_Q , F , H , and M in Fig. 2 all refer to very narrowbeam antennas pointing directly at the source. Noise from such sources (sun, atmospheric gasses, the Earth surface) are also expressed in terms of brightness temperature. These curves can be used to calculate the

antenna temperature of a particular receiving antenna by integrating Eq. (25) in terms of temperature over the region occupied by the noise source

$$T_a = \frac{\gamma_0}{4\pi} \int_{\text{sources}} T(\Omega)p(\Omega) d\Omega \quad (28)$$

where γ_0 is the gain and $p(\Omega)$ is the pattern of the receiving antenna; that is, $\gamma(\Omega) = \gamma_0 p(\Omega)$. For example, the sun has a beamwidth of about $\frac{1}{2}^\circ$. If a receiving antenna with gain γ_0 is aimed at the sun and the pattern is essentially constant over the intersection with the sun’s beam, the antenna temperature is

$$T_a = \frac{\gamma_0}{4\pi} \int_{\text{Sun}} T(\Omega)p(\Omega) d\Omega \cong \gamma_0 T_s \left(\frac{\pi}{1440} \right)^2 \quad (29)$$

where T_s is the brightness temperature of the sun at the desired frequency.

In Fig. 4, there are two curves associated with galactic noise. Curve B is for an omnidirectional antenna, while curve C is for an infinitely narrow beam aimed toward the galactic center. Because of the relative motion of the earth and galaxy, galactic noise is not constant in time. A more accurate determination of galactic noise for other types of antennas can be obtained by using published radio sky data, which gives the brightness temperature as a function of position in the sky. Such data are available in CCIR Report 720-2 [14], which contains maps of the brightness temperature of the radio sky at 408 MHz and an approximate expression for the frequency dependence of the temperature.

Figure 3. Median values of F_a [16].

Figure 4. F_a versus frequency (100 MHz–100 GHz), where A = estimated median business area man-made noise, B = galactic noise, C = galactic noise (toward galactic center with infinitely narrow beamwidth), D = quiet sun ($\frac{1}{2}^\circ$ beamwidth directed at sun), E = sky noise due to oxygen and water vapor (very narrow beam antenna); upper curve 0° elevation angle, lower curve 90° elevation angle, F = cosmic background, 2.7 K [15].

2.3. Atmospheric and Man-Made Noise

The most significant sources of environmental radio noise at frequencies below 1 GHz are man-made and atmospheric. For these sources, the noise data were measured with a grounded electrically short monopole antenna. Since this type of noise most probably arrives at the receiver at relatively low elevation angles and from random directions, such an azimuthally omnidirectional antenna is well suited for noise measurements. Predicting the antenna noise figure for other types of receiving antennas requires an assessment of the differences between the ideal short monopole antenna and the desired receiving antenna. Factors that should be considered are antenna efficiency, directivity, polarization, and height above the ground.

The direction of arrival for both atmospheric and man-made noise has been shown to be nonuniform, varying by as much as 10 dB with direction [17]. Since the noise is nonstationary, predicting F_a for high-gain antennas would likely be arduous if worst-case estimates based on the measured data do not provide sufficient accuracy. For azimuthally symmetric antennas such as a half-wave dipole, a correction factor based on the ratio of the desired antenna gain to the reference antenna gain can be applied to obtain the appropriate value for F_a .

Since these noise processes are nonstationary, the usual design parameter, SNR, is random and the underlying statistics of the noise process as a function of time and geographic location must be understood to assess radio performance properly. These characteristics are discussed in more detail in the following sections.

Another important consideration is that both atmospheric and man-made noise are non-Gaussian. Typically, communication system performance is calculated on the basis of Gaussian noise. A more detailed analysis incorporating the statistics of the actual non-Gaussian noise process may be required in radio design and performance evaluations. Several publications listed in the references provide information regarding the impulsive nature of these noise sources and its effect on radio receivers.

2.3.1. Statistics of F_a for Atmospheric Noise. Atmospheric noise is an important consideration for wireless communication systems operating below 30 MHz. The main source of atmospheric noise is lightning. The electromagnetic energy emitted by electrical storms couples into the Earth–ionosphere waveguide, and hence, local noise levels can be significantly influenced by distant thunderstorms. Because of ionospheric interactions, overall atmospheric noise levels are greater at night, as shown in Fig. 3.

In Fig. 2, curves A , B , C , and D represent the expected range of F_a at the surface of the earth. These data are of the average background, taking into account all times of day, seasons, and the entire surface of Earth. Curves A and B give the maximum and minimum values of F_a from 1 Hz to 10 kHz. In this frequency range, there is very little seasonal, diurnal, or geographic variation. Note that the variation of F_a begins to increase significantly at about 100 Hz. This is due to the variability of the Earth–ionosphere waveguide cutoff. Curves C and D give the atmospheric noise from 10 kHz to about 30 MHz, above which the noise levels are quite low. Curve C is the value of F_a exceeded 0.5% of the time, and curve D is the value of F_a exceeded 99.5% of the time. These results are derived from background atmospheric noise and do not include effects of “nearby” electrical storms. A compilation of measurements showing the peak field strength for 1 mile distant lightning as a function of frequency is given in Fig. 5 [18].

The variability of F_a , particularly in the medium-frequency (MF) and high-frequency (HF) communication bands (300 kHz–30 MHz), is so large that the bounds given in Fig. 2 alone cannot be used to obtain a useful characterization of radio system performance. It is important, therefore, to know how F_a and other noise statistics vary with time and location. Starting in 1957, the average power levels and other relevant statistics were measured on a worldwide basis using a network of 15 stations. These measurements spanned 13 kHz–20 MHz and considered both the time of day and the season. The results of several years of measurements were published in the National Bureau of Standards (NBS) Technical Note Series 18 [19].

Figure 5. Lightning emission peak field strength, 1 mile distant. (Reprinted from p. 369 of Ref. 18, by permission, © 1982 IEEE.)

and later published in CCIR Report 332 [12]. A numerical representation of the data contained in Report 332 is also available [20].

The published data give, for each frequency, location, season, and time of day (measured in 4-h increments), the month-hour median value of F_a along with values exceed 10% (upper decile, D_u) and 90% (lower decile, D_l) of the time. As an example of these data, Fig. 6 shows worldwide values for the median antenna noise figure F_{am} in the winter between 0000 and 0400 local time. The median noise figure at other frequencies, D_u , D_l , and related statistics are obtained using the curves shown in Fig. 7.

The statistical distribution of F_a and hence the radio system SNR is readily obtained from the published data. For a given season and measurement time block (4 h) it has been shown that F_a is adequately represented by two lognormal distributions [21], one above the median value and one below. As an example, the distribution of F_a for 3 MHz at Boulder, Colorado in the winter at 0000–0400 can be determined using the data from Figs. 6 and 7. First, the 1 MHz value of F_{am} at the geographic location of interest is obtained from Fig. 6 and corrected to 3 MHz using Fig. 7. Then D_u and D_l as well as their standard deviations are obtained from Fig. 7. Using normal probability paper, these three points define the two intersecting lines that give the two desired lognormal distributions. The resulting distribution is shown in Fig. 8. Hence, if a radio system is operating at 3 MHz, the system performance can be conveniently specified in terms of the percent of time that the required SNR will be available at a particular geographic location, season, and time.

2.3.2. Statistics of F_a for Man-Made Noise. In 1974, Spaulding and Disney [22] presented results from many years of measurements of man-made radio noise. They devised methods for estimating the noise power and noise amplitude statistics that are important in the design of radio systems. These methods are described in the CCIR reports [13] and have been widely used by industry. Figure 3 summarizes these results in terms of the median antenna noise figure F_{am} . As with atmospheric noise, man-made noise is both nonstationary and non-Gaussian and is a significant source of radio noise for frequencies below a few hundred megahertz. The antenna noise figure F_a varies both in time and location. The noise level depends on the type and extent of human activities, which are conveniently classified into four man-made noise environments [13] described in Table 1.

The within-the-hour time variability of F_a is commonly described by two log-normal distributions [21], as described previously for atmospheric noise. Values of D_u and D_l are given in CCIR Report 258 as a function of frequency and environment. More recently, Spaulding and Stewart [21] have analyzed the data used to obtain these decile values and have found that it is appropriate to use the values $D_u = 9.7$ dB and $D_l = 7$ dB, independent of environmental category and frequency. Other proposed noise models described in Report 258 include a simple Gaussian model that does not describe the skewness observed in measured noise data and a more complex χ^2 model.

As an example, the distributions of F_a using $D_u = 9.7$ dB and $D_l = 7$ dB at 137 MHz for business, residential, rural, and quiet rural noise environments are shown in Fig. 9. These data include the contribution of Galactic

Figure 6. Expected values of atmospheric radio noise, F_{am} (dB above kT_0b at 1 MHz) (winter 0000–0400 LT) (12).

noise, which is only significant in the quiet rural noise environment.

Location variability is also an important consideration when characterizing F_a . The usual assumption [22] is that F_{am} is the noise figure exceeded 50% of the time at 50% of the locations. Hence, the time distribution of F_a as shown in Fig. 9 is the noise power exceeded at 50% of the locations for a particular environment. If it is assumed that the location variability is Gaussian, then the value \tilde{F}_a that is exceeded at other than 50% of locations is obtained from

$$\tilde{F}_a = F_a + \sqrt{2}\sigma_L \operatorname{erfc}^{-1} \left[\frac{\% \text{ locations}}{50} \right] \quad (30)$$

where erfc^{-1} is the inverse complementary error function and σ_L is the standard deviation of the location distribution.

The location variability in terms of the standard deviation σ_L of the median value as a function of frequency and environment is given in Table 2 [13]. As may be expected, σ_L for the business environment is much larger than either the residential or rural environment.

3. APPLICABILITY OF PUBLISHED MAN-MADE NOISE STATISTICS TO CONTEMPORARY ENVIRONMENTS

The man-made noise statistics presented are largely based on measurements that were made many years ago in North America by Spaulding and Disney [22]. More recently, Spaulding has warned that the CCIR data may now be inaccurate due to technological advances [23]. This is largely based on the fact that emissions from newer automobile ignition systems, a major contributor to man-made noise in urban areas, have decreased dramatically over the years. After reviewing more recent measurements and trend analyses, Spaulding concluded [23] that in the business environment “at 100 MHz in the 1970’s time-frame, F_{am} was on the order of 20 dB but now is probably approximately 20 dB less.” This conclusion, however, is not based on a comprehensive set of noise measurements as would be necessary to update the previous survey described in Ref. 23.

While the improvements in automobile ignition systems have likely affected the noise levels in business and residential environments, emissions from gap discharge and corona in power transmission and distribution lines have probably not decreased with time. Figure 10 [22]

Figure 7. (a) Variation of radio noise with frequency (winter; 000–0400 LT) (12). ——— Expected values of atmospheric noise. - - - - - Expected values of galactic noise. (b) Data on noise variability and character (winter; 000–0400 LT) (12). $\sigma_{F_{am}}$: standard deviation of values of F_{am} . D_u : ratio of upper decile to median value, F_{am} . σ_{D_u} : standard deviation of values of D_u . D_t : Ratio of median value, F_{am} , to lower decile. σ_{D_t} : standard deviation of values of D_t . V_{dm} : expected value of median deviation of average voltage. The values shown are for a bandwidth of 200 Hz. σ_{V_d} : standard deviation of V_d [12].

Figure 8. The distribution of F_a values for atmospheric radio noise at Boulder, Colorado, 3 MHz, for the winter season, 0000–0400 hours [21].

shows F_{am} under, and one-quarter mile from, a 115 kV line in rural Wyoming. It is interesting to note that the noise measured one-quarter mile from the power line is about the same as that predicted for a rural environment. A possible conclusion is that if power and distribution lines are the primary noise source in rural environments, rural man-made noise is not likely to have decreased. However, one would not expect noise in an urban environment to be less (than rural), as would be the case with the estimated 20 dB reduction in F_{am} .

Another factor that could significantly affect the level and character of man-made radio noise is the proliferation of electronic devices (e.g., computers, electronic switching devices, microwave ovens) that are unintentional RF emitters. Such devices have become ubiquitous in business, residential, and rural environments and could affect both the magnitude of the noise power as well as its frequency dependence.

The man-made noise data presented in the previous sections are applicable to North America; the validity of extension to other parts of the world cannot be determined precisely. CCIR Report 258 describes very high frequency (VHF) measurements made in business and residential

areas of the United Kingdom where the noise power was found to be some 10 dB below that shown in Fig. 3 [16]. This is attributed to differences in patterns of utilization of electric and mechanical appliances and regulation of interference. The report also states that, due to such differences, the noise statistics should be used with caution. It should be noted, however, that if an overall 10 dB reduction in urban noise can be justified, the man-made noise environments near 100 MHz would be bounded by what are now classified as rural (worst) and quiet rural (best) environments, as shown in Fig. 3.

Relatively recent noise measurements at 137 MHz [24] show that the statistics of man-made noise are significantly different from what is predicted by CCIR Report 258. For example, Fig. 11 shows the median, mean, and peak (exceeded 0.01% of the time) values of F_a measured over a 24-h period in a business environment. Diurnal variations corresponding to human activity are clearly

Table 1. CCIR Report 258 Definitions of Man-Made Noise Environments

Environment	Characteristics
Business	Areas where predominant usage is for any type of business
Residential	Areas used predominantly for single or multiple family dwellings (at least five single-family units per hectare), no large or busy highways
Rural	Areas where dwelling density is no more than one every two hectares
Quiet Rural	No definition given

Figure 9. Distribution of F_a for man-made and galactic noise.

Table 2. Location Variability in Terms of the Standard Deviation for Various Environments

Frequency (MHz)	σ_L Business	σ_L Residential	σ_L Rural
0.25	6.1	3.5	3.9
0.50	8.2	4.3	4.4
1.00	2.3	2.5	7.1
2.50	9.1	8.1	8.0
5.00	6.1	5.5	7.7
10.00	4.2	2.9	4.0
20.00	4.9	4.7	4.5
48.00	7.1	4.0	3.2
102.00	8.8	2.7	3.8
250.00	3.8	2.9	2.3

Figure 10. Power line noise measurements near a 115-kV line in rural Wyoming [22].

evident. The relatively steady within-the-hour values of the mean power (F_a) are not consistent with the predicted within-the-hour distribution of F_a for a business environment (see Fig. 9). Figure 12 shows the distribution of F_a measured at six urban sites plotted on normal probability paper. The distribution at a particular site was obtained by collecting statistics measured within two-minute intervals spaced about an hour apart from hours of continuous

Figure 11. Median, mean, and peak noise power near an office park [24].

Figure 12. Power averages from measurements at six urban sites [24].

measurements made at that particular location. Hence, the results should correspond to the hour-to-hour time variability, which, for the most part, is relatively low at most of the locations. Location variations however are quite large, exceeding 12 dB in some cases. More importantly, these measurements show that there are business environments (down-town urban areas) where F_{am} is still nearly 20 dB.

In summary, the 137 MHz measurements demonstrate that important changes have occurred in both the level and character of man-made noise since the comprehensive noise survey described by Spaulding and Disney [22]. While these measurements can only be considered as a “spot check,” they do show that standard methods used to predict man-made radio noise are probably outdated. It is concluded that additional comprehensive man-made noise measurements at RF frequencies into the ultra-high-frequency (UHF) band will be necessary to provide radio system designers and engineers with the required tools to effectively design modern radio systems.

RADIO ON FIBER SYSTEMS (RoF SYSTEMS)

SHOZO KOMAKI
KATSUTOSHI TSUKAMOTO
Osaka University
Osaka, Japan

1. INTRODUCTION

Trends of user needs in communications are reflected in the advances in (1) wireless communications that enable us to use small and high-spectrum-efficient personal handy terminals (cellular phones) that employ a microcellular

architecture [1,2] and (2) global and seamless communication networking that enable international roaming and wide-area handover capability. Both types of advances are directed toward the same destination in terms of user demands; however, they are diametrically opposed from the viewpoint of technological feasibility. For example, handover among a large number of microcells poses many problems, and a huge number of base stations are required to make microcellular communication more global.

To solve these technical problems, it has been proposed that microcells in wide areas are connected by radio-on-fiber (RoF) links, where RF signals are transported through optically connected links, in the same way as in radio-air-interfaced space transmission [3–24]. One more user demand in multimedia communication has motivated the development of broadband service. To prepare wide-band service to the home, the fibers-to-the-home (FTTH) system has been implemented. Wireless mobile broadband service is easily implemented on the fiber-to-the-curb (FTTC) facility. These two systems, FTTH and FTTC, are collectively termed as the *fiber-to-the-air* (FTTA) system. The RoF systems are also applicable to the home networks, especially in the wireless home network system backbone.

In Section 2 of this article, the basic configuration and devices for RoF system are described. Section 3 discusses the performance calculations and designing method. Section 4 describes various application examples, such as communications, electrooptical sampling (EOS), and radioastronomy. Finally, in Section 5, networking of RF signals on fiber networks collectively referred to as the “Radio Highway” including wavelength-division multiplexing (WDM), optical time-division multiple access (optical TDMA), and optical code-division multiple access (optical CDMA), are described.

2. BASIC CONFIGURATIONS

The basic configuration of the RoF link is shown in Fig. 1. RF signals from different wireless services are accessed by the same base station and are then concentrated in the base station antenna. The received RF signals are converted to the optical signal by using an electrical-to-optical signal converter (E/O). Thereafter the optical signal is transmitted to the central control station (CCS) through the optical fiber, and converted to the RF signal by an optical-to-electrical (O/E) converter, usually by means of a photodiode. The converted RF signal is divided into the radio signals from each wireless service by using the appropriate bandpass filters.

The RoF link is implemented to the mobile systems as shown in Fig. 2, and has following advantages over the conventional microcellular base stations:

1. Use of base station equipment is versatile for various new types of service because the base station does not need to be replaced even if new service is installed.
2. Allowance for user concentration to a specific area is high because the control station equipment and

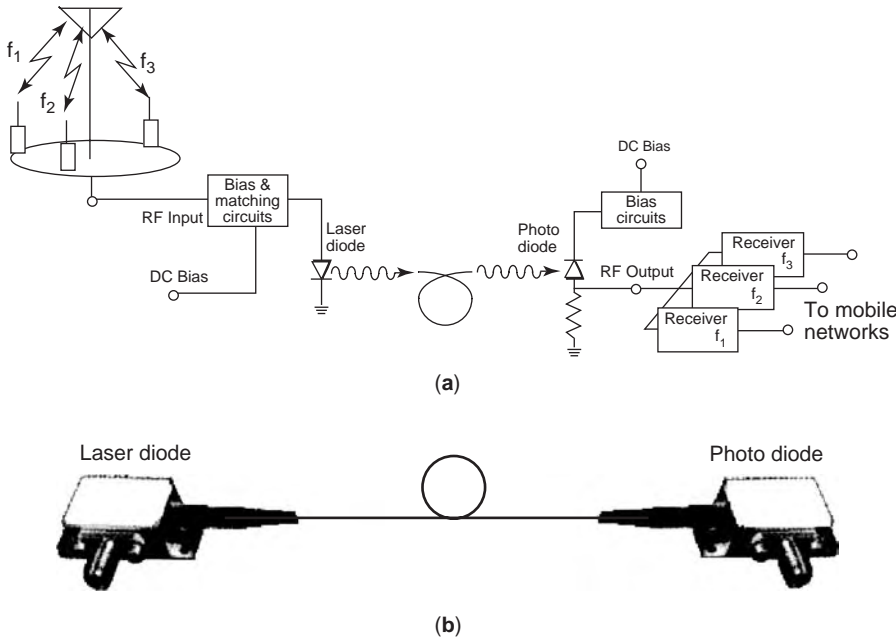

Figure 1. Basic configuration of RoF link: (a) block diagram; (b) photograph.

spectrum resource will be used in the user-concentrated area by switching the central equipment to the appropriate cell(s).

3. Base station operation/maintenance cost is low, because no complicated equipment is required, such as frequency-synthesized transceivers, modems, base-band circuits, and control circuits for frequency assignment.
4. Handover among cells is easy because the control station can observe all the cell signals simultaneously and instantaneous switching to the better signal is available at the control station.

3. DEVICES FOR RoF LINKS

The following components are required to realize the RoF link: (1) a light source, (2) an optical modulator, (3) an optical amplifier, and (4) a photodetector. The E/O converter consists of devices (1) and (2), and the O/E converter consists of device (4). Device (3) is installed in the relay nodes to compensate the fiber loss. In the simplest case of direct modulation, one laser diode (LD). One photodetector (PD), and one fiber can effect an RoF link. The LD, which current is directly modulated by the received RF signals, is used for the light source, and generates an intensity

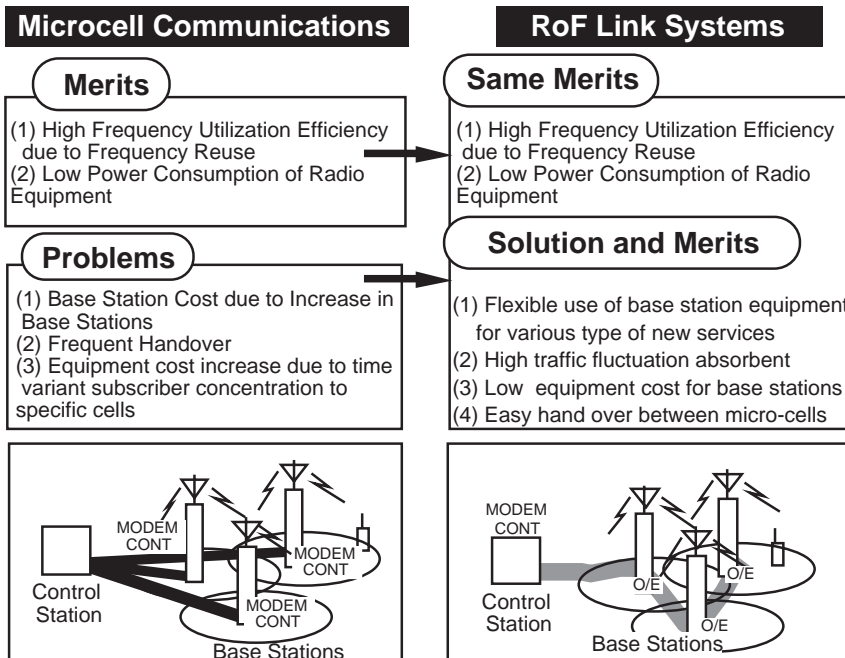

Figure 2. Microcell systems and RoF link solutions.

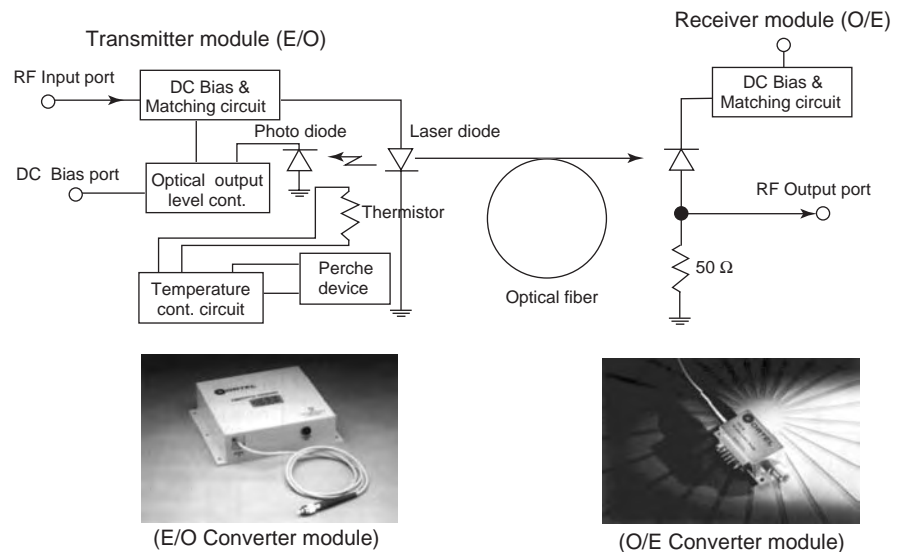

Figure 3. RoF link application (direct modulation).

modulated optical signal. A pin (positive–intrinsic–negative) photodiode (pin PD) is used for the O/E converter, and it converts the optical intensity to diode current in which the RF signals are included. So, in the minimum case, only two diodes can realize the RoF link. Several of these devices are described in the following paragraphs.

3.1. Light Source

Compactness and high output power are required in the same way as in the conventional digital transmission system, and 1.3 or 1.55 μm wavelength is selected for low loss and low dispersion capability of fiber. In case of direct-intensity modulation, modulation bandwidth, linearity, and high quantum efficiency of mobility are required for LD operation. The Fabry–Perot (FP) LD is used for low RF frequency range (< 1 GHz) because of cost considerations. If the range exceeds 1 GHz, a *distributed-feedback* (DFB) LD is used because of the modulation linearity and the optical spectrum coherency under the high-speed transition of diode current. Figure 3 shows the typical configuration of the direct-modulation RoF system in commercial use. In this model, the PD located at the transmitter side monitors LD output power, and optical output power of LD is controlled to maintain the constant level. Also, the *Peltier device* controls the LD temperature to maintain the temperature constant. This model can handle less than 8 GHz, and the link loss from RF input to RF output is about 20–30 dB [25].

3.2. External Modulator

In case of RF ranges beyond 10 GHz, external modulation is usually used. Figure 4 shows examples of the Mach–Zehnder (MZ) external modulator [26]. The MZ modulator is fabricated on the lithium niobium oxide (LiNbO_3) substrate and performs coplanar-type phase modulators, and thus is also called as LN modulator. In this modulator, the phase of two branches are modulated by the electrooptic characteristics of the substrate, and phase change of each branch is converted intensity change in the combined

output optical power. In the figure, two operation schemes of suppressed carrier double-sideband modulation (SC-DSB) and single-sideband modulation (SSB) are illustrated. In the latter case, bandwidth of the modulated optical fiber is narrow, so the optical fiber dispersion is not sensitive and LN modulation is suitable for high-RF signal transmission. The LN modulator requires high RF voltage $V\pi$ to achieve high-intensity change. In the normal case, $V\pi$ exists at several volts and with the driver fabrication, it is slightly difficult to match the 50 Ω impedance in the wide band. Also, the LN modulator characteristics depend on polarization, so polarization adjustment equipment at the input of LN modulator is required.

Another type of external modulation device is the *electroabsorption modulator* (EAM), shown in Fig. 5 [27–29]. This modulator utilizes a photodiode that is biased by DC + RF signals and operates as the optical attenuator and throughpath according with the bias voltage and optical wavelength. So it works as an optical intensity modulator. It is free from polarization and thus does not require a polarization controller even if the EAM is installed at the remote site. Also, as the EAM is a diode in structure, it works as a photodetector when it is appropriately biased. In EAM, RF signal matching is achieved by the stub-matching scheme and this widens the RF bandwidth and enhances modulation efficiency.

3.3. Optical Amplifier

There are no differences between digital transmission and RoF transmission from the viewpoint of optical amplifiers. Linearity and the noise factor (NF) are more sensitive for the RoF case. For the optical amplifier, there are several types, such as the rare-earth metal-doped fiber amplifier, the Raman amplifier, and the semiconductor optical amplifier (SOA). In the first category, the erbium-doped fiber amplifier (EDFA), the thulium-doped fiber amplifier (TDFA), and the praseodymium-doped fiber amplifier (PDFA) are used depending on the signal wavelength, 1.53–1.62 μm , 1.45–1.50 μm , and 1.3 μm , respectively. The Raman amplifier in the second category can amplify any

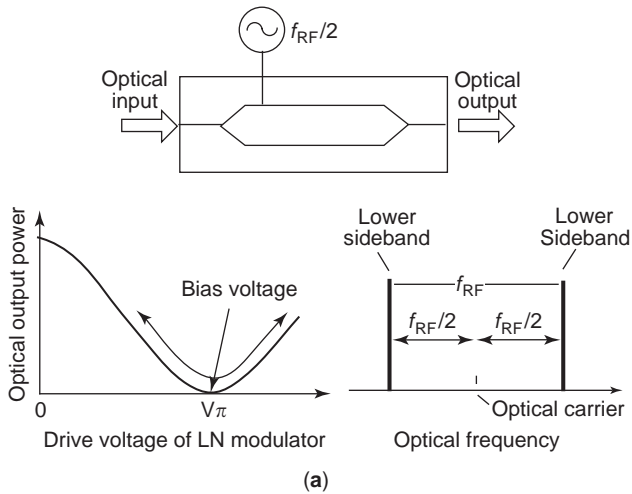

Figure 4. Configurations of Mach-Zehnder-type external modulations: (a) suppressed carrier system; (b) single-sideband system.

wavelength and can undoped normal fiber; however, it is necessary to improve the excited light power efficiency. The final SOA category has the advantage of compact size and power efficiency; however it has a drawback of polarization dependency and spontaneous-emission noise penalty. In the wavelength band 1.55 μm (C band), EDFA is generally used because of the linearity and low-noise features. Figure 6 shows an example EDFA block diagram. Typical performance of this amplifier is as follows: output power +13 dBm, power gain 30 dB, and noise figure less than 10 dB [30].

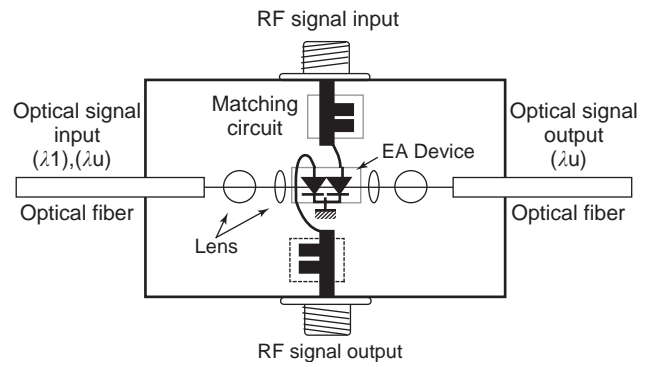

Figure 5. Electroabsorption external modulator (EAM) and detector.

3.4. Photodetector

The pin photodiode (pin PD) is more widely used than the avalanche photodetector (APD), because of the noise floor requirement and linearity. For frequency bands exceeding 10 GHz, the uni-directional-traveling carrier PD (UTC-PD) is used to achieve high maximum output power in the region of high-frequency band [31].

Figure 7 shows the structure and the output power of the pin PD and UTC-PD. From Fig. 7a, a hole in the pin PD deteriorates the response speed of photodetection because of the low mobility of hole and carrier accumulation. In contrast, the UTC-PD works on only high-mobility electron drift, and the light absorption layer is different from the intrinsic layer; this results in high-speed response, and the output power increases in the high-RF-frequency range. A comparison of output power levels is illustrated in Fig. 7b. For the forward link, the detected RF signal should be amplified by the RF stage, because the high transmission power from the antenna to air is required. Thus the detected power level should be high enough to avoid post-RF amplification. The UTC-PD can generate a detected power level of more than 0 dBm, without post-RF amplification. So, the UTC-PD is applicable for short-range wireless communication systems, such as wireless LAN (local-area network) applications.

To reduce the post-RF amplification, a phototransistor using a metal semiconductor field-effect transistor (MESFET) shows promising potential as a device suitable for high functional applications such as a mixer, an oscillator, or an amplifier, which is controlled by optical signals. Active-array applications are now under development. The High-electron-mobility FET (HEMT) is also applicable to photodetection, and has low noise performance; however, the absorption layer is too thin for HEMT, and some structure modification will be necessary for the photoabsorption layer. The EAM described in Section 3.2 can be also applicable to the photo detection by tuning DC bias voltage and/or wavelength.

4. RoF LINK PERFORMANCE AND DEGRADATION FACTORS

This section describes RoF link degradation factors, the process of performance calculation, and some numerical

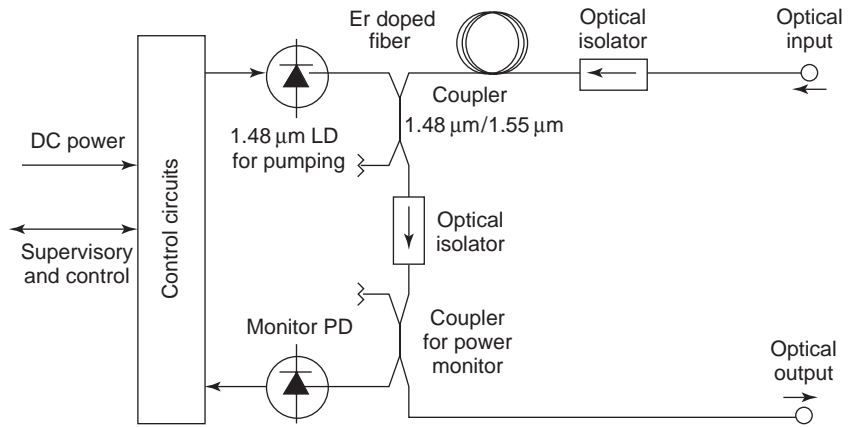

Figure 6. Typical configuration of EDFA amplifier.

(a)

Figure 7. (a) Comparison of pin-PD and UTC-PD structures; (b) output powers.

results of the carrier-to-noise and distortion power ratio (CNDP). Several factors are involved: (1) detected RF signal power, (2) thermal noise, (3) shot noise, (4) relative intensity noise (RIN), and (5) intermodulation distortion (IMD).

4.1. Detected RF Signal Power

Detected RF signal power varies with respect to the received optical signal level, PD responsivity, and the optical modulation index (OMI). Detected RF power is proportional to m^2 and I_{ph}^2 , where m and I_{ph} are the optical modulation index and detected optical current, respectively. I_{ph} is determined by the optical received power, PD responsivity, and matching circuit configuration of PD. RoF RF-to-RF link loss is proportional to the square of optical loss. Detected RF signal power strongly depends on the matching circuit of the post-PD section, and bandpass operation can enhance the detected signal power level [24].

4.2. Thermal Noise

Thermal noise is white Gaussian noise, at the PD, and is proportional to the absolute temperature T , the Boltzmann constant k_B , and signal bandwidth BW. Also, optical amplifier noise (i.e., spontaneous emission) can be assumed to be the white Gaussian noise depending on the amplifier gain, and is treated as an index of the total noise factor (NF) increase.

4.3. Shot Noise

Shot noise is the noise component that is proportional to the input optical power, produced at PD. More recent RoF links utilize pin PD, so shot noise is lower than that associated with the use of the avalanche photodiode (APD). Also, the more recent RoF systems are applied for wide-bandwidth (e.g., 10-MHz) applications, so shot noise power is usually lower than that of thermal noise and can be disregarded in the normal system.

4.4. Relative Intensity Noise (RIN)

The noise component produced at the LD is proportional to the LD diode current, that is, proportional to the optical output power; this type of noise is called *relative intensity noise* (RIN). Usually, RIN is comparable to or greater than the thermal noise, when the LD output power is high. RIN depends on RF frequency and increases when the RF frequency is high. In the normal case, RIN values range between -120 and -150 dB/Hz.

4.5. Intermodulation Distortion

Intermodulation distortion occurs as a result of the nonlinearity of the RoF link, which results mainly from the nonlinearity of the modulator because high power driving is required. The optical modulation index (OMI) is used to indicate the modulation depth of the optical intensity. This parameter is normally defined by the ratio of the maximum envelope to peak-to-peak modulation depth. When OMI is small, the intermodulation distortion is low because the linear part of the optical modulator is used.

From the viewpoint of detected RF output power level, high OMI is desirable to maximize the RF output power. As a result, optimum OMI values occur when the CNDP is maximized.

Because of the intermodulation, multiple harmonic signals are generated. In wideband applications such as CATV systems, multioctave intermodulation should be considered. Second-harmonic and third-order intermodulation is taken into account; *second-order harmonics* is defined by composite second-order (CSO) and *third-order intermodulation* is defined by *composite third-order beats* (CTBs). In the mobile wireless application, bandwidth is narrow compared with the carrier frequency, so the second-order distortion can be filtered out at the RF stage, and third-order intermodulation (IM3) noise is dominant. Third-order distortion components are measured by the parameter of IM3. When the number of carriers becomes large, the intermodulation power increases because the number of intermodulation products also increases.

In case of the IM3 treatment, one example of the output power level of various components is shown in Fig. 8 according to the input RF power level of the RoF link. Desired RF output power increases both linearly and proportionally at input RF power levels less than -5 dBm. For higher levels, output power is gradually saturated. Signal power of third-order components increases in proportion to the cube of the input RF power, and as a result the IM3, defined by the ratio of third-order intermodulation component power and the fundamental output power, increases in proportion to the square of the input RF power. The intercept point as shown in Fig. 8 normally reflects this performance, as in the microwave amplifier case. The output power at the 1 dB gain compression is also used as the measure of RoF link. In the RoF link, the spurious-free dynamic range (SFDR) measure is also used to indicate system performance. SFDR is correlated with the system noise floor, which factors in radio system bandwidth and other properties, and this value is a measure of the allowable fade margin for radio signals.

4.6. Numerical Considerations for Carrier-to-Noise and Distortion Power Ratio

This section presents an example numerical calculation of a real RoF link applied for a mobile link. Deterioration factors and the overall configuration are shown in Fig. 9. There exist two main deterioration factors: (1) intermodulation among the RF carriers, as described in Section 4.5, and (2) time-varying frequency selectivity in received signal level, which is caused by the multipath fading and delay spread. In actual mobile communication systems, distances between mobile stations and a base station are not the same for each mobile station, and moreover multipath fading occurs in the propagation path. So the levels of signals received from every mobile stations differ, and these received signal levels fluctuating with time. This frequency selectivity-intermodulation problem is more severe in case of reverse link, in which transmission power control is not implemented. In the design of the nonlinearity degradation, received signal level variation due to multipath fading should be taken into consideration

Figure 8. Fundamental characteristics of RoF link.

[14,15]. In this article, we assume that every received signal from the mobile station has the Rayleigh distribution of the same average power, and that all these signals are statistically independent of each other. Letting the received signal levels from the i th mobile station be denoted by r_i , the probability density function of r_i is shown as

$$p(r_i) = \frac{r_i}{\sigma^2} \exp - \frac{r_i^2}{2\sigma^2} \quad (1)$$

where σ^2 is the received signal average power. The received signal r is

$$r = \sum_i r_i \cos \omega_i t \quad (2)$$

where ω_i is the carrier frequency of the i th mobile station. The received RF signal is converted to the optical signal by E/O. E/O has nonlinear characteristics, and this nonlinearity causes the undesired intermodulation among r_i . The optical signal is reconverted to the RF signal by the photodetector. The signal-to-noise and distortion power ratio (CNDP) of the detected signal is shown by the following equation [4]

$$\frac{C}{N + D} = \frac{\frac{1}{2} m^2 I_{ph}^2}{(RIN I_{ph}^2 + 2eI_{ph} + \langle I_{th}^2 \rangle + \sigma_{IM}^2) BW} \quad (3)$$

where m , I_{ph} , RIN , e , I_{th}^2 , σ_{IM}^2 , and BW are optical modulation index, detected signal photocurrent, relative

Figure 9. Degradation factors of RoF link.

intensity noise, electron charge, equivalent input noise-current variances, equivalent intermodulation spectrum density, and signal bandwidth, respectively. The output signal of the nonlinear device is denoted by the following equation

$$P = P_0 \left[1 + a_1 \sum_i r_i \cos \omega_i t + a_2 \left(\sum_i r_i \cos \omega_i t \right)^2 + a_3 \left(\sum_i r_i \cos \omega_i t \right)^3 + \dots \right] \quad (4)$$

where a_1 , a_2 , and a_3 are the nonlinear coefficients of the desired signal, second-order signal, and third-order signal respectively. For narrowband transmission as in mobile communications, latest factor that interferes with the desired signal is the third intermodulation as denoted in the previous section, and the intermodulation noise is shown in the following equation, where the radio signal consists of three tones, r_1 , r_2 , and r_3

$$\sigma_{IM}^2 BW = \frac{1}{2} \left(\frac{3}{2} a_3 r_1 r_2 r_3 \right)^2 I_{ph} \quad (5)$$

where the signal that experiences interference is the intermediate tone, signal r_2 . In this analysis, if tones r_i are Rayleigh distributed as shown in Eq. (1), then the average CNDR is calculated by the following equation:

$$\left\langle \frac{C}{N+D} \right\rangle = \int \dots \int_0^\infty \frac{C}{N+D} \times p(r_1)p(r_2) \dots p(r_m) \times dr_1 dr_2 \dots dr_m \quad (6)$$

Figure 10 shows the calculated examples of average CNDR $C/(N+D)$. The results shows the existence of an optimum OMI with a value that depends on the number of carriers.

5. APPLICATION EXAMPLE OF RoF LINK

The RoF link is applied for various application areas, such as (1) the hybrid fiber-coaxial (HFC) system in CATV services; (2) mobile communications, (3) broadband access networks, termed the *fiber-to-the-air* (FTTA) system, (4) electrooptic sampling (EOS), and (5) radioastronomy.

5.1. CATV Applications

Figure 11 shows the hybrid fiber-coaxial (HFC) system for most general application examples. In the conventional CATV system, cable loss and distribution power loss are very large, so a large number of line amplifiers is required to compensate these losses. When the core part of the CATV link is replaced by the RoF link, the cost of line amplifiers and the operation bandwidth are improved because the number of line amplifiers is reduced. In the CATV, 92 AM TV channels exist between 91.25 and 643.25 MHz, so the second-order harmonics CSO should

Figure 10. Calculated carrier-to-noise and distortion power ratio of RoF link [bandwidth 300 kHz per carrier; optical power -3.0 dBm; third nonlinearity 0.01; fiber loss 2 dB; noise power 4.0×10^{-22} W/Hz; photodetector sensibility 0.8 A/W (amperes per watt)].

be considered, and the required value will be more than 60 dBc.

5.2. Mobile Applications

In this section, we described several applications such as indoor wireless and mobile base station links for shadowing areas.

Figure 12 shows one of RoF link application for the mobile service shadowing area extension. In this application, a remote base station named “canister” is installed in the shadowing region of the main service area and the RoF link is used between canisters and a main mobile base station [9]. Many similar examples have been reported for

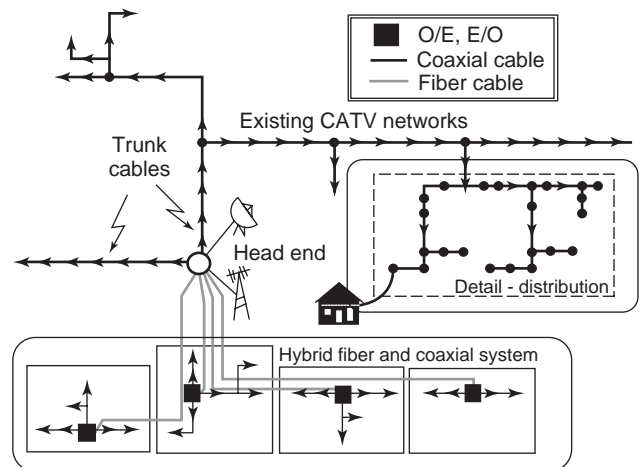

Figure 11. Hybrid fiber-coaxial link (HFC).

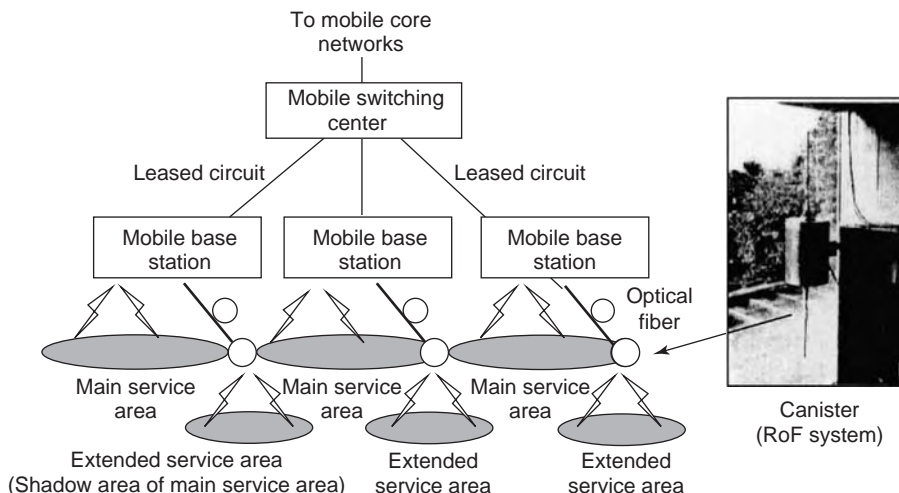

Figure 12. RoF link application for mobile communication system.

shadowing area extensions such as department stores and underground shopping mall parking lots. In some case, both ends are open air, and received RF signals are transmitted through fiber and reemitted to the shadowing area and vice versa. In these applications, the optical fiber length can be reduced; however, the spurious and noise emission to the open air should be strongly protected. In another case, the heterodyning method is applied and IF signal and reference signals for local oscillators are transmitted through fiber to reduce the cost of LD. When the system margin of fiber loss is large, an optical star coupler is used to broadcast one central station signal to several base stations. This configuration enables several base stations to be installed on a single fiber with bus connections, and reduces the cost of both fiber installation and equipment. Downlink signals from one LD are easier to broadcast; however, in the uplink stream, beat noise among the base station LDs is generated because of the optical wavelength difference of LDs and it impairs the detected RF signals. So LD wavelength control is required for uplink design if the bus link configuration is used.

Figure 13 shows another application example of indoor wireless LAN and cordless phone transmission. A 1.9-GHz

digital cordless phone and a 2.4-GHz wireless LAN signal are combined and transmitted from the central station and reemitted at the remote station. In this application, an unmodulated optical source with varying wavelength is supplied from the central stations and is modulated by the upstream RF signal by an electroabsorption (diode) module (EAM) as described in Section 3.2 of this article. So any well-designed remote station can be operated without DC power supply.

Figure 14 shows the intelligent transport system (ITS) application of an RoF link. In this application, several wireless services are frequency-shifted and lined queued up in the higher-frequency band at the central station, and transmitted to the roadside antenna and received by the vehicle. In the vehicle, required service is tuned out from the received signal. In this application, multiple roadside antennas are fed by the same signal, so they can operate as one macrocell and complicated handover is not required, even if a different roadside antenna is selected. So the microcellular system such as the personal handy-phone system (PHS) and Digital European Cordless Telephone (DECT) can be available in a high-speed vehicle, in the same way as are macrocell mobile systems.

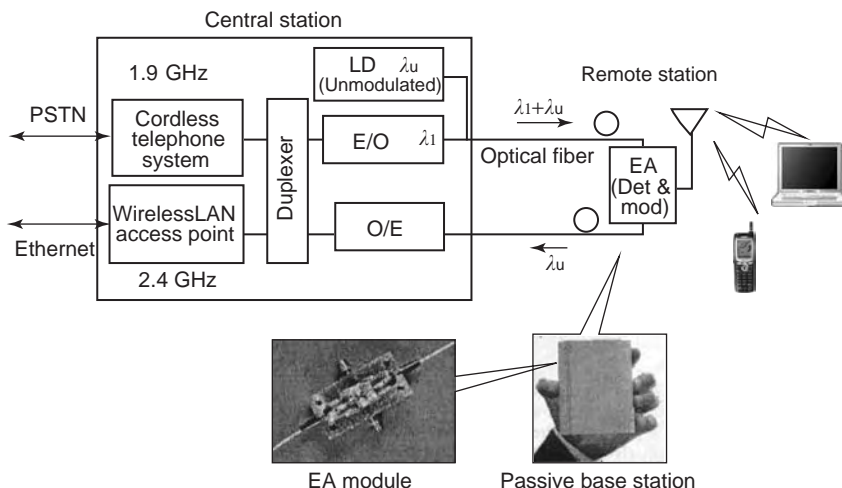

Figure 13. RoF application example for indoor wireless systems.

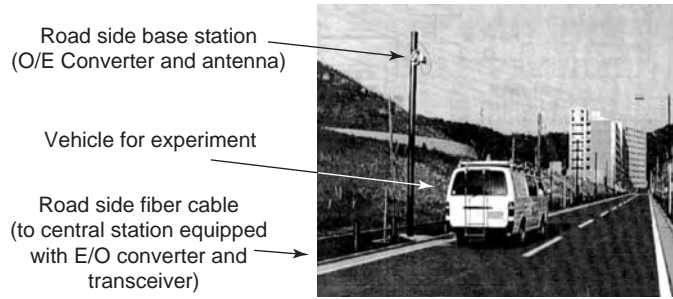

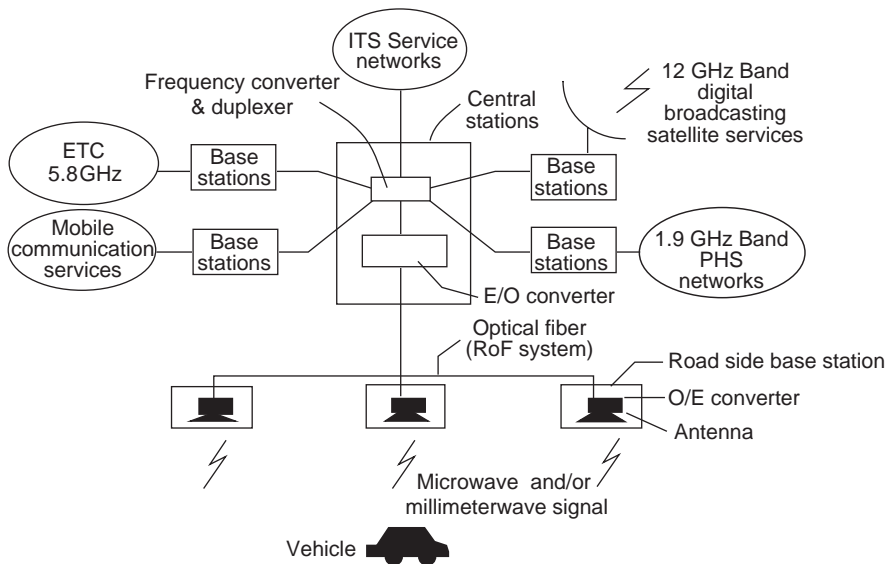

Figure 14. RoF link application example for ITS systems. (ETC=electrical tool correction system.)

5.3. Broadband Wireless Access Networks (BWA)

To realize the broadband service, the fiber infrastructure is considered to be one of the possible solutions. Using these fiber infrastructures, broadband wireless access, termed the *fiber-to-the-air system* (FTTA), is considered to be another available solution, and using the same infrastructure, the system can serve mobile broadband services, such as hotspot and mega and giga air services. Fig. 15 shows an example of a developed FTFTA system. In this system, a 27.7-GHz millimeter-wave 16-level quadrature amplitude-modulated signal (16-QAM), with a speed of 622 Mbps (megabits per second), is implemented and the RF signal is converted to an optical signal, and transmitted to the remote antenna units through passive star networks. From the remote antenna unit, the millimeter-wave signal is emitted to the home customer premise unit. Customers can extract their information from the 622-Mbps stream. For upstream service, data size for each customer is small, so a 40-Mbps frequency shift keying signal (FSK) with the 29.26-GHz carrier frequency is emitted from the customer premise unit. This signal is downconverted to the 615-MHz IF signal by mixing with a 29.875-GHz local signal that is supplied from the central control station. The converted optical signal is carried to the central station through passive star fiber networks. Using this configuration, the remote antenna unit does not require the installation of a millimeter-wave carrier oscillator, whose frequency, in the wide temperature range

experienced by an outdoor remote antenna unit, is expensive to stabilize.

5.4. Other Applications

As the speed of electronic device rapidly increases, scaling down progresses at the same time. Under this condition, on-wafer high-frequency and high-speed performance measurement is required to reduce the cost of fabrication. Conventional coaxial cable test probes interfere with device performance because the probe and cable are not sufficiently compact in size and their frequency-dependent conductor causes errors in performance test results. For a compact and conductorless test probe, electrooptic sampling (EOS), using the optical fiber probe and electrooptic conversion sensor, is one possible solution for this requirement. Figure 16 shows various applications for electrical field, DC voltage level, and radio emission test probe. More recently, > 200-GHz and 0.1–0.3-ps-pulse test probes have been developed. For the electrooptic device, LiTaO₃, KTP (Potassium Titanyl Phosphate), CdSe, and ZnTe are used.

Another RoF application is radioastronomy, such as in the Atacama (Chilean desert) Large Millimeter/submillimeter Array (ALMA). In this application, an array of large antennas is concentrated in central measurement equipment, and an RoF link is used for millimeter and submillimeter signal transmission between the antennas and the central measurement station, to reduce the signal loss and

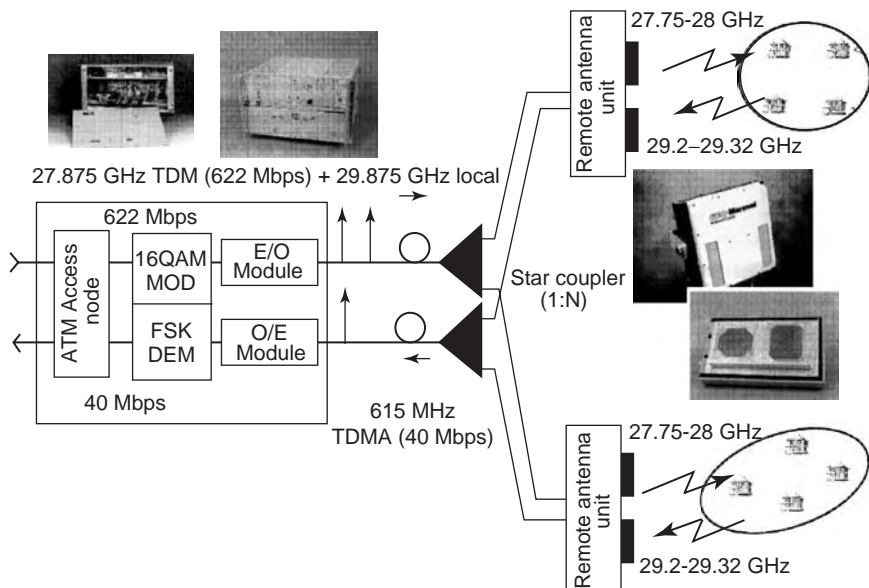

Figure 15. RoF link application example for FTTH systems.

to extend the frequency band. In this measurement, fiber length calibration among the antennas is required to maintain the coherence of received signals. Calibration methods are presented on the ALMA Website [32].

6. NETWORKING OF RoF SYSTEMS

6.1. Introduction to the RoF Networks (Radio Highway)

Figure 17 shows RoF networks where routing functions of the radio signals are developed and routing to various remote stations are conducted depending on their radio format, such as radiofrequency (RF) or modulation format. These RoF networkings are called the “Radio Highway” [3].

There are various types of networking configurations and optic multiplexing schemes, such as wavelength-division multiplexing (WDM), optic time-division multiple ac-

cess (optical TDMA), optical code-division multiple access (optical CDMA), and the chirp multiple transform (CMT) method.

The same as for the optical multiplexing and access methods, there are various access methods at the RF stage, such as subcarrier multiplexing (SCM), TDMA at RF stage, and CDMA at RF stage. These RF-stage access methods can be used in combinations of optic-stage multiple-access methods, independently and simultaneously. For example, optic WDM and optic CDM can be used simultaneously and have certain advantages such as channel number extension and networking flexibility. The simultaneous use of optic CDM and RF CDMA also enables seamless connection of RF and photonics. Conventional SCM with optic WDM is one of the combination solutions. A comprehensive description of all combinations would be elaborate and beyond the scope of this article, so some typical examples are described as follows.

Figure 16. RoF applications for electrooptical sampling (EOS): (a) electric field test; (b) electric voltage; (c) electromagnetic waves.

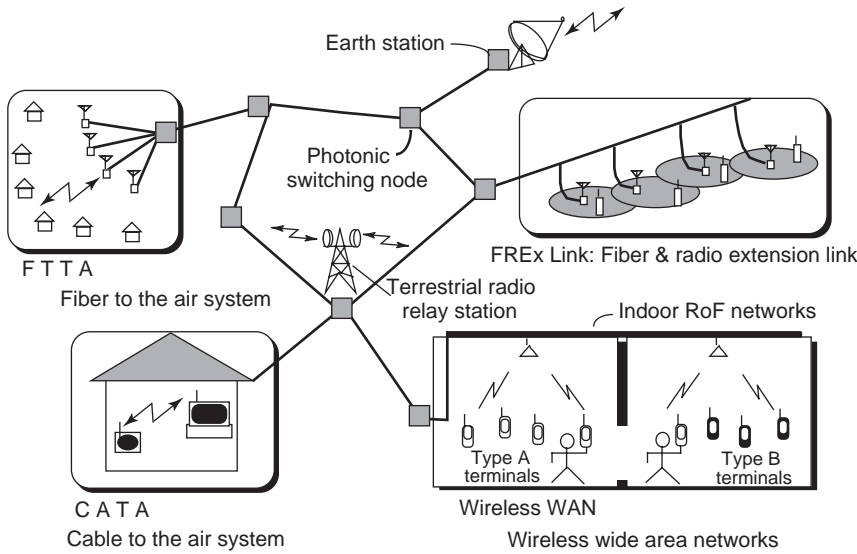

Figure 17. Networking of RoF systems (radio Highway networks).

6.1.1. Optic Wavelength-Division Multiplexing (WDM).

Extensive research on optic networks, such as dense wavelength-division multiplexing (DWDM) and wavelength routing technologies, are rapidly progressing to develop high-speed core networks, such as long line and metro networks. These technologies are applied mainly to the high-capacity baseband transmission, and these WDM technologies are applicable to the RoF link and RoF networks, after some discussion of the design of its signal-to-noise quality.

Figure 18 shows some example WDM applications to RoF systems. Figure 18a illustrates point-to-point bulk transmission on a wavelength-varying signal, in which one fiber and optical amplifier are used for multiple radio base stations (RBSs) that have different wavelengths. All the wavelengths are amplified periodically and transmitted to one destination. The photonic wavelength switch at the central station can reroute the specific RBS signal that has a specific wavelength to the different central stations. This application is used for multiple wireless services operating on single photonic networks.

Other applications are shown in Figs. 18b and 18c. In the Fig. 18c, every wavelength is assigned to every radio signal from one of sector antenna of the RBS. This configuration is suitable for single fiber-RBS applications. Also, different wavelengths can be assigned to forward and reverse links as shown in Fig. 18b.

The next configuration is shown in Fig. 18d. Different wavelengths are assigned for the different RF frequencies at the RBS, and different wireless service is transferred to the different central stations.

6.2. Optical TDMA Operation

For baseband pulse operation, optical TDMA is very easy; however, for RoF formats, TDMA necessitates consideration of, natural bandpass sampling. Pulse amplitude modulation (PAM) systems show promise in realizing RoF type optical TDMA systems, where multiplexing of

Figure 18. RoF networking example configurations using WDM: wavelengths assigned to (a) radio base stations; (b) duplexing; (c) sectors/diversity; (d) radio service/frequency bands.

several signals is achieved by interleaving the samples of the every RBS signal. According to the Nyquist sampling theorem, the signal whose highest frequency spectrum component is f_M is determined and regenerated at regular intervals separated by times $T_s \leq \frac{1}{2}f_M$; that is, the signal has to be periodically sampled every T_s seconds. T_s and $f_s = \frac{1}{T_s}$ are referred to as *sampling interval* and *sampling frequency*, respectively. If this theory is applied to the sampling of radio signals whose highest frequency spectrum component is in the low or medium gigahertz range, then, ultra-high-speed sampling such as twice the RF frequency is required. The radio signals are fortunately bandlimited in general, so natural bandpass sampling is applicable. Let the bandwidth of radio signal be B_{RF} and you can find that the required condition about sampling interval can be reduced to $\frac{1}{2}B_{RF}$. Such a sampling technique is referred as natural bandpass sampling or simply bandpass sampling [33]. Natural sampling is the window multiplication on RF signals, and bandpass filtering of received signal can reproduce the original signal.

Figure 19 shows the configuration of optical TDMA for upstream networks. In the system, the RF signal received by the RBS is intensity modulated to an optical signal and then switched by the photonic switch and multiplexed to one fiber and rerouted at the optical time switch in accordance with the optical digital header attached to the natural sampled RF signal. Asynchronous optical TDMA can be available when the optical signal bandwidth is sufficiently wider than the RF signal bandwidth. The synchronous mode in the downlink is better than the asynchronous mode, because the synchronous TDM is simple and synchronization is easy. One example of this application will be in the use of ITS roadside antennas, in which several broadband services such as videostreams from the central stations, and several low-speed asynchro-

nous TDMA wireless service streams from vehicles to central stations are operated.

6.3. Optical CDMA Operation

The optical CDMA method is suitable for the uplink of fiber-optic radio networks because it does not require any time synchronization among RBSs. There are various types of optical CDMA methods, such as the fiber delay line, the optical phase mask, and coherent optical phase modulation type [18–23]. In the method using fiber delay lines, encoding and decoding are performed by the sum of delayed optical pulses in the time domain. In the method using optical phase masks, spectral encoding and decoding are performed by phase modulation in the optical template mask. However, these methods have no flexibility in assigning code sequences. On the other hand, the direct optical switching CDMA (DOS-CDMA) scheme, using the optical ON/OFF switching by spread-spectrum code, has flexibility in terms of code assignment. Figure 20 shows the configuration of DOS-CDMA. Each radio signal received by each RBS antenna is transmitted to the central control station (CCS) by analog optical PAM formats, and the multiple accesses among many RBSs are performed by codes that differ from each other. Regeneration of radio signal is based on the bandpass natural sampling theory described earlier in the article. At a RBS, received radio signals are converted into optical intensity-modulated (IM) signals by modulating LD current directly, and are sampled by the optical switch (OSW), which is driven by a certain spread-spectrum code sequence. The output signal of the OSW is transmitted to a receiver through optical fiber. At the receiver, many spread-spectrum signals from many RBSs are received simultaneously. At the receiver, an optical polarity-reversed correlator (OPRC) is used to

Figure 19. RoF networking example configurations using optic TDMA.

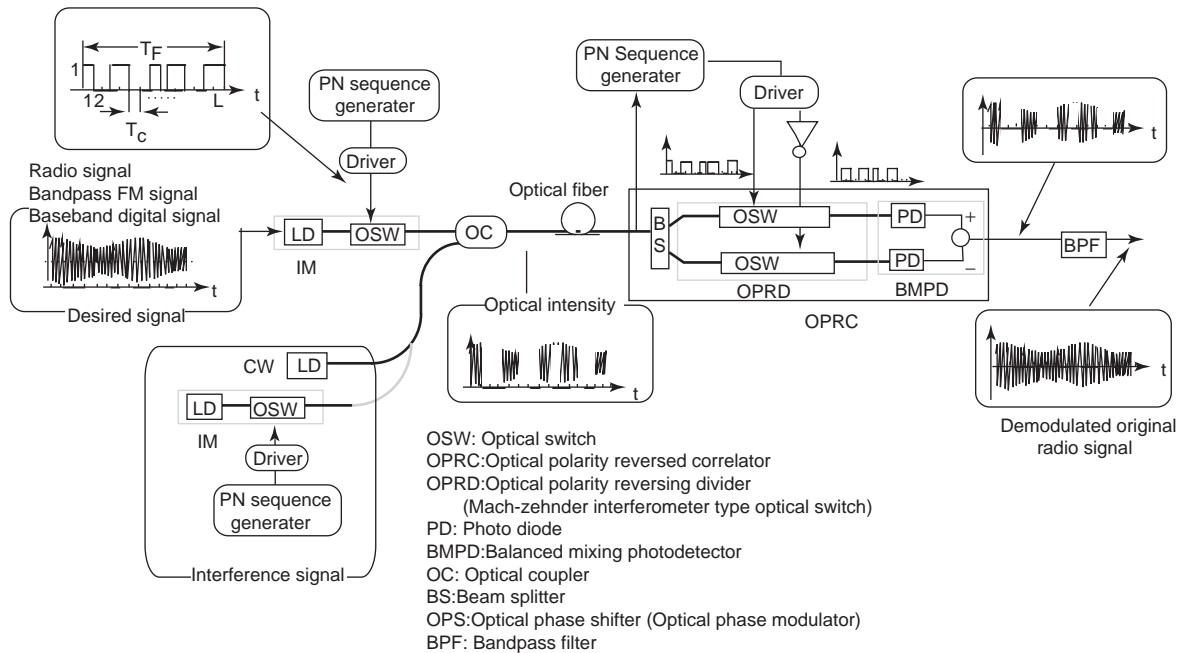

Figure 20. RoF networking example configuration using optic CDMA.

extract the desired signal. At the OPRC, the received signal is split into two signals. It is assumed that the despreading CDMA code, matched with the desired RBS, is regenerated at the RBS by using the retiming code generator such as the retiming block and the code synchronization block. The OPRC is driven by this code and polarity-reversed code, and two optical signals are derived from each branch; then the two RF signals are detected and subtracted. An optical signal from the desired RBS is correlated at the upper branch, and there is no output from the lower branch. From the undesired RBS, the optical signal is uncorrelated in two branches, and random signals are extracted from two branches. So the subtraction and averaging of two signals produces zero output response, and the uncorrelated signals from undesired RBSs are suppressed. As a result, only the desired RF signal is extracted from the mixture of optical signals from many base stations. This CDMA can be used in combination with WDM because the optical spectrum is not as wide in case of natural bandpass sampling and spectrum spreading.

7. SUMMARY

In this article, RoF technologies such as basic configurations, devices, performance design, and application examples are described. Section 6 describes the future trends of RoF networking, named "Radio Highway" technologies.

RADIO RECEPTION

ZORAN ZVONAR
Analog Devices
Wilmington, Massachusetts

Since the early introduction of radio, the significance and number of applications of radio services have constantly grown. From sophisticated satellite and microwave links that provide worldwide communication infrastructure, mobile radio and personal communication services (PCS) that are providing seamless communication capabilities, all the way to consumer products like cordless phones, wireless toy communicators or garage door openers, radio services have changed everyday life in a manner that could have not been predicted decades ago. The growing sophistication of systems and usages is closely related to the technical understanding necessary for putting radio systems into operation. Challenges in radio system design have grown tremendously because of the overcrowding of radio spectrum. The need for coordinating radio services has been identified early, and International Telecommunication Union (ITU) has established necessary regulations. The effective spectrum management is essential to maximizing the benefits that can be obtained from the radio spectrum [1]. After restructuring of the ITU in 1993, these problems have been the focus of ITU Radiocommunication Sector.

Radio systems operate in different radio frequency bands as shown in Table 1 [2]. This influences the characteristics of the radio channel. The signal propagation path may vary from a clear line of sight to being severely obstructed by buildings, mountains, and other environmental effects. Since radio channels are random in nature, understanding of the radio propagation phenomena and consequently their modeling play a major role in the prediction of the radio reception quality, which, in turn, enables efficient design of wireless systems. Large-scale propagation models characterize signal strength over long distances, while small-signal models describe the rapid fluctuation of the received signal over very short distances or short time duration.

Radio reception is influenced by different factors, summarized in Table 2. Radio propagation influences radiolink design, with path-loss models and statistics of large-scale fading as the major elements of a power budget. In addition to the power budget, radiolink design includes geographic positioning of transmitter and receiver, frequency planning, radiolink control schemes, and handover schemes. Requirements for the type of radio service, quality of service, coverage, and availability of the radiolink provide an additional set of parameters that influence radio link design. On the other hand, fading affects factors such as the radio receiver design, selection of modulation and coding scheme, techniques for fading compensation, synchronization circuits, and design of radio front-end. Selection of the appropriate receiver techniques determines the radio sensitivity which is an integral part of the power budget. Results of radiolink and radio receiver design are a part of wireless network design. Network ar-

Table 1. Summary of Frequency Bands for Operating Radio Systems

Frequency Band	Frequency Range	Mode of Radio Propagation	Radio Services	Major Characteristics
Very low frequency (VLF)	3–30 kHz	Ionospheric	Navigation, long-distance radio telegraphy	Small bandwidth, large antennas
Low frequency (LF), medium frequency (MF)	30–300 kHz, 300 kHz–3 MHz	Ground-wave ionospheric	Navigation, AM broadcasting, aeronautical, maritime communication	Quite large antennas, high power transmitters
High frequency (HF)	3–30 MHz	Ionospheric	Amateur radio, broadcasting, aeronautical maritime communication	High variability of channel conditions
Very high frequency (VHF), ultrahigh frequency (UHF)	30–300 MHz, 300 MHz–3 GHz	Direct waves, ground-reflected waves	Radio and television broadcasting, land mobile radio, paging, GPS	Relatively small antennas, considerable bandwidth
Superhigh frequency (SHF)	3–30 GHz	Direct waves	Satellite, radars, short-range communications, microwave terrestrial links	High losses, directional antennas
Extrahigh frequency (EHF)	30–300 GHz	Direct wave	Very short range communication, satellite-to-satellite links	Enormous bandwidths, rain absorption

chitecture, interfaces, and control are closely related to radio reception, which defines the physical layer of the network [4].

1. RADIOLINK DESIGN

1.1. Power Budget

The power budget (link budget) is the starting point for a radiocommunication link design. Major factors influencing the power budget are shown in Fig. 1. These factors include transmitting and receiving antenna gains G_T and G_R , path loss L_p (which depends on operating frequency, environment and type of radio service), fading margin M_F , interference margin M_I , and radio receiver sensitivity RS .

Transmitting antenna gain (usually specified as the gain relative to isotropic radiator) and receiving antenna gain are dependent on the carrier frequency and physical size of the antenna. For a given radio system, selection of the equipment determines antenna gains. Additional sources of signal loss at the antenna may include noise due to protective cover, pointing loss, feeder loss and antenna efficiency, described as the ratio of the effective aperture to the physical aperture of the antenna [5].

Link budget analysis of the radio system defines the maximum acceptable path loss

$$L_p \text{ (dB)} = P_T \text{ (dBm)} + G_T \text{ (dBi)} + G_R \text{ (dBi)} - M_F \text{ (dB)} - M_I \text{ (dB)} - RS \text{ (dBm)}$$

which can be used to estimate the coverage area of the system by determining the maximum transmitter–receiver distance.

The relationship between path loss and coverage area is crucial for the design of a radio system. Other sources of signal loss in radio propagation are caused by environmental effects such as rain, clouds, and fog.

The fading margin determines the outage probability of the system due to large-scale and/or small-scale fading. In a similar way, the interference margin can be built into the link budget to maintain desired performance in the presence of the interference, regardless of the interference mechanism, such as adjacent-channel interference (ACI), cochannel interference (CCI) in cellular systems, and intermodulation distortion (IMD) products created by the large interfering signals. The amount of margin depends on the required quality of service. It is expressed in terms

Table 2. Radio System Design Elements Relevant for Radio Reception

Radio Propagation	Radiolink Design	Radio Receiver Design	Radio Network Design
Large-scale fading	Requirements	Modulation	Architecture
Path loss	Radio services	Multiple access	Interfaces
Shadowing	Quality of service	Coding	Network control
	Coverage/range	Antifading techniques	
Small-scale fading (multipath fading)	Design	Interference suppression	
Delay spread	Power budget		
Coherence time	TX/RX allocation	Synchronization	
	Link control	Receiver hw design	

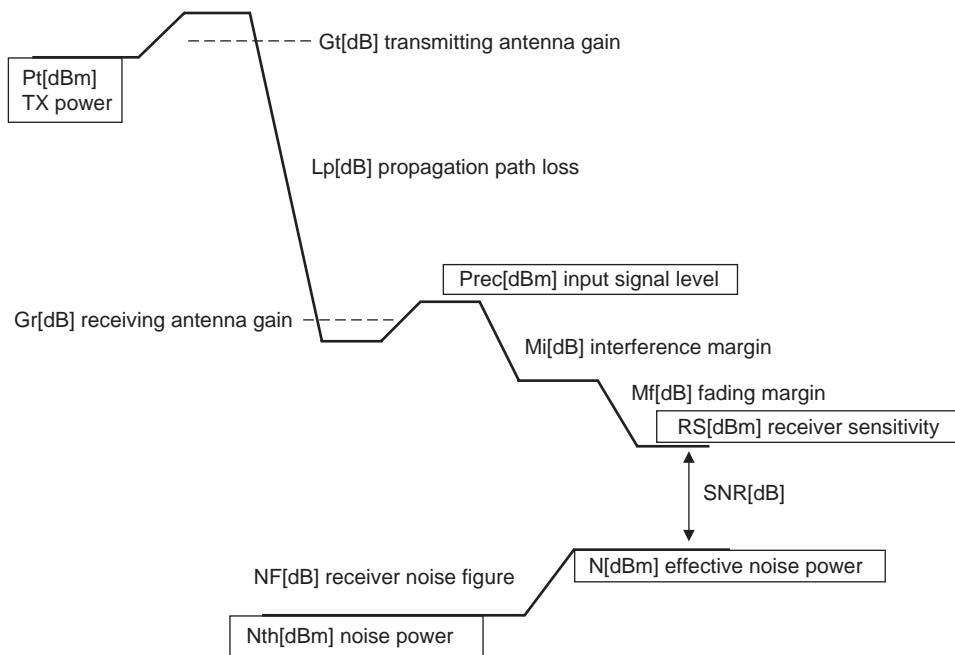

Figure 1. Power budget for radio-link design.

of signal-to-noise ratio (SNR) for analog systems or bit error rate (BER) for digital systems, and availability of the link, which is the measure of long-term link utility stated on an average basis, usually on the annual basis.

Radio receiver sensitivity describes the ability of the radio receiver to detect weak signals, and is derived from the performance objectives of the given radio service. Sensitivity specification includes the impact of techniques that are an integral part of radio reception at the detection level, such as diversity, coding, interleaving, as well as the impact of radio receiver such as noise figure and noise bandwidth.

1.2. Frequency Planning

Frequency planning is a part of link control and is essential part of radiolink design. Since the radio spectrum is the limited resource, coexistence of different services will be practically impossible without the planning procedure. It is effective way to optimize spectrum usage, enhance channel capacity, and reduce different types of interference.

Some of the benefits of frequency planning will be illustrated on the example of the mobile radio services. Frequency planning for mobile radio includes channel numbering, channel grouping into subsets, cell planning, and channel assignment. It controls ACI by channel separation, which provides adequate isolation, and CCI by selection of frequency reuse pattern. Frequency planning can be efficiently combined with cell sectorization to improve the system capacity. Different tradeoffs are involved in frequency planning based on targeted channel capacity and signal-to-interference ratio (SIR). The most popular OMNI frequency plan in mobile radio is $N = 7$ plan, which allows for ACI. This plan is outperformed by the $N = 9$ plan with respect to SIR, but the drawback is the reduced channel capacity. Detailed analysis of various frequency

plans can be found in Ref. 21. Besides the impact on technical parameters of the system, frequency planning greatly influences radio system growth and economics.

2. LARGE-SCALE VARIATIONS: PATH LOSS

The prediction of the path loss is the most important step in the radio system planning process since it determines radio coverage. Prediction models could include only finite number of parameters that can influence radio propagation, and often factors such as environment (effects of buildings, manmade obstacles, vegetation) as well as multipath fading are treated separately.

Three major mechanisms of radio propagation are reflection, diffraction, and scattering. Rather than focusing on the details of radiowave propagation, which are covered in Ref. 6, the models for large-scale path-loss prediction will be summarized indicating critical parameters that are influencing radio reception.

The free-space propagation model is applicable when there is unobstructed line-of-sight path between the transmitter and the receiver. This scenario is typical for satellite systems and microwave radio links. The path loss is given by

$$L_{\text{free space}}(\text{dB}) = -10 \log(G_T(\text{dB})) - 10 \log(G_R(\text{dB})) + 20 \log(f(\text{Hz})) + 20 \log(d(\text{m})) - 147.6$$

where G_T and G_R are transmitter and receiver antenna gains, f is the carrier frequency, and d is the distance between the transmitter and receiver. Free-space path loss has inverse square law dependence with the distance so received power is reduced by 6 dB when the range is doubled (20 dB/decade decay with distance). In the same manner path loss increases with the increase of carrier frequency. While increasing the antenna gains may com-

pensate for the loss due to high operating frequency in point-to-point links, in mobile radio links this is not possible due to required omnidirectional coverage. The equation for free-space path loss is only valid when distance d is in the far-field of the transmitting antenna.

In practical radio channels free-space model conditions do not apply and further corrections to the path loss have to be accounted. A simple but practical scenario includes the direct path and ground-reflected path between transmitter and receiver. This model has been found to be accurate for path-loss prediction over distances of several kilometres for mobile radio systems and for the line-of-sight microwave links. Assuming that transmitter and receiver antenna heights h_T, h_R are much smaller than the distance, path loss is given by

$$L_{\text{ground reflection}}(\text{dB}) = 40 \log(d(\text{m})) - 10 \log(G_T(\text{dB})) - 10 \log(G_R(\text{dB})) - 20 \log(h_T(\text{m})) - 20 \log(h_R(\text{m}))$$

In this case path loss is independent from carrier frequency; however, the inverse fourth power-law decay is observed when increasing distance. For distances that are larger than few tens of kilometres, the Earth curvature should be taken into account and the values of the reflection coefficient should be modified [2]. Also of importance is dependence of the reflection coefficient on polarization and materials of the reflected surface [2,3].

The diffraction mechanism allows the radiolink to be maintained even when receiver is in the obstructed area, shadowed by the object. Huygens' principle could be used to explain the diffraction [2]. For practical applications Fresnel zones should be considered [4]. The simple knife-edge diffraction model is often used to calculate signal attenuation. Objects within Fresnel zones may cause diffraction loss, which is the function of the dimensionless Fresnel–Kirchhoff diffraction parameter

$$v = h \sqrt{\frac{2(d_1 + d_2)}{\lambda d_1 d_2}}$$

The geometry of knife-edge diffraction is depicted in Fig. 2. Diffraction loss can be translated into path loss relative to free-space loss, and it is given by nomograms or by approximations which are expressed as

$$L(v)(\text{dB}) = \begin{cases} 20 \log(0.5 - 0.62v) & -0.8 < v < 0 \\ 20 \log[0.5 \exp(-0.95v)] & 0 < v < 1 \\ 20 \log \left[0.4 - \sqrt{0.1184 - (0.38 - 0.1v)^2} \right] & 1 < v < 2.4 \\ 20 \log \left(\frac{0.225}{v} \right) & v > 2.4 \end{cases}$$

Figure 2. Knife-edge diffraction geometry.

In cases where there are more than one objects affecting the radio propagation, multiple knife-edge models should be introduced. Various approximate solutions have been presented, with different levels of accuracy. They have been compared by Parsons [2].

2.1. Path-Loss Prediction Models

Prediction models have evolved extensively in UHF/VHF bands addressing the growing importance of mobile radio services. Most models provide the prediction of the median path loss, the loss that is not exceeded at 50% of locations and for 50% of the time [2]. Knowledge of the radio signal statistics further allows estimation of the signal variability and prediction of the area where specified signal strength is achieved for a given percentage of location. Path-loss models differ in applicability to different terrain profiles and cover different level of details, from general to very specific scenarios. Most of the models are empirical, based on the interpretation of the measured data in the particular area by fitting curves or analytical expressions. The advantage of this approach is that it takes into account the variety of propagation factors through actual field measurements. However, the models are strictly applicable only to the environments characterized in measurements, and additional measurements are necessary in different frequency bands and on different locations to provide correction factors. Some of the commonly used models for outdoor and indoor environments will be discussed in subsequent sections. For more detailed comparison, the reader is referred to Refs. 2 and 3.

2.1.1. Outdoor Prediction Models. The significance of two models has been established in practice in VHF/UHF band: the Hata model and the Walfisch–Ikegami model [8]. Both models are empirical, derived from experimental data, and are extensively used in commercial computer-aided prediction tools. In general usage and accuracy of models depends on the propagation environment: Hata's model provides good accuracy in urban and suburban environments, the Walfisch–Ikegami model is widely used for dense urban environments and microcells. Extensions to both models are provided by The European Co-operative for Scientific and Technical research (COST) to cover the PCS band [9].

The Hata model, based on measurements of Okumura, has established empirical mathematical formulas for the path loss and considerably enhanced practical value of the

Okumura method [2]. It is restricted for the following range of parameters: frequency f 150–1000 MHz, height of the base station antenna h_{te} 30–200 m, height of the mobile unit antenna h_{re} 1–10 m, and distance d 1–20 km. The standard formula for basic transmission loss in urban area is

$$L_{urban}(dB) = 69.55 + 26.16 \log(f(\text{MHz})) - 13.82 \log(h_{te}(\text{m})) - a(h_{re}) + (44.9 - 6.55 \log(h_{te}(\text{m}))) \log(d(\text{km}))$$

where f is the carrier frequency, h_{te} is the effective transmitter antenna height, h_{re} is the effective receiver antenna height, d is the distance, and $a(h_{re})$ is the correction factor for effective receiver antenna height, which is a function of cell size. The correction factor for mobile antenna height for a small to medium-sized city (urban area) is computed as

$$a(h_{re})(dB) = (1.1 \log(f(\text{MHz})) - 0.7)h_{re}(\text{m}) - (1.56 \log(f(\text{MHz})) - 0.8)$$

and for a large city (dense urban area) as

$$a(h_{re})(dB) = \begin{cases} 8.29(\log(1.54h_{re}(\text{m})))^2 - 1.1, & f_c \leq 300\text{MHz} \\ 3.2(\log(11.75h_{re}(\text{m})))^2 - 4.97, & f_c \geq 300\text{MHz} \end{cases}$$

Suburban area path loss can be calculated using the modified equation

$$L_{suburban}(dB) = L_{urban}(dB) - 2 \left(\frac{\log(f(\text{MHz}))}{28} \right)^2 - 5.4$$

and path loss in open rural areas is given by

$$L_{rural}(dB) = L_{urban}(dB) - 4.78(\log(f(\text{MHz})))^2 - 18.33 \log(f(\text{MHz})) - 40.98$$

The Hata model is well suited for large cell mobile systems, but not for the PCS cells with the radius on the order of 1 km. The COST analysis of several measurements conducted in European cities for PCS band have resulted in an extended range of parameters for Hata's model to include the 1800 MHz frequency band [9]. The COST-231 proposed model for path loss is given by

$$L_{urban}(dB) = 46.3 + 33.9 \log(f(\text{MHz})) - 13.82 \log(h_{te}(\text{m})) - a(h_{re}) + (44.9 - 6.55 \log(h_{te}(\text{m}))) \log(d(\text{km})) + C_M$$

where all parameters are defined for the original Hata's formula and

$$C_M = \begin{cases} 0\text{dB}, & \text{for medium-sized city and suburban areas} \\ 3\text{dB}, & \text{for dense urban area} \end{cases}$$

COST-231-Hata's model is valid for scenarios with base station heights larger than rooftops in the vicinity of the base station. This is the case in large cells and small cells (maximum range 1–3 km), and path loss is determined largely by diffraction and scattering at rooftops in the vicinity of the mobile unit. Main rays propagate in this case above the rooftops. In practical situations it is not recommended to extend the range of validity on base station heights below the roof tops, as in the micro cell scenario. Wave propagation in micro cells (maximum range 0.5–1 km) is determined by diffraction and scattering around buildings, and main rays propagate in street canyons. These phenomena are further addressed by the Walfish-Ikegami model.

The approach of the Walfish-Ikegami model is restricted to radio paths that are obstructed by buildings and is not applicable if a line-of-sight path exists between the transmitter and receiver antennas within a street canyon. Few parameters are introduced to describe the character of the dense urban environment as depicted in Figs. 3 and 4: heights of buildings, widths of roads, building separation, and road orientation with respect to the direct radio path.

However, the model still considers only characteristic values and there is no consideration of the topographical database of the buildings. The models can be applied even when no data on the urban parameters are available by using the default values, which increases the prediction error. For a line-of-sight case in a street canyon the path loss is equal to

$$L_b(dB) = 42.6 + 26 \log(d(\text{km})) + 20 \log(f(\text{MHz})),$$

for $d \geq 20$ m

where the first constant in formula is determined so L_b is equal to free-space loss for 20 m. Otherwise the model is composed by three terms and restricted by the

Figure 3. Parameters used in Walfish-Ikegami model.

Figure 4. Definition of the street orientation in Walfish-Ikegami model.

free-space loss

$$L_b(\text{dB}) = \begin{cases} L_0 + L_{rts} + L_{msd} \\ L_0 \end{cases} \quad \text{for } L_{rts} + L_{msd} \leq 0$$

The free-space loss is given by

$$L_0(\text{dB}) = 32.4 + 20 \log(d(\text{km})) + 20 \log(f(\text{MHz}))$$

the rooftop-to-street diffraction and scatter loss is

$$L_{rts}(\text{dB}) = -16.9 - 10 \log(w(\text{m})) + 10 \log(f(\text{MHz})) \\ + 20 \log(\Delta h_{\text{mobile}}(\text{m})) + L_{\text{ori}}$$

where

$$L_{\text{ori}}(\text{dB}) = \begin{cases} -10 + 0.354\varphi^\circ & \text{for } 0 \leq \varphi < 35^\circ \\ 2.5 + 0.075(\varphi^\circ - 35) & \text{for } 35 \leq \varphi < 55^\circ \\ 4.0 - 0.114(\varphi^\circ - 55) & \text{for } 55 \leq \varphi \leq 90^\circ \end{cases}$$

and

$$\Delta h_{\text{mobile}} = h_{\text{roof}} - h_{\text{mobile}} \\ \Delta h_{\text{base}} = h_{\text{base}} - h_{\text{roof}}$$

The multiscreen diffraction loss

$$L_{\text{msd}}(\text{dB}) = L_{\text{bsh}} + k_a + k_d \log(d(\text{km})) + k_f \log(f(\text{MHz})) \\ - 9 \log(b(\text{m}))$$

consists of a number of terms:

$$L_{\text{bsh}}(\text{dB}) = \begin{cases} -18 \log(1 + \Delta h_{\text{base}}(\text{m})) & h_{\text{base}} > h_{\text{roof}} \\ 0 & h_{\text{base}} \leq h_{\text{roof}} \end{cases}$$

with

$$k_a(\text{dB}) = \begin{cases} 54 & h_{\text{base}} > h_{\text{roof}} \\ 54 - 0.8 \Delta h_{\text{base}}(\text{m}) & d \geq 0.5 \text{ km and } h_{\text{base}} \leq h_{\text{roof}} \\ 54 - \frac{0.8 \Delta h_{\text{base}}(\text{m})d(\text{km})}{0.5} & d \leq 0.5 \text{ km and } h_{\text{base}} \leq h_{\text{roof}} \end{cases}$$

representing the increase of path loss for base station antennas below the roof tops of the adjacent buildings,

$$k_d[\text{dB}] = \begin{cases} 18 & h_{\text{base}} > h_{\text{roof}} \\ 18 - 15 \frac{\Delta h_{\text{base}}}{h_{\text{roof}}} & h_{\text{base}} \leq h_{\text{roof}} \end{cases}$$

controlling the dependence of the multi-screen diffraction loss versus distance and

$$k_f(\text{dB}) = -4 + \begin{cases} 0.7 \left(\frac{f[\text{MHz}]}{925 - 1} \right) & \text{for urban and suburban areas} \\ 1.5 \left(\frac{f[\text{MHz}]}{925 - 1} \right) & \text{for dense urban area} \end{cases}$$

controlling the dependence of the multiscreen diffraction loss versus radiofrequency.

The COST-231-Walfish-Ikegami model is restricted to the following range of parameters: frequency f 800–2000 MHz, height of the base-station antenna h_{base} 4–50 m, height of mobile unit antenna h_{mobile} 1–3 m, and distance d 0.02–5 km. If the data on the structure of buildings and roads are unknown, the default values may be used: for b 20–50 m, $w = b/2$, h_{roof} 3 m times the number of floors plus the roof height, roof height is 3 m for pitched, 0 m for flat, and $\varphi = 90^\circ$.

The COST-Walfish-Ikegami model has been verified for frequencies in the 900 and 1800 MHz band and radio pathlengths from about 100 m to 3 km [9]. The path loss has very steep decay versus the height of the base-station antenna when the latter is close to the height of adjacent buildings and this case generally results in large prediction errors. Prediction errors are larger when $h_{\text{base}} \approx h_{\text{roof}}$. The performance of the model is poor for $h_{\text{base}} \ll h_{\text{roof}}$ because it does not consider waveguiding in the street canyons and diffraction at corners. For good performance of small-cell area coverage, the base-station antenna should be installed several meters (≥ 4 m) above the maximum rooftops of adjacent buildings within a radius of few hundred meters (e.g., 150 m). The prediction error may be quite large for microcells, which requires detailed knowledge of streets and buildings [9].

2.1.2. Indoor Prediction Models. Progress of personal communication services has established the need for accurate models that can support path-loss prediction inside and into the buildings. The major characteristics of indoor

radio channel are much smaller distances than in outdoor cases and higher variability of the environment. Building floorplan, construction materials, and building type greatly influence propagation characteristics. Partition losses at the same floor and partition losses between floors have been extensively measured and categorized [3].

For radio transmission originating outdoors, path loss due to signal penetration into the building should be considered. A number of factors have been found to influence penetration loss, including signal frequency, antenna pattern, and antenna position. Typical values for penetration loss measured in the 900-MHz band are on the order of 12 dB, with 6 dB lower loss when the building front (Facade) had windows [3].

Losses within buildings and penetration losses can be combined in the model characterizing propagation into the building [8]

$$L(\text{dB}) = L_{\text{mean}}(\text{dB}) + 10n \log(d(\text{m})) + kF(\text{dB}) \\ + pW_I(\text{dB}) + W_E(\text{dB})$$

where L_{mean} is the mean path loss from the transmitter to the building, n is the power exponent of the distance dependence, d is the distance into the building, k is the number of floors between transmitter and receiver, F is the floor loss factor, p is the number of interior walls between transmitter and receiver, W_I is the internal wall loss factor, and W_E is the external wall loss. For in-building path loss L_{mean} becomes path loss at 1 m distance from the transmitter antenna and W_E is not used. The wall loss factor depends on the construction materials and varies from 0.4 to 29 dB in the 900-MHz band.

Analysis of the experiments carried out in UK in the 900-MHz band in a typical office building with several floors resulted in the path-loss model

$$L(\text{dB}) = L_0(\text{dB}) + 10n \log(d(\text{m})) + kF$$

where L_0 is the path loss at 1 m distance from the transmitter antenna, n is the distance power-law coefficient, d is the vertical range in the building, k is the number of floors considered, and F attenuation per floor is measured in decibels. At 900 MHz n was approximately 4, $L_0 = 30$ dB, and F was 5.4 dB per floor [8].

More recent advanced methods for coverage prediction within buildings rely on site-specific propagation models and databases that support the ray-tracing method for deterministically modeling of the propagation environment. As three-dimensional building models and databases become widespread, deterministic methods may prevail for determining the path loss in a wide range of operating conditions [3].

2.2. Coverage Prediction Using Path-Loss Models

Propagation loss models can establish median path loss as a function of the distance between the transmitter and the receiver. Both theoretical and empirical models indicate that received signal power decreases logarithmically with distance with a slope of $10n$ dB per decade. The value of

the n ranges from 2 for a free-space propagation to larger values for obstructed paths (e.g., 3–5 for urban mobile radio, 4–6 for obstructed indoor propagation). However, this model does not consider different clutters, which may result in different signal levels for the same distance. The value of the path loss at a particular location is a random variable with a lognormal distribution (Gaussian when measured in dB units) about the mean value, which is distance-dependent. Lognormal statistics describes the shadowing effect at different locations. In practice values of the exponent n and standard deviation of the lognormal fading are determined from measured data. Shadowing is often referred to as a *long-term fading*.

The random effects of shadowing cause the signal level at certain locations to be lower than the specified level. Therefore it is useful to compute the coverage area with a certain radius, in particular the percentage of the area with a received signal equal or greater than the specified level. Tradeoff between the percentage of coverage (for a given exponent loss n and shadowing variance) and the amount of fading margin is an important element of the power budget. Details on the coverage computation procedure can be found in Refs. 3 and 4.

3. EFFECTS OF ENVIRONMENT

In addition to large-scale path loss, different attenuation factors due to the environment may influence the power budget. Additional signal attenuation may be the result of natural phenomena or artificially created environmental conditions.

3.1. Weather Effects

For microwave radio with line-of-sight paths different weather-related effects may contribute to fading and path loss. Examples include absorption and scattering by snow, hail, fog, and rain. Dry snow does not have significant effect on frequencies below 30 GHz; however, wet snow may cause larger attenuation. In general, this attenuation is not of concern. However, degradation of antenna characteristics due to snow and ice buildup on the surface may influence antenna directivity, and precautions may be taken by using protective radomes. For different types of antennas, attenuation loss due to accumulated ice is 2–7 dB. Another effect of snow is that it may affect the reflection coefficient, and in most cases, depending on the type of snow reflection coefficients, is close to 1 [7].

3.2. Molecular Absorption

The absorption from oxygen and water vapor in the atmosphere is an additional factor that has to be considered at certain frequencies. The atmosphere extends to an altitude of approximately 20 km, yet it represents a path-loss source that cannot be neglected.

Specific attenuation (given in dB/km) is calculated in Ref. 8, including local maxima of attenuation occur at frequencies around 22 GHz for the water vapor and 60 and 120 GHz for the oxygen. The respective values are around

0.2 dB/km for water vapor and around 15 and 2 dB/km for oxygen. However, system comparisons indicate that water vapor attenuation is far less important than rain attenuation even in the frequency range of ~ 20 GHz.

3.3. Rain Attenuation

One factor that is important when considering rain attenuation is polarization-related loss due to nonspherical shape of raindrops. The horizontally polarized waves experience larger attenuation than do vertically polarized ones. This can also result in a cross-polarization effect, which may be harmful for microwave systems using channel planning based on different polarizations. The frequency-related attenuation depends on the drop size distribution, and is not considered significant for the signals below 11 GHz for locations with rain climate similar to northern hemisphere. For tropical areas critical frequency is as low as 5 GHz.

Rain attenuation statistics prediction is based on rain rate data, which depends on rainfall microstructure. The ITU-R model is based on rain rate $R_{0.01\%}$ exceeded for 0.01% of the time with an integration time of 1 min. This information can be obtained from local measurements and in the case that measurements are not available from ITU-R reports. The specific attenuation is calculated as $\gamma_R = k R^\alpha$, where R is the rain rate in mm/hour, and k, α are regression coefficients that are a function of frequency and polarization [11]

$$k = \frac{k_H + k_V + (k_H - k_V) \cos^2(\theta) \cos(2\tau)}{2}$$

$$\alpha = \frac{k_H \alpha_H + k_V \alpha_V + (k_H \alpha_H - k_V \alpha_V) \cos^2(\theta) \cos(2\tau)}{2k}$$

where θ is the path elevation angle and τ is the polarization tilt angle relative to horizontal, $\tau = 45^\circ$ for circular polarization, and other parameters are as given in a Table 3. The effective pathlength in this case is calculated by multiplying the actual pathlength L with a reduction factor

$$r = \frac{1}{(1 + L/L_0)}$$

where

$$L_0 = 35 \exp(-0.015 R_{0.01\%})$$

Path attenuation exceeding the 0.01% of the time is estimated by

$$A_{0.01}(\text{dB}) = \gamma_R r L$$

Table 3. Parameters for Regression Coefficients Calculation

Frequency (GHz)	k_H	k_V	α_H	α_V
2	0.000154	0.000138	0.963	0.923
6	0.00175	0.00155	1.308	1.265
10	0.0101	0.00887	1.276	1.264
15	0.0367	0.0335	1.154	1.128

3.4. Attenuation Due to Clouds and Fog

In Earth-space radiocommunication systems for frequencies higher than 10 GHz the attenuation due to clouds may be important factor affecting system performance. The mechanism of attenuation is well understood since clouds and fog consist of small droplets and it is possible to express attenuation in terms of total water content per unit volume [12] as

$$\gamma(\text{dB/km}) = K_1[(\text{dB/km})(\text{g/m}^3)]M(\text{g/m}^3)$$

where γ is specific attenuation within the cloud, K_1 is the specific attenuation coefficient, and M is the liquid water content of the cloud or the fog. The typical water content is about 0.05 g/m^3 for medium fog with visibility ~ 300 m and 0.5 g/m^3 for thick fog with visibility ~ 50 m. The specific attenuation coefficient for the frequencies up to 1000 GHz is given by

$$K_1 = \frac{0.189f[\text{GHz}]}{\varepsilon''(1 + \eta^2)} (\text{dB km}^{-1} \text{ g}^{-1} \text{ m}^{-3})$$

where

$$\eta = \frac{2 + \varepsilon'}{\varepsilon''}$$

and complex dielectric permittivity of water is

$$\varepsilon''(f) = \frac{f(\varepsilon_0 - \varepsilon_1)}{f_p [1 + (f/f_p)^2]} + \frac{f(\varepsilon_1 - \varepsilon_2)}{f_s [1 + (f/f_s)^2]}$$

$$\varepsilon'(f) = \frac{\varepsilon_0 - \varepsilon_1}{[1 + (f/f_p)^2]} + \frac{\varepsilon_1 - \varepsilon_2}{[1 + (f/f_s)^2]} + \varepsilon_2$$

where $\varepsilon_0 = 77.6 + 103.3(\theta - 1)$, $\varepsilon_1 = 5.48$, $\varepsilon_2 = 3.51$ and $\theta = 300/T$, where T is temperature in kelvins. The principal and secondary relaxation frequencies are given by

$$f_p(\text{GHz}) = 20.09 - 142(\theta - 1) + 294(\theta - 1)^2$$

$$f_s[\text{GHz}] = 590 - 1500(\theta - 1)$$

Attenuation due to fog becomes significant at frequencies around 100 GHz with specific attenuation of 0.4 dB/km for medium fog, and 4 dB/km for thick fog.

3.5. Foliage

The leaves of maple, oak, hickory, and similar trees can cause additional signal loss in the frequency range above 400 MHz. In the winter leaves fall and received signal is generally stronger than in the summer. Various factors contribute to this type of loss, including operating frequency, type of leaves, height of the trees, and thickness of the foliage. In general, design practice is to add about 10 dB of allowance in the forest area in addition to predicted path loss [7].

In tropical rainforest areas leaves do not fall and their shape is different, producing different attenuation. Major studies carried out in the 50–800-MHz band indicate that loss increases linearly in log scale from 35 dB/decade at

50 MHz up to 40 dB/decade at 800 MHz. The foliage loss is approximately proportional to the operating frequency raised to fourth power, which is a good approximation for horizontal polarization. Vertical polarization experienced greater loss in general by 8–25 dB at 50 MHz and 1–2 dB at 800 MHz. For a transmitting antenna over tree-tops and a receiving antenna located in the trees, a delay spread of 0.2 μ s has been reported due to foliage [7].

3.6. Constructions

Although path-loss models tend to capture differences between buildup and rural areas, few specific conditions should be emphasized. Street orientation has the channel effect on the received-signal strength. For a mobile unit closer to the base station in the range of 1–2 mi, the difference between signal strengths in the case when the street is parallel to the base station and when it is perpendicular to it is about 10 dB. This phenomenon diminishes for distances over 5 mi.

A mobile receiver moving into a tunnel experiences a signal loss that is dependent on the frequency and the transmitter/receiver positioning. Experiments carried out for the transmitter at the entrance of the tunnel and the mobile receiver moving through the tunnel show that at 300 m inside the tunnel \sim 4 dB loss is observed at 1 GHz. Attenuation at lower frequencies was much higher, approaching 20 dB at 400 MHz [7]. Results from a study in New York have established inverse-law dependence of path loss versus the distance with an inverse law from 4 at 900 MHz reducing to 2 at 2400 MHz. Above this level, the frequency loss is less than in free space, indicating some sort of guiding mechanism.

The underpass effect results in a signal drop between 5 to 10 dB when a mobile receiver drives through. The period of the attenuation depends on vehicle speed. In cellular radio this type of effect usually does not affect the voice channel.

4. SMALL-SCALE VARIATIONS: MULTIPATH FADING

Small-scale *fading* (also referred as *fast fading*, *short-term fading*, or simply *fading*) describes the fluctuations of the received radio signal over a short period of time or a short travel distance. Substantial variations of the signal amplitude are caused mainly by local multipath propagation. Multiple replicas of the signal combine at the receiver antenna in different ways depending on the time of arrival and the phase of individual components, resulting in fluctuations that are fast compared to longer-term variation in mean signal level (shadowing). These fluctuations are seen in the received signal as large changes of amplitude over a small interval of time, random frequency modulation due to Doppler shifts on different multipath arrivals, and possible time dispersion due to different propagation delays of multipath components. Although fading is a basically spatial phenomenon, it is experienced as temporal phenomenon by a radio receiver moving through the multipath field. The motion of surrounding objects (reflectors, scatterers) also impacts fading characteristics in the case of a static transmitter/receiver pair, and/or when it

is comparable to the speed of the mobile. Fast fading is observed over a distance of \sim 0.5 l, with fades of depth \sim 20 dB frequent and larger fades of $>$ 30 dB less frequent, but not uncommon [4].

In practice there is no clear border between slow and fast fading. It is commonly assumed that in the areas where multipath occurs, radio signal consists of a local mean value that is constant over a small area, but varies slowly as the receiver moves, and a fast fading component superimposed on the slowly varying signal.

In mobile radiocommunications multipath fading occurs in urban areas where the height of the mobile antenna is much lower than that of the surrounding buildings and there is no line-of-sight path between the transmitter and the receiver. Propagation is determined mainly by scattering and diffraction around the buildings. In fixed radiolinks where the line-of-sight propagation exists, multipath propagation is caused by reflection from the ground or surrounding objects.

Besides multipath propagation, other factors may influence the fading characteristics. Relative motion between the transmitter and the receiver in mobile and low-Earth orbit satellite communications results in a phase change due to the difference in pathlengths, which can be observed as a Doppler frequency shift in each propagation path as illustrated in Fig. 5. The phase change is given by

$$\Delta\phi = \frac{2\pi\Delta l}{\lambda} = \frac{2\pi v\Delta t}{\lambda} \cos\theta$$

and the corresponding frequency shift is

$$f_d = \frac{1}{2\pi} \frac{\Delta\phi}{\Delta t} = \frac{v}{\lambda} \cos\theta$$

where v is the speed of the mobile unit. If mobile unit is moving toward the transmitter, positive Doppler shift results in increase of the received signal frequency, and if it is moving away from the transmitter, a negative Doppler shift results in decrease of the received-signal frequency. The angle between the incoming wave and the direction of

Figure 5. Geometry for illustration of Doppler effect.

motion determines the maximum rate of phase change that occurs when the waves are coming directly behind or ahead the mobile.

While characteristics of a fading channel are consequences of physical propagation phenomena, their impact on the received radio signal depends on the transmitted signal characteristics as well, primarily on the bandwidth of the transmitted signal. This relationship will be addressed in more detail in the following section.

4.1. Statistical Characterization of Multipath Fading Channels

Two major characteristics of a multipath fading channel can be observed by transmitting a short pulse (ideally impulse):

1. *Time spread* (dispersion) of the channel, resulting in more than one received pulse. Pulses differ with respect to differ in time of arrival, amplitude, and phase.
2. *Time variation*; the structure of multipath varies with time, and the same sounding experiment will produce different number of echoes with different arrival times, amplitudes, and phases if repeated at a different time.

Consequently a multipath fading channel is characterized in statistical terms. The impulse response of the time-varying multipath channel is represented by time-varying linear filter $h(\tau, t)$, where the variable t represents time of transmission and τ represents the channel multipath delay for a fixed value of t . Thus $h(\tau, t)$ represents the response of the channel at time t due to the impulse applied at time $t - \tau$. When the received signal contains discrete multipath components, the equivalent complex baseband impulse response model is given by

$$h(\tau, t) = \sum_n \alpha_n(t) \exp(-j2\pi f_c \tau_n(t)) \delta[\tau - \tau_n(t)]$$

where $\alpha_n(t)$ is the attenuation factor for the n th path, $\tau_n(t)$ is the propagation delay for the n th path, and f_c is the signal carrier frequency.

Statistical characterization of the fading channel is detailed in Ref. 15. In summary, channel impulse response $h(\tau, t)$ can be represented as a zero-mean complex-valued Gaussian process, so that its envelope at any time instant is Rayleigh distributed and the phase is uniform [16]. When a strong signal component (fixed scatterer, strong reflection) exists, $h(\tau, t)$ does not have a zero mean and the statistics of the channel is Rician [17]. Regardless of the probability distribution, a wide-sense stationary channel is characterized by two functions: *multipath intensity profile* and *power delay profile* of the channel, which give the average output power of the channel as a function of the time delay τ . The multipath spread T_m of the channel represents a range of values of τ over which the power delay profile is essentially nonzero.

In practice, power delay profiles are found by averaging instantaneous power delay profile measurements over a

local area to determine an average small-scale power delay profile. A typical spatial separation for sampling the channel is a quarter of a wavelength, over receiver movements no greater than 6 m in outdoor channels and no greater than 2 m in indoor channels [1]. Several statistical parameters quantify the delay characteristics of the channel. The *mean excess delay* is the first moment of the power delay profile

$$\tau_{\text{mean}} = \frac{\sum_n \alpha_n^2 \tau_n}{\sum_n \alpha_n^2}$$

and RMS delay spread is the square root of the second central moment of the power delay profile

$$\sigma_\tau = \sqrt{\overline{\tau^2} - \tau_{\text{mean}}^2}$$

where

$$\overline{\tau^2} = \frac{\sum_n \alpha_n^2 \tau_n^2}{\sum_n \alpha_n^2}$$

All delays are measured relative to the first detectable signal arriving at the receiver at $\tau_0 = 0$. Relative amplitudes of multipath components are also used in computations. Typical values of RMS delay spread are on the order of microseconds for outdoor mobile radio channels and nanoseconds for indoor radio channels [3].

The *maximum excess delay* is defined as $\tau_X - \tau_0$, where τ_X is the maximum delay at which the multipath component is X dB lower than the strongest multipath arrival, which is not necessarily at τ_0 . It is important to note that all parameters highly depend on the noise threshold in the power delay profile, which is used to differentiate multipath components and thermal noise.

The Fourier transform of the power delay profile determines frequency coherence properties of the channel. The inverse of the multipath spread

$$(\Delta f)_c = \frac{1}{T_m}$$

is a measure of the *coherence bandwidth* of the channel. Effectively, two signal components separated in frequency by more than a coherence bandwidth will be affected differently by a channel; that is, they will fade independently. Coherence bandwidth is practically quantified by a level of frequency correlation function and the RMS delay spread. For example, for a correlation function above 0.9 the coherence bandwidth is approximately [3]

$$(\Delta f)_c \approx \frac{1}{50 \sigma_\tau}$$

Time variations of the channel can be described by the *Doppler power spectrum* of the channel, which gives the signal intensity as a function of a Doppler frequency. The range of Doppler frequency over which the Doppler power spectrum is essentially nonzero is called the

Doppler spread B_d of the channel. It measures the spectral broadening caused by the time variations. The inverse of the Doppler spread

$$(\Delta t)_c \approx \frac{1}{B_d}$$

is the *coherence time* of the channel, and defines the time interval over which the characteristics of the channel can be regarded as constant. If the signal components are separated in time by more than the duration of coherence time, they can be regarded as independent.

However, B_d is not uniquely defined. On the other hand, if a purely sinusoidal tone of frequency f_c is transmitted over a channel, the received signal is within $[f_0 - f_d, f_0 + f_d]$, where f_d is the Doppler shift, showing that spectral broadening depends on the velocity of the mobile unit as well. A commonly used relationship describing the coherence time is given by [3]

$$(\Delta t)_c = \frac{0.423}{f_d}$$

The scattering function of the fading channel, representing power density as a two-dimensional function of delay and Doppler frequency, and different correlation functions of the channel are related via different Fourier transform pairs [15].

In the case of a Rayleigh fading channel, two important statistical parameters may clarify design choices of diversity techniques and error control codes:

1. The *level-crossing rate*, defined as the expected value of the rate at which the envelope of the Rayleigh fading process crosses a specified level in a positive-going direction [3]. The number of level crossings per second is given by

$$N_R = \sqrt{2\pi} f_d \rho e^{-\rho^2}$$

where f_d is the maximum Doppler frequency and $\rho = R/R_m$ is the normalized value of the specified level R by the local RMS amplitude of the fading envelope. For example, in the 900-MHz band with vehicle speed of 48 kmph (1000 mi/h), the maximum value is 39 crossings per second.

2. The *average fade duration*, defined as the average period of time for which the received signal is below a given level R . For Rayleigh fading, it is given by

$$\bar{\tau} = \frac{e^{\rho^2} - 1}{\rho f_d \sqrt{2\pi}}$$

showing the dependence on mobile (unit) speed. For a given fading margin, determined in a power budget, it is important to evaluate the rate at which the received signal falls below a certain level and the average time during which it remains below that level. These parameters directly translate into a

SNR reduction during the fade that can be used for the prediction of the radio performance.

4.2. Channel Classification

The impact of the fading channel on the received signal depends on the signal characteristics such as signal bandwidth and signal duration. The relationship between signal characteristics and channel parameters will serve as the criterion for channel classification. Let us consider digital communication system with signaling interval T .

For a signaling interval T much larger than the multipath spread of the channel, $T \gg T_m$, channel introduces a negligible amount of intersymbol interference. On the other hand, for a bandwidth of a signaling pulse $W \approx 1/T$, the previous relationship implies that the signal bandwidth is much smaller than the coherence bandwidth of the channel, resulting in *frequency-nonselective* or *frequency-related flat* fading. This implies that amplitude attenuation and phase shift introduced by channel are the same for all signal components and consequently spectral characteristics of the transmitted signal are preserved at the receiver. Channel distortion is simply a multiplicative random process. In this case multipath components of the signal cannot be resolved. This case is typical for narrowband communication signals. Flat fading may result in deep fades.

In a case where the signaling interval is smaller than the multipath spread of the channel, consecutive transmitted symbols interfere with each other at the receiver, producing intersymbol interference. In this case the signaling bandwidth W is larger than the coherence bandwidth of the channel, and different signal frequencies are subject to different gains and phase shifts. This type of channel is referred to as the *frequency-selective* channel. Frequency-selective channels are typical for wideband communication systems such as time-division multiple-access systems or spread-spectrum systems.

For a signaling interval T smaller than the coherence time of the channel, $T \ll (\Delta t)_c$, channel characteristics can be regarded as fixed during the symbol interval. In the frequency domain, the signaling bandwidth is much larger than the Doppler spread of the channel. This condition corresponds to a *slowly fading channel*. However, the rate of change of the channel depends on both signaling bandwidth and the velocity of the transmitter or the receiver.

For a signaling interval larger than the coherence time, channel impulse response changes within the duration of the symbol. This results in spectral broadening, which in turn leads to signal distortion since the signal bandwidth is smaller than the Doppler spread of the channel. This type of fading is referred to as *fast fading* or *time-selective fading*.

It should be pointed out that there is a slight inconsistency in terminology. The term *fast fading* is used to describe *multipath fading*, which is fast compared to shadowing effects [3]. On the other hand, multipath fading is characterized as *fast fading* when the signaling interval is larger than the coherence time of the channel [15]. Although it might be somewhat confusing, the

precise meaning of the term can be deduced from the context in which it is used.

For a physical channel with a given multipath delay spread and Doppler spread, different scenarios may arise depending on the signal design. A slow fading condition is desirable from the standpoint of receiver design since it allows coherent reception; synchronization circuits are able to track changes of the signal. It is important to note that even in situations characterized as slowly fading, that is, for which $B_d T \ll 1$, receiver performance may be significantly affected by channel fluctuations via non-perfect synchronization. The amount of degradation depends on the exact value of $B_d T$.

If signal bandwidth W cannot be selected independently of the signaling interval T , for a given fading rapidity, the system may be subject to frequency-selective or frequency-nonselective fading. Slow frequency-nonselective fading introduces constant multiplicative distortion and no ISI (intersymbol interference). Both coherent and non-coherent receivers can be employed. In the case of slow frequency-selective fading, equalization techniques should be used to compensate for ISI and equalizer operation is possible because of slow variations of the fading. In the case when signal bandwidth can be selected independently of signaling interval (as in spread-spectrum systems due to bandwidth expansion), one can simultaneously achieve no-ISI and slow fading conditions.

In the case of fast fading and frequency-nonselective channels, noncoherent reception techniques may be employed. On the other hand, fast frequency-selective fading presents a serious obstacle for a communication system.

The product $B_d T_m$ is called the *spread factor* of the channel and has a fixed value for a given physical channel. For underspread channels, $B_d T_m < 1$, the system can be designed to achieve the condition of negligible ISI and slow fading. For digital systems an optimal data rate can be derived to satisfy conditions for slow frequency-nonselective fading [13]

$$R = \frac{1}{T} = \sqrt{\frac{B_d}{T_m}}$$

For overspread channels signal design choices are more restricted and noncoherent reception is generally used.

4.3. Statistical Models for Fading Channels

While path-loss models play a crucial role in the power budget, determining the range and coverage zone of the radio system, statistical models for small-scale fading play an important role in receiver design and evaluation. Performance in the presence of fading is one of the major factors influencing the receiver sensitivity. Few major fading models for different radio scenarios will be summarized in this section.

With the advances in multiinput/multioutput wireless systems and spacetime coding, temporal characterization of the fading channels has been extended to cover spacetime propagation effects as well. Details on spacetime channel models can be found in Ref. 29.

4.3.1. Jake's Model. *Jake's model* of a Rayleigh fading path is based on scattering and is one of the most widely used models for a fading channel. It effectively models a frequency-nonselective fading channel with a Doppler spectrum of the form

$$S(f) = \frac{K}{\pi f_d \sqrt{1 - \left(\frac{f - f_c}{f_d}\right)^2}}$$

where K is a constant that depends on polarization (for detailed model derivation, see Ref. 12), f_c is the signal frequency, and $f_d = v/\lambda$ is the maximum Doppler shift, where v is the speed of vehicle and λ is the signal wavelength. This type of Doppler spectrum can be simulated using a model with $N_0 = 8$ sinusoids where in-phase and quadrature components of the fading signal are given by

$$x_c(t) = 2 \sum_{n=1}^{N_0} \cos(\beta_n) \cos(\omega_n t) + \sqrt{2} \cos \alpha \cos(\omega_d t)$$

$$x_s(t) = 2 \sum_{n=1}^{N_0} \sin(\beta_n) \cos(\omega_n t) + \sqrt{2} \sin \alpha \cos(\omega_d t)$$

and Doppler shift is given by $\omega_d = 2\pi f_d$, frequencies of the sinusoids are $\omega_n = \omega_d \cos(2\pi n/N)$, $N_0 = (N/2 - 1)/2$, and phases $\beta_n = \pi n/N_0$ and $\alpha = \pi/4$. This model shows excellent agreement with Rayleigh distribution, the autocorrelation Bessel function, and the Doppler spectrum [12]. This technique can be extended to generate up to N_0 independent fading signals, which is of importance for tapped-delay-line fading channel models for frequency-selective fading.

4.3.2. Tapped-Delay-Line Model for Outdoor Mobile Systems. Tapped-delay line models are commonly used to specify mobile radio channels. The structure of the model is straightforward, and measurements for a particular frequency band and geographic environment are used to develop model parameters. The model is specified in terms of number of multipath arrivals (usually fixed), relative delays, relative power of multipath components, and Doppler spectrum for each component. For a given radio standard these parameters may vary widely not only with different measurements but also with different signal characteristics considered.

As an example of the tapped-delay-line model, a wide-band propagation model for the GSM (global system for mobile communications) digital cellular standard is summarized. Discrete number of taps (6 and 12) is determined by their time delay and their average power, amplitudes of each tap are Rayleigh-distributed and varying according to a Doppler spectrum $S(f)$ [19]. Two types of Doppler spectrum are defined: *classical*, to be used in all except one case

$$S(f) = \frac{A}{\sqrt{\left(1 - \frac{f}{f_d}\right)^2}} \text{ for } f \in [-f_d, f_d]$$

where $f_d = v/\lambda$ is the maximum Doppler shift, and *Rician*, which is the sum of a classical Doppler spectrum and one direct path

$$S(f) = \frac{0.41}{2\pi f_d \sqrt{\left(1 - \frac{f}{f_d}\right)^2}} + 0.91\delta(f - 0.7f_d) \text{ for } f \in [-f_d, f_d]$$

Depending on the environment, few typical cases are specified: rural area, hilly terrain, and typical urban environment. Six tap models are summarized in Table 4.

4.3.3. Rumlmer Fading Model for Fixed Microwave Systems. This is a three-path model developed for a line-of-sight microwave radio channels is based on channel measurements on a typical link in a 6-GHz band. Since the differential delay of two multipath components is small, the channel transfer function is given by

$$H(f) = \alpha[1 - \beta \exp(-j2\pi(f - f_{\min})\tau_0)]$$

where α is the overall attenuation, β is a shape parameter resulting from multipath propagation, f_{\min} is the frequency of the fade minimum, and τ_0 is the relative time delay between the direct and multipath components. By fitting the model to the measurement data parameter, α is modeled as lognormally distributed, while distribution for β is given as $(1 - \beta)^{2.3}$. Two random variables are statistically independent. For $\beta > 0.5$, the mean of $-20 \log \alpha$ is

Table 4. Tapped-Delay Fading Channel Models for GSM Mobile Radio

25 dB, with a standard deviation of 5 dB. For smaller values of β , the mean decreases to 15 dB. The delay parameter was estimated to be $\tau_0 = 6.3$ ns.

4.3.4. Saleh-Valenzuela Indoor Statistical Model. This model is based on statistical modeling of the measurements of indoor propagation with a multipath resolution of 5 ns. The maximum reported multipath delay spread was on the order of 100–200 ns within rooms in the building and 300 ns in hallways. This model is based on multipath components arriving in clusters. Amplitudes of the components are independently Rayleigh distributed, with variance that decays exponentially with the cluster delay as well as with excess delay within a cluster. The difference from the tapped-delay-line model is that clusters and multipath components within the cluster are modeled as Poisson arrival processes with different rates and exponentially distributed interarrival time [3].

4.4. Effects of Fading on System Performance

Analog radio systems are relatively narrowband, even for high-capacity microwave links, and the major factor contributing to the degradation of system performance is the fading depth [8]. Therefore, a flat fading margin should be provided to ensure robust performance. This margin defines the additional loss that can be tolerated before the system SNR reaches an unacceptable level.

For a digital system, BER (bit error rate) is the performance measure and it should be specified for particular fading condition. Important note is that performance degradation of the digital signal is not graceful as in the analog one. For a narrowband system, performance may be specified in terms of flat-fading margin. For wideband systems, effects of frequency selectivity are more emphasized and use of equalization techniques and/or other forms of diversity are necessary to ensure desired performance. In that case, the fading margin may not be specified explicitly, but the receiver sensitivity may be specified for fading conditions, and will include the effects of fading countermeasures.

5. MANMADE NOISE AND INTERFERENCE

Radio systems are limited by either noise or interference. Characteristics of the noise greatly influence radio receiver design; however, most of the radio systems nowadays are interference-limited because of coexistence with other radio systems and/or multiple-access schemes employed. Interference level in the radio system is dependent on frequency, time, spatial location, and signal separation. Some of the major interference mechanisms for radio systems will be described in this section.

5.1. Impulse Noise

The nature and characteristics of noise are important for the radio reception in two ways. Understanding the noise phenomena leads to more efficient system design. Characterizing noise is crucial in performance prediction of any radio system since it directly affects the receiver

sensitivity. Radio systems are subject to different noise sources. Effects of thermal noise and receiver noise are well understood and are described by noise density and noise figure. This type of noise is characterized as Gaussian. Atmospheric noise has nonflat spectral density and decreases rapidly with frequency. Galactic noise is due to energy radiation from stars and planets; however, it is usually below the level of thermal noise.

The type of noise referred to as manmade noise is impulsive in nature and is generated by radiation of various types of electrical equipment such as vehicle ignition systems, alternator, power lines, neon lights, industrial noise from current switches, and from various domestic appliances. This type of noise can significantly affect the performance of a radio system. Its spectral characteristics are very irregular, and it also varies in level with location and time. Impulsive noise may be viewed as a combination of successive impulses, with random amplitudes and random time spacing. Different parameters have been established to qualitatively describe this type of noise, including mean or average voltage, peak voltage, amplitude probability distribution, pulse height distribution, level-crossing rate, and pulse duration distribution [2].

The median value of manmade noise power is given as a function of frequency up to 200 MHz by [10]

$$F_{\text{am}} = c - d \log(f(\text{MHz}))$$

where c and d take values from Table 5. In the frequency range 200–900 MHz the relationship is given by

$$F_{\text{am}} = 44.3 - 12.3 \log(f(\text{MHz}))$$

As mentioned earlier, ignition impulses from motor vehicles produce the significant component of manmade noise, in particular in the VHF band. Noise amplitude distribution in this case can be determined by

$$A[\text{dB}(\mu\text{V}/\text{MHz})] = 106 + 10 \log V(\text{vehicles}/\text{km}^2) - 28 \log(f(\text{MHz}))$$

where V is the traffic density.

Predicting the performance of the receiver in the presence of impulse noise is extremely difficult compared to relatively straightforward methods for Gaussian noise. Different techniques are presented in Ref. 2.

Table 5. Parameters for Calculation of Impulse Noise Median

Environmental Category	c	d
Business	76.8	27.7
Residential	72.5	27.7
Rural	67.2	27.7
Quiet rural	53.6	28.6

5.2. Cochannel Interference

Cochannel interference (CCI) is the consequence of better spectrum utilization. It is generated in a scenario where two or more communication signals are assigned to the same frequency and operate at the same time. CCI may be caused by a number of scenarios depending on the radio service: bad route planning for microwave radiolinks, failure to carry out coordination procedures for the same type of service, cross-polarization degradation in cross-polar frequency plan, cochannel interference due to frequency reuse in mobile radio systems, and cochannel interference due to multiple-access methods such as CDMA.

In any case, the result of cochannel interference is the presence of the same-type modulated signal at the receiver input, which may be lower than (in cellular TDMA and microwave systems) or on the same level as (in satellite and cellular CDMA systems) the desired signal. In most cases cochannel interference can be avoided by careful system planning. This will reduce the cochannel interference to an acceptable level such that system performance is not significantly degraded. Technical measures include proper cell design for cellular systems, including cell sectorization, power control techniques, and the use of orthogonal codes on the forward link in CDMA cellular systems (note that orthogonal codes in a CDMA system can be used only to eliminate intracell interference, the interference from neighboring cells will still be present). In the case when planning methods fail to reduce the amount of interference, a solution may be found in more sophisticated receiver design using interference suppression techniques.

5.3. Adjacent-Channel Interference

Adjacent-channel interference is the result of closely spaced radio channels in frequency, where the spectral content of the adjacent channels is spilling into the bandwidth of the desired channel. Factors determining the level of the interference are signal power and spectral distribution, power, and spectral distribution of the interfering signal intercepted by the receiver and distance dependence of the transmission losses between interfering transmitter and the desired signal receiver. ACI can be somewhat controlled by tight filtering; however, limiting factors are spectral utilization of the system and, on the other hand, the finite slope that can be achieved for filtering functions. Another way to improve adjacent channel performance is to design spectrally efficient modulation techniques that have largely concentrated power in a limited bandwidth with good rolloff properties, which in turn requires more elaborated demodulation schemes. Adjacent-channel interference in cellular systems can also be avoided by careful frequency planning, to ensure that adjacent channels are not used within the same cell or in the neighboring cells.

5.4. Near-Far Interference

Near-far interference in a radio system occurs when two different signals arrive at the receiver input with largely different power levels and may be interpreted as a special

form of cochannel interference. This may be the result of difference in distance of different transmitters from the same receiver, or in some cases fading conditions on the link, so that a closer transmitter may have lower power at the receiver when subjected to a deep fade. A consequence of the near-far problem is the performance degradation for weaker-signal reception. Although the near-far problem is general for radio reception, it is especially critical in direct-sequence CDMA systems where all signals are present at the receiver input, and may significantly reduce the capacity of a CDMA system. Countermeasures for the near-far problem include tight power control, which should ensure that all signals arrive to the receiver with the power level required for desired operation. Another possibility for cellular systems is to develop a frequency management plan that can greatly reduce the possibility of the near-far problem. Specific techniques for radio design include multiuser detection techniques [22].

6. RADIO RECEIVER DESIGN

The radio receiver consists of a channel interface followed by the demodulation component [23]. Channel interface of the radio receiver is characterized by the receiver selectivity and its ability to process both desired and undesired (interfering) signals. In order to achieve specified performance, the radio receiver must be designed to operate in the presence of noise, fading, and interference.

6.1. Basic Radio Receiver Parameters

Radio receiver sensitivity determines the input level of the weak radio signal that can be processed by a radio receiver to meet performance requirements. For analog receivers, performance measure is given in terms of required SNR, usually specified at the input to the detection circuit. For digital systems the performance measure is given in terms of BER or other parameters that can be derived from the BER requirement, depending on the type of radio service. The detection algorithm includes coding, interleaving, equalization, diversity, and other signal processing functions used to improve radio reception.

Receiver sensitivity is usually expressed by minimum detectable signal level for a required SNR, which includes the knowledge of the system bandwidth and is defined as

$$\begin{aligned} \text{RS(dBm)} = & -174 \text{ dBm} + 10 \log(\text{NF(dB)}) \\ & + 10 \log(\text{BW(Hz)}) + \text{SNR(dB)} \end{aligned}$$

where NF is the overall system noise figure referred to the input of the receiver and BW is the system noise bandwidth. For digital systems, the system requirement is commonly given in terms of energy per bit–noise density ratio E_b/N_0 . The relation between E_b/N_0 and SNR is given by $E_b/N_0 = \text{SNR} \cdot \text{BW} \cdot T$, where T is the bit duration [23]. Depending on the particular radio system and targeted operating environment, performance measure of the system (SNR or BER) can be evaluated under either fading or static conditions. In the first case the fading margin is derived from the statistics of the large-scale signal variation

such as lognormal fading. Small-scale signal variations are accounted for implicitly during BER evaluation. When BER of the system is specified under static conditions, the fading margin is derived from combined statistics of both large-scale and small-scale variation. The fading margin effectively defines the increase in SNR required to preserve the same BER as in the static case.

Radio sensitivity specifies the lowest detectable signal level at the radio input; however, both desired and unwanted signals may be present at the radio receiver input at high levels, and it is important to specify the performance for undesired response rejection. The unwanted strong signal may reduce a nearby weak (desired) signal, resulting in radio desensitization. The desensitization level is specified for a 1-dB weak-signal reduction and is a consequence of radio front-end saturation.

Another factor that may severely limit the performance of a radio receiver is intermodulation distortion (IMD), where unwanted strong signals produce a number of intermodulation products due to receiver front-end nonlinearities. IMD products, particularly third-order products, may fall directly in the bandwidth of the desired signal. To limit the level of the IMD products, the receiver is required to have a high intercept point in a particular order.

Dynamic range (DR) of the receiver is defined as the range of input signals that a radio receiver can process. Different factors may be taken into account depending on the radio service; however, the most common, the spurious-free dynamic range (SFDR), is defined as

$$\text{SFDR(dB)} = \frac{2}{3}(\text{IIP3(dBm)} - \text{RS(dBm)})$$

where IIP3 is the third-order input intercept point.

6.2. Modulation and Coding

Choice of the modulation method for radiocommunication depends on many factors. In all cases the goal of the radio receiver design is to achieve the required quality of the output signal (voice, video, data) using minimum SNR or E_b/N_0 . For power-limited systems, where bandwidth is not of concern (e.g., space communication links) noncoherent M -ary frequency shift keying (FSK) can be used to reduce the required E_b/N_0 for a given BER, at the expense of bandwidth expansion. For a bandwidth-limited system (as in most of the modern radio systems) spectrally efficient, coherent modulation schemes such as phase shift keying (PSK) or quadrature amplitude modulation (QAM) can be used at the expense of increasing required E_b/N_0 as the spectral efficiency increases [5]. However, additional requirements for the modulation format in radio communications such as robustness to fading, interference, and nonlinear distortions, motivated development of constant-envelope or near constant-envelope modulation such as offset quadrature phase shift keying (OQPSK) and minimum shift keying (MSK). Different forms of such modulation formats can be found in wireless systems [3]. Inherent resistance of a modulation method to the interference can be measured by determining required SIR for a specified BER. Performance functions for digital

modulations in the presence of interference are presented for various types and statistical characteristics of interferers in Ref. 23. Further advances in signaling methods for radio channels include the application of coded modulation techniques [15].

Additional performance gain can be obtained by using coding techniques at the expense of introducing redundancy to the transmitted digital signal. Channel coding protects the signal from the effects of noise, fading, and/or interference. Functions of channel codes are error detection and forward error correction. Both block and convolutional codes have been applied in radiocommunications [15]. Lately, there has been increasing attention to space-time codes [29] and turbo codes [30].

6.3. Diversity Reception for Fading Channels

Diversity reception techniques are used to reduce the effect of fading by exploiting the random nature of the radio channel. Independent or highly uncorrelated signal paths, known as *diversity channels*, are used to improve quality of the received signal. The concept of diversity is relatively simple—if one diversity channel is subject to a deep fade, another channel with a higher signal level can be selected or appropriate combining techniques can be applied to increase the signal level. The probability of all diversity channels being simultaneously below a given level is much less than the probability of any one of them being below that level. Therefore, a combination of different diversity channels will be subject to fewer severe fading conditions compared to any individual channel.

Diversity techniques may address different types of signal fluctuations. Large-scale fading is caused by shadowing due to variations in the propagation profile (hills, mountains) and the surrounding objects (buildings). To reduce the effect of the long-term fading, two geographically separated antennas may be used (for transmission or for reception), and the stronger signal may be selected. This type of diversity, known as *macroscopic diversity*, is often used in shortwave radio systems to reduce the ionospheric effects and in cellular systems to improve the performance of the forward link (where the mobile unit is selecting to receive signal from a base station that is not covered by the shadow) or of the reverse link (where signals from two base stations may be combined). The selective combining techniques is the most usual approach for macroscopic diversity [7].

Small-scale fading caused by multipath propagation in the vicinity of the receiver results in deep and rapid signal fluctuations. They occur over very short distances of a few wavelengths, and microscopic diversity techniques are employed to reduce the deep fades of the received signal. Different methods may be used to derive the diversity branches (channels).

Space diversity methods use physically separated antennas that can provide signals with low correlations. Typically, a separation of a few wavelengths is sufficient to obtain independently fading channels. Antenna separation is also dependent on antenna height, and can be reduced as the signal frequency increases. This type of diversity is widely used in microwave radiolinks and in

cellular radio, particularly for base-station reception. For base stations in mobile radio, the recommended ratio between antenna height and antenna separation is about 11, suggesting about 9 ft of antenna separation for a 100-ft antenna in the 900-MHz band [7]. Antenna diversity at the mobile unit can be achieved with an antenna separation as low as 17.5% of the signal wavelength. Practical antenna separation for microwave links is on the order 150–200 signal wavelengths. Receiver configuration for space diversity is relatively simple. The number of branches is selectable, and no extra bandwidth or power is needed to achieve diversity, making the space diversity one of the most popular schemes [4].

Frequency diversity relies on the diversity channels being separated (in frequency) by more than the coherence bandwidth of the channel, so the signal replicas will have very little correlation. Typical values used for mobile radio in 900-MHz band exceed 50 kHz in urban areas and 300 kHz in suburban areas [7]. This technique is often applied in microwave links, where diversity frequencies are available as the backup frequencies in the case of deep fading. Beside the requirements for additional bandwidth, a disadvantage of frequency diversity is the need for multiple receivers at different frequencies.

Polarization diversity is based on the fact that horizontal and vertical polarization signal components fade independently and may be combined (selected) at the receiver. This technique is used primarily for microwave links, where channel conditions vary slowly in time, although it has been increasingly considered for base-station reception in mobile radios. Two differently polarized antennas may be at the same place, hence there is no separation requirement as in space diversity. The drawback of the technique is the 3 dB power reduction at the transmitter since the power must be split between differently polarized antennas. Also, only two diversity branches are available in polarization diversity [7].

Angle diversity may be used at high operating frequencies (over 10 GHz) by pointing directional antennas in different directions at the receiver site. It is used predominantly by mobile units in cellular radio, since most of the multipath is created by local scatterers. Directive antennas also help in reducing the Doppler spread for each diversity branch.

Time diversity relies on transmitting the same signal at different times, so these signals fade at independent instances, so the fading characteristics will be changed and signals will be uncorrelated. The two transmissions should be separated by more than the coherence time of the channel. This diversity method is effective in applications where the fading mechanism is not related to the movement of the receiver. However, this method fails in the scenario where the mobile unit may remain still at the given location, which is the subject of deep fade, and the repeated signal components are highly correlated. While this method requires more spectrum and large buffer memory to store different signal replicas, the advantage is in simple implementation.

Interleaving is the technique used to obtain time diversity effect in modern digital communication systems. The function of the interleaver is to spread transmitted

bits in time so that a block of bits is not subject to a deep fade at the same time. This helps randomize burst errors and aid channel-coding techniques in reducing the overall BER [3].

The path diversity technique relies on receiver capability to resolve different multipath components in the time domain and subsequently combine them. This type of diversity is also referred to as the *implicit diversity* as opposed to other techniques that explicitly define diversity channels, since multipath diversity channels are obtained after signal reception. Adaptive equalizers and the RAKE receiver [15] are receiver techniques that provide path diversity, and are very effective in frequency-selective channels. Diversity gain depends largely on the delay profile of the channel.

Diversity techniques are usually applied at the receiver side, although some of the implementation complexity can be moved to a transmitter. For example, the base station in the mobile radio scenario may use the antenna that can provide better path propagation to a mobile unit at a specific location. Transmitter diversity allows the receiver to obtain diversity gain while operating as a standard non-diversity receiver [4,31].

Once the diversity channels are created, it remains to be decided how are they going to be combined in order to utilize the diversity effect. While macrodiversity schemes use almost exclusively selection combining, microdiversity schemes may employ one of the combining techniques outlined below. The methods of linear combining are derived from different optimization criteria, different levels of information available at the receiver, and different complexity constraints.

Selective combining simply selects the diversity branch with the highest signal level. This type of combining is easy to implement; additional requirements are antenna switch and monitoring circuitry. While in selective combining only one branch is used for subsequent signal processing and others are discarded, maximal ratio combining performs coherent combining of all diversity channels. This is the optimal method because it provides the maximal signal-to-noise ratio for signal detection. The weights applied to different diversity branches are proportional to the SNRs in each branch, and can be obtained by utilizing either pilot signals or sophisticated channel estimation techniques. When variable weighting is not available at the receiver, equal-gain combining may be utilized by coherently summing the signals from different diversity branches without weighting. This method still allows the receiver to exploit all diversity channels. Performance of equal-gain combining is better than selection combining and worse than maximal ratio combining, thus representing a viable technique as a tradeoff between performance and complexity. Performance improvement obtained by different combining schemes is summarized in Table 6.

Diversity reception may be interpreted as the simple case of coding, namely, repetitive coding, since the information is simply repeated on each diversity channel. Better spectrum utilization can be achieved by employing more sophisticated coding techniques for fading channels, in particular concatenated coding [15].

Table 6. SNR Improvements (in dB) for BER of 1% Relative to Single-Channel Reception: Comparison of Various Diversity Combining Schemes

Diversity Branches	Selection	Maximal Ratio	Equal Gain
2	10.0	11.5	10.8
4	16.0	19.0	18.0
6	18.0	22.0	21.5

6.4. Interference Suppression Techniques

Every radio system operates in the presence of some form of interference. Regardless of the origin of interference (intentional or unintentional), some form of interference suppression must be employed in order to preserve system performance. Because of the increased number of services, most of the radio systems in operation are interference-limited rather than noise-limited. For power budget calculation, in addition to radio sensitivity, which is a function of the noise bandwidth of the receiver and the required SNR, the interference margin should be specified. Alternatively, the signal-to-interference ratio should be specified to satisfy required BER. Depending on the type of interference (CCI, ACI), different requirements may be imposed on the receiver.

Different approaches may be pursued to improve the efficiency of a radio system, such as reducing the channel spacing (increasing ACI), narrowband and wideband system overlay (creating narrowband cochannel interference to the wideband system), smaller cell design in mobile radio (increasing CCI), and overlapping footprints of the satellites.

With respect to the signal observation methods, interference suppression techniques could be broadly divided into *multichannel techniques*, where multiple sensors (antenna array) are employed for signal reception and *single-channel techniques*, where only one antenna is employed [25]. In a multichannel scenario, spatial filtering techniques may be realized via adaptive antenna arrays, relying on the different spatial distribution of the interfering signals. Single-channel techniques rely purely on temporal processing, usually using adaptive filtering. The most promising path for the modern receiver design is to incorporate spatiotemporal processing, efficiently combining capabilities of antenna arrays and temporal signal processing [26].

Spatial processing for interference signal suppression can be carried out using different techniques, including directional antennas, tilted beams, and height adjustment. However, adaptive antenna arrays with capability of adaptive beamforming have shown great potential for congested radio environments. Different algorithms and optimization criteria for adaptive beamforming are presented in Ref. 27.

Single-channel interference suppression techniques can be applied both in cases of spread-spectrum signaling and conventional techniques. Although all forms of spread-spectrum signals (direct sequence, frequency hopping, time hopping) provide certain interference

margin due to their inherent processing gain, additional techniques can be applied to further improve performance. Depending on the nature of interfering signal, different interference suppression algorithms have been developed. For narrowband interference rejection in direct sequence systems solutions include adaptive notch filters, decision feedback techniques, adaptive analog-to-digital conversion, and other nonlinear techniques. In the case of CDMA signals, where interference has the same characteristics as the desired signal, multiuser detection techniques are developed either in decentralized form (detection of single user of interest) or in centralized form (joint detection of all active users) [22]. Special techniques have been analyzed for frequency-hopping systems as well [25].

In non-spread-spectrum systems different techniques have been developed to cope with CCI, ACI, and ISI. Adaptive equalization techniques were shown to be efficient in combatting all three types of interference. Other methods include self-optimizing or blind receivers (based on different techniques such as constant modulus, higher-order statistics, probabilistic approaches etc.), neural network receivers, and other nonlinear techniques [25].

Most of the abovementioned interference suppression algorithms are performed in baseband. In addition to this different practical interference suppression schemes are developed at RF/IF stages of the receivers [28].

6.5. Signal Losses in Radio Receiver

Because of the inherent complexity of the radio receiver, a number of signal loss sources are associated with receiver design. Bandlimiting loss in transmitter and receiver is the result of finite-bandwidth usage, usually restricted by the radio regulations. Intersymbol interference in which received digital symbols overlap with each other may result from different effects: bandlimited operation, physical multipath radio propagation, and usage of partial response modulation formats. Local oscillator phase noise results in the phase jitter in the receiver and consequently degrades the performance of the detection algorithm. Nonlinear distortions in radio equipment include AM/AM and AM/PM conversion, limiter loss, and intermodulation distortion. AM/PM conversion produces phase variations in the signal, mostly after nonlinear amplification. Signal sidelobe growth is another effect that can produce excessive interference despite tight filtering at the transmitter. Hardlimiting stages in the receiver may cause suppression of weak-signal components in the presence of stronger ones. Intermodulation products are the result of multiple signals interacting in a nonlinear device and create additional noise source, which contributes to total noise level. Also, receiver operation can be largely affected by several imperfections associated with demodulation, such as imperfections of the synchronization circuits that are producing noisy estimates of received-signal parameters necessary for the detection process and finite numeric precision effects associated with programmable of fixed logic implementation of the demodulation functions.

RADIOMETRY

IAN A. GLOVER
University of Bradford
Bradford, West Yorkshire,
United Kingdom

Radiometry is concerned with the measurement, analysis, and interpretation of radiant electromagnetic energy. The simplest and most common measurement, made using an instrument called a *radiometer*, is of received electromagnetic power in a given frequency band. Some instruments, however, analyze the received energy's spectral distribution (spectroradiometers), its polarization (polarimeters), or its angular distribution in space (imaging radiometers). The usual objective of radiometric measurements is the inference from them of the physical and/or chemical state of the material from, or through which, the received electromagnetic energy has been emitted, reflected, or transmitted. Radiometry is therefore a branch of remote sensing and could be considered to include radar. In practice, however, the term *radiometry* is usually used to describe the measurement and characterization of naturally occurring radiation, or (unlike radar) scattered radiation originating as a narrowband signal. The former, called *passive radiometry*, deals principally with self-emitted thermal radiation and reflected radiation of solar origin. The latter, called *active radiometry*, relies on artificial illumination. Figure 1 illustrates these different types of radiometer. Active radiometers are sometimes called *scatterometers*.

Since all radiometers depend for their operation on the measurement of one or more parameters of electromagnetic radiation, a brief review of such radiation follows.

1. ELECTROMAGNETIC RADIATION

Whenever charges accelerate (other than those carried by electrons in stable orbits around the nuclei of atoms), or a subatomic particle in an atom makes a transition to a lower energy level, electromagnetic energy is radiated. This energy propagates as a disturbance of the electric and magnetic fields existing in space. An electromagnetic

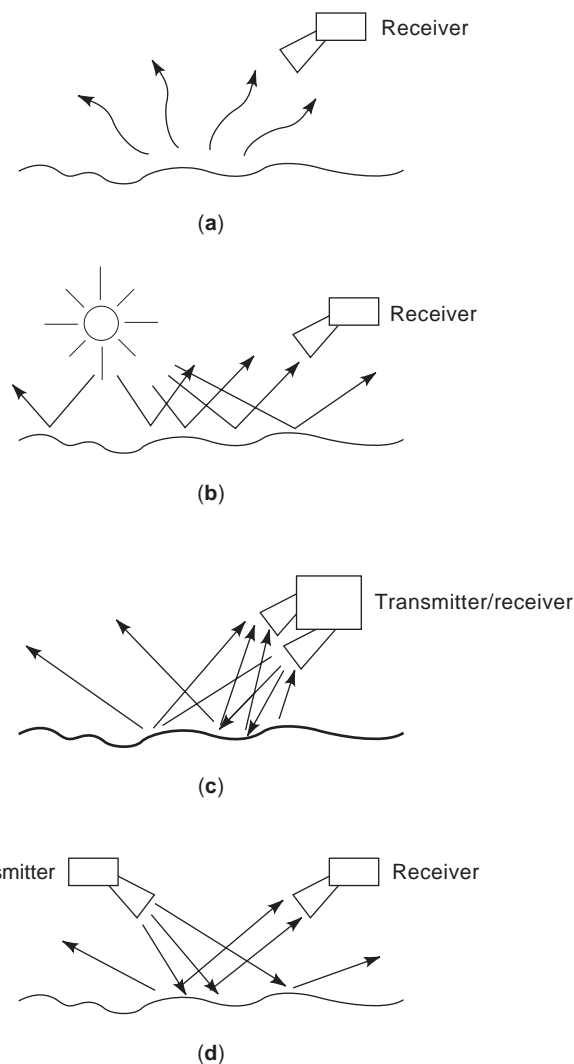

Figure 1. Passive and active radiometry: (a) passive measurements of self-emitted thermal radiation; (b) passive measurements of scattered solar radiation; (c) active (scatterometer) measurements employing monostatic geometry; (d) active (scatterometer) measurements employing bistatic geometry.

wave propagating in an isotropic, homogeneous medium has, sufficiently far from its source, an electric field vector \mathbf{E} , magnetic field vector \mathbf{B} , and unit vector pointing in the direction of wave propagation \mathbf{u} , which are mutually perpendicular. Furthermore, the wavefront has a curvature that is sufficiently small for it to be considered locally plane. (In a truly plane wave \mathbf{E} and \mathbf{B} would be constant with respect to position in any plane normal to the direction of propagation.)

For radiation of a single frequency (said to be *monochromatic*), \mathbf{E} and \mathbf{B} will vary sinusoidally with time and space. The amplitude (V/m) of such a wave is the peak value of its electric field strength, and its cyclical frequency f (Hz) is the number of oscillations (or cycles) that the electric field completes, at a given point in space, in one second. [The radian frequency ω (rad/s) is the phase advance in radians, at a given point in space, that the wave

RADIOMETRY

IAN A. GLOVER
University of Bradford
Bradford, West Yorkshire,
United Kingdom

Radiometry is concerned with the measurement, analysis, and interpretation of radiant electromagnetic energy. The simplest and most common measurement, made using an instrument called a *radiometer*, is of received electromagnetic power in a given frequency band. Some instruments, however, analyze the received energy's spectral distribution (spectroradiometers), its polarization (polarimeters), or its angular distribution in space (imaging radiometers). The usual objective of radiometric measurements is the inference from them of the physical and/or chemical state of the material from, or through which, the received electromagnetic energy has been emitted, reflected, or transmitted. Radiometry is therefore a branch of remote sensing and could be considered to include radar. In practice, however, the term *radiometry* is usually used to describe the measurement and characterization of naturally occurring radiation, or (unlike radar) scattered radiation originating as a narrowband signal. The former, called *passive radiometry*, deals principally with self-emitted thermal radiation and reflected radiation of solar origin. The latter, called *active radiometry*, relies on artificial illumination. Figure 1 illustrates these different types of radiometer. Active radiometers are sometimes called *scatterometers*.

Since all radiometers depend for their operation on the measurement of one or more parameters of electromagnetic radiation, a brief review of such radiation follows.

1. ELECTROMAGNETIC RADIATION

Whenever charges accelerate (other than those carried by electrons in stable orbits around the nuclei of atoms), or a subatomic particle in an atom makes a transition to a lower energy level, electromagnetic energy is radiated. This energy propagates as a disturbance of the electric and magnetic fields existing in space. An electromagnetic

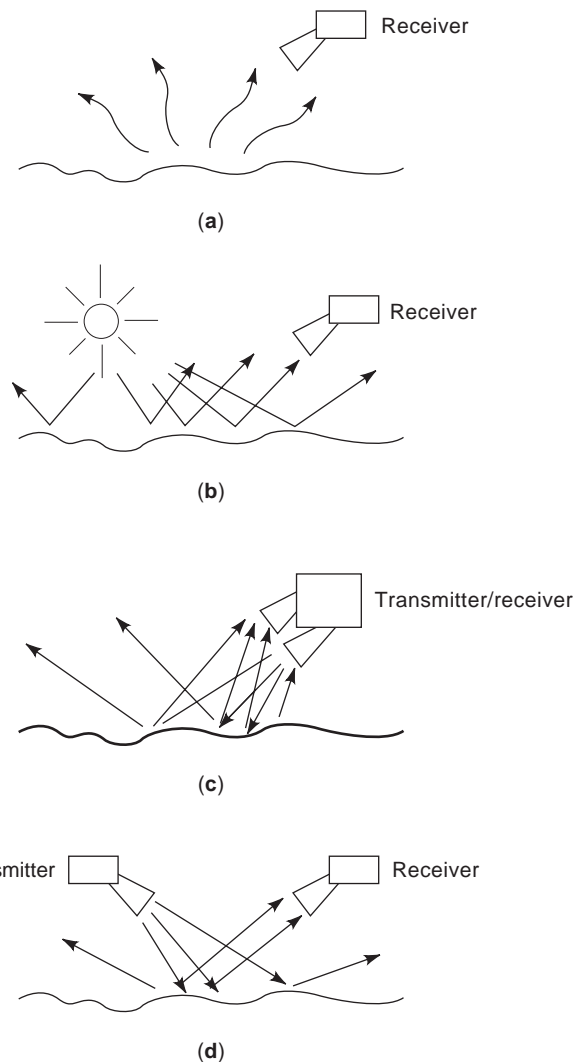

Figure 1. Passive and active radiometry: (a) passive measurements of self-emitted thermal radiation; (b) passive measurements of scattered solar radiation; (c) active (scatterometer) measurements employing monostatic geometry; (d) active (scatterometer) measurements employing bistatic geometry.

wave propagating in an isotropic, homogeneous medium has, sufficiently far from its source, an electric field vector \mathbf{E} , magnetic field vector \mathbf{B} , and unit vector pointing in the direction of wave propagation \mathbf{u} , which are mutually perpendicular. Furthermore, the wavefront has a curvature that is sufficiently small for it to be considered locally plane. (In a truly plane wave \mathbf{E} and \mathbf{B} would be constant with respect to position in any plane normal to the direction of propagation.)

For radiation of a single frequency (said to be *monochromatic*), \mathbf{E} and \mathbf{B} will vary sinusoidally with time and space. The amplitude (V/m) of such a wave is the peak value of its electric field strength, and its cyclical frequency f (Hz) is the number of oscillations (or cycles) that the electric field completes, at a given point in space, in one second. [The radian frequency ω (rad/s) is the phase advance in radians, at a given point in space, that the wave

makes in one second and is related to cyclical frequency by $\omega = 2\pi f$.] The phase constant β (rad/m) is the phase advance in radians that the wave makes, at a given instant of time, over one meter of space in the direction of propagation and is related to wavelength λ by $\beta = 2\pi/\lambda$. ($1/\lambda$ and β are therefore the spatial equivalent of cyclical and radiant frequency, respectively.)

Radiation of nonzero bandwidth has an amplitude at a point in space that fluctuates over time as the phase relationships between the constituent (and elemental) monochromatic waves change. The timescale over which this amplitude fluctuation occurs is related to the bandwidth Δf of the radiation and is characterized by a coherence time Δt . *Coherence time* is defined as the maximum timeshift for which the field of the original and timeshifted waves (at a given point in space) are correlated. An equivalent quantity, coherence length Δl , is defined (for a given instant in time) as the maximum spatial shift for which the fields of original and shifted waves are correlated. For quantitative work the term *correlated* must be interpreted as a correlation value greater than some specified fraction of its maximum. For consistent definitions of bandwidth, coherence length, and coherence time, these quantities are related by

$$\Delta l = c\Delta t = \frac{c}{\Delta f} \quad (1)$$

If the tip of the \mathbf{E} vector, representing a wave at a single point in space, traces out an elliptical curve, the wave is said to be (fully) polarized. If the curve traced out is random, the wave is said to be unpolarized. A wave with an \mathbf{E} vector locus that can be resolved into a deterministic component and a random component is said to be partially polarized. A fully polarized wave having a polarization ellipse with an axial ratio of 1.0 or ∞ is said to be circularly, or linearly, polarized, respectively. A linearly polarized wave therefore has an \mathbf{E} vector that traces out a straight line and that, in an isotropic medium, remains in a fixed plane as the wave propagates forward.

The concepts of coherence and polarization are not entirely unrelated since a wave observed on a timescale that is short with respect to its coherence time is always fully polarized. As the observation time increases, the polarization of the wave may gradually change; however, the changes appear random on a timescale large with respect to the wave's coherence time. A wave will remain fully polarized even when observed on a timescale much longer than its coherence time if energy is radiated in one polarization only.

In passive radiometry the received electromagnetic radiation is usually incoherent, spread across a wide band of frequencies, and unpolarized. The useful measurable quantities in this case are power density (W/m^2), radiation intensity (W/sr), power spectral density (W/Hz), and angular/spatial radiation distribution. In radiometry the first three of these quantities are generally referred to as *irradiance* (E), *radiant intensity* (I), and *radiant spectral flux* (Φ_f), respectively. In some applications, however (e.g., microwave radiometry), different terminologies are also often used (see Table 1).

2. DEFINITIONS OF RADIOMETRIC QUANTITIES

The commonly used radiometric quantities are as follows:

- Radiant energy Q (J)—the quantity of electromagnetic energy in a specified region of space or associated with a specified process
- Radiant flux Φ (W)—radiant energy per unit time crossing a specified surface
- Radiant density w (J/m^3)—radiant energy per unit volume
- Radiant flux density E or M (W/m^2)—radiant flux per unit area normal to a specified direction
- Irradiance E (W/m^2)—radiant flux density arriving at a specified surface
- Radiant exitance (or emittance) M (W/m^2)—radiant flux density leaving a specified surface
- Radiant intensity I (W/sr)—radiant flux per unit solid angle in a specified direction
- Radiance L ($\text{W sr}^{-1} \text{m}^{-2}$)—radiant intensity in a specified direction per unit projected area of the source normal to the specified direction

Radiation consisting of electromagnetic power distributed over a continuum of frequencies has infinitesimally small power at any single frequency. Each of the preceding quantities can be characterized at a single frequency, however, by considering the quantity to be measured within a small bandwidth Δf (centered on frequency f), dividing by Δf , and taking the limit as $\Delta f \rightarrow 0$. The result is a spectral density having those units of the original quantity per hertz. (An obvious variation on this definition uses radian frequency instead of cyclical frequency.) At optical frequencies spectral densities are usually expressed as quantities per meter of wavelength rather than per hertz of frequency. A spectral density is typically indicated by preceding the quantity with the word *spectral* and adding a subscript f , ω , or λ to the appropriate symbol. Spectral irradiance, for example, can be expressed in any of the following ways:

$$E_f(f) = \lim_{\Delta f \rightarrow 0} \left[\frac{\text{power density contained in frequency band } f - \frac{\Delta f}{2} \text{ to } f + \frac{\Delta f}{2}}{\Delta f} \right] \quad (2)$$

$$E_\omega(\omega) = \lim_{\Delta \omega \rightarrow 0} \left[\frac{\text{power density contained in frequency band } \omega - \frac{\Delta \omega}{2} \text{ to } \omega + \frac{\Delta \omega}{2}}{\Delta \omega} \right] \quad (3)$$

Table 1. Radiometric and Photometric Quantities

Quantity	Symbol	SI Unit	Other Common Units	Defining Equation	Comments
Radiant energy	Q_e	J	erg, kWh		Electromagnetic energy
Radiant flux	Φ_e	W	erg/s	$\Phi_e = \frac{dQ_e}{dt}$	Electromagnetic power
Radiant density	w_e	J/m ³	erg/cm ³	$w_e = \frac{dQ_e}{dV}$	Energy density
Irradiance	E_e	W/m ²	W/cm ²	$E_e = \frac{d\Phi_e}{dA}$	Power density (also called <i>radiant flux density</i>)
Radiant excitance	M_e	W/m ²	W/cm ²	$M_e = \frac{d\Phi_e}{dA}$	Power density (also called <i>emittance</i> and <i>radiant flux density</i>)
Radiant intensity	I_e	W/sr		$I_e = \frac{d\Phi_e}{d\Omega}$	Angular concentration of power (also called <i>radiation intensity</i>)
Radiance	L_e	W sr ⁻¹ m ⁻²	W sr ⁻¹ cm ⁻²	$L_e = \frac{dI_e}{(dA \cos \psi)}$	Angular concentration of power per unit projected area of source (also called <i>radiometric brightness</i> , especially in microwave applications)
Luminous energy	Q_v	lm s (talbot)	lm h	$\Phi_v = K_m \int_{0.36\mu m}^{0.83\mu m} \Phi_{e,\lambda}(\lambda) V(\lambda) d\lambda$	Photopic definition; scotopic definition uses primed versions of K_m and $V(\lambda)$.
Luminous flux	Φ_v	lm (lumen)		$\Phi_v = \frac{dQ_v}{dt}$	
Luminous density	w_v	lm s m ⁻³		$w_v = \frac{dQ_v}{dV}$	
Illuminance	E_v	lx (lux)	fc, ph	$E_v = \frac{d\Phi_v}{dA}$	1 lux (lx) = 1 lm/m ² 1 foot-candle (fc) = 1 lm/ft ² 1 phot (ph) = 1 lm/cm ² Also called <i>illumination</i>
Luminous excitance	M_v	lx		$M_v = \frac{d\Phi_v}{dA}$	Also called <i>luminous emittance</i>
Luminous intensity	I_v	cd (candela)		$I_v = \frac{d\Phi_v}{d\Omega}$	1 candela (cd) = 1 lm/sr
Luminance	L_v	cd/m ² (nit, nt)	sb, L, fL, asb	$L_v = \frac{dI_v}{(dA \cos \psi)}$	1 stilb (sb) = 1 cd/cm ² 1 lambert (L) = 1 cd/(π cm ²) 1 foot lambert (fL) = 1 cd/(π ft ²) 1 apostilb (asb) = 1 cd/(π m ²) Also called <i>photometric brightness</i>

$$E_\lambda(\lambda) = \lim_{\Delta\lambda \rightarrow 0} \left[\frac{\text{power density contained in wave band } \lambda - \frac{\Delta\lambda}{2} \text{ to } \lambda + \frac{\Delta\lambda}{2}}{\Delta\lambda} \right] \quad (4)$$

The relationship between these various expressions is summarized by

$$E_f(f) = E_\omega\left(\frac{\omega}{2\pi}\right) 2\pi = E_\lambda\left(\frac{c}{\lambda}\right) \frac{c}{f^2} \quad (5)$$

Spectral densities may be a function of frequency and, if so, may be measured by a spectroradiometer to yield information about the source of the radiation, material through which it has passed, or a surface from which it has been reflected. Often, however, spectral densities are constant with frequency (at least over the frequency band of interest). In this case they are referred to as white and are characterized by a single value.

2.1. Related Photometric/Luminous Quantities

Radiometric quantities relate to objective measures of energy and power carried by electromagnetic radiation of any

wavelength. Photometric (or luminous) quantities relate to the subjective visual impact that these quantities have on an observer [1]. In practice, photometric quantities are usually measured objectively but in such a way as to reflect the visual sensation experienced by a normal human observer. This is achieved by using detectors that mimic the response of the human eye/brain system and is called physical photometry. The definition of photometric quantities therefore involves the visual response of a (hypothetical) standard observer [2]. In fact, two standard responses, $V(\lambda)$ and $V'(\lambda)$, called the *photopic* and *scotopic spectral luminous efficiencies*, are defined (Fig. 2). These responses correspond closely to those of human observers under conditions of high (nominally daytime) and low (nominally nighttime) illumination, respectively. (The principal reason for the difference in these two responses is that different types of retinal receptors dominate under the two conditions; cones in the former case and rods in the latter case.)

Spectral luminous efficiencies are used to define a photometric/luminous quantity corresponding to each radiometric quantity, the same symbol usually being used for both. When confusion between the two is possible, the radiometric version is identified using a subscript e and the luminous version using a subscript v . For photopic vision, luminous flux Φ_v , for example, is related to the radiometric

Figure 2. Spectral luminous efficiencies: photopic $V(\lambda)$ and scotopic $V(\lambda)$.

quantity, radiant spectral flux $\Phi_{e,\lambda}(\lambda)$, by

$$\Phi_v = K_m \int_0^\infty \Phi_{e,\lambda}(\lambda) V(\lambda) d\lambda \quad (6)$$

[Note that since $V(\lambda)$ is zero outside the range 0.36–0.83 μm , the limits of the integral in Eq. (6) can be replaced with these values.] The coefficient K_m (= 683.002 lm/W) in Eq. (6) is a conversion factor that changes radiometric units of watts (represented by the integral) into photometric units of lumens (lm). The scotopic version of Eq. (6) has identical form but is distinguished by primes added to Φ_v , $V(\lambda)$, and K_m . The value of K'_m is 1700.06 lm/W (rods, which are more sensitive than cones, dominate vision under conditions of poor illumination). The curves $K(\lambda) = K_m V(\lambda)$ and $K'(\lambda) = K'_m V'(\lambda)$, called the *photopic* and *scotopic spectral luminous efficiencies* (Fig. 3), intersect at a wavelength of 0.555 μm (540×10^{12} Hz), for which $V(\lambda)$ is

Figure 3. Spectral luminous efficacies: photopic $K(\lambda)$ and scotopic $K'(\lambda)$.

a maximum (unity). At this frequency, therefore, the luminous efficiency is 683 lm/W under all illumination conditions. At other frequencies the luminous efficiency is illumination-dependent. The wavelength of maximum visual response for scotopic vision is 0.507 μm .

Table 1 summarizes the radiometric and the corresponding photometric quantities.

2.2. Photon Flux

At optical and quasioptical frequencies, the interaction of electromagnetic fields with matter cannot always be explained in terms of smoothly varying field quantities, and recourse must be made to quantum theory. In this description electromagnetic fields are made up of discrete, quantized packets of energy called *photons*. The energy Q (joules) carried by each packet or quanta is related to the radiation's frequency by $Q = hf$ (J), where $h = 6.626 \times 10^{-34}$ (J · s), is Planck's constant. The probability that the energy carried by a photon will be transferred to a material particle (in a detector, for example) at some specific time and location is proportional to the irradiance (power density) at that time and location. In applications where individual photons may be detected, electromagnetic power is often referred to as a *photon flux*.

3. BLACKBODY RADIATION AND EMISSIVITY

A body that absorbs all electromagnetic radiation falling on it (converting the incident radiant energy to thermal energy) and that would therefore appear black at optical frequencies is called a *blackbody*. Such a body, in thermal equilibrium with its surroundings, must supply precisely as much energy back to, as it receives from, these surroundings. In the absence, of conduction and convection the energy transfer mechanism is limited to thermal radiation. The thermal radiant energy emitted by a body can never, therefore, be greater than that emitted by a blackbody of the same size, shape, and physical temperature. The degree of blackness of a body is quantified by its surface emissivity, defined as follows.

Emissivity, ϵ —ratio of spectral radiant exitance at the surface of a body to the spectral radiant exitance at the surface of a blackbody with the same physical temperature

The maximum value of emissivity, corresponding to that of a blackbody, is therefore unity and the minimum value, corresponding to a surface that reflects all radiant energy falling on it, is zero. A body with an emissivity that is independent of frequency, but less than unity, is called a *graybody*. Many natural materials have emissivities that are frequency-dependent, however, and this dependence, if measured radiometrically, can yield useful information about the material's composition and physical state.

The reflecting, transmitting, and absorbing properties of a material's surface, which can also be inferred from

radiometric measurements, are quantified as follows:

Reflectance, ρ —ratio of reflected to incident spectral radiant flux at a surface

Transmittance, τ —ratio of transmitted to incident spectral radiant flux at a surface

Absorptance, α —ratio of absorbed to incident spectral radiant flux at a surface

It is clear that

$$\rho + \tau + \alpha = 1 \tag{7}$$

The surface of a blackbody has an absorptance of unity and, therefore, a reflectance and transmittance of zero. More generally, for any opaque ($\tau = 0$) material, $\rho = 1 - \alpha$ and emissivity is numerically equal to absorptance (i.e., $\varepsilon = \alpha$).

A good model of a blackbody is the surface represented by a small hole drilled in a hollow cavity. Provided that the reflectance of the interior surface of the cavity is not too close to unity, then any radiant energy falling on to the hole is reflected a sufficient number of times inside the cavity for it to be fully absorbed before it can reemerge.

The spectral radiant excitation $M_f(f)$ of a blackbody (Fig. 4), is given by Planck's law [3]:

$$M_f(f) = \frac{2\pi h}{c^2} \frac{f^3}{\exp(hf/kT) - 1} \tag{8}$$

For optical frequencies, where it is traditional to express spectral quantities on a per meter of wavelength, rather than a per hertz of frequency, basis Eq. (8) can be written as

$$M_\lambda(\lambda) = \frac{2\pi hc^2}{\lambda^5} \frac{1}{\exp(hc/\lambda kT) - 1} \tag{9}$$

For $hf \ll kT$, which is appropriate for microwave radiometry at all commonly encountered temperatures, Eq. (8)

Figure 4. Planck's law for blackbody radiation.

Figure 5. Rayleigh-Jeans approximation for blackbody radiation.

reduces to the Rayleigh-Jeans approximation (Fig. 5):

$$M_f(f) = \frac{2\pi}{c^2} kT f^2 \tag{10}$$

[The Rayleigh-Jeans version of Eq. (9) is $M_\lambda(\lambda) = 2\pi ckT/\lambda^4$.] The spectral radiant excitation of a body with emissivity < 1.0 is therefore given by

$$M_f(f) = \varepsilon(f) \frac{2\pi}{c^2} kT f^2 \tag{11}$$

3.1. Lambert's Law and Lambertian Radiators

Lambert's cosine law is that the radiant intensity from a blackbody surface is proportional to $\cos \psi$, where ψ is the angle between the direction of observation and the surface normal. Any surface (irrespective of its emissivity) that has this distribution of radiant intensity is said to be *Lambertian*. The radiance of such a surface (viz., radiant intensity per unit projected area) is independent of ψ . The spectral radiant excitation of an arbitrary surface is related to its spectral radiance by

$$M_f(f) = \int_0^{2\pi} \int_0^{\pi/2} L_f(\psi, f) \cos \psi \sin \psi \, d\psi \, d\gamma \tag{12}$$

which, for a Lambertian surface, reduces to

$$M_f(f) = L_f(f) \pi \tag{13}$$

The spectral radiance of a blackbody surface is therefore given by

$$L_f(f) = \frac{2h}{c^2} \frac{f^3}{\exp(hf/kT) - 1} \tag{14}$$

which for $kT \gg hf$ gives the Rayleigh–Jeans approximation

$$L_f(f) = \frac{2kT}{c^2} f^2 = \frac{2kT}{\lambda^2} \quad (15)$$

3.2. Radiometric Brightness and Antenna Temperatures

Consider a lossless antenna (i.e., one having an ohmic efficiency of 100%) with effective aperture area $A_e(\theta, \phi)$ receiving radiant energy from a surface S (Fig. 6). If a surface element of area dS (m²) lies at a distance R (m) from the antenna in the direction (θ, ϕ) , then the spectral radiant flux density arriving at the antenna due to this element is

$$dE_f = \frac{I_f(\theta, \phi)}{R^2} = \frac{L_f(\theta, \phi) dS \cos \psi}{R^2} \quad (16)$$

The power spectral density (or spectral radiant flux) received by the antenna is therefore

$$d\Phi_f = 0.5 A_e(\theta, \phi) dE_f = \frac{0.5 A_e(\theta, \phi) L_f(\theta, \phi) dS \cos \psi}{R^2} \quad (17)$$

(The factor of 0.5 accounts for the fact that the antenna will be polarization-matched to only half of the randomly polarized incident energy.) The quantity $dS (\cos \psi)/R^2$ in Eq. (17) can be identified as the solid angle $d\Omega$ subtended by the surface element at the antenna (Fig. 7). The power spectral density available at the antenna output terminals can therefore be expressed as either a surface, or a solid angle, integral:

$$\begin{aligned} \Phi_f &= 0.5 \int_S \int \frac{A_e(\theta, \phi) L_f(\theta, \phi) \cos \psi dS}{R^2} \\ &= 0.5 \int_{\Omega} \int A_e(\theta, \phi) L_f(\theta, \phi) d\Omega \end{aligned} \quad (18)$$

The power, or radiant flux, received within a band of frequencies f_{\min} to f_{\max} is then given by

$$\Phi = \int_{f_{\min}}^{f_{\max}} \Phi_f(f) df \quad (19)$$

Figure 6. Spectral irradiance at radiometer antenna aperture due to radiating surface element dS .

Figure 7. Solid angle subtended at radiometer antenna aperture by radiating surface element dS .

Since Eq. (18) is a power spectral density, an antenna aperture temperature T_a may be defined such that the noise power measured by a noiseless radiometer (i.e., one that has a noise figure of 0 dB), with a lossless antenna, is $kT_a B_N$ (where B_N is the radiometer noise bandwidth and k is Boltzmann's constant). For small B_N , such that $\Phi_f(f)$ can be considered white, $T_a = \Phi/kB_N = \Phi_f/k$ and

$$T_a = \frac{0.5}{k} \int_{\Omega} \int A_e(\theta, \phi) L_f(\theta, \phi) d\Omega \quad (20)$$

In a lossless antenna, effective area is related to antenna directivity by $A_e(\theta, \phi) = D(\theta, \phi) \lambda^2 / 4\pi$ [4], where $D(\theta, \phi)$ is the antenna directivity pattern. Equation (20) may therefore be written as

$$T_a = \frac{0.5 \lambda^2}{k 4\pi} \int_{\Omega} \int D(\theta, \phi) L_f(\theta, \phi) d\Omega \quad (21)$$

The quantity $(0.5 \lambda^2/k) L_f(\theta, \phi)$ is usually referred to as a *radiometric brightness temperature* $T_B(\theta, \phi)$, allowing Eq. (21) to be written as

$$T_a = \frac{1}{4\pi} \int_{\Omega} \int D(\theta, \phi) T_B(\theta, \phi) d\Omega \quad (22)$$

(In microwave radiometry the term *brightness* is often used as a synonym for spectral radiance.) The radiometric brightness temperature of a body is related to the body's physical temperature T by the body's emissivity:

$$T_B(\theta, \phi) = \varepsilon(\theta, \phi) T(\theta, \phi) \quad (23)$$

[The emissivity's dependence on ψ is not shown explicitly in Eq. (23) but is implied in its θ, ϕ dependence. The frequency dependence is suppressed only for clarity.] The first step in conventional radiometer data analysis usually requires that the radiometric brightness temperature of a particular region be estimated from a measurement of an antenna noise temperature T_A , defined by

$$T_A = \frac{\Phi_R}{kB_N} \quad (24)$$

where Φ_R is the power supplied to the radiometer by the antenna. If the antenna has nonzero ohmic loss, the measured antenna noise temperature will comprise an attenuated aperture temperature (the aperture temperature is the temperature measured by a lossless antenna) and a thermal contribution from the physical antenna structure itself. For an antenna with ohmic (or radiation) efficiency, η_Ω (expressed as a per unit, not percent, quantity), and physical structure temperature T_s the measured antenna noise temperature will be

$$T_A = \eta_\Omega T_a + (1 - \eta_\Omega) T_s \quad (25)$$

If the antenna loss is sufficiently small, then $T_a \cong T_A$. Equation (22) shows, however, that the antenna aperture temperature is a weighted average of the observed brightness temperature in which the weighting function is the antenna directivity pattern. If the antenna has a radiation pattern with low sidelobes and a beamwidth that is narrow with respect to the angular rate of change of brightness temperature, then T_a gives the required brightness temperature, in the direction of the mainlobe, directly. For an imaging radiometer (which scans a beam over some solid angle, e.g., to form an image), with a beam that is not sufficiently narrow, deconvolution of the antenna pattern from the resulting image may be necessary.

Since antenna directivity and gain are related [4] by $G(\theta, \phi) = \eta_\Omega D(\theta, \phi)$, then Eqs. (22) and (25) can be combined and written as

$$T_A = \frac{1}{4\pi} \int_{4\pi} G(\theta, \phi) T_B(\theta, \phi) d\Omega + (1 - \eta_\Omega) T_s \quad (26)$$

In the absence of significant atmospheric effects (losses and scattering), Eq. (26) shows that an adequate knowledge of antenna ohmic efficiency and antenna gain pattern will allow the brightness temperature of a surface (with a spatial resolution determined by the antenna beamwidth) to be found from a measurement of antenna noise temperature. (The noise figure of the radiometer must be considered, of course, when making this measurement [5].)

3.3. Atmospheric Loss and Scattering

If atmospheric effects cannot be neglected, then the brightness temperature inferred from Eq. (26) must be interpreted as an apparent brightness temperature since it will comprise a contribution from the target surface plus a contribution from the thermal emission of the atmosphere itself. Furthermore, the thermal radiation from each source (i.e., each surface element of the target and each volume element of the atmosphere) will be attenuated by the loss associated with the intervening atmosphere. Since atmospheric thermal emission is essentially isotropic, half of the thermal energy from each element is radiated upward (called *upwelling radiation*) and half is radiated downward (called *downwelling radiation*). For a downward-pointing radiometer (such as might be used in planetary surface remote sensing applications), downwelling radiation may be reflected by the ground back into the

antenna's mainlobe. The contribution of this ground-scattered radiation will depend on the ground reflectance and the integrated specific attenuation along the ground-reflected path to the radiometer. An upward-pointing radiometer (such as might be used in terrestrial atmospheric remote sensing applications) observes downwelling radiation from the atmosphere directly. The contribution from ground-scattered downwelling radiation, and ground thermal emission, will now be coupled into the antenna through its downward-pointing side- or backlobes. The significance of this radiation will depend on the gain of these lower hemisphere lobes and the brightness temperature of the region within the antenna's mainlobe. (If a microwave radiometer with high antenna gain is pointed at high elevation angle into a clear sky, well away from any discrete sources of radiation, then the brightness temperature observed by its mainlobe may be as low as a few degrees kelvin. Radiation emitted by, or reflected from, the ground may, under these conditions, be a very significant source of measurement error.)

The preceding description assumes that the atmosphere is an absorbing, but nonscattering, medium. For an atmosphere filled with scattering particles, or more general scattering inhomogeneities, this simplified description is inadequate. (The operating wavelength, and the physical size and composition of inhomogeneities, will determine whether they act as significant scatterers or not [6].) In this case more rigorous theories must be used to account for, and interpret, observed radiometric measurements [7].

4. APPLICATIONS

The most important application of radiometry lies in remote sensing of the earth's surface and its atmosphere [8]. Polar ice mapping, for example, is possible using passive microwave radiometers located on Earth-orbiting platforms. Microwave radiometry is especially useful for ice mapping because the contrast in emissivity between ice and water is particularly large at microwave frequencies. Furthermore, since passive microwave radiometry depends on self-emitted thermal radiation, and since Earth's atmosphere is essentially transparent at the microwave frequencies used, then data collection does not rely on solar illumination or the absence of cloud cover. (A requirement for solar illumination is particularly problematic in the polar regions, of course, due to the absence of the sun in winter.) Knowledge of annual, and longer-term, changes in the extent of the polar ice shelves is important in the field of climatology generally and to more recent concerns about possible climate change in particular.

Other surface materials (e.g., water/rock/sand) can be discriminated using microwave radiometers, and soil moisture mapping is also possible [9]. Radiometer measurements applied in this area are of obvious interest in climatology, agriculture, and environmental science. Processes of desertification, like changes in the polar ice cover, are of concern in the context of global warming.

A rather different application of microwave radiometry concerns the development of the worldwide satellite

communications network. Since a material's thermal emission and absorption are directly related, a brightness temperature measured at a given frequency can be used to infer the attenuation that an electromagnetic wave of that frequency would experience when propagating along the path observed. Ground-based, upward-pointing microwave radiometers can therefore be used to estimate the expected statistics of Earth-space signal attenuation for use in the design of microwave satellite communication systems [10]. The dominant mechanism resulting in large attenuation is the presence of precipitation along the path. Measurements of this type can, therefore, also be used in conjunction with appropriate signal attenuation/rain rate models to estimate rainfall intensity statistics for hydrological applications. (In more recent years, however, the use of meteorological radar has probably become the preferred rainfall remote sensing tool.)

Active microwave radiometry can, like its passive variant, operate independently of solar illumination and is immune to cloud cover (and, depending on frequency, other meteorological phenomena that may make the atmosphere opaque). Downward-pointing scatterometers, for example, can be used to map surface wind velocities by measuring the effective reflectance of the ocean surface. The technique used in this application depends on the fact that the received signal for a nadir pointing, monostatic scatterometer decreases as the wind speed increases and the water surface becomes rough. This is due to the tendency of the reflected energy to be scattered in many directions by the rough surface, rather than reflected, specularly, back along the illuminating path. The apparent reflectance of the ocean surface can therefore be used as a measure of wind-speed. Other reflectance measurements, using forward- and side-looking radiometer beams, allow wind velocity to be inferred since the reflecting facets of the waves have a preferred orientation that depends on wind direction.

Downward-pointing, millimeter-wave, spectroradiometer observations of brightness temperature around the absorption/emission lines of a homogeneously mixed atmospheric constituent can be used to estimate the vertical temperature profile of the atmosphere. Oxygen, which has a cluster of closely spaced resonance lines around 60 GHz, is often used for this purpose [11]. The basic principle of such temperature measurements is as follows. The brightness temperature observed at any given frequency represents a weighted mean taken over the observed path. The weighting factor at a particular altitude depends on the density of the oxygen at that altitude and on the attenuation of the intervening atmosphere. Thus at high altitudes (near the radiometer) the contribution to total brightness will be small because the density of the gas is low. At low altitudes (far from the radiometer) the contribution to total brightness will also be low because the intervening atmosphere will greatly attenuate this contribution. The observed brightness temperature will therefore be dominated by a region of the atmosphere at some intermediate height. If measurements are made across a band of frequencies coincident with the skirt of an atmospheric constituent's absorption band where atmospheric attenuation changes rapidly with frequency, then the height from which the dominant contribution arises also

changes with frequency. In this way a brightness temperature-frequency profile can be transformed to a brightness temperature versus altitude profile.

In a related area, microwave radiometry has been applied in the estimation, using zenith pointing radiometers, of integrated atmospheric water content (both liquid and gaseous phases). The large specific, and latent, heats of water mean that mapping of this quantity is important in understanding the global energy balance. If spectroradiometer measurements are made across a significant band of frequencies close to the water vapor absorption line at 22 GHz, then the water vapor's density profile can be inferred. The technique here is essentially the same as that described previously in the context of temperature profiling using the 60 GHz oxygen absorption line(s). The temperature profile is first estimated (using the oxygen line, e.g.), and the brightness temperature-frequency profile in the skirt region of the water vapor's absorption line is transformed to a brightness temperature-altitude profile. The water vapor's density at a given altitude is then inferred from the brightness at that altitude. Similar measurement can be used to find vertical profiles of many other atmospheric constituents with applications to environmental monitoring and pollution control.

Infrared radiometry (especially at 4 and 11 μm) can be used for ocean surface temperature mapping with obvious applications to meteorology and climatology. In practice, both these frequencies, and at least one other intermediate frequency, are usually required in order to correct for errors introduced by atmospheric water vapor and scattering by atmospheric aerosols. Multifrequency measurements can yield data with accuracies of 1 K.

Chlorophyll, the dominant pigmentation in most species of plants, has absorption lines close to 440 and 650 nm corresponding to the blue and red parts of the visible spectrum, thus giving vegetation its predominantly green color. (In fact, there are two distinct varieties of chlorophyll, blue-green and yellow-green, which both have absorption lines located about 10 nm either side of these frequencies [11].) In the near-infrared region, however, absorption by chlorophyll is very low and reflectance correspondingly high. Infrared and visible reflectance measurements can, together, yield information about the photosynthetic capacity of selected areas of the biosphere [12]. The presence of pigmentation other than chlorophyll can also be detected by spectroradiometric measurements and used to discriminate between different plant species. Furthermore, water absorption lines at 1.45 and 1.95 μm allow the water content of plant material to be estimated from infrared measurements. High-resolution, multiband, visible, and infrared radiance measurements can thus be used to assess the quantity, variety, health, and photosynthetic vigor of much of Earth's surface vegetation.

Visible multiband measurements of radiance can also be used to gather information about the phytoplankton of the oceans' surface layers. A particular problem associated with these measurements is that upwelling radiation originating in the intervening atmosphere must generally be accounted for. One solution relies on the fact that the oceans do not contribute to upwelling radiance in the red part of the spectrum. Measurements in the red region of

the spectrum over the oceans can therefore be used to estimate atmospheric upwelling radiance, which in turn can be used to infer atmospheric contributions at other wavelengths.

RADIOTELEMETRY

HAIPING TSOU
KAR-MING CHEUNG
California Institute of
Technology

Radiotelemetry, by definition, is the science and technology of automatically measuring and transmitting data by radio from remote sources, as from space vehicles, to receiving stations for recording and analysis. It involves preparing of data generated at remote sources, transmitting data through radio channels, and processing data at the receiving stations. Behind these three tasks, how to convey the information in a reliable and timely manner through a communication link is the most fundamental problem in this field.

There are many ways to define a communication link, depending on where the link starts and ends. Customarily,

a communication link is the transmission path through which information-bearing waveform flows from one point to another. A generic link includes the modulator, the transmitter, the channel, the receiver, and the demodulator. Another popular view of a link is to include error correction coding and encoding as part of the link because, as we see in a later discussion, link performance is a function of both modulation and coding. Yet, for a communication system that uses data compression, one might want to take an end-to-end view and include the error propagative effect of data compression in link design and analysis, because the error propagative property affects the integrity and throughput of the link. In the following sections, we briefly discuss some important elements of a communication link: data compression, forward error correction coding, modulation, demodulation, and synchronization. However, before moving on to these individual topics, we first discuss a higher level consideration of the overall link reliability, namely, the link budget analysis.

The main objective of link budget analysis is to maximize the data return for a communication link subject to (1) the available communication resources and (2) the required data quality. Power and bandwidth are the two primary resources in communication, and data quality is usually expressed in terms of the frequency of errors in the received data, that is, the bit error rate (BER). To design a communication system, the first step is to understand what the available resources are. Whether a system is power-limited (e.g., deep-space communications) or bandwidth-limited (e.g., near-Earth satellite communications) determines the available options for modulation and error correction coding schemes.

1. COMMUNICATION LINK BUDGET ANALYSIS

The link budget is a balance sheet of the gains and losses in decibels (dB) of various parameters in the communication path. Many of these parameters are statistical or time-varying or both. The required BER is a direct function of the bit signal-to-noise ratio (SNR), denoted as E_b/N_0 , which in turn is a function of the modulation and error-correction coding used. Because of the statistical nature (uncertainty) of these parameters, a safety margin M is built in to guarantee the transmission data quality at any given time.

To put link budget analysis into perspective, more parameters need to be defined and they are given as follows. To begin with, the total received signal-power-to-noise-power-spectral-density ratio, P_T/N_0 , which encompasses all the power gains and losses in the communication path, is conveniently expressed as [1]

$$\frac{P_T}{N_0} = \frac{\text{EIRP}(G/T)}{kL_sL_0} \quad (1)$$

where EIRP is the effective isotropic radiated power of the spacecraft, G/T is the receiver sensitivity of the ground system, k is Boltzmann's constant, $L_s = (4\pi d/\lambda)^2$ is the space loss where d is the distance between the transmitter and receiver, λ is the wavelength, and L_0 denotes all other

losses and degradation factors not specifically addressed in this equation. Note that all gains and losses are statistical quantities. Then, let R_s be the symbol rate and R_c be the code rate expressed as the ratio of the number of information bits in a code word to the number of coded bits in a codeword. The data rate or bit rate, denoted as R_b , is related to the symbol and code rates via $R_b = R_s R_c$. The bit SNR is written as

$$\frac{E_b}{N_0} = \frac{P_T/N_0}{R_s R_c} \quad (2)$$

Finally, let $(E_b/N_0)_{\text{req}}$ be the required E_b/N_0 to guarantee a certain BER. To ensure a reliable link, the constraining dependency is expressed in dB as follows:

$$\left(\frac{E_b}{N_0}\right)_{\text{req}} + M \leq \frac{P_T}{N_0} - R_s - R_c \quad (3)$$

The essence of link-budget analysis is to determine how much link margin M is required and this, in turn, is determined by how well the statistics of various link parameters are known. If M is too small, one might get a large data return but the data might have frequent errors. If M is too large, one might get continuous clean data but the throughput might be low. The analyst needs to make the right tradeoff on quantity versus quality, depending on the requirements and objectives of the service the link supports. Also, in an operational scenario, one usually starts out with a large M (a conservative approach) for a newly deployed system, and gradually reduces M (an aggressive approach) as more experience and confidence accumulates.

2. DATA COMPRESSION

In the midst of the Information Age, when new data—texts, images, sensor data, and many other forms of knowledge—are generated at a lightning pace, how these data are efficiently communicated and/or archived becomes increasingly important. Data obtained directly from sources usually contains much redundancy, and data compression is the process of applying “pressure” to remove the redundancy. The processes of compression and decompression add complexity to the overall system. The main issue in the use of data compression is the tradeoff between the efficiency of data handling and the complexity of signal processing to retrieve the information.

In the English language, letters such as “a” and “e” are used more frequently than “y” and “z,” and words like “and” and “the” are much more often than “data” and “compression”. For images and sensor data, the differences between adjacent samples are small rather than large. This nonuniform frequency distribution of data associated with most information sources allows one to assign shorter bit patterns to represent the more frequent elements from the source and longer bit patterns to represent the less frequent elements from the source. This is the simplest view of data compression.

Data compression is broadly classified in two categories: lossless and lossy compression. Lossless compression

denotes compression in which the decompressed or reconstructed data exactly match the original. Lossy compression represents compression methods where some degradation of quality is tolerable if a more compact but approximate representation is achieved. Next, we give brief surveys on text compression (lossless) and image compression (lossless and lossy). However, the compression of audio, video, and facsimile is beyond the scope of this article. Interested readers are encouraged to consult specialized books and technical journals in these areas.

Textual data is probably the first area where people applied compression. In 1832 Samuel Morse developed a code using dots, dashes, and spaces to represent letters, numbers, and punctuation for telegraph transmission. Each dot or dash is delimited by a space. A dot and a space take the same time. A dash is three times longer. Morse assigned fewer time units to more commonly occurring letters (e.g., “e” is a dot), and more time units to ones (e.g., “q” is dash–dash–dot–dash) that rarely occur. Today, most popular text compression schemes are different variations of the Lempel–Ziv (LZ) scheme developed in 1977 [2] and 1978 [3]. LZ schemes use a dictionary approach. Dictionary coding operates by replacing groups of consecutive characters with indices in some dictionary. It exploits the frequent reoccurrence of certain exact patterns that are very typical of textual data. Other than compressing text, LZ schemes are reasonably good at compressing images and other sources. LZ schemes are generally considered universal compression algorithms. The UNIX command “compress” and the modem standard V42.bis are examples of applications using LZ schemes.

Image compression and other waveform compression is lossless or lossy. For scientific and medical applications that demand further processing and analysis, one might prefer lossless compression to ensure data accuracy. In other applications, such as image database, electronic photography, and desktop publishing, where transmission and storage bandwidths are limited, lossy compression is usually employed to reduce the data size at the expense of image quality.

Lossless image compression consists of two steps: modeling and coding. A predictive model predicts a pixel value based on a previously transmitted one, and compares it with the current value. The error value is coded instead of the original pixel value. On the receiver side, because the errors and the predictive scheme are known, the receiver recovers the value of the original pixel. An example of lossless image compression is the Rice code used in space and satellite communications.

Lossy image compression involves an irreversible quantization step that causes distortion between the original and the reconstructed image. Popular techniques in lossy image compression include differential pulse-code modulation (DPCM), transform coding, subband coding, vector quantization, and some hybrid techniques. The Joint Photographic Expert Group (JPEG) established an international standard on still image compression that uses the discrete cosine transform along with scalar quantization and entropy coding. Currently, JPEG encoder and decoder chips are available from many semiconductor manufacturers.

3. FORWARD ERROR CORRECTION CODING

In 1948, the landmark paper “A mathematical theory of communication” [4] by Claude Shannon provided a mathematical framework for analyzing communication, the process of sending information from one point to another through a noisy media, by using the concept of entropy. He provided an existence proof showing that communication systems can be made arbitrarily reliable as long as the fraction of redundant signals in the signal stream exceeds a certain value, which is a function of the signal and noise statistics. The process of introducing redundancy in the signal stream to combat noise, so that retransmission is not needed, is called forward error correction coding. Shannon did not show how this could be done in his famous theorem. Later on, much research effort has yielded a variety of interesting theoretical and practical results in this area.

Because redundant signals are deliberately introduced in the signal stream as error correction coding, bandwidth expansion is expected. Encoding and decoding processes inevitably also add complexity to the overall system. However, it can be shown that, with a proper choice of coding scheme, the resulting E_b/N_0 can be considerably lower compared with an uncoded system. Thus error-correction coding allows one to trade power for bandwidth and complexity. In this article, the application of two popular error correction coding schemes, block codes and convolutional codes are explained, without providing the detailed performance analysis of these codes. Other more advanced coding schemes, like trellis codes and turbo codes, are not covered here. Interested readers are encouraged to consult specialized books and technical journals in this field.

In block coding, a block of k bits is encoded into a block of n bits, where $n > k$. There are 2^k codewords in a code space of 2^n . The code rate R_c , which is the ratio k/n , is a measure of the amount of added redundancy. The minimum distance d_{\min} , which is the Hamming distance between two closest code words, is a measure of the error correction capability of the code. It can be shown that $d_{\min} \leq n - k + 1$ (Singleton bound). For bounded-distance decoding, the number of errors t that the code can correct is related to d_{\min} by

$$2t + 1 \leq d_{\min} \quad (4)$$

In convolutional coding, sequences of k information bits long are encoded as continuous sequences using a kK -stage shift register, where K is called the constraint length. n output sequences are produced, each of which is generated by a selected set of combinations of these K input sequences. The n output sequences are multiplexed into a single-bit stream for transmission. Similar to a block code, the ratio k/n is a measure of the redundancy of the convolutional code. The minimum distance d_{free} between two closest code sequences, is a measure of the error correction capability of the code.

The most popular block code used today is the class of Reed–Solomon (RS) codes. RS codes are maximum-distance-separable codes that achieve maximum error

correction capability in the bounded-distance decoding sense. Well-known encoding and decoding algorithms exist that are reliable in software and hardware. RS codes are flexible. Long, powerful RS codes exist for demanding applications, and short RS codes for simple applications. Deep-space communications use the (255,223) RS code as the outer code of the concatenated coding system. This code is block-interleaved and is used in conjunction with an inner convolutional code to provide reliable communications between the spacecraft and the ground stations. The concatenated coding system is designed to combat the additive white Gaussian noise of the deep-space communication links. Simpler RS codes are used in compact disks (CD), a mass-marketed consumer product. The coding system used, called the cross-interleaved Reed–Solomon code (CIRC), is composed of two RS codes with (n,k) values (32,28) and (28,24). In between the two encoders are sets of delay lines which scramble the datastream. The CIRC coding system is designed to correct the burstlike errors, typical of a CD channel.

The most popular decoding scheme for convolutional codes is the Viterbi algorithm. The complexity of Viterbi decoding grows exponentially with the constraint length of the code, which is the number of memory elements in the encoder shift register. As mentioned earlier, convolutional codes are used in deep space communications. In the past, short constraint-length codes (7 or 9) are used because of the limitations in hardware technologies. Today, long constraint-length Viterbi decoders (up to 15) are designed and built. Convolutional codes are also popular in satellite communications and wireless communications. Presently, only short constraint-length convolutional codes are used in these areas.

4. INTERACTION BETWEEN DATA COMPRESSION AND ERROR CONTROL IN A COMMUNICATION SYSTEM

This section addresses the interaction between data compression and error control (containment/detection/correction) processes, two indispensable building blocks in modern digital communication systems. Data compression conserves transmission and storage bandwidth by removing redundancy in the source data. Error correction introduces controlled redundancy to the data to eliminate channel errors. A combination of both techniques ensures efficient and reliable transmission of information from one point to another. The famous separation principle indicates that data compression and error control processes can be completely separated, that is, the task of transmitting the output of a source through a channel can be separated without loss into the task of forming a binary representation of the source output and the task of sending a binary sequence through the channel. This is not quite true in practice, however. In evaluating an end-to-end communication system, we have to consider effects, like instrument failures, adverse weather conditions, synchronization loss, and other unpredictable phenomena in the communication system and the channel. The error control process cannot handle all possible kinds of errors. Thus the effect of error propagation should be considered

when evaluating a data compression scheme in a communication system.

There are two issues to be dealt with: how to prevent errors from occurring and, if errors occur, how to contain the errors. The former issue can be dealt with easily (at least in the conceptual sense) by using higher transmission power or more powerful error correction coding techniques on the channel and better fault-tolerance techniques on various system components. The second issue of how to contain errors is more intricate and has commonly been overlooked. There are mainly two approaches (or a combination of both) to deal with the problem. The first approach is to add extra redundancy to the compressed data to detect and confine errors. Some simple ways are adding a delimiter pattern at regular intervals and forcing fixed block-size transmission by appending filling 0s, and so on. These techniques reduce compression performance. The second approach is to choose data compression schemes that are less susceptible to error propagation. These schemes usually transmit the compressed data in fixed block size or inherently have delimiter patterns in their compressed data streams. We illustrate the interaction between data compression and error correction coding with an example in a later section.

5. MODULATION AND DEMODULATION

5.1. Modulation

Modulation is the process of transforming signals into waveforms suitable for transmission through a certain type of medium or channel. For example, when transmitting electronic signals through free space with an antenna that converts electronic signals into electromagnetic (EM) waves, the physical dimensions of the antenna aperture are at least of the same order of the wavelength of the EM wave. Therefore, a baseband signal has to modulate a sinusoidal signal at radiofrequency (RF), called the carrier, before transmitting it by antennas of reasonable size.

The typical modulation procedure for digital signal transmission starts with a baseband pulse-code modulation (PCM), which converts the analog signal into a binary datastream. Depending on the subsequent RF modulation schemes, this binary datastream is fed into different devices. For example, fixed-length blocks of the binary data are used to determine the instantaneous frequencies of the carrier for a frequency-shift-keyed (FSK) system. On the other hand, the binary data drive a pulse generator whose output modulates the subcarrier (if used) and the RF carrier in a typical phase-shift-keyed (PSK) system. There are several different binary data formats [5]. For example, non-return-to-zero (NRZ) and biphase (also known as the Manchester code) are the ones more commonly used. In some applications, pulseshapes other than the square pulse are selected to represent a binary digit in the datastream. The choice of a particular data format and pulseshape is determined by several factors, for example, considerations of bandwidth efficiency, inherent synchronization features, and the noise immunity of each data format.

PSK modulation has been widely adopted for deep-space communications mainly because it is a very efficient

type of modulation in bit error performance and the resulting signal has a constant envelope that allows the power amplifier to achieve the maximum efficiency by operating at the saturation point. In general, a communication system using the PSK modulation is designed to have a multiple phase-shift-keyed (MPSK) signal of which the number of phasor states, denoted by M , is any power of 2. The increased BER with M for MPSK signals, however, prevents its use when M is large. Furthermore, because of the ease of being decomposed into two orthogonal channels for further signal processing, the MPSK modulated signals commonly used for radiotelemetry are limited to the cases where $M = 4$ or lower, namely, the binary phase shift keying (BPSK), the quadrature phase shift keying (QPSK) or its variations, such as offset QPSK, unbalanced QPSK, and pulseshaped QPSK. For some applications, the quadrature amplitude shift keying (QAM) modulation is used to allow multilevel signals transmitted on either one or both of the mutually orthogonal channels.

It is possible to include subcarrier(s) for BPSK modulation. The purpose of using subcarrier(s) is to separate data sidebands of different signals and the carrier so that they do not interfere with each other. Whether or not to use subcarrier(s) depends on the mission design. For example, a subcarrier is preferred when a residual carrier component is preserved for spacecraft navigation or certain radio science experiments. On the contrary, it may not be a good idea to keep a subcarrier when transmission power is weak or the bandwidth efficiency becomes a major concern. Two types of subcarriers, the sine wave and the square wave, are commonly used. The sine-wave subcarrier along with the phase-modulated carrier produces fast-decaying data sidebands and, therefore, is recommended for near-Earth space missions where the interference caused by the power spillover to the adjacent frequency bands is the major concern [6]. The same recommendation also suggests using the square-wave subcarrier for deep-space missions because of the ease of generating a square wave onboard spacecraft and the relatively less stringent bandwidth allocation for this type of mission.

A phase-modulated (PM) telemetry signal is represented mathematically by

$$S_T(t) = \sqrt{2P_T} \sin\left(\omega_c t + \sum_{i=1}^N m_i S_i(t)\right) \quad (5)$$

where P_T is the total power of the received signal, ω_c is the carrier frequency, m_i is the modulation index associated with the i th data source, and

$$S_i(t) = \begin{cases} \sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT), \\ \text{for PCM/PM (without subcarrier)} \\ \left[\sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT) \right] \sin(\omega_{sc} t), \\ \text{for PCM/PSK/PM with a sine - wave subcarrier} \\ \left[\sum_{k=-\infty}^{\infty} d_{k,i} P_i(t - kT) \right] \text{sgn}[\sin(\omega_{sc} t)], \\ \text{for PCM/PSK/PM with a square - wave subcarrier} \end{cases} \quad (6)$$

represents either a normalized baseband waveform (with $d_{k,i} = \pm 1$) or a normalized BPSK modulated subcarrier waveform (at the frequency ω_{sc_i}). $P_i(t)$ is the pulse function of unit power and T is the reciprocal of the symbol rate. Note that, when more than one data sources are included [that is, $N > 1$ in Eq. (5)], only one data source output is allowed to directly modulate the carrier, denoted by its processing order as PCM/PM, and the rest must be put on subcarrier(s) before modulating the carrier, similarly denoted as PCM/PSK/PM in Eq. (6). An exception of this single PCM/PM rule is the code division multiplexing, in which multiple data sources are put directly on the carrier and remain distinguishable because of the unique code sequence (for example, pseudorandom codes or Walsh-Hadamard codes) used by each of them.

Typically, a deep-space downlink signal (i.e., a signal sent from spacecraft to Earth) consists of two or more data sources of which, besides the telemetry signal, a ranging signal is included for spacecraft navigational purpose [7]. For example, a mathematical expression of a downlink signal consisting of a sinusoidal ranging signal at the frequency ω_1 and a binary telemetry signal of NRZ format, $d(t)$, which is modulated onto a square-wave subcarrier, is given by

$$\begin{aligned}
 S_T(t) &= \sqrt{2P_T} \sin\{\omega_c t + m_1 \sin(\omega_1 t) \\
 &\quad + m_2 d(t) \operatorname{sgn}[\sin(\omega_{sc} t + \theta_{sc})] + \theta_c\} \\
 &= \sqrt{2P_T} \left\{ \begin{aligned}
 &J_0(m_1) \cos(m_2) \sin(\omega_c t + \theta_c) \\
 &+ d(t) J_0(m_1) \sin(m_2) \operatorname{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \cos(\omega_c t + \omega_c) \\
 &+ \cos(m_2) \left[\sum_{n=1}^{\infty} 2J_{2n}(m_1) \cos(2n\omega_1 t) \right] \sin(\omega_c t + \theta_c) \\
 &+ \cos(m_2) \left\{ \sum_{n=0}^{\infty} 2J_{2n+1}(m_1) \sin[(2n+1)\omega_1 t] \right\} \cos(\omega_c t + \theta_c) \\
 &+ d(t) \sin(m_2) \left[\sum_{n=1}^{\infty} 2J_{2n}(m_1) \cos(2n\omega_1 t) \right] \\
 &\operatorname{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \cos(\omega_c t + \theta_c) \\
 &- d(t) \sin(m_2) \left\{ \sum_{n=0}^{\infty} 2J_{2n+1}(m_1) \sin[(2n+1)\omega_1 t] \right\} \\
 &\operatorname{sgn}[\sin(\omega_{sc} t + \theta_{sc})] \sin(\omega_c t + \theta_c)
 \end{aligned} \right\} \quad (7)
 \end{aligned}$$

where $J_n(\cdot)$ is the n th-order Bessel function and θ_c and θ_{sc} are random carrier and subcarrier phases, respectively, each uniformly distributed over 0 to 2π . The first term in this expression is the residual carrier component, which is fully suppressed if the data modulation index m_2 equals $\pi/2$. The second term is the desired data-bearing component containing the telemetry information that needs to be demodulated. The third and the fourth terms contain

the ranging information to be extracted separately, and the rest are from inter-modulation of telemetry and ranging signals. Typically, on one hand, the ranging modulation index m_1 chosen is small (around $\frac{1}{2}$ or smaller) so that the power consumption by this ranging signal is relatively small. On the other hand, the data modulation index selected is large (close to its upper limit $\pi/2$) to ensure that only sufficient power goes to the residual carrier component and the rest of power is allocated solely for telemetry data transmission. The strategy of optimizing modulation indices for efficient power allocation is discussed in Ref. 8.

A QPSK phase-modulated telemetry signal is usually treated as a combination of two orthogonal BPSK signals. Mathematically, a general QPSK (or, more specifically, an unbalanced QPSK) signal takes the form

$$\begin{aligned}
 S_T(t) &= \sqrt{\alpha P_T} \sin\left(\omega_c t + \sum_{i=1}^M m_{c,i} S_{c,i}(t)\right) \\
 &\quad + \sqrt{(1-\alpha)P_T} \cos\left(\omega_c t + \sum_{i=1}^N m_{s,i} S_{s,i}(t)\right) \quad (8)
 \end{aligned}$$

where α is the percentage of transmitted power in one of the two channels. When only one binary signal of NRZ format is transmitted on each channel, that is, $M = N = 1$, with the modulation indices $m_{s,1} = m_{c,1} = \pi/2$, the QPSK signal is rewritten as

$$\begin{aligned}
 S_T(t) &= \sqrt{\alpha P_T} S_{c,i}(t) \cos(\omega_c t) \\
 &\quad - \sqrt{(1-\alpha)P_T} S_{s,i}(t) \sin(\omega_c t) \quad (9)
 \end{aligned}$$

a combination of two BPSK signals on two orthogonal basis functions. As long as the orthogonality is maintained, these two BPSK signals do not interfere with each other and the bandwidth efficiency, measured as how many bits of information transmitted over a unit bandwidth, of a QPSK signal is twice that of a BPSK signal [5]. Several variants of QPSK modulation, including the offset QPSK (OQPSK) and the minimum shift keying (MSK), are also commonly used in near-Earth space missions. A detailed description of these modulation schemes is not covered here.

5.2. Demodulation

Demodulation is the process of transforming received waveforms back into their original state by reversing the modulation procedure. After traveling through various types of media or channels, the received waveform is corrupted in many ways. For example, it is corrupted by receiver's internally generated noise which is typically modeled as an additive white Gaussian noise (AWGN), or externally introduced interference, such as multipath, fading. Hence, for demodulation, it is important to correctly estimate the vital parameters in the transmitted signal from the corrupted waveform and apply the locally generated reference signals to remove the modulation. The following simple example illustrates how an AWGN

corrupted BPSK signal is demodulated. The received signal is given by

$$r(t) = \sqrt{2P_T} \sin \left(\omega_c(t + \tau) + \left(\frac{\pi}{2} \right) \sum_{k=1}^{\infty} d_k P(t + \tau - kT) + \theta \right) + n(t) \quad (10)$$

where τ is the random propagation delay, θ is a uniformly distributed (over 0 to 2π) carrier phase, and $n(t)$ is a noise modeled as an AWGN with a two-sided power spectral density level at $N_0/2$ W/Hz. For the signal of NRZ format, the phase-modulated signal is equivalent to the product of the carrier and the baseband binary data waveforms, which is rewritten as

$$r(t) = \sqrt{2P_T} \left[\sum_{k=1}^{\infty} d_k P(t + \tau - kT) \right] \cos(\omega_c t + \theta_c) + n(t) \quad (11)$$

where $\theta_c = (\theta + \omega_c \tau)_{\text{mod } 2\pi}$ is the total carrier phase. To demodulate the carrier, the receiver needs to generate a local reference, say, $\sqrt{2} \cos(\omega_c t + \hat{\theta}_c)$, where $\hat{\theta}_c$ is an estimate of θ_c . A lowpass filtered version of the product of the local carrier reference and the received signal becomes

$$r'(t) = \sqrt{P_T} \left[\sum_{k=1}^{\infty} d_k P(t + \tau - kT) \right] \cos(\phi_c) + n'(t) \quad (12)$$

where $\phi_c = \theta_c - \hat{\theta}_c$ is the phase error between the actual and the estimated carrier phases. For constant or at least slowly varying ϕ_c , the factor $\cos(\phi_c)$ represents a signal amplitude attenuation, which is inevitably translated into degradation in bit error performance. To make a decision on each of the transmitted bits, say, the i th bit d_i , the resulting signal $r'(t)$ is sent to a matched filter whose operation is mainly to form a product of the input signal and a local replica of the pulse function followed by an integrate-and-dump (I&D) operation. The accurate timing estimate $\hat{\tau}$ is very important in this matched filter operation because an error renders integrating across 2 bits, which reduces the detected symbol (for coded system) or bit (for uncoded system) energy when adjacent bits are of opposite polarities and results in a higher probability of decision error.

Additional signal power degradation due to imperfect subcarrier synchronization, similar to the carrier case given here, is expected when a subcarrier is used. The power degradation resulting from each of the carrier, subcarrier, and symbol tracking operations is discussed later.

6. SYNCHRONIZATION

The process of estimating the phase and timing parameters from the incoming noise-corrupted signal and using this information to keep the locally generated reference signal aligned with these estimates and, therefore, with the incoming signal is called synchronization.

As indicated previously, coherent reception and demodulation require phase information about the carrier and subcarrier (if used) and also symbol timing information. This information must be provided and updated for coherent receivers all the time because they are usually time-varying with the changing characteristics of the channel. Therefore, individual tracking loops which continuously update their estimates of specific parameters are required to track and provide the needed information for a coherent receiver.

Although the tracking of carrier, subcarrier, and symbol timing are individually discussed in following, one should keep in mind that, strictly speaking, all these loops are effectively coupled together in the sense that no one achieves lock without help from others, except for residual carrier tracking in which a carrier tone is separately tracked. However, in practice, each loop's performance is usually analyzed independently to keep the problem manageable.

It is also important to know that all the tracking loops discussed later are motivated by the maximum a posteriori (MAP) estimation, which suggests only the open-loop structure of a one-shot estimator. The closed-loop structure derived by differentiating the likelihood function and equating the resulting loop feedback signal (also known as the error signal) to zero is only motivated by the MAP estimation [8].

6.1. Carrier Tracking

6.1.1. BPSK. The most commonly used device to track the phase of a sinusoidal signal, for example, the residual carrier component in Eq. (7), is the phase-locked loop (PLL). The PLL is composed of a phase detector, a loop filter, and a voltage-controlled oscillator (VCO) or, in a digital PLL design, a numerically controlled oscillator (NCO). The lowpass component of the phase detector output is a periodic function (of period 2π) of the phase error ϕ_c , which is called the S curve of the loop. A stable lock point exists at $\phi_c = 0$, one of the zero-crossing points where the S curve has a positive slope. The phase error for the first-order PLL, which has its loop filter implemented as a constant gain, is a Tikhonov distributed random variable and its probability density function (pdf) is given by [5]

$$p(\phi_c) = \frac{\exp[\rho_{\phi_c} \cos(\phi_c)]}{2\pi I_0(\rho_{\phi_c})} \quad |\phi_c| \leq \pi \quad (13)$$

where $I_k(\cdot)$ denotes the modified Bessel function of order k and $\rho_{\phi_c} = (\sigma_{\phi_c}^2)^{-1}$ is the loop SNR defined as the reciprocal of the phase error variance in radian². The loop SNR for the first-order PLL is expressed by

$$\rho_{\phi_c} = \frac{P_c}{N_0 B_L} \quad (14)$$

where B_L is the loop bandwidth. The detailed description of a PLL is discussed in another article in this encyclopedia and is not to be repeated here.

For the suppressed carrier in which no discrete carrier component appears in its spectrum, the carrier phase, embedded in the data-bearing component as the second term of Eq. (7), must be tracked by the Costas loop. The Costas loop is a phase-tracking loop whose functionality is similar to that of a PLL. Except for the same feedback path consisting of a loop filter and an NCO, a Costas loop has a double-arm loop structure, denoted, respectively, as the in-phase (I) and quadrature (Q) arms, with a phase detector and a lowpass arm filter in each. The incoming signal is first mixed with each of the two locally generated reference signals 90° apart, that is, $\sqrt{2} \sin(\omega_c t + \hat{\theta}_c)$ and $\sqrt{2} \cos(\omega_c t + \hat{\theta}_c)$, at the corresponding phase detector and then passed through the arm filter. Although the lowpass arm filter is either a passive RC-type filter or an active filter, it turns out that a matched filter (that is, an active filter) is the optimal design. The output of the two arm filters are multiplied, which effectively removes the data modulation, to form the loop feedback signal before it is fed into the loop filter. Because of this multiplication, a Costas loop is actually tracking twice the error phase. Accordingly, the Costas loop has two equally stable lock points at $\phi_c = 0$ and $\phi_c = \pi$, each corresponding to a zero-crossing point in the S curve (of period π) where the slope is positive. These dual lock point inevitably introduce phase ambiguity such that the demodulated data has inverted polarity if the loop locks at $\phi_c = \pi$. This 180° phase ambiguity is resolved in several ways. For example, a known sequence pattern is inserted in the transmitted symbol stream from time to time so that the inverted polarity is detected by examining the received sequence pattern. However, the most efficient method is employing a differential encoding scheme in the transmitted data so that the information is kept in the relative phase between adjacent symbols instead of in the absolute phase of each symbol [5]. On the receiver side, a corresponding differential decoding scheme is applied to extract the relative phase (or the transmitted information) after the symbol decision. A small penalty in terms of error performance exists for this differential encoding/decoding scheme because one incorrect symbol decision creates two consecutive errors in the relative phase.

The phase error for the first-order Costas loop with I&D arm fitters is similarly found as a Tikhonov distributed random variable and its pdf is given by

$$p(\phi_c) = \frac{\exp\left[\frac{\rho_{\phi_c}}{4} \cos(2\phi_c)\right]}{\pi I_0\left(\frac{\rho_{\phi_c}}{4}\right)} \quad |\phi_c| \leq \frac{\pi}{2} \quad (15)$$

and the associated loop SNR is given by

$$\rho_{\phi_c} = \frac{P_d}{N_0 B_L} \left(1 + \frac{1}{2E_s/N_0}\right)^{-1} \quad (16)$$

where $E_s/N_0 = P_d T/N_0$ is the symbol SNR. Note that the term in the parentheses is usually called the squaring loss, which results from the signal-noise product in the

loop feedback signal. At low symbol SNR, the squaring loss is significant.

As discussed previously, transmitted power is allocated to the residual carrier component and data-bearing component by the choice of the modulation index for the telemetry data. It has been proved that a fully suppressed carrier is the best way to maximize data throughput [9]. However, if a residual carrier component is desired for purposes other than communications, it is always a dilemma to set this modulation index because, on one hand, sufficient power must be given to the residual carrier so that it is successfully tracked by a PLL, and, on the other hand, the power allocated for data transmission should be kept as high as possible to maximize data throughput. Because the residual carrier and data sidebands are coherently related, a hybrid loop [10] that consists of the phase-locked loop and Costas loop structures is used to exploit this coherence and thereby improve carrier phase tracking in this scenario. This technique is also known as sideband aiding because it utilizes the power in the data-bearing component as the second term Eq. (7) to help residual carrier tracking.

In the hybrid loop, both error signals from the single-arm PLL structure and the double-arm Costas loop structure are weighted and added together to form an effective loop feedback signal. As a result, there are usually dual lock points for the hybrid loop, that is, $\phi_c = 0$ and $\phi_c = \pi$ and similar to those of a Costas loop. Yet, these two lock points generally are not equiprobable. It can be shown that [11] the lock point at $\phi_c = \pi$ vanishes when the modulation index is smaller than a threshold as a function of the symbol SNR.

With a given modulation index, an optimal relative weight between the PLL and Costas loop portion is derived to minimize the hybrid loop tracking jitter. Because the relative tracking performance between a PLL and Costas loop is determined by the relative power allocation and the additional squaring loss incurred in the Costas loop, it is not surprising to find that the optimal weight is a function of the modulation index and the symbol SNR.

6.1.2. QPSK. The carrier tracking of a QPSK signal is usually done by a generalized Costas loop motivated by MAP estimation theory. There are basically two variants of this generalized Costas loop: the polarity type known as the crossover Costas loop for high-SNR scenarios and the squaring type or low-SNR scenarios [7]. In the crossover loop, two products are formed by multiplying the hard-limited version of one arm-filter output with the other arm filter output before they are combined as the loop error feedback. The phase error for the first-order crossover Costas loop is a Tikhonov distributed random variable with pdf given by

$$p(\phi_c) = \frac{2 \exp\left[\frac{\rho_{\phi_c}}{16} \cos(4\phi_c)\right]}{\pi I_0\left(\frac{\rho_{\phi_c}}{16}\right)} \quad |\phi_c| \leq \frac{\pi}{4} \quad (17)$$

The associated loop SNR for this first-order crossover loop is

$$\rho_{\phi_c} = \frac{P_d}{N_0 B_L} \left\{ \frac{\left[\operatorname{erf}\left(\sqrt{\frac{E_s}{2N_0}}\right) - \sqrt{\frac{2}{\pi}} \left(\frac{E_s}{N_0}\right) \exp\left(-\frac{E_s}{2N_0}\right) \right]^2}{1 + \frac{E_s}{N_0} - \left[\sqrt{\frac{2}{\pi}} \exp\left(-\frac{E_s}{2N_0}\right) + \sqrt{\frac{E_s}{N_0}} \operatorname{erf}\left(\sqrt{\frac{E_s}{2N_0}}\right) \right]^2} \right\} \quad (18)$$

where the error function $\operatorname{erf}(\cdot)$ and its complimentary $\operatorname{erfc}(\cdot)$ are defined as

$$\operatorname{erf}(x) = 1 - \operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-x^2} dx$$

Note that, similar to Eq. (16) of the Costas loop, the term in the braces in Eq. (18) is the squaring loss of the crossover Costas loop. The squaring-type loop has a different squaring loss which is smaller than that of its polarity-type sibling in low SNR region. More details about the crossover Costas loop can be found in Ref. 13. Another alternative in tracking a QPSK signal is to use the demod-remod quadriphase tracking loop, which can be viewed as a fourth-power loop with a multiplication done at the IF level [7].

6.2. Subcarrier Tracking

Subcarrier tracking is almost identical to suppressed carrier tracking for BPSK signals because there is no residual tone left for the binary-phase-shift-keyed subcarrier. The Costas loop is used here to remove the data modulation and a squaring loss associated with this process is inevitable. However, depending on the use of a sine-wave or square-wave subcarrier, tracking performance is quite different. For the sine-wave subcarrier, there is no difference between its tracking and that of a suppressed carrier. On the contrary, additional improvement in the square-wave subcarrier tracking is realized by using a time-domain windowing function on the quadrature arm [13]. In this case, the windowing function around the midphase transition of the Q-arm reference signal is treated as an approximation of the time-domain derivative of its I-arm counterpart. According to the derivation of the MAP estimation, which implies the existence of an optimal open-loop structure when one of I-arm and Q-arm reference signals is the derivative of the other, the resulting loop SNR is greatly improved by shrinking the window size. The first-order loop SNR is given by

$$\rho_{\phi_{sc}} = \left(\frac{2}{\pi}\right)^2 \frac{P_d}{N_0 B_L} \left(\frac{1}{W_{sc}}\right) \left(1 + \frac{1}{2E_s/N_0}\right)^{-1} \quad (19)$$

where W_{sc} is the quadrature window size (between 0 and 1) relative to a subcarrier cycle. It is clear that the loop SNR is inversely proportional to the window size. However, using a small window inevitably reduces the loop's pullin range and raises the issue of loop stability. A reasonable window size of one-quarter or one-eighth is usually used to provide a 6–9 dB improvement in loop SNR.

No such improvement from quadrature windowing is realized for a sine-wave Costas loop of which the I-arm and Q-arm reference signals are two sine functions separated by 90° and, therefore, have the derivative relationship between them as suggested by the MAP estimation. Applying a quadrature window in this case actually destroys the derivative relationship and renders inferior loop performance.

6.3. Symbol Timing Tracking

Symbol synchronization has a direct impact on the data detection process because inaccurate symbol timing reduces the probability of making a correct decision. Although a separate channel may be used to send timing signals for synchronization, to extract the synchronization information directly from the data-bearing signal has the advantage that no additional power and frequency spectrum are required. Of course, to successfully extract symbol timing information from the transmitted symbol stream relies on the presence of adequate symbol transitions (zero crossings).

The data transition tracking loop (DTTL) is widely used for symbol synchronization. Similar to the Costas loop, DTTL has a double-arm loop structure with a hard decision followed by a transition detector in its in-phase arm and a delay in its quadrature arm to keep signals on both arms properly aligned. It is important to note that the term “in phase” refers to an operation synchronous with the timing of the received symbols and, therefore, the I-arm phase detector becomes a matched filter integrating from one symbol epoch to the next. The Q-arm phase detector performs another integration within a window, which is of a size W_{sym} (between 0 and 1) relative to the symbol interval and centered at the symbol epoch, causing the midpoint of the Q-arm integration interval offset by a half-symbol from its I-arm counterpart. Similar to square-wave subcarrier tracking, the time-domain windowing function on the quadrature arm improves the tracking performance but inevitably raises the issue of loop stability at the same time [5].

The DTTL has a single stable lock point at $\phi_{sym} = 0$. The phase error for the first-order DTTL is a Tikhonov distributed random variable and its pdf is given by

$$p(\phi_{sym}) = \frac{\exp(\rho_{\phi_{sym}} \cos(\phi_{sym}))}{2\pi I_0(\rho_{\phi_{sym}})} |\phi_{sym}| \leq \pi \quad (20)$$

with the corresponding loop SNR given as

$$\rho_{\phi_{\text{sym}}} = \frac{1}{(2\pi)^2} \frac{P_d}{N_0 B_L} \left(\frac{1}{W_{\text{sym}}} \right) \left\{ \frac{\left[\operatorname{erf} \left(\sqrt{\frac{E_s}{N_0}} \right) - \frac{W_{\text{sym}}}{2} \sqrt{\frac{1}{\pi}} \left(\frac{E_s}{N_0} \right) \exp \left(-\frac{E_s}{N_0} \right) \right]^2}{1 + \frac{W_{\text{sym}}}{2} \left(\frac{E_s}{N_0} \right) - \frac{W_{\text{sym}}}{2}} \right\} \left\{ \left[\sqrt{\frac{1}{\pi}} \exp \left(-\frac{E_s}{N_0} \right) + \sqrt{\frac{E_s}{N_0}} \operatorname{erf} \left(\sqrt{\frac{E_s}{N_0}} \right) \right]^2 \right\} \quad (21)$$

7. SYMBOL SNR DEGRADATION

Symbol SNR degradation is the direct cause of poor bit error performance and is translated into the telemetry system loss as seen in the next section when the receiver performs a hard decision on each demodulated symbol. When no hard decision is performed by the receiver, symbol SNR degradation directly affects decoder performance because the demodulated symbols, called soft symbols, are fed to the decoder without going through a hard-decision device.

Because of the difficulty of analyzing the coupled-carrier, subcarrier, and symbol-tracking loops, SNR degradation of the demodulated symbol (for a coded system) or bit (for an uncoded system) caused by imperfectly synchronized references is usually approximated as a product of degradation factors of the individual loops; each factor is derived on the basis of assuming perfect tracking in other loops. The overall degradation, conditioned on the corresponding phase errors, for the telemetry signal given in Eq. (7) is expressed by

$$\begin{aligned} D_{\text{SNR}}(\phi_c, \phi_{\text{sc}}, \phi_{\text{sym}}) &= D_c(\phi_c) D_{\text{sc}}(\phi_{\text{sc}}) D_{\text{sym}}(\phi_{\text{sym}}) \\ &= [\cos(\phi_c)]^2 \left[1 - \frac{2}{\pi} |\phi_{\text{sc}}| \right]^2 \left[1 - \frac{|\phi_{\text{sym}}|}{\pi} + \frac{\phi_{\text{sym}}^2}{2\pi^2} \right] \end{aligned} \quad (22)$$

Where $D_c(\phi_c)$, $D_{\text{sc}}(\phi_{\text{sc}})$ and $D_{\text{sym}}(\phi_{\text{sym}})$ are the degradation factors for the imperfect carrier, subcarrier, and symbol (or bit) synchronization, respectively. Hence, the averaged symbol (or bit) SNR degradation due to imperfect synchronization becomes

$$\overline{(D_{\text{SNR}})}_{\text{dB}} = \overline{(D_c)}_{\text{dB}} + \overline{(D_{\text{sc}})}_{\text{dB}} + \overline{(D_{\text{sym}})}_{\text{dB}} \quad (23)$$

where $\overline{D_c}$, $\overline{D_{\text{sc}}}$ and $\overline{D_{\text{sym}}}$ are the averaged power degradation factors obtained by averaging over the corresponding Tikhonov distributed phase errors.

In addition to the degradation caused by imperfect synchronization, it is also important to know that there are other sources of SNR degradation, for example, the

intermodulation terms and possible interference from the ranging signal found in Eq. (7), and the subcarrier and symbol waveform distortion introduced by the bandlimited channel.

8. BIT ERROR PERFORMANCE (UNCODED SYSTEM) AND TELEMETRY SYSTEM LOSS

Telemetry information is extracted from the demodulated data stream by a symbol decision process. For binary signals, it is typically a hard-limiting decision on an AWGN corrupted, antipodal, random variable. For an uncoded system, the bit (or symbol) error probability of a BPSK signal is well known as

$$P_b = \int_{-\pi}^{\pi} \frac{1}{2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] p(\phi_c) d\phi_c \quad (24)$$

where $p(\phi_c)$, is the pdf of the carrier phase error given in Eq. (13), when the carrier is tracked by a PLL so that no phase ambiguity exists. However, with a fixed-loop SNR, an irreducible error probability exists no matter how large the bit SNR. This irreducible error probability is characterized solely by the carrier tracking loop SNR and, for a given loop bandwidth, is reduced only by allocating more power to the residual carrier component, which serves no purpose in transmitting telemetry except being tracked by PLL.

For suppressed carrier tracking of a BPSK signal by the Costas loop, the phase ambiguity exists and must be resolved. The bit error probability for a special case of perfect phase ambiguity resolution (say, by other means, such as a periodically inserted known sync pattern) is given by

$$P_b = \int_{-\pi/2}^{\pi/2} \frac{1}{2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] p(\phi_c) d\phi_c \quad (25)$$

where $p(\phi_c)$ is the pdf in Eq. (15).

If a differential coding scheme is utilized to resolve the phase ambiguity, the biterror probability becomes [7]

$$\begin{aligned} P_b &= \int_{-\pi/2}^{\pi/2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] \\ &\left\{ 1 - \frac{1}{2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0}} \cos(\phi_c) \right] \right\} p(\phi_c) d\phi_c \end{aligned} \quad (26)$$

where $p(\phi_c)$ is the pdf in Eq. (15). No irreducible error probability exists in the suppressed carrier tracking because the tracking loop SNR for a fixed loop bandwidth and bit duration product increases with the bit SNR. So far, only the impact of bit error probability from carrier tracking has been discussed, and one can find the SNR degradation from imperfect carrier tracking, that is, $\cos^2(\phi_c)$ appears repeatedly in Eqs. (24)–(26). When the overall impact of bit-error performance from all levels

of imperfect tracking, including carrier, subcarrier, and symbol, is considered, the bit error probability becomes a threefold integration involving the overall symbol SNR degradation given in Eq. (22). For example

$$P_b = \int_{-\pi}^{\pi} \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} \frac{1}{2} \operatorname{erfc} \left[\sqrt{\frac{E_b}{N_0} D_{\text{SNR}}(\phi_c, \phi_{\text{sc}}, \phi_{\text{sym}})} \right] p(\phi_c) p(\phi_{\text{sc}}) p(\phi_{\text{sym}}) d\phi_c d\phi_{\text{sc}} d\phi_{\text{sym}} \quad (27)$$

where $p(\phi_{\text{sc}})$ and $p(\phi_{\text{sym}})$ are Tikhonov distributed pdf's of subcarrier and symbol phase errors, respectively. In fact, $p(\phi_{\text{sc}})$ takes the form of Eq. (15) of the Costas loop and $p(\phi_{\text{sym}})$ is given by Eq. (20). Note that the product of pdf's of individual phase errors is used in lieu of the hard-to-establish joint pdf from the coupled loops. For QPSK signals, the biterror probability is given by [7]

$$P_b = \int_{-\pi/4}^{\pi/4} \left(\frac{1}{4} \operatorname{erfc} \left\{ \sqrt{\frac{E_b}{N_0}} [\cos(\phi_c) - \sin(\phi_c)] \right\} + \frac{1}{4} \operatorname{erfc} \left\{ \sqrt{\frac{E_b}{N_0}} [\cos(\phi_c) + \sin(\phi_c)] \right\} \right) p(\phi_c) d\phi_c \quad (28)$$

where $p(\phi_c)$ is the pdf in Eq. (17).

The telemetry system loss is defined as a loss factor $L \geq 0$ dB, which represents the amount of additional bit SNR required for a lossy system to meet the same bit error performance of a perfectly synchronized system. For example, the bit error probability for a perfectly synchronized BPSK or QPSK system is given by

$$P_b = \frac{1}{2} \operatorname{erfc} \left(\sqrt{\frac{E_b}{N_0}} \right) \quad (29)$$

and, therefore, the required bit SNR for this ideal system at a given bit error probability p_b^* is expressed by

$$\left(\frac{E_b}{N_0} \right)^* = [\operatorname{erfc}^{-1}(2P_b^*)]^2 \quad (30)$$

The lossy system with a system loss L needs L times as much bit energy, namely, $E_b/N_0 = L(E_b/N_0)^*$, to achieve the same biterror probability or, in other words, to compensate for the loss incurred within.

9. ADVANCED TOPICS

9.1. Antenna Arraying

With recent space missions moving toward high data rate and low transmitting power operations, combining signals from several antennas to improve the effective SNR becomes the only viable option when the existing technologies of building larger single-aperture antenna and

lowering the system noise temperature are pushed to their limits.

Three arraying techniques [14] are briefly discussed here: symbol-stream combining, baseband combining and full spectrum combining, each combining signals at a different stage of signal processing.

For symbol-stream combining, each participating antenna performs carrier, subcarrier, and symbol synchronization individually. Then the symbols at each receiver output are combined, with the appropriate weights, to form the final symbols for detection or decoding. This scheme has the advantage of a small combining loss. It is also suitable for real-time combining from intercontinental antenna sites because combining is performed at a relatively low processing rate, that is, the symbol rate. The disadvantage is that each antenna needs a full set of receiver hardware and must lock on the signal individually.

In baseband combining, each antenna needs to lock on and remove the (residual) carrier by itself. Then the resulting baseband signals, including the data-modulated subcarrier, are combined for further synchronization and demodulation. The advantage of this scheme is that less hardware is required because only a single set of subcarrier and symbol tracking devices is needed to process the combined signal. The disadvantage is that each antenna still must lock on, at least, the carrier, individually.

In full spectrum combining, signals are combined at an intermediate frequency (IF). Before they are combined, the relative time delay and phase difference must be properly estimated and compensated for so that signals are coherently combined. Then the resulting IF signal is directed to a single receiver for further synchronization and demodulation. The advantage of this scheme is that only one of the participating antennas must lock on the combined IF signal, which allows including smaller antennas in this arraying scheme even though they cannot lock on the signal. The disadvantage is the very large transmission or recoding bandwidth required to carry the IF signals through the networked antenna sites for combination.

Besides the above-discussed arraying techniques, a scheme called the carrier arraying, which employs coupled carrier tracking devices from participating antennas should be mentioned here. This scheme by itself does not combine the signals and, thus, must be operated with symbol-stream or baseband combining to array the telemetry. In a carrier array scenario, a large master antenna generally locks on the signal by itself and then helps other smaller antennas to track by estimating and removing the signal dynamics in their input.

9.2. Buffered Telemetry Processing

The Deep Space Communications Complex (DSCC) Galileo Telemetry (DGT) is developed and implemented by the Jet Propulsion Laboratory to support the Galileo S-Band Mission. Many advanced technologies have been developed for this mission to cope with the failure to fully deploy the high-gain antenna of the Galileo spacecraft, making itself a showcase of future signal processing

technologies in the radiotelemetry field. In the following, selected key features of the DGT and the technologies behind these features are briefly described to illustrate the concept of buffered telemetry processing in which telemetry is recorded, processed, and reprocessed to minimize data loss in space missions operated with low link margins.

DGT is composed of four major subsystems, the full-spectrum recorder (FSR), the full-spectrum combiner (FSC), the buffered telemetry demodulator (BTD), the feedback concatenated decoder (FCD), and other control functions to coordinate the operations of these subsystems. Except for the FSR, the rest of the DGT is implemented in software and can be run on general-purpose workstations, which allows greater flexibility of signal processing without expensive custom-made hardware.

The FSR downconverts the RF signal to IF for digitization and then further open-loop downconverts each data sideband to the baseband, individually and coherently, before it is sampled and recorded. This significantly reduces the required bandwidth for transmission through the intercontinental antenna network because the processing rate is linked to the symbol rate, instead of the much higher subcarrier frequency.

The recorded signals (residual carrier and data sidebands centered at the first four harmonics of the square-wave subcarrier) are kept for the Galileo S-Band Mission) from arrayed antennas are combined by the FSC, which estimates and adjusts the time delay and phase for each recorded sideband coherently to a reference point chosen as the center of the Earth, and then combines the time- and phase-aligned signals from arrayed antennas to form an enhanced signal. The combined telemetry is archived and transferred to the BTD on request for synchronization and demodulation.

The BTD, known as the software receiver, is the signal processing core of DGT, which provides acquisition, synchronization, demodulation, and miscellaneous monitoring functions through its carrier, subcarrier, symbol-tracking loops and associated lock indicators [15]. In the BTD, the individually combined data sidebands are processed coherently and then are synthesized to form an equivalent signal as if it were a single signal processed by a regular receiver. The end product of the BTD is a demodulated soft symbol stream that is written to a file and transferred to the FCD on request for decoding and decompression.

Because the FSR/FSC combined data are recorded on tape, the BTD is actually designed to be able to work on any segment of data offline in either direction, forward or backward in time. In fact, with the availability of multiple CPU workstations, simultaneous BTD sessions are initiated on different segments of data. For example, one session is dedicated to process real-time samples forward (in time) while the others reprocess other recorded segments as needed. Then the soft symbol streams from these simultaneous sessions are merged into a single stream because each of them is properly time tagged. By taking advantage of the flexibility in software implementation, many noncausal signal processing techniques can be performed to process or reprocess the data to further

enhance the quality of the telemetry. One important feature of the BTD is the so-called gap closure processing [16], which greatly reduces possible data loss due to receiver acquisition, resynchronization, and loss of lock.

The need to reprocess a segment of sampled data arises from the failure of the BTD to maintain the in-lock status in any of its tracking loops or the failure of the FCD to properly decode the soft symbols. A segment of sampled data on which the telemetry cannot be extracted reliably is called a gap, and the processing of a gap to extract any valid information not available when that segment of samples was first processed is called gapclosure processing. Gaps caused by acquisition are found in the beginning of each pass or at instants when the receiver drops out of lock, whereas gaps generated by cycle slips in one of the loops occur randomly in a pass. Along with its demodulation efforts, the BTD tracks its internal states, including the lock indicators, the symbol SNR estimates, and the state variables inside the loop filter and the NCO for all three loops. These state variables are recorded at fixed intervals as checkpoints and, with them, a software receiver is easily restored to its state at checkpoint immediately before or after a gap. By estimating the parameters of a phase process in a region near a restored checkpoint where the phase tracking was successfully carried out, gap closure processing can start from this checkpoint and move into the gap. Two configurations, one for closed loop and the other for open loop, are used here. The closedloop configuration needs to initiate the loop filter with phase parameters estimates in a particular way, so that, when the loop is closed and starts to track at the checkpoint, the loop virtually starts immediately with steady state tracking. For a relatively stable phase process and a gap of small size, an openloop configuration is applied by using an estimated phase profile as the reference without resorting to a loop operation. Both configurations are applied to gap closure processing in either direction, forward or backward in time, because the buffered data can be processed in either order. This is especially useful when a gap occurs at the beginning of a track so that all the available checkpoint information is from the region behind this gap.

Another useful feature of BTD is its capability of seamless tracking through symbol rate changes. The reason for changing the symbol rate during a pass is to take advantage of the changing G/T figure as the elevation angle of an antenna changes in a pass. With a higher elevation angle, an antenna has a higher G/T figure and supports a higher symbol rate when the symbol SNR is fixed. The software implementation of BTD handles symbol rate changes without dropping a lock on symbol timing, as long as the rate changes follow a set of specific rules and their schedule is roughly known in advance.

The FCD is a subsystem that performs error correction decoding and data decompression in the DGT. Implemented in software on a multiprocessor workstation, it employs a feedback mechanism that passes intermediate decoding information from the outer code of the concatenated code to the inner code to facilitate multipass decoding which achieves a final bit error rate of 10^{-7} at a 0.65 dB bit SNR. The architecture and the detailed operations of the FCD are described in the next section.

9.3. Advanced Source and Channel Coding for Space Applications

In this section, we use the Galileo S-Band Mission again as an example to illustrate the application of advanced source and channel coding schemes to enhance telemetry return (17). First, using the integer cosine transform (ICT) for lossy image compression is briefly explained. Then, an advanced error correction coding scheme used to protect the heavily edited and compressed data is discussed, followed by a discussion of the interaction between data compression and error control (containment/detection/correction) processes.

9.3.1. Galileo's Image Compression Scheme. Galileo image compression is a block-based lossy image-compression algorithm that uses an 8×8 ICT. The ICT was first proposed in 1989 [18], and was streamlined and generalized a few years later [19,20]. It is an integral approximation of the popular discrete cosine transform (DCT), which is regarded as one of the best transform techniques in image coding. Its independence from the source data and the availability of fast transform algorithms make the DCT an attractive candidate for many practical image processing applications. In fact, the ISO/CCITT standards for image processing in both still-image and video transmissions include the two-dimensional DCT as a standard processing component in many applications.

The elements in an ICT matrix are small integers with sign and magnitude patterns resembling those of the DCT matrix. Besides, the rows of the ICT matrix are orthogonal. The integral property eliminates real multiplication and real addition operations, thus greatly reducing computational complexity. The orthogonality property ensures that the inverse ICT has the same transform structure as the ICT. Notice that the ICT matrix is required only to be orthogonal, but not orthonormal. However, any orthogonal matrix may be made orthonormal by multiplying it by an appropriate diagonal matrix. This operation is incorporated in the quantization (dequantization) stage of the compression (decompression), thus sparing the ICT (inverse ICT) from floating-point operations and, at the same time, preserving the same transform structure as in the floating-point DCT (inverse DCT). The relationship between the ICT and DCT guarantees efficient energy packing and allows the use of fast DCT techniques for the ICT. The ICT matrix used in the Galileo mission is given as follows:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 5 & 3 & 2 & 1 & -1 & -2 & -2 & -5 \\ 3 & 1 & -1 & -3 & -3 & -1 & 1 & 3 \\ 3 & -1 & -5 & -2 & 2 & 5 & 1 & -3 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 2 & -5 & 1 & 3 & -3 & -1 & 5 & -2 \\ 1 & -3 & 3 & -1 & -1 & 3 & -3 & 1 \\ 1 & -2 & 3 & -5 & 5 & -3 & 2 & -1 \end{bmatrix}$$

Figure 1. Rate distortion performance of ICT.

Figure 1 shows the rate distortion performance of the ICT scheme compared with the JPEG scheme. Simulation results indicate that the difference in performance between the use of floating-point DCT and the ICT is insignificant.

9.3.2. Galileo's Error Correction Coding Scheme. The Galileo error-correction coding scheme uses a $(255, k)$ variable redundancy RS code as the outer code and a $(14, \frac{1}{4})$ -long constraint-length convolutional code as the inner code. The RS codewords are interleaved to depth 8 in a frame. The redundancy profile of the Reed–Solomon codes is $(94, 10, 30, 10, 60, 10, 30, 10)$. The staggered redundancy profile was designed to facilitate the novel feedback concatenated decoding strategy [21,22]. This strategy allows multiple passes of channel symbols through the decoder. During each pass, the decoder uses the decoding information from the RS outer code to facilitate the Viterbi decoding of the inner code in a progressively refined manner. The FCD is implemented in software on a multiprocessor workstation. The code is expected to operate at a bit signal-to-noise ratio of 0.65 dB at a bit error rate of 10^{-7} . Figure 2 shows a schematic of the FCD architecture. In this article, only the implementation and operational aspects of the FCD task are discussed. The FCD novel node/frame synchronization scheme is discussed in Ref. 23, and its code selection and performance analysis are discussed in detail in Ref. 24.

9.3.2.1. The $(255, k)$ Variable-Redundancy Reed–Solomon Code. All RS codes for the Galileo mission use the same representation of the finite field $\text{GF}(256)$. Precisely, $\text{GF}(256)$ is the set of elements

$$\text{GF}(256) = \{0, a^0, a^1, a^2, \dots, a^{254}\} \quad (31)$$

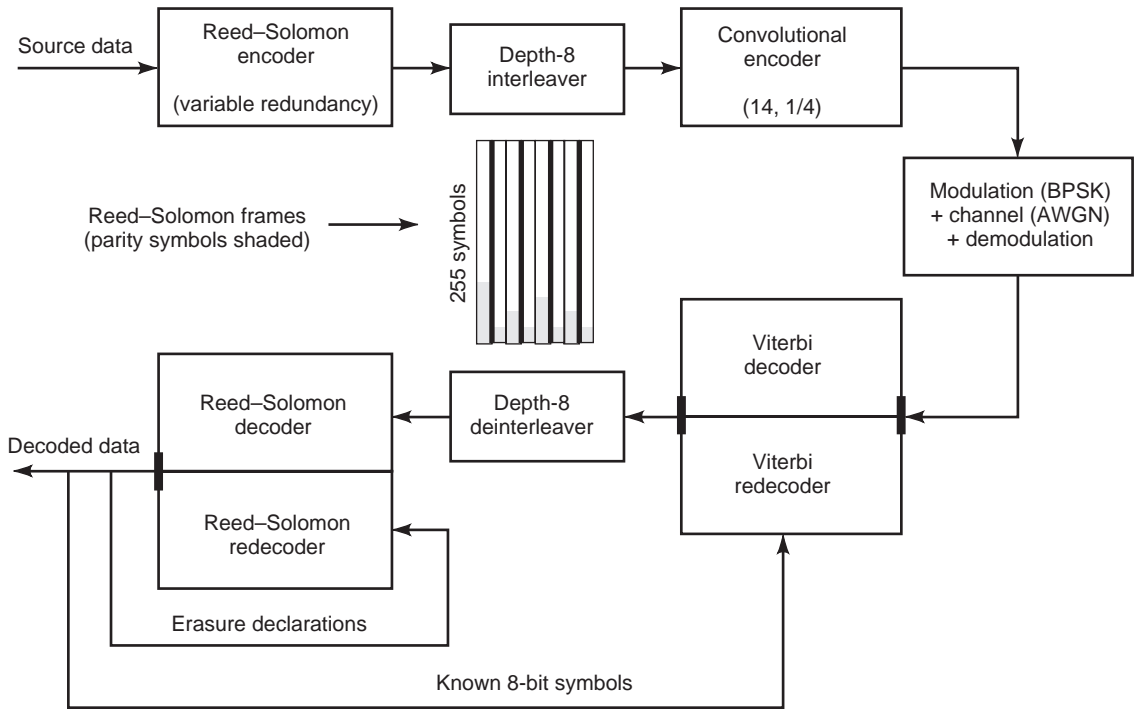

Figure 2. Schematic of the FCD.

where a , by definition, is a root of the primitive polynomial

$$p(x) = x^8 + x^7 + x^2 + x + 1 \quad (32)$$

[i.e., $p(a) = 0$].

In the encoding/decoding process, each power of a is represented as a distinct nonzero 8-bit pattern. The zero byte is the zero element in $GF(256)$. The basis for $GF(256)$ is descending powers of a . Note that this is the conventional representation, not Berlekamp's dual basis (25). The RS generator polynomial is defined as

$$g(x) = \prod_{i=0}^{n-k-1} (x - \alpha^{\beta(i+L)}) = \sum_{i=0}^{n-k} g_i x^i \quad (33)$$

where n denotes the codeword length in bytes, k denotes the number of information bytes, and α^β is a primitive element of $GF(256)$. The parameter b is chosen in some applications to minimize the bit-serial encoding complexity. Because the Galileo RS encoders are implemented in software, there is little advantage in preferring a particular value of b . The parameter L is chosen so that the coefficients of $g(x)$ are symmetrical. This reduces the number of Galois field multiplications in encoding by nearly a factor of 2.

The Galileo mission utilizes four distinct RS codes. We define $RS(n, k)$ as an RS code which accepts k data bytes as input and produces n bytes as a code word, where $n > k$. An $RS(n, k)$ code corrects t errors and s erasures if $2t + s \leq n - k$. These codes are referred to as $RS(255, 161)$, $RS(255, 195)$, $RS(255, 225)$, $RS(255, 245)$. Specifically, the parameters b

and L of these four codes are as follows:

- $RS(255, 161)$ $b = 1, L = 81$
- $RS(255, 195)$ $b = 1, L = 98$
- $RS(255, 225)$ $b = 1, L = 113$
- $RS(255, 245)$ $b = 1, L = 123$

These RS codes, being interleaved to depth 8, are arranged in a transfer frame as shown in Fig. 2. The RS decoders use a time-domain Euclid algorithm to correct errors and erasures. The details of the decoding algorithm are discussed in Ref. 26.

9.3.2.2. The $(14, \frac{1}{4})$ Convolutional Code and Its Parallel Viterbi Decoder. The $(14, \frac{1}{4})$ convolutional code used for the Galileo mission is the concatenation of a software $(11, \frac{1}{2})$ code and an existing hardware $(7, \frac{1}{2})$ code. The choice of convolution code is constrained by the existing $(7, \frac{1}{2})$ code, which is hardwired in the Galileo Telemetry Modulation Unit (TMU), and by the processing speed of the ground FCD. The generator polynomials of the $(11, \frac{1}{2})$ code and the $(7, \frac{1}{2})$ code in octal are (3403, 2423) and (133, 171), respectively. The generator polynomials of the equivalent $(14, \frac{1}{4})$ code are (26042, 36575, 25715, 16723).

The Viterbi decoder for the $(14, \frac{1}{4})$ code is implemented in software in a multiprocessor workstation with shared memory architecture. The use of a software decoder is possible because of the slow downlink data rate of the Galileo S-Band Mission. The advantages of a software-based decoder are that the development cost is low and it allows the flexibility to perform feedback concatenated decoding. We examined two different approaches to

parallelize the Viterbi algorithm: (1) state-parallel decomposition in which each processor is equally loaded to compute the add-compare-select operations per bit and (2) round-robin frame decoding that exploits the multiple processors by running several complete but independent decoders for several frames in parallel. Our early prototypes indicate that the first approach requires a substantial amount of interprocessor synchronization and communication and this greatly reduces the decoding speed. The second approach requires much less synchronization and communication because each processor is now an entity independent of the others. The performance scaling is nearly perfect. We chose the round-robin approach for the FCD Viterbi decoder. The details of the FCD software Viterbi decoder implementation are described in Ref. 27.

9.3.2.3. Redecoding. Redecoding, as shown in Fig. 2, uses information fed back from codewords successfully decoded by the RS decoder to improve the performance of Viterbi decoding. A correctly decoded RS bit forces the add-compare-select operation at each state to select the path that corresponds to the correct bit. Thus the Viterbi decoder is constrained to follow only paths consistent with known symbols from previously decoded RS codewords. The Viterbi decoder is much less likely to choose a long erroneous path because any path under consideration is pinned to coincide with the correct path at the locations of the known symbols. Each RS frame is decoded with four feedback passes. In the first pass, only the first code word RS(255,161) is decoded. In the second pass, the fifth codeword RS(255,195) is decoded. In the third pass, the third and seventh codewords RS(255,225) are decoded, and finally, in the fourth pass, the second, fourth, sixth, and eighth codewords RS(255,245) are decoded. During each pass, the decoder uses the decoding information from the Reed-Solomon outer code to facilitate Viterbi decoding of the inner code in a progressively refined manner. The details of the FCD redecoding analysis are given in Ref. 24.

9.3.3. Interaction between Data Compression and Error Control Processes. Packet loss and other uncorrectable errors in a compressed datastream cause error propagation, and the way the error propagates depends on the compression scheme. To maximize the scientific objectives with the limited transmission power of the low-gain antenna used in the Galileo S-Band Mission, most of the data (image and nonimage) are expected to be heavily edited and compressed. These valuable compressed data must be safeguarded against catastrophic error propagation caused by packet loss and other unforeseeable errors.

The ICT scheme for solid-state imaging (SSI) data is equipped with a simple but effective error containment strategy. The idea is to insert synchronization markers and counters at regular intervals to delimit uncompressed data into independent blocks so that, in case of packet loss and other anomalies, the decompressor searches for the next available synchronization marker and continues to decompress the rest of the data. In this case, the interval chosen is eight lines of uncompressed data. The error containment strategy guarantees that error propagation

does not go beyond the compressed code block where errors reside. Other options to prevent error propagation are also considered, but these options usually result in great onboard implementation complexity or excessive downlink overhead. For example, a self-synchronizing feature in Huffman code may be used to contain errors, but it is difficult to implement. A packetizing scheme with varying packet sizes may also be used to contain errors (by matching packet boundaries and the compressed data block boundary), but the packet headers introduce excessive downlink overhead in SSI data.

The SSI ICT error containment scheme works as follows. On the compression side, every eight lines of data are compressed into a variable-length, compressed data block. The dc (steady-state bias) value is reset to zero at the start of each compressed data block, thus making every block independent of the others. A 25-bit synchronization marker and a 7-bit modulo counter are inserted at the beginning of every compressed data block. The sync marker is chosen to minimize the probability of false acquisition in a bursty channel environment. The 25-bit synchronization marker pattern is 024AAAAB in hex. Simulation results indicate that this synchronization marker gives a probability of false acquisition of less than 10^{-8} . The decompression scheme consists of two program modules, the SSI ICT decompression module and the error detection/sync module. The SSI ICT decompression module reconstructs the data from the compressed datastream, and the error detection/sync module checks the prefix condition of the Huffman codes to detect any anomaly. When an anomaly is detected, a synchronization marker search is initiated to find the next available one. Decompression resumes from there on, and the reconstructed blocks are realigned by using the modulo counter. The corrupted portion of the data is flagged and reported.

The downlink overhead of the SSI ICT error containment scheme is a function of compression ratio (CR) and image width W. It is measured by the percentage of sync data (sync marker and counter) compared to the compressed data and is given by following equation:

$$\frac{4 \times CR}{8 \times W}$$

For example, an 800×800 SSI image has the following overhead as a function of the compression ratio:

Compression Ratio	Overhead
2	0.00125
4	0.00250
8	0.00500
16	0.01000

9.3.4. Multiple Spacecraft Support. Traditionally, every spacecraft is supported by one of the ground antennas for its uplink and downlink. This dedication requires efficient scheduling of the resources on the ground, including hardware, software, and personnel. With more and more

concurrent missions, the need for multiple spacecraft support by a single ground antenna to alleviate the scheduling problem becomes evident. For example, several proposed future missions to Mars by various joint efforts of international space agencies will place more than a dozen spacecraft, including orbiters, landers, and rovers, on or around Mars in the next 10 years. For these missions, it is highly possible that more than one spacecraft will come within the same beam width of a single ground antenna, and it constitutes the opportunity to communicate with them by using this single antenna with a considerable amount of operational cost saving over multiple antennas. In multiple spacecraft support, a telecommand uplink from a single ground antenna will be shared by the supported spacecraft, and multiple telemetry downlinks originated from these spacecraft will also have to be established by a single ground antenna.

Several options have been studied to support this multiple spacecraft scenario [28]. The most straightforward (and the most inefficient) option is to carefully assign different subcarrier frequencies to the supported spacecraft, allowing sufficient guard band to accommodate Doppler effects and tolerating some degree of spectrum overlapping in data sidebands in exchange for more simultaneous support. This method requires very tedious planning and is extremely inflexible when facing a dynamic scenario.

Another option is to redesign the spacecraft transponder so that the coherent turnaround ratio (TAR), which specifies the uplink to downlink carrier frequency ratio, is programmable. Each supported spacecraft receives its unique TAR from the uplink commands. As a result, different spacecraft will be instructed to use different downlink carrier frequencies because their TARs are distinct. Currently, a new digital transponder, known as the *small transponder modem* developed by the Jet Propulsion Laboratory, has such a built-in feature.

The third option is to use code-division multiple-access (CDMA) techniques similar to those used in commercial mobile cellular systems. CDMA offers far more simultaneous support than that of the previous two options. However, to support various types of spacecraft, the power dissimilarity problem between weak rover and strong orbiter signals has to be properly solved to avoid severe performance degradation for weaker signals. This option may be the best choice when more and more multiple spacecraft support scenarios emerge in the future.

RADIOWAVE PROPAGATION CONCEPTS

CURT A. LEVIS
The Ohio State University

An advantage of electronic communication is that an artificial link (e.g., transmission line, cable, or waveguide) is not necessarily required between the signal source and the receiver. Indeed, the term “wireless” is used in many parts of the world in preference to “radio,” and even in the United States “wireless” is often used to describe commercial personal communication by radio. Although radiowaves also propagate in waveguides, cables, and transmission lines, the term “radiowave propagation” is used generally, and specifically in this article, for signal travel between a source and a receiver without guidance by such artificial devices. Examples of such systems are radio and television broadcasting, radio point-to-point communication, radar, radio navigation, and remote sensing.

The concept of radiowave propagation allows division of the total system problem into three separate parts: the transmitter or signal source, the receiver, and propagation. Thus propagation is defined as what happens between the source and the receiver. For this concept to be valid, the distances must be such that far-field criteria for

the antennas are satisfied; this allows separating antenna effects from propagation effects. In radar two propagation paths are involved: from the transmitter to the target and from the target to the receiver.

Much has been learned about radiowave propagation since Hertz first demonstrated wireless transmission from one room to another. Now radiowave propagation is considered a moderately mature science, yet new understanding continues to emerge. This article presents an overview of radiowave propagation concepts. More detailed information will be found in articles on specific topics in radiowave propagation.

1. THE INFLUENCE OF FREQUENCY AND ENVIRONMENT

1.1. Frequency

The spectrum of useful electromagnetic waves covers an extraordinarily wide range of frequencies from as low as 70 Hz to X rays at approximately 10 EHz (10^{19} Hz). For convenience, the lower part of the spectrum has been divided into frequency bands as shown in Table 1. The VLF to SHF band designations have been adopted as an international standard. The others are commonly used, but not all authors adhere to those definitions. Because the propagation behavior of radio waves does not change abruptly with frequency, the band designations are often used somewhat loosely with respect to radiowave propagation. For example, a system operating in the range 200–500 MHz might be described as a UHF system. In the microwave region of the spectrum, frequency bands are often denoted by letter codes originally applied to radar systems. These are given in Table 2.

1.2. Environment

The most important environmental influences on terrestrial propagation are those of the troposphere, the ionosphere, and the ground. The troposphere is the lower region of the atmosphere where ionization is too small to affect radio waves appreciably. Tropospheric effects are caused by refractive index variations, absorption of energy by atmospheric gases, and absorption and scattering by precipitation. The ionosphere is the region of the

Table 1. Frequency Band Designations

Band Designation	Abbreviation	Frequency Range	Free-Space Wavelength Range
Ultralow frequency	ULF	< 3 Hz	> 100 Mm
Extremely low frequency	ELF	3 Hz–3 kHz	100 Mm–100 km
Very low frequency	VLF	3–30 kHz	100–10 km
Low frequency	LF	30–300 kHz	10–1 km
Medium frequency	MF	300 kHz–3 MHz	1 km–100 m
High frequency	HF	3–30 MHz	100–10 m
Very high frequency	VHF	30–300 MHz	10–1 m
Ultrahigh frequency	UHF	300 MHz–3 GHz	1 m–10 cm
Super high frequency	SHF	3–30 GHz	10–1 cm
Extremely high frequency	EHF	30–300 GHz	1 cm–1 mm
Submillimeter		300 GHz–1 THz	1 mm–300 μ m

atmosphere where free electrons produced by ionization strongly affect radio waves in the frequency ranges below about 30 MHz to 50 MHz. The lower altitudinal limit of the ionosphere is in the range of 60 km to 70 km. The term ground designates the surface of the earth, including bodies of water. Local structures, such as buildings, may also have important effects.

1.3. Interaction of Frequency and Environment

The effect of the environment depends greatly on the system frequency. For example, in frequency ranges below about 30 MHz, the ionosphere is likely to be of prime importance. At VHF and UHF, under certain meteorological conditions, tropospheric layering may form “ducts” that guide waves very efficiently in one frequency band, but not in another. The system frequency is also important with respect to the ground. At microwave frequencies, the wavelength and depth of penetration into the ground are on the order of centimeters; thus the dielectric constant and conductivity at the very surface are important, and even intuitively smooth ground may need to be considered rough if its vertical variations are not small compared to wavelength. In contrast, at VLF the penetration depth is many hundreds of meters; therefore the dielectric constant and conductivity far below the visible surface are important, and the ground may appear smooth even in mountainous areas. As these examples show, it is important to characterize the environment by parametric values appropriate to the system frequency.

The system design also influences the extent to which the environment affects signal propagation. For example, in many satellite communication system calculations the effects of the ground are neglected because the ground station antennas are highly directive and pointed upward. Thus little energy hits the ground on Earth-to-space

transmission, and little of the energy impinging on the ground is received by the antenna on the space-to-Earth path.

The effects of the troposphere, ionosphere, and ground vary with frequency and also with geographic location. In addition, the troposphere and ionosphere vary in time. This variability adds complexity to predicting signal propagation. In many cases, such predictions are limited to statistical estimates.

1.4. Noise Considerations

System performance depends on signal strength and also on noise that corrupts the signal. Depending on the system frequency, significant external noise sources may be impulses due to lightning propagated via the ionosphere, emissions from astronomical sources (e.g., the sun, radio stars), or the “blackbody” noise emanating from the transmission medium.

2. PROPAGATION MECHANISMS AND MODELS

An exact solution of the radiowave propagation problem entails solving Maxwell’s equations in the presence of the source and the environment. Such calculations are beyond the state of the art. Instead, approximations based on physical processes are used. For example, the reception of two rays from the transmitter might be considered, one directly and the other via reflection by the ground. Such physically based, mathematical or empirical approximations for calculating signal strength are called propagation models [3]. The term “propagation mechanism” is used here for the physical processes that lead to relatively simple propagation models.

In principle, all of the propagation mechanisms discussed later might be considered in every application, but generally one or a few account sufficiently well for the system performance, so that the others are neglected. However, the specific application must be kept in mind. For example, a very small interfering signal may be objectionable, and thus an interference calculation may require including a propagation mechanism that would otherwise be unimportant.

2.1. Direct Propagation

The simplest propagation mechanism is direct propagation in which the signal travels from the emitter to the receiver unaffected by any propagation medium, except possibly for attenuation and mild refraction. When attenuation and refraction are absent, propagation occurs as in free space. Direct propagation takes the form of a spherical wave, which can be approximated locally at the receiver as a plane wave.

Although free-space propagation is a highly idealized approximation, it has important applications. Many radars and many satellite communication systems operating in the UHF to C-band frequency range have antennas sufficiently directive to exclude ground effects, and at these frequencies atmospheric effects may generally be neglected. In these cases, the free-space model is applicable. For

satellite communications at higher frequencies, atmospheric effects become important, but the direct propagation model is still applicable when attenuation and refractive effects are included. Predictions are very much more complicated if the refractive index is inhomogeneous and time-varying.

In general, the direct propagation model applies when the emitter and receiver are in plain view with respect to one another, provided the effects of other propagation mechanisms are negligible. This situation is most frequently encountered in the atmosphere at UHF to SHF with systems utilizing highly directive antennas.

2.2. Terrain Reflections

When antennas are not highly directional, signals may travel directly from the emitter to the receiver and also by reflection from the ground. In this case, both paths must be considered in evaluating the system performance. Typical examples are ground-to-air, air-to-ground, and air-to-air communication at UHF. In air-to-air communication, the size limitation of aircraft antennas makes it impossible to use highly directive antennas in this frequency range, so that it is not possible to keep the signal from reaching the ground. In practical ground-to-air and air-to-ground communication, the ground station antenna is situated somewhat above the ground and is not sufficiently directive to discriminate against the ground-reflected ray. Thus the propagation model for these systems must include both the direct and the ground-reflection mechanisms.

2.3. Ducting

The effects of gravity and meteorological conditions make atmospheric density and humidity functions of altitude. Though the resulting variations of the refractive index are small, significant bending of the signal path in the vertical plane can occur. This refraction may be sufficiently strong to guide the wave along the Earth's surface, a behavior called ducting. Tropospheric ducts are most commonly observed at VHF and UHF. They may also exist at higher frequencies, but the more directional antennas employed at these frequencies are less likely to couple efficiently into a duct. Ducting is much more common at some geographic locations than others because it is closely related to meteorological phenomena. Although ducting is a fairly reliable means of communication in some locations, it is generally more likely to be a source of potential interference.

2.4. Terrain Diffraction

When the emitter and receiver are not within plain view of each other at VHF and higher frequencies, diffraction is an appropriate propagation mechanism. When the intervening terrain is hilly or mountainous, the diffracting obstacles are often modeled as cylinders or even as vertical half planes ("knife-edge" diffraction). Diffraction by a conducting sphere is the most common model for relatively flat terrain. More detailed computational models are becoming

increasingly available as a result of increased computer power, more theoretical insights, and better algorithms.

2.5. Ground Wave

When antennas operate near (in terms of wavelength) and on the ground, it is found that the direct and ground-reflected waves cancel almost completely. In this case, however, it is found that a wave can be excited that travels along the surface and decreases rapidly with altitude. Since efficient transmitting antennas at MF and lower frequencies are necessarily large structures because the wavelength is long, they are generally on or near the ground, and ground-wave propagation is important at these frequencies. It is the dominant mechanism for local standard AM broadcast reception in the 540 kHz–1.7 MHz band. It is also dominant at LF and VLF for relatively short distances.

2.6. Tropospheric Scatter

The troposphere is never truly homogeneous, as common experience with weather indicates. In fact, variations over a wide range of dimensional scales are ever present. These variations can be used to advantage when very reliable wireless point-to-point communications are needed over a path of hundreds of kilometers. When very strong signals are beamed at an atmospheric region within the line of sight of both stations, the relatively small signal scattered out of the beam toward the receiving station may, nevertheless, be sufficient to enable communication at rates on the order of 5 megabits per second over 150–400 km distances at UHF. This technique is useful for communication with communities in arctic regions, where other forms of communication (e.g., satellite communications, ionospheric reflection) are less reliable.

2.7. Ionospheric Reflection

In the upper LF, MF, and HF bands, signals give the appearance of traveling in rays that are reflected by the ionosphere above and by the ground below, resulting in a series of "hops." Actually, the rays are bent rather than sharply reflected in the ionosphere, but the effect is essentially the same. Signal transmission by this means is very efficient, and great distances are spanned with modest power and equipment. For these reasons the "short-wave" bands, as they are often called popularly, are utilized for broadcasting, point-to-point communications, and amateur use, and portions of this band of the radio frequency spectrum have become exceedingly crowded.

2.8. Waveguide Modes

Ray theory requires that the medium vary slowly with respect to wavelength. Thus it fails for radiowave propagation at frequencies lower than about 100 kHz because the corresponding wavelengths no longer meet the requirement that they be much smaller than the Earth-ionosphere distance. Instead, at VLF and ELF the Earth-ionospheric space is modeled as a concentrically spherical waveguide with the ground as the lower boundary and the ionosphere as the upper. In the ELF and lower VLF bands

only one, or at most a few, modes need to be considered. The number of modes and therefore the computational difficulty increases with frequency. Calculations in the LF frequency band are especially laborious, and a combination of ray and mode theory is often used.

2.9. Ionospheric Scatter

Signals with a frequency too high to be reflected coherently from the ionosphere may, nevertheless, still be affected by it. One possible effect is the scattering of small amounts of energy out of the beam by local irregularities. This is analogous to the scattering by local irregularities of the troposphere, as discussed previously. Ionospheric scattering is most pronounced in the frequency range immediately above that which supports coherent ionospheric reflections. Ionospheric D-region scatter systems have been operated successfully in the VHF band over 1000–2000 km distances with a bandwidth on the order of 100 Hz.

2.10. Meteor Scatter

Meteors are popularly considered rare phenomena, perhaps because our daytime habits and increasingly urbanized existence allow many of us to see them only rarely. Actually, visually observable meteors are not rare by any means, but those too small to observe visually are even more abundant. The number of meteors of a given mass entering the atmosphere approximates an inverse exponential function of the mass. As these meteors enter the atmosphere, they heat and ionize the gas around them, forming trails of ionization. Where this ionization is substantially more intense than that of the ambient ionosphere, the trails reflect signals of a higher frequency than normally reflected from the ionosphere. Meteor-scatter communication systems are operated successfully in the VHF band. Because suitably oriented trails are not always present, such systems must store the information to be transmitted between the occurrence of suitable trails and transmit the information in bursts when such trails are present. This limits the average data rate. Also, a means must be provided for sensing the occurrence of suitable trails. Usually each station continually transmits a pilot signal, and the other station is assured that a trail exists when it receives that signal.

2.11. Whistlers

Electromagnetic signals in the ELF/VLF frequency range can propagate through the ionosphere in a peculiar mode in which they closely follow the lines of the earth's magnetic field. It is not easy to launch artificial waves with such very long wavelengths, but lightning generates electromagnetic energy in this frequency range quite effectively. Lightning-generated signals travel along Earth's magnetic field lines, often going out to a distance of several Earth radii, and so are guided to the antipode, that is the point on the opposite hemisphere where the field line terminates. Part of the signal may be reflected from the antipode along the same field line to the point of origin and may be reflected there again, and so forth. The frequency

components of the signal are dispersed in the travel, so that the frequency at the receiver changes with time. When amplified, the resulting audio has a sound reminiscent of whistling; hence the name of the propagation mechanism. Although not useful for information transmission, this propagation mechanism is utilized to obtain information about the upper ionosphere. The same propagation mechanism, but using much stronger artificial magnetic fields, has been investigated for communicating at much higher frequencies through the much denser ion sheath that forms around space vehicles as they reenter the atmosphere.

2.12. Nonatmospheric Propagation

The propagation mechanisms discussed so far are those commonly encountered with electromagnetic signal propagation through space or the earth's atmosphere. A different environment prevails when signals propagate through the ocean, through the earth's crust, or through some planetary atmospheres. In the ocean, only signals at ELF or in the visible-light frequency band penetrate to substantial depths. Propagation to substantial depths through the ground also presents difficulties. Nevertheless, radar systems for locating objects, such as water and gas lines at typical shallow depths, are quite successful.

3. TRANSMISSION LOSS

The most significant question relating to propagation for a radar or telecommunication system is the adequacy of the received signal level. The ratio, usually expressed in decibels (dB), between the power at some point in the transmitting system and a corresponding point in the receiving system is called a loss. Although time delay or phase shift may also be important parameters in some systems, loss is a universal and primary consideration because it relates directly to signal strength. In many cases, the loss varies randomly in time or with location. Then statistical parameters relating to the loss are often the quantities of interest, for example, the median loss.

Several types of losses are defined; see Fig. 1. The usual symbol for loss is L , although A (for attenuation) is also used, and subscripts denote the specific loss under consideration. The loss definitions below follow, with some emendations, those in "The concept of transmission loss for radio links," Recommendation ITU-R P.341-4, of the International Telecommunication Union [4].

3.1. Total Loss

The total loss (L_t or A_t) of a link is the ratio between the power supplied by the transmitter and the power supplied to the corresponding receiver under real installation, propagation, and operational conditions. Note: it is necessary to specify the points at which these powers are determined.

3.2. System Loss

System loss (L_s or A_s) is the ratio of the RF power input to the transmitting antenna terminals and the resultant RF

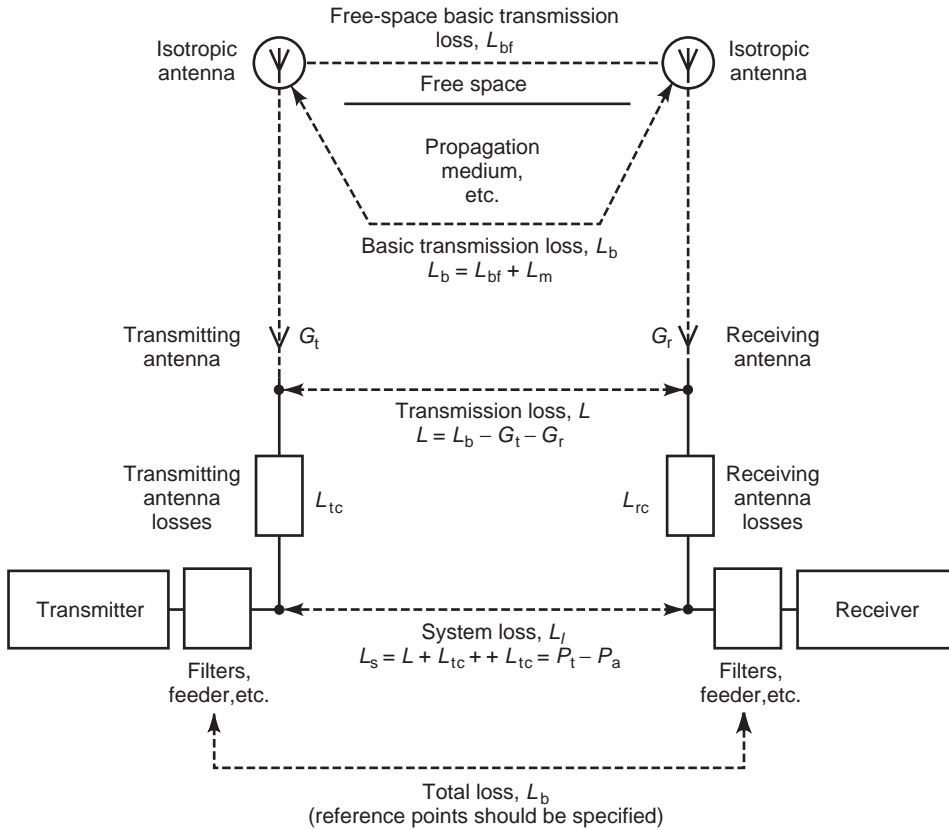

Figure 1. Definitions of losses. [Adapted from “The concept of transmission loss for radio links” (Recommendation ITU-R P.341-4), © International Telecommunication Union, 1996, Ref. 4. By permission.]

power available at the receiving antenna terminals. It is expressed in decibels by

$$L_s = 10 \log(p_t/p_a) = P_t - P_a \quad (1)$$

where P_t denotes the RF power input to the transmitter antenna terminals, P_a the available power at the receiving antenna terminals, both measured in the same units, and P_t , P_a are the corresponding power relative to a common reference level (e.g., 1 W) in decibels. Because the system loss is referred to the antenna terminals, it excludes all losses in feeder lines but includes all losses associated with the antenna, for example, antenna-grounding losses, dielectric losses in the antenna, antenna loading-coil losses, and antenna-terminating resistor losses, if applicable.

3.3. Transmission Loss

Transmission loss (L or A) is defined as the ratio between the power radiated by the transmitting antenna and the power that would be available at the receiving antenna terminals if this antenna were lossless but its radiation diagram, that is, its directional and polarization characteristics, were unchanged. In Fig. 1 the antenna losses L_{tc} and L_{rc} for transmitting and receiving, respectively, are defined as $10 \log(R'/R)$, where R' is the resistive component of the impedance of the designated antenna and R is its radiation resistance.

3.4. Basic Transmission Loss

Basic transmission loss, denoted by L_b or A_i , is the transmission loss that would occur if the antennas were replaced by hypothetical isotropic antennas with the same polarizations in the direction of propagation as the real antennas. The propagation path is retained, but the effects of obstacles close to the antennas are disregarded. The symbols G_t and G_r in Fig. 1 denote the directivity gains of the antennas for the polarization and direction of propagation being considered. The basic transmission loss is the ratio of the equivalent isotropic radiated power (EIRP) of the transmitter system to the available power from a hypothetical isotropic, lossless receiving antenna with the same polarization as that of the real antenna in the propagation direction.

3.5. Free-Space Basic Transmission Loss

The free-space basic transmission loss (L_{bf} or A_0) is the transmission loss that would occur if the antennas were replaced with hypothetical isotropic antennas, matched in polarization for maximum power transfer and located in an unbounded, lossless, homogeneous, isotropic environment, retaining the distance between antennas. Free-space basic transmission loss is a function only of the ratio of the distance d between transmitter and receiver to the wavelength λ . It is given in decibels by

$$L_{bf} = 20 \log\left(\frac{4\pi d}{\lambda}\right) \quad (2)$$

where d and λ are measured in the same units.

3.6. Loss Relative to Free Space

Loss relative to free space (L_m or A_m) is defined as the difference between the basic transmission loss and the free-space basic transmission loss in decibels:

$$L_m = L_b - L_{bf} \quad (3)$$

Loss relative to free space may be divided into losses of different types, for example, extinction loss, diffraction loss, wave interference loss, reflection loss, polarization-coupling loss, aperture-to-medium coupling loss. Because these losses are directly connected with propagation mechanisms, the end result of propagation studies is frequently presented in the form of loss relative to free space.

3.6.1. Extinction Loss. Extinction is the total attenuation due to absorption of signal power in the propagation medium and scattering of power out of the beam by the medium. In the troposphere at X band and higher frequencies, oxygen, water vapor, and precipitation absorb power from a propagating wave. Precipitation also scatters power out of the beam in the frequency range where particle or droplet size is not small compared to the wavelength. In the ionosphere, absorption is caused primarily by collision between electrons and neutral molecules. In ground-wave propagation, currents in the ground cause absorption losses.

3.6.2. Diffraction Loss. On a propagation path using diffraction by terrain features or by the spherical Earth, only a fraction of the power is scattered in a direction useful to the receiver. The resulting decrease in useful power density is considered a diffraction loss.

3.6.3. Wave Interference Loss. When several rays combine to produce the effective received wave, interference may cause a signal decrease relative to that of the ray directly received. This effect can be characterized as a wave interference loss, although this terminology is not encountered frequently in practice. Of course, signals may also be enhanced by interference, resulting in a negative wave interference loss.

3.6.4. Reflection Loss. Several phenomena result in reflection loss. If reflection from the ground occurs at a non-grazing incidence, the amplitude of the effective plane-wave reflection coefficient of the interface is less than unity, resulting in a reflection loss in the reflected ray. If the surface is rough on a scale comparable to the wavelength, energy is reflected in a range of angles about the specular, resulting in an effective specular reflection coefficient less than unity, and hence a reflection loss in the specular direction. If the reflecting surface is curved, the defocusing (or focusing) effect of the curvature decreases (or enhances) the reflected power density in the propagation direction of interest, resulting in a positive (or negative) reflection loss. The concave curvature of the ionosphere, as seen from the ground, causes focusing. The convex curvature of the Earth surface, as seen from above, causes defocusing.

3.6.5. Polarization-Coupling Loss. In an isotropic medium, polarization-coupling loss occurs when the receiving and transmitting antenna polarizations are not matched for optimum power transfer. This situation arises most frequently when interfering signals are being considered.

In an anisotropic medium, such as the ionosphere, plane waves of arbitrary polarization are split into two rays of characteristic polarizations. These rays propagate with generally different attenuations and phase shifts, and they recombine into a single plane wave when emerging from the medium or even within the medium. Polarization-coupling loss occurs when the transmitted wave polarization does not match that of a desired characteristic mode and when the receiving antenna does not match the polarization of the wave received.

3.6.6. Aperture-to-Medium Coupling Loss (Antenna-Gain Degradation). For some propagation mechanisms under certain conditions, the free-space directivity gain of the antennas is not realized. Then the directivity gain is said to be degraded, and the resulting signal loss is termed an aperture-to-medium coupling loss. As an example, in tropospheric scatter propagation a highly directive antenna is used to illuminate a region of the turbulent troposphere that is visible from both transmitter and receiver. The receiver utilizes a highly directive antenna to receive the signal scattered from the illuminated region. The part of the region within both the transmitting antenna beam and the receiving antenna beam is called the common volume. Increasing the directivity of each antenna increases the signal level, but the increase is not proportional to the directivity increase because the narrower beams reduce the common volume. Thus the full free-space directivity of the antennas is not realized. The loss in directivity, when considered an antenna effect, is called antenna-gain degradation; when considered as a propagation effect, it is called antenna-to-medium coupling loss. It is most pronounced for antennas with very high directivity.

FURTHER READING

The P (propagation) series of the Recommendations of the Radio Sector (ITU-R) of the International Telecommunication Union (ITU) is a very authoritative source, for example, Ref. 4. The Recommendations include propagation models, definitions, and other technical material relating to radiowave propagation adopted and updated at International Radiocommunication Assemblies. [Before 1994, what is now ITU-R was called the International Radio Consultative Committee (CCIR) of the ITU, and its publications included Reports and Recommendations. Volume 5 dealt with propagation in nonionized media and Volume 6 with ionized media.]

An excellent, concise, yet fairly complete text for the mature reader is M. P. M. Hall, L. W. Barclay, and M. T. Hewitt, eds., *Propagation of Radiowaves*, IEE, London, 1996.

Much current research in radiowave propagation is published in *Radio Science*.

RADIOWAVE PROPAGATION GROUND EFFECTS

DAVID A. HILL
National Institute of Standards
and Technology

Radiowave propagation plays an important role in modern communication, radar, and navigation systems. The mathematical theory of radiowave propagation is based on Maxwell's equations [1], which were formulated by James Clerk Maxwell in the 1860s [2]. The first free-space radiowave transmission experiments between a pair of antennas were performed by Heinrich Hertz in the 1880s [3]. In

1897 Marconi first patented a wireless telegraphy system based on long-distance, radiowave propagation.

1. RADIOFREQUENCY SPECTRUM

Table 1 summarizes the frequency range, propagation characteristics, and applications of the letter-designated bands of the radiofrequency spectrum. The lower and upper bounds of the radiofrequency spectrum in Table 1 are somewhat arbitrary, but the indicated frequency range, 3 Hz–300 GHz, encompasses the portion of the electromagnetic spectrum for which conventional antennas are used to transmit and receive radiowaves. Some of the characteristics of the individual bands are as follows.

1.1. Extremely Low Frequency

Because free-space, extremely low-frequency (ELF) wavelengths are extremely long (greater than 100 km), antennas are very inefficient radiators because they are electrically small. The other major disadvantage of ELF is lack of bandwidth for information transmission. Despite these disadvantages, ELF is useful for worldwide communication with submarines because the long wavelengths have a useful penetration depth (also called skin depth) of several tens of meters in seawater. In addition, the earth and the ionosphere support a low-attenuation waveguide mode at ELF [4] so that a wave, once launched, will propagate around the world with little loss of intensity. The ionosphere is the part of the upper atmosphere where sufficient ionization exists to affect radiowave propagation, and these effects are covered thoroughly in Ref. 5. The earth-ionosphere waveguide can actually support cavity modes with resonances [6] in the ELF range, and these resonances (called Schumann resonances) further enhance the field strength worldwide. Unfortunately,

Table 1. The Radiofrequency Spectrum

Frequency Range	Band	Characteristics	Applications
3 Hz–3 kHz	ELF	Long wavelength; inefficient antennas; Earth-ionosphere waveguide; penetration of ground and seawater	Submarine communications; underground mine communications; geophysics
3–30 kHz	VLF	Large transmitting antennas; Earth-ionosphere waveguide	Long-range communication; navigation, and time-frequency dissemination; geophysics
30–300 kHz	LF	Earth-ionosphere waveguide; high atmospheric noise	Navigational beacons
300 kHz–3 MHz	MF	Ground wave; ionospheric reflections (at night)	AM broadcasting; maritime communications
3–30 MHz	HF	Long-distance ionospheric propagation; maximum usable frequency	Maritime and aeronautical communications; citizens band and amateur radio
30–300 MHz	VHF	Line-of-sight propagation; ionosphere scatter; meteor scatter	Television and FM broadcasting; air-traffic control; navigation
300 MHz–3 GHz	UHF	Line-of-sight propagation	Television broadcast; radar; satellite communication; mobile communication; global positioning system
3–30 GHz	SHF	Line-of-sight propagation; atmospheric absorption	Radar; satellite communication; microwave links
30–300 GHz	EHF	Line-of-sight propagation; severe atmospheric absorption	Radar; secure communication; satellite links

these resonances also enhance the competing atmospheric noise caused by thunderstorms.

ELF waves have an even larger skin depth (typically greater than 100 m) in ground or rock (which have lower electrical conductivities than sea water) and have been found useful for communication to and within underground mines [7]. Because of this ability to penetrate rock, ELF waves have also been used in direction-finding applications for location of miners trapped in underground mines [8].

1.2. Very Low Frequency

The free-space wavelengths at very low frequency (VLF) are still very long (10–100 km), and this generally dictates the use of large vertical transmitting antennas with large ground systems to reduce ground current losses. Smaller antennas, such as vertical whips, loops, and grounded horizontal wires, can be used for receiving. VLF antennas and propagation are thoroughly covered in Ref. 9.

Even though the bandwidth is limited, VLF systems are useful for long-range reliable communications, long-range dissemination of standards for frequency and time, long-range navigation (including the U.S. Navy Omega system), and geophysical probing of the ground and the ionosphere. For short ranges, VLF propagates predominantly by the ground wave. For long ranges, the reflections from the ionosphere become important, and multiple reflections between Earth and the ionosphere can be described by Earth–ionosphere waveguide modes [9].

1.3. Low Frequency

The low frequency (LF) band is also characterized by low attenuation of ground wave propagation and Earth–ionosphere waveguide propagation. Thus the LF band is useful for long-range communication and for marine and aeronautical radio navigation beacons. The LORAN-C navigation system is based on the arrival time of a ground-wave pulse with a carrier frequency of approximately 100 kHz so that later-arriving ionospheric reflections do not affect the system. The wavelengths are long enough (1–10 km) that large transmitting antennas are needed.

1.4. Medium Frequency

The most popular use of the medium-frequency (MF) band is AM broadcasting, which uses the frequency range from 535 to 1705 kHz. The propagation mode is generally vertically polarized ground wave, although ionospheric reflections (sky wave) can extend the range at night. Maritime communications is another application.

1.5. High Frequency

In the high-frequency (HF) band, ionospheric reflections provide the possibility of long-distance communications. The maximum usable frequency (MUF) for ionospheric reflection generally occurs in the upper part of the HF band, but the MUF is a complicated function of the incidence angle and the state of the ionosphere [5]. HF appli-

cations include maritime, aeronautical, amateur, and citizens band communications.

1.6. Very High Frequency

At frequencies above 30 MHz, propagation is predominantly by line of sight with some refraction (bending) caused by the atmosphere. However, in some cases ionospheric reflections can occur at frequencies up to 60 MHz. Scattering from ionized meteor trails (which can be up to 25 km in length) can be used for meteor burst communications [10]. Very high frequency (VHF) applications include television and FM radio broadcasting and air traffic control and navigation.

1.7. Ultrahigh Frequency

Ultrahigh-frequency (UHF) propagation is essentially by line of sight with some atmospheric refraction and some scattering by ionospheric irregularities. Applications include UHF television broadcasting, various radars, satellite communications, and personal communications [11]. The global positioning system (GPS) uses transmitting satellites in the UHF band.

1.8. Superhigh Frequency

Superhigh frequency (SHF) propagation is primarily line of sight, and atmospheric absorption becomes significant, particularly above 10 GHz. A water vapor absorption line exists at approximately 21 GHz, and rain absorption and scattering increase with frequency throughout the band. SHF applications include radar, satellite communication, and microwave links.

1.9. Extremely High Frequency

The extremely high-frequency (EHF) band is also called the millimeter-wave spectrum since the wavelength ranges from 1 to 10 mm. Atmospheric absorption becomes extreme in this band. An oxygen absorption band is centered at approximately 60 GHz, and numerous absorption peaks due to oxygen and water vapor occur above 100 GHz. Rain attenuation is significant throughout the entire EHF band. Satellite-to-satellite links are not affected by atmospheric absorption, and secure short-range communication systems take advantage of high attenuation to limit propagation range.

2. LINE-OF-SIGHT PROPAGATION

Line of sight is the dominant mode of propagation for elevated antennas and high frequencies, as indicated Table 1. The mathematical description of line-of-sight propagation is most easily obtained by considering simple antennas in a free-space environment. In this section two classical cases are discussed. First a Hertzian dipole source is considered to illustrate radiation of a spherical wave. Then transmission between a pair of antennas is analyzed to derive the classical expression for basic free-space transmission loss.

2.1. Radiation from a Hertzian Dipole

This article covers only steady-state, time-harmonic sources and fields [12] with time variation $\exp(j\omega t)$, where the angular frequency $\omega = 2\pi f$ and f is the radio frequency. The time dependence is suppressed in the equations. The basic source is a current I extending over an incremental length l . This elementary dipole source is called a Hertzian dipole and has a moment Il . If the dipole is directed along the z axis, as shown in Fig. 1, the radiated electric field has two components, E_θ and E_r , and the radiated magnetic field has only a single component H_ϕ . The expressions for these field components can be derived from scalar and vector potentials [12]

$$E_\theta = \frac{Il\eta_0}{4\pi} e^{-jk_0 r} \left(\frac{jk_0}{r} + \frac{1}{r^2} + \frac{1}{jk_0 r^3} \right) \sin \theta \quad (1)$$

$$E_r = \frac{Il\eta_0}{2\pi} e^{-jk_0 r} \left(\frac{1}{r^2} + \frac{1}{jk_0 r^3} \right) \cos \theta \quad (2)$$

and

$$H_\phi = \frac{Il}{4\pi} e^{-jk_0 r} \left(\frac{jk_0}{r} + \frac{1}{r^2} \right) \sin \theta \quad (3)$$

where the free-space wave number $k_0 = \omega \sqrt{\mu_0 \epsilon_0}$ the free-space impedance $\eta_0 = \sqrt{\mu_0 / \epsilon_0}$, μ_0 is the magnetic permeability of free space, and ϵ_0 is the dielectric permittivity of free space. The equations for radiation by the dual source (a magnetic dipole or small loop) are given in Ref. 12.

Very close ($k_0 r \ll 1$) to the Hertzian dipole, the electric field is dominated by the r^{-3} inverse cube term, and Eqs. (1) and (2) can be approximated by

$$E_\theta \approx \frac{Il \sin \theta}{4\pi j \omega \epsilon_0 r^3} \quad \text{and} \quad E_r \approx \frac{Il \cos \theta}{2\pi j \omega \epsilon_0 r^3} \quad (4)$$

Figure 1. Geometry for radiation from a short electric dipole.

Equation (4) gives the electric field components of charges $\pm Il/j\omega$ separated by a distance l . The magnetic field of an electric dipole has no quasistatic term. At intermediate distances ($k_0 r \approx 1$), the inverse-square terms dominate Eqs. (1)–(3), and the field is called the induction field.

For most practical applications, such as communications or radar, the far fields are of interest. At large distances ($k_0 r \gg 1$), the inverse-distance terms dominate Eqs. (1) and Eq. (3), and the fields are approximated by

$$H_\phi \approx \frac{jk_0 Il}{4\pi r} e^{-jk_0 r} \sin \theta \quad \text{and} \quad E_\theta \approx \eta_0 H_\phi \quad (5)$$

Even though Eq. (5) applies to a Hertzian dipole, it illustrates the more general far-field properties that the electric and magnetic fields are related by the free-space impedance and they are orthogonal to each other and to the radial direction of propagation. Hence the radial electric field E_r in Eq. (2) has no inverse-distance term.

The power density of the electromagnetic field is called the Poynting vector \mathbf{S} and can be written

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}^* \quad (6)$$

where boldface denotes vectors and $*$ denotes complex conjugate. The far-field expression for \mathbf{S} can be obtained by substituting Eq. (5) into Eq. (6)

$$\mathbf{S} \approx \hat{\mathbf{r}} \eta_0 \left(\frac{k_0 |I| l \sin \theta}{4\pi r} \right)^2 \quad (7)$$

where $\hat{\mathbf{r}}$ is the unit vector in the radial direction. The $\sin^2 \theta$ factor in Eq. (7) is specific to the radiation pattern of a Hertzian dipole, but the inverse-square dependence applies to the far field of any radiator. The total radiated power P can be obtained by integrating Eq. (7) over a far-field sphere [12]:

$$P = \int_0^{2\pi} d\phi \int_0^\pi d\theta r^2 \sin \theta \hat{\mathbf{r}} \cdot \mathbf{S} \quad (8)$$

$$= \frac{\eta_0 (k_0 |I| l)^2}{6\pi}$$

The result for the total radiated power in Eq. (8) is independent of the radius r at which the integration is evaluated, but the evaluation is simplest in the far field, where \mathbf{S} can be approximated by Eq. (7).

2.2. Free-Space Transmission Loss

Now consider free-space transmission between a pair of antennas in the far fields of each other. The received power P_r can be written [13]

$$P_r = \frac{P_t G_t G_r}{(2k_0 D)^2} = \frac{P_t G_t G_r \lambda_0^2}{(4\pi D)^2} \quad (9)$$

where P_t is the transmitted power, G_t is the gain of the transmitting antenna, G_r is the gain of the receiving antenna, D is the separation distance between the antennas,

and the free-space wavelength $\lambda_0 = 2\pi/k_0$. The D^{-2} factor represents the inverse-square dependence of the radiated power density available at the receiving antenna.

The antenna and propagation effects can be separated by writing Eq. (9) in the following form:

$$\frac{P_r}{P_t} = G_t G_r \left(\frac{\lambda_0}{4\pi D} \right)^2 \quad (10)$$

The squared factor on the right side of Eq. (10) is dimensionless and does not involve the antenna gains. The reciprocal is called the free-space transmission loss L_0 and is usually expressed in decibels:

$$\begin{aligned} L_0 &= 10 \log_{10} \left(\frac{4\pi D}{\lambda_0} \right)^2 \text{ dB} \\ &= 20 \log_{10} \left(\frac{4\pi D}{\lambda_0} \right) \text{ dB} \end{aligned} \quad (11)$$

Normally the antenna gains and the power ratio in Eq. (10) are also expressed in decibels.

3. REFLECTION FROM A PLANAR INTERFACE

3.1. Plane-Wave Incidence

Radiowaves are often reflected from smooth, flat surfaces, such as building walls or ground. When the reflecting surface is not a perfect conductor, part of the radio energy penetrates the surface, and part of the energy is reflected. Reflection of a plane wave from a uniform half-space with a planar interface can be analyzed exactly by matching boundary conditions at the interface, and the derived reflection coefficients can then be used in other practical applications.

Consider the idealized geometry in Fig. 2. A free-space plane wave propagating at an angle θ_0 to the surface normal is incident on a half-space with permittivity ϵ , electrical conductivity σ , and permeability μ . The angle of reflection θ_r equals the angle of incidence, $\theta_r = \theta_0$. The reflection coefficient depends on the polarization of the incident field.

For horizontal polarization (electric field perpendicular to the plane of incidence), the reflection coefficient Γ_h is given by [1]

$$\Gamma_h = \frac{\mu k_0 \cos \theta_0 - \mu_0 \sqrt{k^2 - k_0^2 \sin^2 \theta_0}}{\mu k_0 \cos \theta_0 + \mu_0 \sqrt{k^2 - k_0^2 \sin^2 \theta_0}} \quad (12)$$

Figure 2. Geometry for plane-wave reflection from a homogeneous half space.

where $k = \omega \sqrt{\mu(\epsilon - j\sigma/\omega)}$. For vertical polarization (electric field parallel to the plane of incidence), the reflection coefficient Γ_v is

$$\Gamma_v = \frac{\mu_0 k^2 \cos \theta_0 - \mu k_0 \sqrt{k^2 - k_0^2 \sin^2 \theta_0}}{\mu_0 k^2 \cos \theta_0 + \mu k_0 \sqrt{k^2 - k_0^2 \sin^2 \theta_0}} \quad (13)$$

The reflection coefficients in Eqs. (12) and (13) apply to both the reflected electric and magnetic fields. The power reflection coefficients are obtained by taking the squares of the magnitudes of the field reflection coefficients, $|\Gamma_v|^2$ and $|\Gamma_h|^2$. In general, the reflection coefficients in Eqs. (12) and (13) are complex because k is complex. Thus the reflected field undergoes phase shift as well as reduction in amplitude. In the limiting case of grazing incidence ($\theta_0 = \pi/2$), both Γ_h and Γ_v equal -1 .

For the common case where the reflecting medium is non-magnetic ($\mu = \mu_0$), the reflection coefficients in Eqs. (12) and (13) simplify to

$$\Gamma_h = \frac{\cos \theta_0 - \sqrt{(k/k_0)^2 - \sin^2 \theta_0}}{\cos \theta_0 + \sqrt{(k/k_0)^2 - \sin^2 \theta_0}} \quad (14)$$

and

$$\Gamma_v = \frac{(k/k_0)^2 \cos \theta_0 - \sqrt{(k/k_0)^2 - \sin^2 \theta_0}}{(k/k_0)^2 \cos \theta_0 + \sqrt{(k/k_0)^2 - \sin^2 \theta_0}} \quad (15)$$

For the further simplification to a dielectric ($\sigma = 0$) reflecting medium, Eqs. (14) and Eq. (15) reduce to

$$\Gamma_h = \frac{\cos \theta_0 - \sqrt{\epsilon_r - \sin^2 \theta_0}}{\cos \theta_0 + \sqrt{\epsilon_r - \sin^2 \theta_0}} \quad (16)$$

and

$$\Gamma_v = \frac{\epsilon_r \cos \theta_0 - \sqrt{\epsilon_r - \sin^2 \theta_0}}{\epsilon_r \cos \theta_0 + \sqrt{\epsilon_r - \sin^2 \theta_0}} \quad (17)$$

where $\epsilon_r = \epsilon/\epsilon_0$.

As incidence angle θ_0 varies from 0 (normal incidence) to $\pi/2$ (grazing incidence), Γ_h varies smoothly from $(1 - \sqrt{\epsilon_r})/(1 + \sqrt{\epsilon_r})$ to -1 . However, for vertical polarization, the reflection coefficient Γ_v equals 0 at the Brewster angle, $\theta_B = \tan^{-1}(\sqrt{\epsilon_r})$. At this angle, all of the incident energy is refracted into the dielectric. An examination of Eq. (15) reveals that the presence of nonzero conductivity σ (which yields a complex k) prevents Γ_v from going to zero. However, if the imaginary part of k is small, there is nevertheless a pseudo-Brewster angle [14], where $|\Gamma_v|$ goes through a minimum.

3.2. Dipole Sources

Consider now a vertical electric dipole source located at a height h over a reflecting half space, as in Fig. 3. In the far

Figure 3. Far-field radiation from a vertical electric dipole over a homogeneous half-space. The reflection coefficient Γ_v is a function of the incidence angle θ .

field the electric field has only a θ component E_θ , which can be written as the sum of a direct and a reflected ray:

$$E_\theta = \frac{j\omega\mu_0 Il \sin \theta}{4\pi r} e^{-jk_0 r} \times (e^{jk_0 h \cos \theta} + \Gamma_v e^{-jk_0 h \cos \theta}) \quad (18)$$

where Γ_v is given by Eq. (13). For the special case of a perfectly conducting ground plane ($\sigma = \infty$), the reflection coefficient equals 1, and Eq. (18) reduces to

$$E_\theta|_{\sigma=\infty} = \frac{j\omega\mu_0 Il \sin \theta}{2\pi r} e^{-jk_0 r} \cos(k_0 h \cos \theta) \quad (19)$$

Equation (19) has a maximum at the interface, $\theta = \pi/2$.

The dual case of a vertical magnetic dipole source is shown in Fig. 4. The source is a small loop of area A and current I , and the loop axis is in the vertical direction. The electric field is horizontally polarized, and in the far field the ϕ component E_ϕ is

$$E_\phi = \frac{\eta_0 k_0^2 IA \sin \theta}{4\pi r} e^{-jk_0 r} \times (e^{jk_0 h \cos \theta} + \Gamma_h e^{-jk_0 h \cos \theta}) \quad (20)$$

where Γ_h is given by Eq. (12). For the special case of a perfectly conducting ground plane ($\sigma = \infty$), the reflection coefficient equals -1 , and Eq. (20) reduces to

$$E_\phi|_{\sigma=\infty} = \frac{j\eta_0 k_0^2 IA \sin \theta}{2\pi r} e^{-jk_0 r} \sin(k_0 h \cos \theta) \quad (21)$$

Equation (21) has a null at the interface, $\theta = \pi/2$.

Figure 4. Far-field radiation from a vertical magnetic dipole over a homogeneous half space. The reflection coefficient Γ_h applies to horizontal polarization.

For realistic (finite) ground parameters, the reflection coefficients for both vertical polarization Γ_v and horizontal polarization Γ_h equal -1 at grazing incidence ($\theta = \pi/2$). Hence the direct and reflected rays cancel in Eqs. (18) and (20), and the electric field is 0:

$$E_\theta|_{\theta=\pi/2} = 0 \quad \text{and} \quad E_\phi|_{\theta=\pi/2} = 0 \quad (22)$$

In reality, only the space wave (the inverse-distance field that occurs for $\theta > 0$) is 0 at the interface. The ground wave is the dominant field component near the interface, and it will be discussed in detail later. It has a more rapid decay with distance, but it does not equal 0 at the interface.

4. PLANE-WAVE REFRACTION

4.1. Dielectric Medium

Consider a plane wave incident on a dielectric half-space, as in Fig. 5. For simplicity, the dielectric is taken to be lossless ($\sigma = 0$) and nonmagnetic ($\mu = \mu_0$). The incident field propagates at an angle θ_0 to the normal, and the transmitted field is refracted at an angle θ_t to the normal. The angle of refraction is determined by requiring that the phases of the refracted field and the incident field maintain the same relationship at all points along the interface. This requirement is met if the tangential wave numbers in the two media are equal: $k_0 \sin \theta_0 = k \sin \theta_t$. For the case of a dielectric medium, this reduces to

$$\frac{\sin \theta_t}{\sin \theta_0} = \sqrt{\frac{\epsilon_0}{\epsilon}} \quad \text{or} \quad \theta_t = \sin^{-1} \left(\frac{\sin \theta_0}{n} \right) \quad (23)$$

where $n = \sqrt{\epsilon/\epsilon_0} = \sqrt{\epsilon_r}$ is the refractive index. Equation (23) is called Snell's law (14). As with the reflection coefficient, the transmission coefficient depends on the polarization of the incident field.

For horizontal polarization (electric field perpendicular to the plane of incidence), the electric field transmission

Figure 5. Reflection from and refraction into a dielectric half-space. The diffraction angle θ_t is determined from Snell's law.

coefficient T_h is given [1]

$$T_h = \frac{2 \cos \theta_0}{\cos \theta_0 + \sqrt{\epsilon_r - \sin^2 \theta_0}} \quad (24)$$

For vertical polarization (electric field parallel to the plane of incidence), the electric field transmission coefficient T_v is given by [1]

$$T_v = \frac{2\sqrt{\epsilon_r} \cos \theta_0}{\epsilon_r \cos \theta_0 + \sqrt{\epsilon_r - \sin^2 \theta_0}} \quad (25)$$

The magnetic field transmission coefficients are obtained by multiplying the electric field transmission coefficients in Eqs. (24) and (25) by $\sqrt{\epsilon_r}$.

4.2. Lossy Medium

Transmission into a lossy medium at oblique incidence is complicated by the fact that the planes of constant phase do not coincide with the planes of constant amplitude. Such a transmitted field is called an inhomogeneous plane wave [1]. To simplify the mathematics, the case of normal incidence, as shown in Fig. 6, will be considered.

For normal incidence the electric field is transverse to the z direction. The incident electric field E^i in the free-space region ($z > 0$) has unit amplitude:

$$E^i = \exp(jk_0z) \quad (26)$$

The reflected electric field E^r in the free-space region is

$$E^r = \Gamma_h|_{\theta_0=0} \exp(-jk_0z) \quad (27)$$

where Γ_h is given by Eq. (12). The transmitted electric field E^t in the lossy medium ($z < 0$) is

$$E^t = T \exp(jkz), \text{ where } k = \omega\sqrt{\mu(\epsilon - j\sigma/\omega)} \quad (28)$$

Figure 6. Reflection from and transmission into a lossy half-space for normal incidence.

The transmission coefficient T is given by

$$T = \frac{2\mu k_0}{\mu k_0 + \mu_0 k} \quad (29)$$

Equation (29) can be written compactly in terms of impedances:

$$T = \frac{2\eta}{\eta + \eta_0} \quad (30)$$

where η_0 is the free-space impedance and $\eta = \sqrt{\mu/(\epsilon - j\sigma/\omega)}$ is the impedance of the lossy medium. In general, T is complex, and the transmitted field undergoes both phase shift and reduction in amplitude.

As the transmitted field propagates into the lossy medium, it undergoes further attenuation and phase delay, as indicated by Eq. (28). The attenuation and phase shift can be isolated by normalizing the field to the value at the interface

$$\frac{E^t}{T} = \exp[\text{Im}(k)d] \exp[-j\text{Re}(k)d] \quad (31)$$

where Re indicates real part, Im indicates imaginary part, and $d = -z$ is the depth in the medium. The first exponential factor on the right side of Eq. (31) represents attenuation, and the second factor represents phase shift.

The skin depth δ is defined as the distance over which the amplitude of the field decreases to $1/e$ times its initial value. The expression for δ is

$$\delta = \frac{-1}{\text{Im}(k)} = \sqrt{\frac{2}{\sqrt{a^2 + b^2} - a}}, \text{ where } a = \omega^2\mu\epsilon \text{ and } b = \omega\mu\sigma \quad (32)$$

For a lossless medium ($\sigma = b = 0$), the skin depth δ is ∞ (no attenuation).

For the case where conduction currents dominate displacement currents ($\sigma \gg \omega\epsilon$), Eq. (32) simplifies to

$$\delta \approx \sqrt{\frac{2}{\omega\mu\sigma}} = \sqrt{\frac{1}{\pi f \mu\sigma}} \quad (33)$$

Equation (33) applies to high-conductivity metals, such as copper, and to soil and rock at low frequencies.

5. THROUGH-THE-EARTH PROPAGATION

The antenna and propagation issues are similar for subsurface communications [7] and geophysical probing of Earth [15]. Both applications require transmission of electromagnetic waves through Earth, and both face the problem of high attenuation. To penetrate Earth to depths of 100 m or more, it is necessary to employ frequencies below about 3 kHz (ELF). The reason for this is that the skin depth is proportional to $1/\sqrt{f}$, as indicated in Eq. (33). Although plane-wave propagation as discussed in the previous section gives valid results for distant sources, it does

not give valid quantitative results for the typical case where the transmitting antenna is located at or below the air–Earth interface. So this section will deal with the fields of surface or buried antennas.

At frequencies below 3 kHz, the free-space wavelength is greater than 100 km. Consequently, ELF antennas are electrically small even though they could be physically large. The methods and antennas used in geophysical probing are too varied to give a complete description. However, if we limit the applications to deep, subsurface probing and to through-Earth communication, then the most useful antennas are of two types: wire-loop antennas and straight-wire antennas grounded at the ends.

5.1. Fields of Loop Antennas

Loop antennas are commonly used in geophysical sounding and subsurface communications, and they have the advantage that no grounding is required. In geophysical sounding, loop antennas transmit a time-varying magnetic field into the earth, and eddy currents are excited in conducting bodies. These eddy currents generate a secondary magnetic field that can be received by a second loop antenna. In mine communications, transmitting loops can be used either at or below the Earth surface. Horizontal transmitting loops are typically a large, single turn of wire laid out on ground Earth. Various shapes, such as circular or rectangular, are used depending on the application. When the loop dimensions are small compared with the skin depth in Earth and the observer distance, the horizontal loop radiates as a vertical magnetic dipole.

A circular loop of radius a located at the earth surface ($z = 0$) is shown in Fig. 7. The earth conductivity is σ , and the magnetic permeability of both the air and Earth is μ_0 . For the low frequencies considered here, displacement currents are negligible, and the fields are independent of permittivity. This is called the quasistatic approximation and is obtained by setting the free-space wave number k_0 equal to 0. The wavenumber in Earth is approximated by $k \approx \sqrt{\omega\mu_0\sigma/j}$, where the square root is taken so that the imaginary part is negative.

When the circular loop carries a uniform current I , the nonzero field components are H_z , H_ρ , and E_ϕ . The vertical

Figure 7. Circular loop on a conducting half-space with a subsurface observer.

magnetic field H_z in Earth ($z < 0$) is of primary interest for downlink communication between horizontal loops. At a depth h and a horizontal distance d , H_z is given by [16]

$$H_z = \frac{IA}{2\pi h^3} Q \quad (34)$$

where

$$Q = \int_0^\infty \frac{g^3 e^{-\sqrt{g^2 + jH^2}}}{g + \sqrt{g^2 + jH^2}} J_0(gD) \frac{2J_1(ga/h)}{ga/h} dg \quad (35)$$

$H = \sqrt{\omega\mu_0\sigma h}$, $D = d/h$, and J_0 and J_1 are the zero- and first-order Bessel functions [17]. The integration variable g is a normalized wavenumber; so the integration in Eq. (35) can be interpreted as the result of a superposition of all the waves that the loop antenna transmits into Earth. The exponential factor is consistent with skin depth attenuation because for small g it is given by $|\exp(-\sqrt{jH^2})| = \exp(-h/\delta)$, where δ is given by Eq. (33).

When $a/h \ll 1$, the factor $2J_1(ga/h)/(ga/h)$ approaches 1 over the significant range of g . In that case the dependence on a enters only on through the loop area $A (= \pi a^2)$, and the loop radiates like a magnetic dipole of moment IA . If the loop is buried at a depth h and the observer is located at the surface (as in uplink communications), the result for H_z is identical.

For the special case of $H = a/h = 0$, the quantity Q reduces to the following result for a static magnetic dipole:

$$Q \Big|_{H=a/h=0} = \frac{2 - D^2}{2(1 + D^2)^{5/2}} \quad (36)$$

If, in addition, $D = 0$, then $Q = 1$. Thus Q is the vertical magnetic field normalized to the on-axis magnetic field of a static magnetic dipole. For $D = 0$, both H_ρ and E_ϕ are 0.

In general, the integration in Eq. (35) must be performed numerically. The infinite upper limit presents no practical difficulty because of the exponential decay for large g . Figure 8 shows the normalized vertical magnetic field magnitude $|Q|$ on the loop axis ($D = 0$) as a function of normalized depth H for a magnetic dipole source ($a/h = 0$). For large values of H , the field strength decays exponentially just as a plane wave does. For geophysical probing, vertical sounding [18] is accomplished by varying the frequency, and low frequencies are required to obtain information on earth conductivity at great depth.

In mine communication [7] and source location [8], the off-axis ($D > 0$) field is of interest. Figure 9 shows the dependence of the vertical magnetic field strength on normalized horizontal distance D . For the static case ($H = 0$), there is a null at $D = \sqrt{2}$, as shown in Eq. (36), and that null can be useful in source location [8]. For nonzero values of H , Q is complex, and the null is filled in.

The magnetic field results in Figs. 8 and 9 are actually valid for small loops of any shape that can be represented by a magnetic dipole. When the loop dimensions are large, the field depends strongly on shape. The theory has been developed for loops of arbitrary shape in a conducting medium that is homogeneous or layered [19]. Results for a loop of nonzero radius are shown in Fig. 10 for the static

Figure 8. Magnitude of the normalized vertical magnetic field of a small circular loop ($a = 0$) as a function of the normalized depth H on the axis ($D = 0$), (From Ref. 16.)

case ($H = 0$). As the loop radius is increased, the vertical magnetic field is reduced on the axis ($D = 0$), but is increased at the larger horizontal distances. A similar behavior occurs for nonzero values of H .

Also, similar results have been calculated for rectangular loops [19].

Figure 10. Magnitude of the normalized vertical magnetic field of a circular loop of radius a as a function of normalized distance D . (From Ref. 16.)

5.2. Fields of Grounded Wire Antennas

Grounded wire antennas are the other antenna type commonly used to transmit fields through Earth. In addition to geophysical sounding, these antennas are used for uplink and downlink communications in mines and for ELF communications with submarines [4]. A typical configuration is shown in Fig. 11. The antenna is of length $2l$, and the current I is assumed to be constant over the length of the antenna. This assumption is valid for insulated antennas grounded at the ends when the length of the antenna is much less than a free-space wavelength [20]. Because of the use of low frequencies, displacement currents are neglected in air and in the earth. The earth has conductivity σ and permeability μ_0 .

Figure 11. Electric line source on a conducting half space with a subsurface observer.

The subsurface electric and magnetic fields are both of interest in mine communication and in probing of geophysical features. In mine communication, the subsurface magnetic field is received with a loop antenna, or the subsurface electric field is received with a grounded wire antenna.

First consider the fields produced by an incremental current source of length dx' located at x' , as shown in Fig. 11. Because of the quasistatic approximation, the Sommerfeld integral forms for an incremental source of current moment $I dx'$ can be greatly simplified [21]. As a result, the magnetic field components are

$$dH_x = \frac{Idx'}{2\pi\gamma^2} \left(\frac{\partial^4 N}{\partial x \partial y \partial z^2} - \frac{\partial^3 P}{\partial x \partial y \partial z} \right) \quad (37)$$

$$dH_y = \frac{Idx'}{2\pi\gamma^2} \left(\frac{\partial^3 P}{\partial z^3} + \frac{\partial^3 P}{\partial x^2 \partial z} + \frac{\partial^4 N}{\partial z^2 \partial y^2} \right) \quad (38)$$

and

$$dH_z = \frac{Idx'}{2\pi\gamma^2} \left(\frac{\partial^4 N}{\partial y \partial z^3} - \gamma^2 \frac{\partial^2 N}{\partial y \partial z} - \frac{\partial^3 P}{\partial y \partial z^2} \right) \quad (39)$$

where $N = I_0[(\gamma/2)(R+z)]K_0[(\gamma/2)(R-z)]$, $P = R^{-1} \exp(-\gamma R)$, $R = \sqrt{(x-x')^2 + y^2 + z^2}$, $\gamma = \sqrt{j\omega\mu_0\sigma}$, and I_0 and K_0 are modified Bessel functions [17]. Similarly, the electric field components are

$$dE_x = \frac{-Idx'}{2\pi\sigma} \left(\frac{\partial^2 P}{\partial z^2} + \frac{\partial^3 N}{\partial y^2 \partial z} \right) \quad (40)$$

$$dE_y = \frac{Idx'}{2\pi\sigma} \frac{\partial^3 N}{\partial y \partial x \partial z} \quad (41)$$

and

$$dE_z = \frac{Idx'}{2\pi\sigma} \frac{\partial^2 P}{\partial x \partial z} \quad (42)$$

Although all six field components are, in general, nonzero, the dominant field components of interest are H_y , H_z , and E_x . These are the only nonzero components for a line source of infinite length, and all other field components vanish in the plane $x=0$, even for a line source of finite length. To obtain the fields of the entire line source, Eqs. (38)–(40) must be integrated over the range of x' from $-l$ to l . For normalization purposes, it is convenient to write the fields in the following forms:

$$H_y = \frac{I}{2\pi h} A(H, Y, X, L) \quad (43)$$

$$H_z = \frac{I}{2\pi h} B(H, Y, X, L) \quad (44)$$

and

$$E_x = \frac{-j\omega\mu_0 I}{2\pi} F(H, Y, X, L) \quad (45)$$

where $H = \sqrt{\omega\mu_0\sigma h}$, $Y = y/h$, $X = x/h$, $L = l/h$, and $h = -z$. The normalized quantities A , B , F , H , Y , X , and L are dimensionless. The specific forms for the normalized fields are

$$A(H, Y, X, L) = \frac{h}{\gamma^2} \int_{-l}^l \left(\frac{\partial^3 P}{\partial z^3} + \frac{\partial^3 P}{\partial x^2 \partial z} + \frac{\partial^4 N}{\partial z^2 \partial y^2} \right) dx' \quad (46)$$

$$B(H, Y, X, L) = \frac{h}{\gamma^2} \int_{-l}^l \left(\frac{\partial^4 N}{\partial y \partial z^3} - \gamma^2 \frac{\partial^2 N}{\partial y \partial z} - \frac{\partial^3 P}{\partial y \partial z^2} \right) dx' \quad (47)$$

and

$$F(H, Y, X, L) = \frac{1}{\gamma^2} \int_{-l}^l \left(\frac{\partial^2 P}{\partial z^2} + \frac{\partial^3 N}{\partial y^2 \partial z} \right) dx' \quad (48)$$

The integral forms in Eqs. (46)–(48) simplify for both the low-frequency (small H) and high-frequency (large H) cases [21], but numerical integration is required in general. Typical numerical results for $H=2$ are shown in Figs. 12–14. Although A , B , and F are complex for $H>0$, only the magnitudes are plotted. The phases are relatively constant as a function of L . For very small values of L , the fields are essentially those of a short dipole and are proportional to L , as indicated by Eqs. (38)–(40). For large L ,

Figure 12. Magnitude of the normalized horizontal magnetic field as a function of the normalized line length L . The dashed lines indicate the limit, $L = \infty$. From Ref. 16.

Figure 13. Magnitude of the normalized vertical magnetic field as a function of the normalized line length L . (From Ref. 16.)

the field components eventually reach those of an infinite line source [22]. The limits for large L are shown for the horizontal magnetic field as dashed lines in Fig. 12. In some geophysical applications, it is desirable to make the grounded wire long enough to simulate an infinitely long line source. An examination of Figs. 11–14 and other calculations [21] shows that this is approximately achieved

Figure 14. Magnitude of the normalized horizontal electric field as a function of the normalized line length L . (From Ref. 16.)

for L greater than ~ 2 . This means that the antenna length $2l$ should be at least 4 times the depth h of interest in a particular geophysical application.

Straight, grounded wires are also used to excite broadband, transient fields in Earth. To illustrate the dispersive nature of Earth, it is useful to examine the frequency dependence of the subsurface electric fields. The frequency dependence of all three components of the electric field has been analyzed [23], but only the dominant component E_x , will be considered here. Equations (45) and (48) can be recast in the following equivalent form

$$E_x = \frac{-I}{2\pi\sigma h^2} E_{xn}(W, L, X, Y) \tag{49}$$

where

$$E_{xn} = h^2 \int_{-l}^l \left(\frac{\partial^2 P}{\partial z^2} + \frac{\partial^3 N}{\partial y^2 \partial x} \right) dx' \tag{50}$$

and $W = \omega\mu_0\sigma h^2$. Equations (49) and (50) are consistent with Eqs. (45) and (48), but here the frequency dependence is explicitly displayed through the dimensionless frequency parameter W .

Some numerical results for $|E_{xn}|$ as a function of W are shown in Fig. 15. As W approaches 0, E_{xn} approaches the dc result E_{xn}^{dc} , which is obtained from the gradient of a scalar potential [23]

$$E_{xn}^{dc} = (L - X)R_1^{-3} + (L + X)R_2^{-3} \tag{51}$$

where

$$R_1 = \sqrt{(X - L)^2 + Y^2 + 1} \quad \text{and} \tag{52}$$

$$R_2 = \sqrt{(X + L)^2 + Y^2 + 1}$$

Figure 15. Magnitude of the normalized horizontal electric field of a horizontal line source as a function of the normalized frequency W .

When W becomes large, $|E_{xn}|$ decreases exponentially because the skin depth becomes small.

Straight, grounded wire antennas are also used underground. For example, long wire antennas have been laid out in mine tunnels for uplink transmission. The surface fields of such antennas have been computed for the general case where the antenna is not parallel to the air–earth interface [24] to model cases where either the tunnel or the Earth surface is not level.

6. GROUND-WAVE PROPAGATION

When both the transmitting and receiving antennas are located on the ground, the direct and reflected waves cancel. Consequently, the inverse-distance space wave is 0 as indicated in Eq. (22). In this case the ground wave is the dominant field component, and it can be calculated for either a flat-Earth model or a curved-earth model.

6.1. Flat-Earth Model

The flat-Earth model is useful for analyzing propagation along flat surfaces [25] or curved surfaces with very large radii of curvature (such as Earth). Consider a vertical electric dipole (VED) source located at an impedance surface, as shown in Fig. 16. The air region has free-space permittivity ϵ_0 , and free-space permeability μ_0 is assumed everywhere. The non-zero field components are E_z , and E_ρ , and H_ϕ .

For propagation analysis, Earth can be characterized by a surface impedance Z_s under fairly general conditions. The surface impedance is the ratio of the horizontal electric and magnetic fields at the earth surface: $Z_s = -(\mathbf{E}_\rho/H_\phi)|_{z=0}$. For the two-layer model shown in Fig. 16, the surface impedance for grazing incidence (as in ground-wave propagation) is given by [26]

$$Z_s = Z_1 Q \quad (53)$$

where

$$Z_1 = \eta_1 \sqrt{1 - \frac{\eta_1^2}{\eta_0^2}} \quad (54)$$

Figure 16. Vertical electric dipole source at the surface of a two-layer half-space. The surface impedance Z_s depends on the properties of both layers.

$$Q = \frac{(u_2/u_1) + (\gamma_2^2/\gamma_1^2) \tanh u_1 h_1}{(\gamma_2^2/\gamma_1^2) + (u_2/u_1) \tanh u_1 h_1} \quad (55)$$

$$\eta_1 = \sqrt{\frac{\mu_0}{\epsilon_1 - j\sigma_1/\omega}}, \quad u_1 = \sqrt{\gamma_1^2 + k_0^2}, \quad u_2 = \sqrt{\gamma_2^2 + k_0^2}, \quad \gamma_1^2 = j\omega\mu_0(\sigma_1 + j\omega\epsilon_1)$$

and $\gamma_2^2 = j\omega\mu_0(\sigma_2 + j\omega\epsilon_2)$. The layer thickness h_1 and the layer constitutive parameters are defined in Fig. 16. Q is a correction factor to account for the layering, and $Q = 1$ for a homogeneous earth. For any passive Earth model, the real part of the surface impedance must be nonnegative: $\text{Re}(Z_s) \geq 0$. For a homogeneous Earth, the phase of Z_s ranges from 0 to $\pi/4$. For a layered Earth, the phase of Z_s can range from $-\pi/2$ to $\pi/2$.

At large distances from the source ($k_0\rho \gg 1$), the dominant vertical electric field component E_z can be written [26]

$$E_z = \frac{-j\omega\mu_0 I l}{2\pi\rho} e^{-jk_0\rho} F(p) \quad (56)$$

where

$$F(p) = 1 - j\sqrt{\pi p} e^{-p} \text{erfc}(j\sqrt{p}) \quad (57)$$

$p = (-jk_0\rho/2)\Delta^2$, $\Delta = Z_s/\eta_0$, and erfc is the complementary error function (17). The function $F(p)$ is called the Sommerfeld attenuation function and is actually a correction to the field of a vertical electric dipole located at the surface of a perfectly conducting plane. The quantity p is dimensionless and called the numerical distance. For $|p| \ll 1$, we obtain $F(p) \approx 1$.

For large numerical distance ($|p| \gg 1$), the asymptotic form of F depends on the phase of p [26]:

$$F(p) \approx -\frac{1}{2p}, \quad -3\pi/2 \leq \text{phase}(p) \leq 0 \quad (58)$$

or

$$F(p) \approx -2j\sqrt{\pi p} e^{-p} - \frac{1}{2p}, \quad 0 < \text{phase}(p) \leq \pi/2 \quad (59)$$

The first term on the right side of Eq. (59) corresponds to a trapped surface wave [26] that can occur when the surface impedance is highly inductive (phase of $\Delta > \pi/4$). It does not occur for a homogeneous Earth, as indicated in Eq. (58). If Eq. (58) is substituted into Eq. (56), the following result is obtained for the electric field:

$$E_z \approx \frac{\eta_0 I l}{2\pi\rho^2 \Delta^2} e^{-jk_0\rho} \quad (60)$$

The ρ^{-2} dependence of the field in Eq. (60) is characteristic of a lateral wave that requires an interface to support it. A similar analysis is possible for horizontal polarization as produced by a horizontal electric dipole or vertical magnetic dipole source [26], but it is of less interest for

Figure 17. Elevated source and observer for propagation over a flat surface with surface impedance Z_s .

ground-wave propagation because it decays more rapidly with distance than vertical polarization.

If the height of either the transmitting dipole or the observer is raised above the interface, the field is increased by a factor called the height-gain function G [26]. Consider the case shown in Fig. 17, where both the source and observer are elevated. Then the electric field can be approximately written

$$E_z = \frac{-j\omega\mu_0 l l}{2\pi\rho} e^{-jk_0\rho} F(\rho) G(h) G(z) \quad (61)$$

where

$$G(h) = 1 + jk_0\Delta h \quad \text{and} \quad G(z) = 1 + jk_0\Delta z \quad (62)$$

By reciprocity, the height-gain function G is the same for the source and observer. Equation (62) is valid only for small heights ($k_0|\Delta|h \ll 1$).

6.2. Spherical Earth

The spherical-Earth model is used to account for diffraction loss that occurs for ground-wave propagation into the shadow region. The mathematical theory is complicated, but it has been well developed [26] and has been used to generate extensive numerical results for field strength as a function of distance, frequency, and Earth surface properties [27–29]. For short paths, the flat-Earth and spherical-Earth models give similar results, but for long paths the spherical-Earth model must be used for accurate predictions.

The geometry for a radial electric dipole source located at the surface of a sphere of radius a is shown in Fig. 18. The surface is characterized by a surface impedance Z_s , which can be determined by Eqs. (53)–(55) for a layered Earth. The non-zero field components are E_r , E_θ , and H_ϕ . The radial electric field E_r is the component of most interest, and its value at the surface ($r = a$) is

$$E_r = \frac{-j\omega\mu_0 l l}{2\pi d} e^{-jk_0 d} W \quad (63)$$

where d is the arc distance along the surface and W is the spherical-Earth attenuation function. It is a correction to the field of a vertical electric dipole on a perfectly conducting plane in the same manner as F for the flat Earth in Eq. (56). For large $k_0 a$ and $k_0 d$, W can be written as the classical residue series [25]

$$W = \sqrt{\frac{\pi x}{j}} \sum_{s=1}^{\infty} \frac{\exp(-jx t_s)}{t_s - q^2} \quad (64)$$

Figure 18. Vertical electric dipole source at the surface of a spherical earth with a surface impedance Z_s .

where $x = (k_0 a/2)^{1/3}(d/a)$, $q = -j(k_0 a/2)^{1/3}\Delta$, and $\Delta = Z_s/\eta_0$. The roots t_s satisfy the equation

$$w_1'(t_s) - q w_1(t_s) = 0 \quad (65)$$

where w_1 is an Airy function and w_1' is the derivative with respect to the argument. The Airy function w_1 is defined by

$$w_1(t) = \sqrt{\pi} [Bi(t) - jAi(t)] \quad (66)$$

where Ai and Bi are the Airy functions defined by Miller [30]. A systematic method for determining the roots of Eq. (65) has been presented for arbitrary values of the magnitude and phase of q [27].

The residue series in Eq. (64) is valid for any value of x , but converges slowly for small values of x . Two alternative methods are available for the calculation of W for small x . The power series in $x^{1/2}$ is most useful for small $|q|$, and the small-curvature expansion is most useful for large $|q|$.

The power series representation for W is given by (27,31)

$$W = \sum_{m=0}^{\infty} A_m (e^{j\pi/4} q x^{1/2})^m \quad (67)$$

where

$$A_0 = 1, \quad A_1 = -j\pi^{1/2}, \quad A_2 = -2$$

$$A_3 = j\pi^{1/2} \left(1 + \frac{1}{4q^3}\right), \quad A_4 = \frac{4}{3} \left(1 + \frac{1}{2q^3}\right)$$

$$A_5 = -\frac{j\pi^{1/2}}{2} \left(1 + \frac{3}{4q^3}\right), \quad A_6 = -\frac{8}{15} \left(1 + \frac{1}{q^3} + \frac{7}{32q^6}\right)$$

$$A_7 = \frac{j\pi^{1/2}}{6} \left(1 + \frac{5}{4q^3} + \frac{1}{2q^6}\right), \quad A_8 = \frac{16}{105} \left(1 + \frac{3}{2q^3} + \frac{27}{32q^6}\right)$$

$$A_9 = \frac{-j\pi^{1/2}}{24} \left(1 + \frac{7}{4q^3} + \frac{5}{4q^6} + \frac{21}{64q^9}\right)$$

and

$$A_{10} = - \left(\frac{32}{945} + \frac{64}{945q^3} + \frac{11}{189q^6} + \frac{7}{270q^9} \right)$$

In the numerical results to follow, the series has been truncated at $m = 10$ because higher-order coefficients A_m are not available in the literature.

The small-curvature expansion for W is given by [31,32]

$$W = F(p) + \frac{1}{4q^3} [1 - j\sqrt{\pi p} - (1 + 2p)F(p)] + \frac{1}{4q^6} \left[1 - j\sqrt{\pi p}(1 - p) - 2p + \frac{5p^2}{6} + \left(\frac{p^2}{2} - 1 \right) F(p) \right] \tag{68}$$

where $p = jxq^2 = -jk_0d\Delta^2/2$ and the flat-earth attenuation function $F(p)$ is given by Eq. (57). When the radius a approaches ∞ (zero curvature), q approaches ∞ , and W approaches F . An additional term in Eq. (68) proportional to q^{-9} has been obtained [31], but numerical results [27] indicate that it adds little improvement.

To illustrate the range of applicability of the various methods for computing W , a specific example for propagation at a frequency of 10 MHz is considered. The effective Earth radius a is taken to be 4/3 times the actual Earth radius of 6368 km in order to account for normal atmospheric refraction [33]. The magnitude of the normalized surface impedance $|\Delta| = 0.1$; this yields a value of 9.62 for the magnitude of q . For the phase of Δ , two values, 30° and 75° , are considered. The 30° value (phase of $q = -60^\circ$) lies in the range encountered for a typical homogeneous earth. The 75° value (phase of $q = -15^\circ$) lies in the highly inductive region, where a trapped surface wave is important. Numerical results for the magnitude of W as a function of distance are shown in Fig. 19, where the computations were carried out by four different methods. The oscillations in the vicinity of $d = 10$ km for the phase $(\Delta) = 75^\circ$ curve are due to interference between the trapped surface wave and the usual ground wave.

Figure 19. Magnitude of the spherical-Earth attenuation function as computed by various methods. (Results are shown outside their regions of validity for comparison purposes.) (From Ref. 27.)

Although the curve for phase $(\Delta) = 75^\circ$ contains more structure than that for phase $(\Delta) = 30^\circ$, the range of validity of the various computational methods depends only weakly on the phase of Δ . For graphical accuracy in Fig. 19, the different methods have the following ranges of validity. The residue series calculation from Eq. (64) using 50 terms is valid for d greater than about 10 km ($x > 0.11$). This value of d or x can always be decreased by increasing the number of terms. The small-curvature formula in Eq. (68) is valid for d less than ~ 50 km ($x < 0.57$). The power series in Eq. (67) is valid for d less than ~ 1 km ($x < 0.011$). The flat-Earth approximation in Eq. (57), which is the first term in Eq. (68), is valid for d less than ~ 15 km ($x < 0.17$). The characteristic of the flat-Earth approximation for large d is an algebraic decay (d^{-2}) as opposed to the correct exponential decay of the first term of the residue series. The small-curvature formula is far superior to the power series in this example because of the large value of $|q| = 9.62$.

Further calculations (27,34) reveal the following general criteria for the method of calculation. The residue series is most useful for $x > 0.2$ regardless of the magnitude of q . For $|x| < 0.2$, the power series is better for $|q| < 1$, and the small-curvature formula is better for $|q| > 1$. The phase of q does not have to be considered in deciding which method of calculation to use for W .

The magnitude of W as a function of d is shown in Fig. 20 for a larger value of $|\Delta| = 0.2$ and for numerous values of phase (Δ) . The results for $0^\circ \leq \text{phase } (\Delta) \leq 45^\circ$ show the expected smooth decay of the ground wave, but the trapped surface wave has a dominant effect for phase $(\Delta) > 45^\circ$. The root t_0 for the trapped surface wave, also called the Elliott mode [35], has the following asymptotic expansion [27] for large $|q|$:

$$t_0 \sim q^2 + \frac{1}{2q} + \frac{1}{8q^4} + \frac{5}{32q^7} + \frac{11}{32q^{10}} + \frac{539}{512q^{13}} - j2q^2 \exp \left(-\frac{4}{3}q^3 - 1 - \frac{7}{12q^3} - \frac{31}{48q^6} - \frac{397}{288q^9} \right) \tag{69}$$

Figure 20. Magnitude of the spherical-Earth attenuation function for different values of the phase of the surface impedance. (From Ref. 27.)

Part of the reason for interest in inductive surface impedances is in modeling propagation over a layer of sea ice on the ocean [29].

The residue series in Eq. (64) can be generalized to the case of an elevated source and an elevated observer. For a source height of h_0 and an observer height of h , W takes the following form [28,29]

$$W = \sqrt{\frac{\pi x}{j}} \sum_{s=1}^{\infty} \frac{\exp(-jxt_s)}{t_s - q^2} G_s(y_0) G_s(y) \quad (70)$$

where

$$G_s(y) = \frac{w(t_s - y)}{w(t_s)} \quad (71)$$

$y_0 = k_0 h_0 (2/k_0 a)^{1/3}$, and $y = k_0 h (2/k_0 a)^{1/3}$. Since G_s depends on t_s , it is a function of s . G_s as given by Eq. (71) can be expanded in a power series in y [28,29]:

$$G_s(y) = 1 - qy + \frac{t_s}{2} y^2 - \frac{1 + t_s q}{6} y^3 + \dots \quad (72)$$

For low heights and small values of s , G_s can be approximated by the first two terms in Eq. (72):

$$G_s \approx 1 - qy = 1 + jk_0 \Delta h \quad (73)$$

G_s as approximated by Eq. (73) is independent of s and is equal to the height-gain function for the flat-Earth model in Eq. (62).

7. VARIABLE TERRAIN

Although the flat-Earth and spherical-Earth models are useful for analyzing ground-wave propagation, many propagation paths involve variable terrain where the ground properties or surface height vary along the path. The analysis of such paths usually requires approximate or numerical methods [36–39].

7.1. Mixed Path

Mixed-path theory has been developed to analyze smooth terrain that has a change in the Earth properties (conductivity and permittivity) between the source and the receiver. The mathematical theory has been developed for both a flat Earth [40] and a spherical Earth [41] but only the more general spherical-Earth model will be considered here.

The geometry for a two-section path is shown in Fig. 21. Propagation along a three-section path [41] has also been analyzed, but will not be covered here. As in the previous section, the radial electric field E_r is normalized to the case of a flat, perfectly conducting plane.

$$E_r = \frac{-j\omega\mu_0 I l}{2\pi d} e^{-jk_0 d} W'(x, q, q_1) \quad (74)$$

where W' is the mixed-path attenuation function, $q = -j(k_0/a)^{1/3} \Delta$, $q_1 = -j(k_0/a)^{1/3} \Delta_1$, $\Delta = Z_s/\eta_0$, $\Delta_1 = Z_{s1}/\eta_0$,

Figure 21. Propagation along a spherical Earth with a change in surface impedance from Z_s to Z_{s1} .

and a is the Earth radius. Consider first the case, where the source and observer are located at the surface ($h = h_1 = 0$). In this case, the following form of W' is most useful [42,43]

$$W'(x, q, q_1) = W(x, q) + \sqrt{\frac{x}{j\pi}} (q_1 - q) \int_0^{x_1} \frac{W(x - \hat{x}, q) W(\hat{x}, q_1)}{\sqrt{\hat{x}(\hat{x} - x)}} d\hat{x}, d_1 > 0 \quad (75)$$

where

$$W(x, q) = \sqrt{\frac{\pi x}{j}} \sum_{s=1}^{\infty} \frac{\exp(-jxt_s)}{t_s - q^2} \quad (76)$$

$x = (k_0 a/2)^{1/3} (d/a)$, and $x_1 = (k_0 a/2)^{1/3} (d_1/a)$. The spherical-Earth attenuation function in Eq. (76) is the same as that for the uniform path in Eq. (64), but the arguments are shown explicitly for use in Eq. (75). The square-root singularity in Eq. (75) is integrable, and its numerical evaluation [42] presents no difficulty. A useful alternative to Eq. (75) can be obtained by reciprocity [41]:

$$W'(x, q, q_1) = W(x, q_1) + \sqrt{\frac{x}{j\pi}} (q - q_1) \int_0^{x-x_1} \frac{W(x - \hat{x}, q_1) W(\hat{x}, q)}{\sqrt{\hat{x}(\hat{x} - x)}} d\hat{x} \quad (77)$$

Equations (75) and (77) have been used to calculate W' for a variety of paths and parameters [42]. Results for $|W'|$ are shown in Fig. 22 for propagation along a land-to-sea path for various lengths of the land section. The frequency is 10 MHz, the land constants are $\epsilon/\epsilon_0 = 15$ and $\sigma = 0.01$ S/m, and the sea constants are $\epsilon_1/\epsilon_0 = 80$ and $\sigma_1 = 4$ S/m. The increase in field strength that occurs in crossing the land-sea boundary has been called the recovery effect, and it has been observed experimentally by Millington [43]. A similar drop in phase has been calculated [42] and observed experimentally by Pressey et al. [44]. In Fig. 23, the length of the land section is fixed at 5 km, and the frequency is varied from 1 to 30 MHz. The recovery effect is most prominent at 30 MHz because the attenuation over land is so rapid at that frequency.

When either height, h or h_1 , is nonzero, Eqs. (75) and (77) are still valid, but W needs to be modified by the

Figure 22. Magnitude of the attenuation function for a land-to-sea path for various lengths of the land section. Parameters: $f = 10$ MHz, $h = h_1 = 0$, $\epsilon/\epsilon_0 = 15$, $\sigma = 10^{-2}$ S/m, $\epsilon_1/\epsilon_0 = 80$, and $\sigma_1 = 4$ S/m. (From Ref. 42.)

appropriate height-gain function

$$W(x, q) = \sqrt{\frac{\pi x}{j}} \sum_{s=1}^{\infty} \frac{\exp(-jxt_s)}{t_s - q^2} \frac{w_1(t_s - y)}{w_1(t_s)}, \quad (78)$$

where $y = (2/k_0 a)^{1/3} k_0 h$

and

$$W(x, q_1) = \sqrt{\frac{\pi x}{j}} \sum_{s=1}^{\infty} \frac{\exp(-jxt_s)}{t_s - q_1^2} \frac{w_1(t_s - y)}{w_1(t_s)}, \quad (79)$$

where $y_1 = (2/k_0 a)^{1/3} k_0 h_1$

Figure 23. Magnitude of the attenuation function for a land-to-sea path for various frequencies. Parameters: $d - d_1 = 5$ km, $h = h_1 = 0$, $\epsilon/\epsilon_0 = 15$, $\sigma = 10^{-2}$ S/m, $\epsilon_1/\epsilon_0 = 80$, and $\sigma_1 = 4$ S/m. (From Ref. 42.)

It is possible to cast the integral forms of Eqs. (75) and (77) into a modal sum of the following form [42]

$$W'(x, q, q_1) = \sqrt{\frac{\pi x}{j}} (q_1 - q) \sum_{s=1}^{\infty} \sum_{t=1}^{\infty} \frac{\exp[-j(x - x_1)t_s - jx_1 t_r^{(1)}]}{(t_r^{(1)} - t_s)(t_s - q^2)(t_r^{(1)} - q_1^2)} \frac{w_1(t_s - y)}{w_1(t_s)} \frac{w_1(t_r^{(1)} - y_b)}{w_1(t_r^{(1)})} \quad (80)$$

where the roots $t_r^{(1)}$ satisfy the mode equation that is similar to Eq. (65):

$$w_1'(t_r^{(1)}) - q_1 w_1(t_r^{(1)}) = 0 \quad (81)$$

The double summation in Eq. (80) converges slowly when either x_1 , or $x - x_1$ is small, but the roots t_s and $t_r^{(1)}$ can be computed rapidly (27).

Results for $|W'|$ are shown in Fig. 24 for propagation along a land-to-sea path for various observer heights. The length of the land section is 10 km. As many as 600 roots, t_s and $t_r^{(1)}$, were used in computing the results [42] in Fig. 24. A good confirmation of the validity of the numerical results in Fig. 24 as computed by Eq. (80) is that the curve for $h_1 = 0$ agrees with the corresponding curve in Fig. 22 as computed by Eq. (75). As the observer height h_1 is increased, the recovery effect decreases in magnitude and begins at a range beyond the land-sea boundary.

Figure 24. Magnitude of the attenuation function for a land-to-sea path for various observer heights. Parameters: $f = 10$ MHz, $d - d_1 = 10$ km, $h = 0$, $\epsilon/\epsilon_0 = 15$, $\sigma = 10^{-2}$ S/m, $\epsilon_1/\epsilon_0 = 80$, and $\sigma_1 = 4$ S/m. (From Ref. 42.)

7.2. Irregular Terrain

For many propagation paths, the ground parameters and terrain height vary as a function of position along the path. Analytical methods are not general enough to handle such variations, but the integral equation approach [45,46] has been found useful for ground-wave propagation over irregular, inhomogeneous terrain. Ott's program WAGNER has been thoroughly tested and used on a wide variety of paths [47], and Hill has generalized it to allow for an anisotropic layer over a homogeneous Earth [48]. The anisotropic layer is intended to model a forest layer, snowcover, or a layered Earth.

The general terrain model is shown in Fig. 25. The terrain height y , the slab thickness D , and the slab and ground constitutive parameters are functions of the horizontal distance ξ from the vertical electric dipole source. The terrain is represented by a normalized surface impedance Δ (referred to the top of the slab), which is a function of the slab and ground parameters and is thus a function of ξ . The problem is first solved by considering the case where the source and observer are located at the surface ($h_a = h_r = 0$). The vertical electric field E_y is normalized to the field of a vertical electric dipole on a conducting plane

$$E_y = \frac{-j\omega\mu_0 I l}{2\pi x} e^{-jk_0 x} f(x) \quad (82)$$

where $f(x)$ is the attenuation to be determined from the integral equation. The integral equation is [47,48]

$$f(x) = F(x, 0) - \sqrt{\frac{jk_0}{2\pi}} \int_0^x f(\xi) e^{-jk_0 \phi(x, \xi)} \left(y'(\xi) F(x, \xi) - \frac{y(x) - y(\xi)}{x - \xi} + [\Delta(\xi) - \Delta_a] F(x, \xi) \right) \frac{\sqrt{x}}{\sqrt{\xi(x - \xi)}} d\xi \quad (83)$$

Figure 25. Geometry for the integral equation solution of propagation over irregular, inhomogeneous terrain. The slab and ground parameters can vary as a function of x , but are constant in y .

where

$$\phi(x, \xi) = \frac{[y(x) - y(\xi)]^2}{2x(x - \xi)} + \frac{y^2(\xi)}{2\xi} - \frac{y^2(x)}{2x}$$

$$F(x, \xi) = 1 - j\sqrt{\pi p} e^{-u} \operatorname{erfc}(j\sqrt{u})$$

$$p = -jk_0 \Delta^2(\xi)(x - \xi)/2, \quad u = p \left(1 - \frac{y(x) - y(\xi)}{\Delta(\xi)(x - \xi)} \right)^2$$

and $y'(\xi)$ is the slope $dy/d\xi$. The normalized surface impedance $\Delta(\xi)$ is a function of the slab and ground parameters [48]

$$\Delta(\xi) = \Delta_1 \frac{\Delta_2 + \Delta_1 \tanh(v_0 D)}{\Delta_1 + \Delta_2 \tanh(v_0 D)} \quad (84)$$

where

$$\Delta_1 = \frac{\sqrt{\varepsilon_{hc} - \kappa}}{\varepsilon_{hc}}, \quad \Delta_2 = \frac{\sqrt{\varepsilon_{gc} - 1}}{\varepsilon_{gc}}, \quad v_0 = jk_0 \sqrt{\varepsilon_{hc} - \kappa}$$

$$\varepsilon_{hc} = \varepsilon_h + \sigma_h / (j\omega\varepsilon_0), \quad \varepsilon_{gc} = \varepsilon_g + \sigma_g / (j\omega\varepsilon_0),$$

$$\varepsilon_{vc} = \varepsilon_v + \sigma_v / (j\omega\varepsilon_0), \quad \kappa = \varepsilon_{hc} / \varepsilon_{vc}$$

σ_v and ε_v are the vertical conductivity and relative permittivity of the slab, σ_h and ε_h are the horizontal conductivity and relative permittivity of the slab, and σ_g and ε_g are the conductivity and permittivity of the ground. The ground and the slab have free-space permeability μ_0 . The normalized surface impedance Δ_a is evaluated at the source.

Before discussing the numerical solution of Eq. (83), it is useful to examine the special case of a uniform path: $y(\xi) = y(x) = y'(\xi) = 0$ and $\Delta(\xi) = \Delta_a$. Thus the integrand is 0, and $f(x)$ is

$$f(x) = F(x, 0) = 1 - j\sqrt{\pi p_a} e^{-p_a} \operatorname{erfc}(j\sqrt{p_a}) \quad (85)$$

where $p_a = -jk_0 \Delta_a^2 x^2 / 2$. Equation (85) agrees with the flat-earth result in Eq. (56). When either y or Δ varies along the path, the integral equation must be solved numerically. A forward-stepping solution [49] in x is used to obtain values of f at discrete values of x along the path. Since Eq. (83) is a Volterra integral equation of the second kind, the value of $f(x)$ depends only on the previously computed values of $f(\xi)$ for $\xi < x$. Physically this means that backscatter is neglected.

To account for nonzero source and receiver heights, h_a and h_r , an attenuation function f_h is determined by use of height-gain functions G_s for a slab medium [48]:

$$f_h(x) = f(x) G_s(h_a) G_s(h_r) \quad (86)$$

The source and receiver can be located either in air (positive height) or in the slab (negative height). For the source or receiver in air, the height-gain function is

$$G_s(h) = 1 + jk_0 \Delta h, \quad h \geq 0 \quad (87)$$

where Δ is evaluated at the appropriate source or receiver location. For the source or receiver in the slab, the height-gain function is

$$G_s(h) = \frac{1}{\epsilon_{vc}} \frac{e^{v_0 z} + R e^{-v_0(2D+h)}}{1 + R e^{-2v_0 D}}, \quad -D < h < 0 \quad (88)$$

where $R = (\Delta_1 - \Delta_2) / (\Delta_1 + \Delta_2)$. The limit of G_s as h approaches 0 from above is 1:

$$G_s(0^+) = 1 \quad (89)$$

The limit of G_s as h approaches 0 from below is

$$G_s(0^-) = 1/\epsilon_{vc} \quad (90)$$

This is a consequence of the continuity of normal current flow.

The numerical solution of Eq. (83) has been thoroughly studied, and comparisons with experimental results have been shown [47,48]. Also, a comparison with an approximate analysis for propagation from a forest to a clearing has been made. This comparison provides an independent check because the approximate solution uses a Kirchhoff integration over the vertical aperture above the forest-clearing boundary [48] in contrast to the integral equation

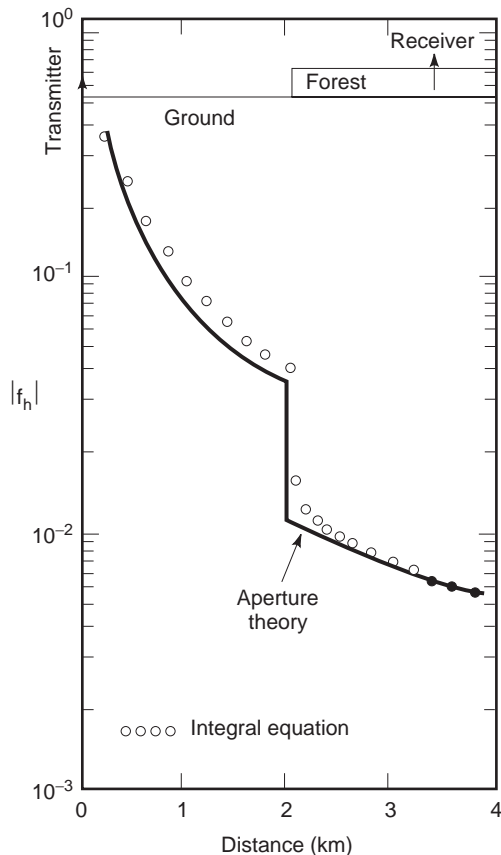

Figure 26. Propagation from a clearing to a forest at a frequency of 10 MHz. (From Ref. 48.)

solution, which integrates over the terrain surface. The numerical comparison for $|f_h|$ is shown in Fig. 26. The frequency is 10 MHz, the ground parameters are $\sigma_g = 10^{-2}$ S/m and $\epsilon_g = 10$, and the slab parameters are $D = 10$ m, $\sigma_h = 10^{-4}$ S/m, $\epsilon_h = 1.1$, $\sigma_v = 2.5 \times 10^{-4}$, and $\epsilon_v = 1.25$. Both the source and receiver are located at a height of 10^+ m. The approximate aperture theory shows a non-physical jump for the receiver at the forest boundary, but the more accurate integral equation solution smooths out the jump. Away from the boundary the two solutions agree well.

For typical terrain profiles and moderate path lengths (less than 100 km), the numerical solution of Eq. (83) is reasonably accurate and efficient for frequencies up to about 10 MHz. At higher frequencies the numerical solution can become unstable and predict a nonphysical oscillatory field strength as a function of distance. Also, the computer run time, which is roughly proportional to frequency squared, can become large. To improve the stability at higher frequencies, Ott [50] has modified the integral equation and computer code and has obtained stable numerical results for frequencies up to about 100 MHz.

7.3. Knife-Edge Diffraction

At high frequencies where the wavelength is small compared to terrain features and other obstacles such as buildings, knife-edge diffraction models [51] can provide useful field predictions. The simplest model is based on a single knife edge, as shown in Fig. 27. If the Kirchhoff approximation that the field in the semiinfinite aperture above the knife edge is equal to the incident field is made, then the aperture integration can be approximated with the following result for the diffracted field E_d at the receiver location R [14]:

$$E_d = E_0 F(v) = E_0 \frac{1+j}{2} \int_v^\infty \exp(-j\pi t^2/2) dt, \quad (91)$$

$$\text{where } v = h \sqrt{\frac{2(d_1 + d_2)}{\lambda_0 d_1 d_2}}$$

E_0 is the free-space field in the absence of the knife edge and $F(v)$ is the complex Fresnel integral. When the knife edge extends above the line connecting S and R (as in Fig. 27), h and v are positive. In this case, $|F| < 1/2$. When the top of the knife edge is below the line connecting S and R , h and v are negative. In this case, $|F| > 1/2$. As v approaches $-\infty$, $|F|$ approaches 1 in an oscillatory manner. The diffraction gain (in decibels) due to the presence of the

Figure 27. Geometry for diffraction by single knife edge.

knife edge is

$$G_d = 20 \log_{10} |F(v)| \quad (92)$$

To avoid computation of the Fresnel integral in Eq. (92), Lee [51] has provided simple approximations for F . The geometric theory of diffraction [52] provides a more rigorous high-frequency method for analyzing diffraction from knife edges and wedges, and it predicts results that depend on the polarization of the incident field.

A number of extensions to the single knife-edge model in Fig. 27 have been studied. The knife edge can be replaced by a rounded diffracting obstacle [53,54], which is a better model for broad-terrain features in some cases. Multiple knife edges [55–57] can be used to model paths with multiple diffracting obstacles. Vogler's analysis [58] is valid for an arbitrary number of knife edges, and his computer code will handle up to 10 knife edges.
