respectively. Thus, the output obtained at each frequency ω_1 and ω_2 , is dependent on the amplitude of the signal component of the other frequency. If the amplitude of the wanted unmodulated carrier is V_1 and the instantaneous amplitude of the unwanted amplitude-modulated carrier is

$$V_2(t) = V_2(1 + m \cos \omega_m t) \quad (15)$$

then, using Eq. (13), the amplitude of the wanted carrier will be

$$b_1 = k_1 V_1 + \frac{3}{4} k_3 V_1^3 + \frac{3}{2} k_3 V_1 V_2^2 (1 + m \cos \omega_m t)^2 \quad (16)$$

For small values of m and with $k_3 \ll k_1$, Eq. (16) can be approximated by

$$b_1 \cong k_1 V_1 + 3k_3 V_1 V_2^2 m \cos \omega_m t \quad (17)$$

Thus the wanted carrier will be modulated by a modulation index

$$p = 3 \frac{k_3}{k_1} V_2^2 m \quad (18)$$

The cross-modulation factor is then defined as

$$K = \frac{p}{m} \quad (19)$$

Thus, one frequency will be modulated by the modulation of the other frequency. Similar results can be obtained if the unwanted carrier is FM-modulated.

Cross-modulation can be measured as the change in the amplitude of the wanted unmodulated carrier as a function of the amplitude of the unwanted unmodulated carrier. This is the procedure recommended by the NCTA (National Cable Television Association) standard cross-modulation measurement [63]. Alternatively, cross-modulation can be measured using the definition of Eq. (19): measuring percentage modulation that appears on an unmodulated desired carrier due to the presence of an undesired modulated carrier, divided by the percentage modulation on the undesired carrier [64].

Cross-modulation can also be measured using two equal-amplitude carriers. The wanted carrier, ω_2 , is unmodulated while the unwanted carrier, ω_1 , is FM-modulated. The output spectrum clearly shows the frequency deviation of the wanted carrier. Moreover, it can be shown that the frequency deviation of the intermodulation components, of the output spectrum, is larger than that of the original FM-modulated unwanted carrier. For the intermodulation product of frequency $\alpha\omega_1 \pm \beta\omega_2$, the deviation will be multiplied by α . Thus, it may be easier to measure the cross-modulation by measuring the deviation of an intermodulation product rather than the deviation of the wanted unmodulated carrier [65].

7.1.6. Differential Gain. *Differential gain* (DG), a parameter of special interest in color-TV engineering, is conventionally defined as the difference in gain encountered by a low-level high-frequency sinusoid at two stated instantaneous amplitudes of a superimposed slowly varying sweep signal. In video signal transmission, the high-frequency sinusoid represents the chromatic signal and the low-frequency sinusoid represents the luminance signal. Corresponding to the theoretical conditions of the differential measurement, DG measurement is performed by a signal of the form of Eq. (3) with $\omega_2 \gg \omega_1$ and $V_2 \rightarrow 0.0$ at $V_1 = 0.0$ and X [66]. Therefore, recalling that when the input to a nonlinear system is formed of a two-tone signal of the form of Eq. (3), the amplitude of the output component at frequency ω_2 will be given by

$$c_1 = k_1 V_2 + \frac{3}{4} k_3 V_2^3 + \frac{3}{2} k_3 V_1^2 V_2 \quad (20)$$

Thus, DG can be expressed as

$$DG = 1 - \frac{k_1 + \frac{3}{4} k_3 V_2^2}{k_1 + \frac{3}{4} k_3 V_2^2 + \frac{3}{2} k_3 X^2} \quad (21)$$

DG can, therefore, be considered to some extent as a measure of the intermodulation performance of a system under test.

7.1.7. Dynamic Range. *Dynamic range* can be defined as the amplitude range over which a circuit or a system can operate without performance degradation. The minimum amplitude is dictated by the input thermal noise and the noise contributed by the system. The maximum amplitude is dictated by the distortion mechanisms of the system under consideration. In general, the amount of

tolerable distortion will depend on the type of signal and the system under test. However, for the purpose of an objective definition the maximum amplitude will be considered the input signal level at which the intermodulation distortion is equal to the minimum amplitude [67]. The dynamic range can, therefore, be considered to some extent as a measure of the intermodulation performance of a system under test.

A useful working definition of the dynamic range is that it is (1) two-thirds of the difference in level between the noise floor and the intercept point in a 3 kHz bandwidth [68] or (2) the difference between the fundamental response input level and the third-order response input as measured along the noise floor (sometimes defined as 3 dB bandwidth above the noise floor) in a 3 kHz bandwidth, as shown in Fig. 4. Reducing the bandwidth improves dynamic range because of the effect on noise.

Because the power level at which distortion becomes intolerable varies with signal type and application, a generic definition has evolved. The upper limit of a network's power span is the level at which the power of one IM product of a specified order is equal to the network's noise floor. The ratio of the noise floor power to the upper-limit signal power is referred to as the network's *dynamic range* (DR). Thus the DR can be determined from [69]

$$DR_n = \frac{n - 1}{n} [IP_{n,in} - MDS] \quad (22)$$

where DR_n is the dynamic range in decibels, n is the order, IP_{in} is the input intercept power in dBm, and MDS is the minimum detectable signal power in dBm.

Alternatively, in receiver circuits the spurious-free dynamic range (SFDR) and the intermodulation-free

Figure 4. The dynamic range is the difference between the fundamental response input level and the third-order response input as measured along the noise floor: (a) fundamental response; (b) third-order intermodulation response; (c) noise floor.

dynamic range (IFDR) are widely used to quantify the capability of the receiver to listen to a weak station, without disturbance from an intermodulation product generated by strong stations on other frequencies. The SFDR and the IFDR are in fact measures of how strong two signals can be before the level of their intermodulation products can reach the noise floor of the receiver. The SFDR, or the IFDR, is defined as the difference in decibels between the power levels of the third-order intermodulation IM3 (assuming that there is only a third-order non-linearity) and the carrier when the IM3 power level equals the noise floor at a given noise bandwidth. It can be expressed as [70]

$$\text{SFDR} = \frac{2}{3} [\text{IIP3} - \text{EIN} - 10 \log_{10}(\text{NBW})] \quad (23)$$

where IIP3 is the third-order input intercept point, EIN in (dB/Hz) is the equivalent input noise, and NBW (in Hz) is the noise bandwidth.

7.1.8. Adjacent- and Cochannel Power Ratio Tests. In modern telecommunication circuits, signals constituting one or more modulated carriers are handled. Characterization of the intermodulation performance of such circuits cannot, therefore, be performed using two-tone and three-tone input signals; a combination of equally spaced tones—in practice, more than ~ 10 sinusoids [71], with constant power and correlated or uncorrelated phases—would be more appropriate [72].

Because of the nonlinearity of the device under test, intermodulation products will be generated. These intermodulation products can be classified as *adjacent-channel distortion* when their frequencies are located to the right or to the left of the original spectrum, or *cochannel distortion* when their frequencies are located exactly over the original spectrum. The *adjacent-channel power ratio* (ACPR) is defined as the ratio between the total linear output power and the total output power collected in the upper and lower adjacent channels [73]. The *cochannel power ratio* (CCPR) is defined as the ratio between total linear output power and total distortion power collected in the input bandwidth [73]. The *intermodulation distortion ratio* (IMR) is the ratio between the linear output power per tone and the output power of adjacent-channel tones [73].

In fact, the ACPR, CCPR, and IMR distortion measurements are simple extensions of the two-tone intermodulation measurement [74]. However, it is important to first generate a very clean multitone signal. This can be easily achieved using the technique described in Ref. 75.

8. INTERMODULATION MEASUREMENT

8.1. Measurement Equipment

8.1.1. Multitone Tests. A block diagram of the system used for multitone intermodulation measurement is shown in Fig. 5. The multiple-frequency source can be implemented from two or three synthesized sine/square/triangular-wave generators. Amplifier/attenuator pairs

Figure 5. Block diagram of the two-tone test setup; multitone tests require additional signal generators, combiners, amplifiers, and bandpass filters (SG—signal generator; A—amplifier; BPF—bandpass filter; C—combiner; DUT—device under test; SA—spectrum analyzer).

can be added at the output of each generator. Bandpass filters can also be added to suppress the harmonic contents at the output of each generator. For RF measurements, harmonic suppression and isolation between different generators is achieved by using amplifier/circulator combinations and cavity resonators [76]. The synthesized sources are combined using hybrids or combiners of adequate isolation. Spectral purity at this point is crucial to the accuracy of the measurement. The multitone output is fed to the device under test (DUT). The output of the DUT is fed to the spectrum analyzer. For RF measurements, the output of the DUT can be fed to directional couplers. The outputs of the directional couplers are fed to a television oscilloscope and/or a spectrum analyzer.

Alternatively, for audiofrequency measurements, the intermodulation components of interest can be filtered out, using bandpass filters, and fed to AC voltmeters. For audiofrequency measurements, resistive combiners are widely used for combining the outputs of two or more signal generators.

8.1.2. Measurement Using a Microcomputer. Intermodulation can also be measured using a microcomputer [77]. A block diagram of this technique is shown in Fig. 6. This technique is based on measuring the single-tone input-output characteristic of the DUT using a vector voltmeter. The output of the vector voltmeter is fed to a microcomputer that converts it into three digital data lines representing the input amplitude, the output amplitude, and the phase lag between the input and output signals. After storing the data, the microcomputer increments the amplitude of the input signal. After storing all the necessary data, the microcomputer, using a stochastic method, calculates the amplitudes of the intermodulation components of the DUT. Although the procedure reported in Ref. 77 uses a stochastic method for calculating the amplitudes of the intermodulation components resulting from a two-tone input signal, the same procedure can be applied to any number of input tones using different analytic techniques for modeling the nonlinear characteristics of the DUT.

Alternatively, microcomputers can be added to the measurement setup of Fig. 5 to

1. Control the frequencies of the signal sources, especially in the millimeter-wave range, where the

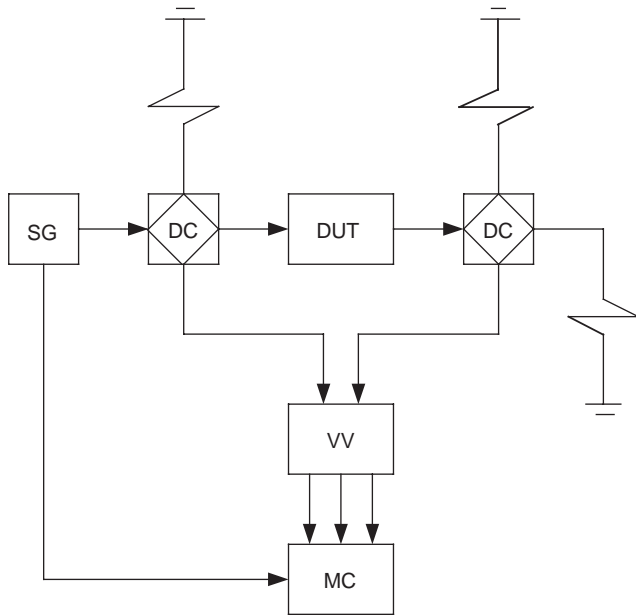

Figure 6. Block diagram of a microcomputer-based intermodulation measurement setup (SG—signal generator; DC—directional coupler; DUT—device under test; VV—vector voltmeter; MC—microcomputer).

difference in frequencies between the signal sources may be less than 0.001 of the base signal frequency [78].

2. Scan the base signal frequency over the measurement range of interest in predefined steps [79].
3. Correct the power from each source so that power delivery to the DUT will be the same across the whole frequency range scanned.
4. Read and calculate the parameters of interest during the measurements [80,81].

8.1.3. Noise Power Ratio Test. Figure 7 shows a block diagram of a noise power ratio test setup [62]. The setup consists of a white-noise generator that applies an accurate level of white Gaussian noise power with known bandwidth (equaling $\Delta\omega$ and centered around ω_0) to the DUT. The output of the DUT is measured with the band-reject filter out. When the band-reject filter, with bandwidth = $\delta\omega$ and centered around ω_0 , is switched in, a narrow band of frequencies is attenuated by about 70 dB, and a quiet channel, of width $\delta\omega$ and centered around ω_0 , is formed as shown in Fig. 3. At the output of the DUT, the noise power is measured in the quiet channel, using a bandpass filter with bandwidth $\delta\omega$ and centered around

Figure 7. Block diagram of the noise power ratio test setup (WNG—white-noise generator; BPF1—bandpass filter with bandwidth $\delta\omega$ centered around ω_0 ; BRF—band-reject filter with bandwidth $\delta\omega$ centered around ω_0 ; DUT—device under test; BPF2—bandpass filter with bandwidth $\delta\omega$ centered around ω_0 ; PM—power meter).

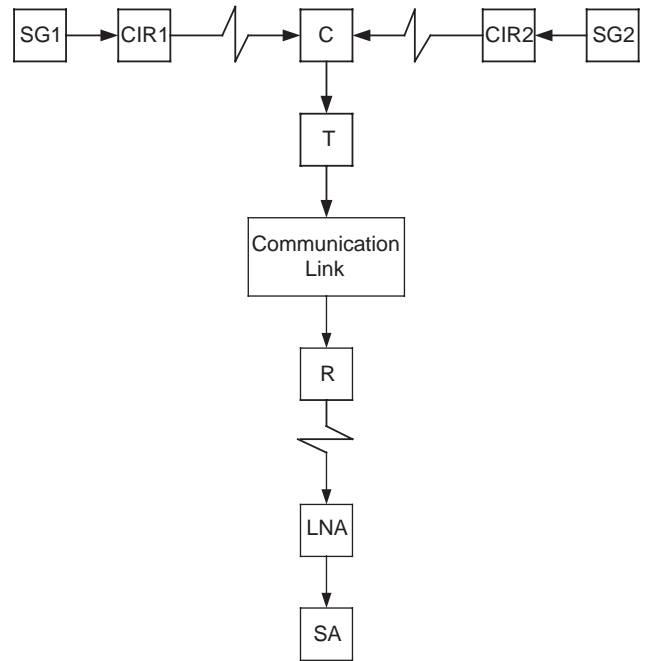

Figure 8. Setup for noise floor and SFDR measurement (SG—signal generator; CIR—circulator; C—combiner; T—transmitter; R—receiver; LNA—low-noise amplifier; SA—spectrum analyzer).

ω_0 . This noise power is due to the thermal noise and the intermodulation introduced by the DUT. The NPR is the ratio between the noise power measured without the band-reject filter inserted before the DUT to that measured with the band-reject filter inserted. The white-noise generator corrects the loading power level for the insertion loss of the band-reject filter.

8.1.4. Noise Floor and SFDR Test. Figure 8 shows a test setup for measurement of noise floor and the SFDR of a communication link [70]. To measure the noise floor of the communication link, the transmitter is switched off. Then the noises of the low-noise amplifier and the spectrum analyzer are measured. Switching the transmitter on increases the noise floor by the transmitter noise and therefore the difference between the two noise measurements is the noise generated by the transmitter.

To measure the SFDR, the input power is decreased until the IM3 level equals the noise floor. Recall that decreasing the input power by 1 dB decreases the IM3 level by 3 dB. However, this is true only if the third-order non-linearity is dominant. Higher-order nonlinearities will contribute to the third-order intermodulation (IM3), and

in such cases the measured SFDR will be different from calculations obtained using Eq. (23).

8.1.5. Externally Induced Intermodulation Test. This is a two-tone test with one signal applied to the input and the other signal applied to the output [9]. A test setup is shown in Fig. 9. Two directional couplers are used to gauge both the forward-carrier power and the intermodulation product levels. Two more directional couplers are added to inject the interfering signal and to measure the actual injected value using the spectrum analyzer.

8.2. Measurement Accuracy

8.2.1. Multitone Tests. For accurate measurements of the intermodulation products using multitone tests, it is essential to reduce, or remove, the nonlinear distortion originating in the signal sources and/or the measurement equipment. Measurement accuracy may, therefore, be affected by the purity of the signal sources, the linearity of the combiners, and the performance of the spectrum analyzer.

8.2.2. Signal Sources. Measurement of the amplitudes of the intermodulation components requires the use of two or more signals. The frequencies of these signals must be noncommensurate. Otherwise, harmonics in one source might interfere with the fundamental(s) of other signal(s) and thus interfere with the desired intermodulation components.

Ideally the signal generators would produce perfect sinusoids, but in reality all signals have imperfections. Of particular interest here is the *spectral purity*, which is a measure of the inherent frequency stability of the signal. Perhaps the most common method used to quantify the

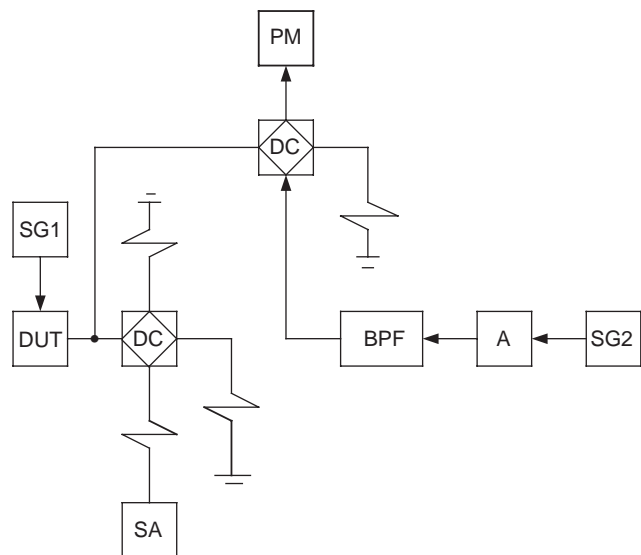

Figure 9. Measurement of externally induced intermodulation can be performed by using two tones: one injected at the input and one injected at the output of the DUT (SG—signal generator; DC—directional coupler; PM—power meter; SA—spectrum analyzer; BPF—bandpass filter; A—amplifier).

spectral purity of a signal generator is its phase noise [82]. In the time domain, the phase noise manifests itself as a jitter in the zero crossings of a sine wave. In the frequency domain, the phase noise appears as sidebands surrounding the original frequency. Thus, mixing with other frequencies, due to the nonlinearities of the DUT, would result in additional intermodulation products. It is, therefore, important to consider the intermodulation due to phase noise when calculating the intermodulation performance of the DUT [83].

Signal generators with automatic level control (ALC) may produce signals with unwanted modulation. The ALC is implemented by rectifying the output signal of the generator and feeding back the resulting DC voltage to drive an amplitude modulator. If a second signal is applied to the output of the signal generator, the detector will produce a signal at the point of difference between the two frequencies. This signal will modulate the generator's output. The frequency of the modulation sidebands will share the same spectral lines as the intermodulation products of interest. Isolating the signal generators and the combiners can minimize such an effect. This can be achieved by ensuring that there is as much attenuation as possible between them.

8.2.3. Combiners. Measurement of intermodulation products is performed by applying to the input of the circuit, or the system, under test a signal consisting of two or more different frequencies obtained from different signal generators. The outputs of the signal generators are, therefore, combined by a combiner. The combiner must provide sufficient isolation between the signal sources to reduce the possibility of producing intermodulation products before the combined input signal is applied to the circuit or the system under test. While resistive combiners are adequate for input signal levels up to a few millivolts, for larger voltage levels the use of power combiners may be inevitable [84]. Insertion of an attenuator in each arm of the combiner helps minimize the distortion components resulting from the interaction between the two signal sources. Such components, if generated, should be at least 80 dB below the fundamental components.

A simple test to determine whether adequate isolation has been achieved can be effected by introducing a variable attenuator between the signal source combiner and the DUT in Fig. 6. This is set to a low value during measurements, but at setup, when IMPs have been located on the spectrum analyzer, increasing the attenuation by 3 dB will result in a reduction in the observed IMP level. If this reduction is only 3 dB, it has to be assumed that the IMP observed has originated in the signal sources, not in the DUT. If, however, the reduction is 6 dB for a second-order IMP or 9 dB for a third-order IMP [see Eq. (4)], then it is safe to assume that the IMP has originated in the DUT or the spectrum analyzer.

Alternatively, a technique that attenuates the parasitic intermodulation products that result from the interaction between the generators of the fundamental components, before the input of the spectrum analyzer, was described in Ref. 85. A block diagram of the technique is shown in Fig. 10. The input to the system under test is formed by

Figure 10. A technique for attenuating the intermodulation products resulting from interaction between the signal generators of the fundamental components (SG—signal generator; C—combiner; DUT—device under test; BRF—band-reject filter; PS—phase shifter; DA—differential amplifier).

combining the outputs of two signal generators at frequencies ω_1 and ω_2 in the combiner. The first hybrid combiner/splitter (HCS1) splits the combined signal into two branches with voltage transfer ratio $a = \alpha$ and $b = \sqrt{1 - \alpha^2}$ at the first and second outputs. Using Eq. (1), and assuming that the system under test and the compensator have identical nonlinear characteristics, the inputs of the second hybrid combiner/splitter (HCS2) can be expressed as

$$V_a = \sum_{n=0}^N k_n (\alpha V_i)^n \quad (24)$$

and

$$V_b = \sum_{n=0}^N k_n (\sqrt{1 - \alpha^2} V_i^n) \quad (25)$$

Using Eqs. (24) and (25), the output of the second hybrid combiner/splitter (HCS2), with voltage transfer ratio opposite in sign and equal to the reciprocal of that of HCS1, can be expressed as

$$V_{\text{out}} = \sum_{n=0}^N -k_n \left(\sqrt{1 - \alpha^2} (\alpha V_i)^n - \alpha (\sqrt{1 - \alpha^2} V_i^n) \right) \quad (26)$$

According to Eq. (26), broadband compensation occurs for the linear components of the combined signal, with $n = 1$. Thus, all the linearly transformed spectral components are eliminated. This is also true for the intermodulation components that may result from the nonlinear interaction between the two signal generators. The output of HCS2 can, therefore, be applied directly to the spectrum analyzer.

This technique does not require complicated high-order selective filters and can attenuate the parasitic intermodulation components and the fundamental frequency components by about 50 dB over a wide range of frequencies differing by 7–10 octaves. However, it requires a compensator with a nonlinear characteristic similar to that of the system under test.

8.2.4. Spectrum Analyzers. Spectrum analyzers are widely used in measuring the intermodulation performance of electronic circuits and systems. Internal circuits of the spectrum analyzers are, themselves, imperfect and

will also produce distortion products [46]. The distortion performance of the analyzers is usually specified by the manufacturers, either directly or lumped into a dynamic range specification. The performance of the analyzer can be stretched, however, if the nature of these distortion products is understood.

Amplitudes of the distortion products, resulting from the internal circuits of the analyzer, can be reduced by reducing the signal levels at the analyzer's input. Thus, using internal and/or external attenuators can reduce the input signal levels to the analyzer and hence reduce its distortion products and improve the intermodulation measurement range of the spectrum analyzer. However, reduced input levels to the analyzer mean reduced signal-to-noise ratio, and the distortion component to be measured may be buried in the noise. While reducing the resolution bandwidth of the analyzer can reduce noise, this may lead to slower sweep rate. Thus, achieving an optimum dynamic range involves tradeoffs between input signal levels and analyzer distortion. Usually, datasheets of analyzers will contain information about noise level in each resolution bandwidth and distortion products generated by the analyzer for each input level. Using this information, one can determine the dynamic range of the analyzer for various input levels [86].

Whenever good selectivity, as well as sensitivity and dynamic range, are of prime importance, test receivers may be used in preference to spectrum analyzers [6]. Alternatively, if the frequencies of the intermodulation components of interest are sufficiently lower (or higher) than the fundamental frequencies, then lowpass (or highpass) filters can be used to remove the fundamental components that would give rise to other nonlinear distortion components in the spectrum analyzer. Attenuation factors of 80 dB or more, at frequencies outside the band of interest, are recommended. The insertion loss of the lowpass (or the highpass) filter should be as small as possible; 0.4 dB or less is recommended.

If the frequency of the intermodulation component of interest is not sufficiently higher (or lower) than the fundamental frequencies, then it would be necessary to have complicated multiple-section high-order filters with amplitude–frequency characteristics that are nearly rectangular. Such filters will change, to some extent, the amplitude of the intermodulation components, and this will complicate calculation of the intermodulation performance of the system under test. A method for compensating for a large fundamental component, thus allowing the measurement of small intermodulation components in its presence, was described in Ref. 87.

A block diagram of the compensation method is shown in Fig. 11. The input to the system under test is formed of one large amplitude signal at frequency ω_1 and one small amplitude signal at frequency ω_2 with $\omega_1 \ll \omega_2$. The output of the system under test contains fundamental components at frequencies ω_1 and ω_2 , and intermodulation components at frequencies $\omega_2 \pm n\omega_1$, $n = 1, 2, \dots, N$. In order to measure the small amplitude intermodulation components, it is necessary to avoid applying to the analyzer the fundamental component at frequency ω_2 . This can be achieved as follows. The output of the system under test is

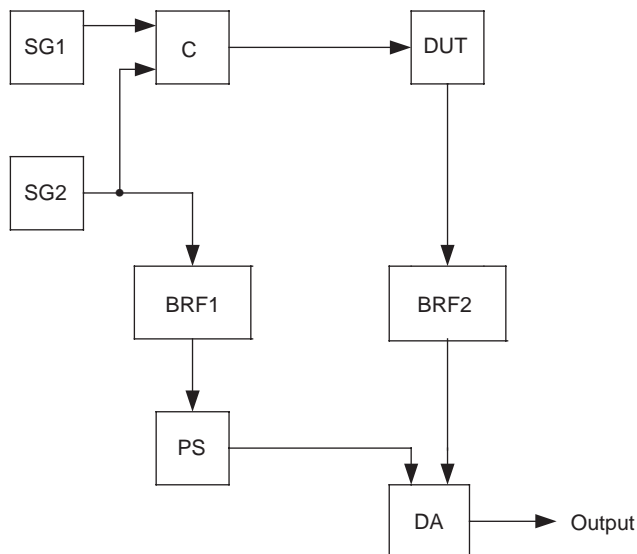

Figure 11. Compensation method for the measurement of small-amplitude intermodulation products in the presence of a large fundamental (SG—signal generator; C—combiner; HSC—hybrid splitter/combiner; DUT—device under test; CO—compensator; SA—spectrum analyzer).

fed to the second band-reject filter BRF2 to suppress the fundamental component at ω_1 . The output of the signal generator of frequency ω_2 is fed to the first band-reject filter BRF1 to suppress any component at frequency ω_1 before reaching the phase shifter through the combiner. The phase shifter compensates, at the frequency ω_2 , the phase shift through the system under test.

Ideally, the voltages of frequency ω_2 at the inputs of the differential amplifier are equal. Thus, the output of the differential amplifier at frequency ω_2 is ideally zero. In practice, the output voltage at ω_2 will be attenuated by 50–60 dB [6]. The output of the differential amplifier, with suppressed fundamental component at frequency ω_2 , can be applied to the spectrum analyzer. This compensation technique, which entails additional filters and matching units, can be used only for broadband measurements with $\omega_1 \ll \omega_2$.

Although spectrum analyzers using digital IF sections may not suffer from the internally generated distortion, discussed above, they may suffer from the relatively low-level distortion products resulting from the analog-to-digital conversion. The amplitudes of these products is usually less sensitive to the amplitude of the signal components.

8.2.5. Noise Power Ratio Test. The accuracy of the noise power ratio (NPR) test is affected mainly by two factors: (1) the noise floor of the amplifier that will dominate under very low loading conditions and (2) the distortion products produced under very high loading conditions. It is, therefore, recommended to sweep the loading between two pre-specified start and stop levels. The NPR is measured at different levels, and the largest measured value of NPR is considered as the worst case.

8.2.6. Microcomputer-Based Tests. Quantization errors associated with the analog-to-digital conversion of the data in microcomputer-based intermodulation test must be taken into account. Measurement errors due to quantization are affected by the length of the binary digits and determine the dynamic range of operation [77].

ITERATIVE METHODS

ROBERT J. BURKHOLDER
JIN-FA LEE
The Ohio State University
Columbus, Ohio

1. INTRODUCTION

Iterative methods are used in RF and microwave engineering to solve complex systems by repeatedly refining an approximate solution until a desired level of accuracy or performance is achieved. In many such problems, an exact solution does not exist and a direct numerical solution may not be feasible because of the very large number of degrees of freedom. Typical applications include the solution of large systems of differential and integral equations that may involve thousands or millions of unknown variables. For these problems it may not be possible to generate and store a full system matrix, and then solve it directly (e.g., by inversion, factorization, or Gauss elimination). Iterative methods only need to apply an operator (or system matrix) to the solution at each iteration. They are particularly well suited for the solution of sparse matrix systems because a large percentage of the operations involved are negligible.

Mathematically, an iterative algorithm starts with an initial approximate solution, and repeatedly applies an operator to the solution to improve its accuracy at each iteration. Eventually the solution should converge to a given level of accuracy. Convergence is the primary issue associated with any iterative method. The solution may converge very slowly if the iterative operator is not well conditioned, or it may even diverge. Figure 1 illustrates the basic iterative loop.

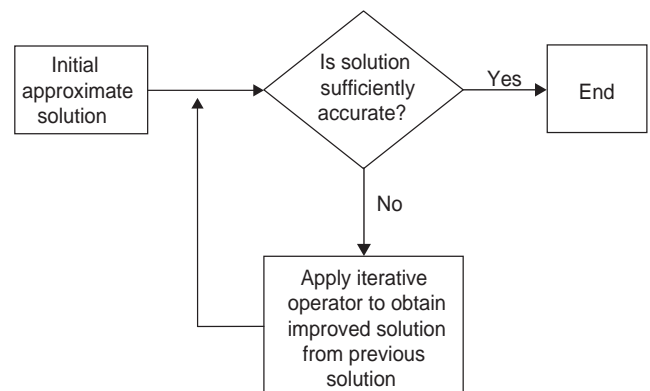

Figure 1. Schematic diagram of an iterative solution.

There are two broad categories of iterative methods: stationary and nonstationary. *Stationary* methods are characterized by an operator that does not change with each iteration. *Classical iterative methods* are included in this category, such as Jacobi and Gauss–Seidel. *Conjugate-gradient methods* are included in the class of nonstationary methods, wherein some parameters in the operator change with each iteration [1].

In general, conjugate-gradient iterative methods have better convergence properties than do classical iterative methods when compared over a wide range of problems. The convergence of classical methods tends to be very problem-dependent. In fact, classical methods are often based on the underlying physics of a particular scenario. For example, a classical iterative algorithm may be designed to model the multiple electromagnetic (EM) wave scattering between two or more objects. Such an algorithm could be very rapidly convergent for that problem, but slowly convergent or even divergent for a different problem. On the other hand, conjugate-gradient methods have theoretically guaranteed convergence if the system matrix is nonsingular, although in practice the limited numerical precision of a computer may cause the algorithm to stall.

The convergence of any iterative method may be improved by altering the formulation so that it is better conditioned. This is referred to as *preconditioning* the operator or system of equations. The accuracy of the solution at each iteration may be gauged in terms of the *residual error*, which is a measure of how well the solution satisfies the original system of equations.

2. HISTORICAL REVIEW OF ITERATIVE METHODS IN ELECTROMAGNETICS

Iterative methods in EM did not become popular until advances in computer technology made it possible to solve large systems of equations. Classical iterative methods were developed to model physical EM interactions between different parts of a geometry. Thiele et al. first developed a hybrid technique to combine physical optics and the method of moments in 1982 [2–4]. The solution iterates between the optically lit region and the shadow region of an arbitrary scattering geometry. This method was extended further and made more general by Hodges and Rahmat-Samii [5], including the interactions between antennas and their supporting platform. Domain decomposition was used by Sullivan and Carin to break up a method-of-moments (MoM) problem into multiple, simpler, solution regions [6]. Iterative method of moments and iterative physical optics have been used to solve multi-bounce problems such as the EM scattering from large open-ended cavities [7,8]. Classical iterative methods have also been applied extensively to compute the scattering from rough surfaces. The forward-backward method developed by Holliday et al. [9], and the method of ordered multiple interactions of Kapp and Brown [10], take advantage of the dominant forward and backward propagation of EM waves over a rough surface. The generalized forward-backward method extended this work to include an obstacle on the rough surface by modifying the matrix

splitting used in the forward-backward method [11]. Comparisons of stationary with nonstationary iterative methods are presented in Refs. 12–14.

The conjugate gradient (CG) method was developed in 1952 by Hestenes and Stiefel [15]. However, like the classical iterative methods, it was not used in the area of electromagnetics until advances in computers made it possible to solve large linear systems. Sarkar and Rao used the CG method to solve method of moments problems in 1984 [16], and Sarkar and Arvas presented a more general CG development for electromagnetics problems in 1985 [17]. The CG-fast Fourier transform method (CG-FFT) became popular for solving quasiplanar geometries in the late 1980s [18,19]. The development of fast integral equation methods, such as the CG-FFT, the fast multipole method [20], the adaptive integral method [21], and the precorrected FFT method [22] gave CG methods a boost. These methods greatly reduce the computational cost of applying the integral equation operator, thereby allowing very large systems of equations to be solved.

3. MATRIX NOTATION FOR ITERATIVE METHODS

The solution of a system of equations with N degrees of freedom, or unknown variables, may be expressed in matrix format as

$$\mathbf{A}x = b \quad (1)$$

where \mathbf{A} is an $N \times N$ system matrix, x is a column vector containing the N unknown coefficients, and b is a known excitation-dependent column vector. The individual elements of this equation may be expressed as

$$b_m = \sum_{n=1}^N A_{mn}x_n \quad (2)$$

This matrix equation is obtained by discretizing the EM operator governing the problem of interest, whether it is from a differential equation or integral equation formulation. The unknown quantity, such as the EM fields or equivalent currents, are expanded into a set of N known basis functions with unknown coefficients comprising the column vector x . The N basis functions are *tested* (or sampled) with N test functions to yield a system of N equations.

The preceding equation for the unknown coefficients may be solved using direct matrix inversion or factorization. However, the *operational complexity* for the direct approach is $O(N^3)$, that is, of order N -cubed. This means that the number of computations necessary to solve the system is proportional to N^3 , which may be too costly when there are thousands or millions of unknowns. Iterative methods have an operational complexity of no more than $O(N^2)$ per iteration, which is the cost of doing one matrix-vector multiplication. So as long as the solution converges quickly, the iterative method is much more efficient.

Iterative methods seek to solve Eq. (1) by successively improving an initial solution to a desired degree of

accuracy. The *residual error* vector is a measure of the accuracy of the solution after k iterations and is defined by

$$r^{(k)} = b - \mathbf{A}x^{(k)} \quad (3)$$

The *residual error norm*, or simply the residual error, is the length of this vector normalized to the length of the excitation vector, $\|r^{(k)}\|/\|b\|$, where $\|r^{(k)}\| = \sqrt{r^{(k)}r^{(k)*}}$. Here, the inner product (or vector product) of two column vectors is Hermitian, defined by

$$ab = \sum_{n=1}^N a_n^* b_n \quad (4)$$

where the $*$ superscript denotes the complex conjugate. (Note: The CG algorithm described later does not use the complex conjugate in the inner product, as will be made apparent.) The residual error tells us how well the solution satisfies the system of equations, and is most often used as the criterion for halting the iterations. The *absolute error* vector is defined by

$$e^{(k)} = x^{(k)} - x \quad (5)$$

where x is the exact solution to (1). The *spectral radius* of a matrix is defined as the magnitude of its largest eigenvalue. This quantity is important for determining convergence of classical iterative methods, whereas the *eigenvalue spectrum* of a matrix determines the convergence of CG methods.

4. CLASSICAL ITERATIVE METHODS

As is apparent from the historical review presented earlier, classical iterative methods are often used to solve problems via a physical decomposition of the geometry, sometimes even using a different solution technique for each region. All of these methods can be cast in the form of *matrix splittings*, where the original system matrix is decomposed in some manner that makes the problem easier to solve. Figure 2 shows some common matrix splittings. We will focus on the lower-upper (LU) triangular splitting. The block-diagonal and banded matrix splittings are extensions of the LU splitting, where the diagonal \mathbf{D} is replaced by the block-diagonal or banded portion of the matrices. Likewise, the hybrid decomposition is a special case of the block-diagonal splitting with only two blocks on the diagonal.

All the matrix splittings of Fig. 2 have the general form $\mathbf{A} = \mathbf{M} - \mathbf{N}$. We may then write an iterative equation from Eq. (1) as

$$\mathbf{M}x^{(k)} = \mathbf{N}x^{(k-1)} + b \quad (6)$$

starting with some initial solution candidate $x^{(0)}$ and solving repeatedly. It is easy to show that if $x^{(k)} = x^{(k-1)}$, then Eq. (1) is satisfied and $x^{(k)} = x$. To solve (6) for $x^{(k)}$, we need \mathbf{M} to be easily invertible or factorizable. Diagonal matrices are trivial to invert, and block-diagonal matrices are

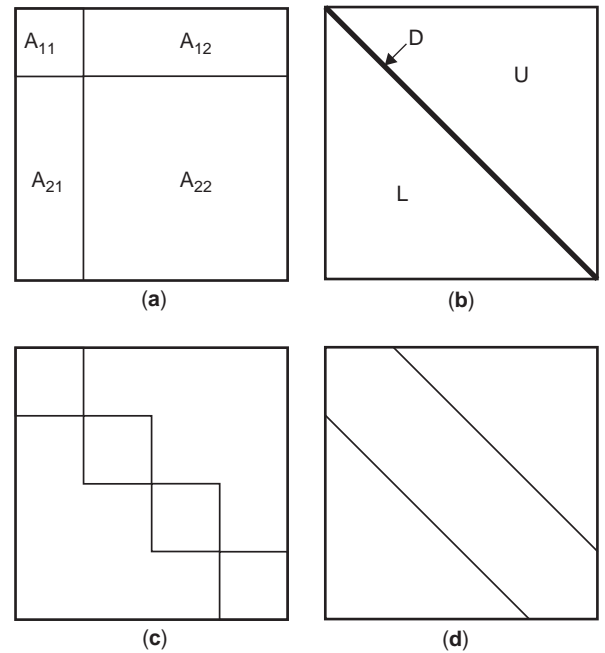

Figure 2. Some common matrix splittings. (a) hybrid decomposition; (b) lower-upper triangular; (c) block-diagonal; (d) banded.

easily inverted by inverting each block independently of the other blocks. Lower triangular and upper triangular matrices are also easy to invert via backward and forward substitutions, respectively [1]. All of these types of inversions are computed much more efficiently than inverting the entire system matrix \mathbf{A} .

The absolute error vector at the k th iteration may be shown to be

$$e^{(k)} = (\mathbf{M}^{-1}\mathbf{N})^k(x^{(0)} - x) \quad (7)$$

Therefore, the spectral radius of the matrix $(\mathbf{M}^{-1}\mathbf{N})$ must be less than unity to guarantee convergence [1]. This ensures that the absolute error approaches zero as k goes to infinity. The residual error vector for the k th iteration may be shown to be

$$r^{(k)} = \mathbf{N}(x^{(k)} - x^{(k-1)})$$

which is easily computed by saving the matrix-vector product $\mathbf{N}x^{(k-1)}$ from the previous iteration. Some common iterative algorithms based on the matrix splittings of Fig. 2 are discussed next.

4.1. Jacobi Iteration

This is the simplest classical iteration algorithm. We choose $\mathbf{M} = \mathbf{D}$ and $\mathbf{N} = -(\mathbf{L} + \mathbf{U})$, so the iterative equation becomes

$$\mathbf{D}x^{(k)} = b - (\mathbf{L} + \mathbf{U})x^{(k-1)} \quad (8)$$

The magnetic field integral equation (MFIE) has this form, which is also used in the iterative physical optics

technique [8]. The operational cost is $O(N^2)$, which is the cost of computing the matrix–vector product $(\mathbf{L} + \mathbf{U})x^{(k-1)}$ on the right-hand side (RHS) of (8).

4.2. Gauss–Seidel Method

This is an improvement over simple Jacobi iteration [1]. Here we choose $\mathbf{M} = \mathbf{D} + \mathbf{L}$ and $\mathbf{N} = -\mathbf{U}$, resulting in

$$(\mathbf{D} + \mathbf{L})x^{(k)} = b - \mathbf{U}x^{(k-1)} \tag{9}$$

This equation is solved using forward substitution. This is easy to see by writing the expression for the individual elements as

$$x_m^{(k)} = \frac{b_m - \sum_{n=1}^{m-1} x_n^{(k)} - \sum_{n=m+1}^N x_n^{(k-1)}}{D_m} \tag{10}$$

The elements $x_m^{(k)}$ are updated sequentially for $m = 1, 2, \dots, N$, so the updated values can be used on the RHS of (10). The convergence of Gauss–Seidel is expected to be somewhat better than Jacobi, and with the same operational cost.

4.3. Symmetric Gauss–Seidel Method

The Gauss–Seidel method can be formulated using forward or backward substitution. A symmetric form of Gauss–Seidel iteration is obtained using both forward and backward substitution in the following two-step algorithm:

$$(\mathbf{D} + \mathbf{L})x^{(k-1/2)} = b - \mathbf{U}x^{(k-1)} \tag{11}$$

$$(\mathbf{D} + \mathbf{U})x^{(k)} = b - \mathbf{L}x^{(k-1/2)}$$

This is the form of the forward–backward method [9], or the method of multiple ordered interactions [10]. This two-step algorithm has the same operational cost of a one-step algorithm because the half-matrix–vector product $\mathbf{L}x^{(k-1/2)}$ is reused in step 2 of each iteration, and $\mathbf{U}x^{(k-1)}$ may be saved from the previous iteration and reused.

4.4. Relaxation

Unless the problem geometry is very well ordered, or the system matrix is strongly diagonally dominant, the classical iterative algorithms above will probably have poor convergence properties. To improve convergence, a *relaxation parameter* [1] (or damping coefficient), ω may be introduced. This is a constant usually in the range $0 < \omega < 2$ such that the relaxed iterative equations reduce to the basic equations above for $\omega = 1$. The relaxed Jacobi iterative equation is given by

$$\mathbf{D}x^{(k)} = \omega b + [(1 - \omega)\mathbf{D} - \omega(\mathbf{L} + \mathbf{U})]x^{(k-1)} \tag{12}$$

It is easy to show that (12) reduces to (8) for $\omega = 1$, and if $x^{(k)} = x^{(k-1)}$ then (1) is satisfied and $x^{(k)} = x$ for any non-zero ω .

Figure 3. Convergence of classical iterative methods compared with BCGS.

Likewise, the relaxed Gauss–Seidel method, also known as *successive overrelaxation* (SOR) [1], is given by

$$(\mathbf{D} + \omega\mathbf{L})x^{(k)} = \omega b + [(1 - \omega)\mathbf{D} - \omega\mathbf{U}]x^{(k-1)} \tag{13}$$

The relaxed form of symmetric Gauss–Seidel is known as *symmetric successive overrelaxation* (SSOR) [1], and is given by

$$(\mathbf{D} + \omega\mathbf{L})x^{(k-1/2)} = \omega b + [(1 - \omega)\mathbf{D} - \omega\mathbf{U}]x^{(k-1)} \tag{14}$$

$$(\mathbf{D} + \omega\mathbf{U})x^{(k)} = \omega b + [(1 - \omega)\mathbf{D} - \omega\mathbf{L}]x^{(k-1/2)}$$

Figure 3 shows a plot of the convergence of relaxed Jacobi, SOR, SSOR, and the biconjugate gradient stabilized (BCGS) algorithms for the problem of radar scattering from a perfect electrically conducting cylinder computed by the method of moments [14]. For this relatively simple problem, the SSOR method has the best convergence and the BCGS, the worst. However, for more arbitrary geometries the classical iterations may fail to converge, and may eventually diverge.

5. CONJUGATE-GRADIENT (CG) METHODS

CG methods are superior to classical iterative methods in the sense that they are theoretically guaranteed to converge in no more than N iterations if the matrix is

nonsingular. (In practice, the numerical precision of the computer may limit this theoretical convergence.) They are not limited to specific types of problems or physics, and can be used as general matrix solvers. This is achieved by generating a sequence of search vectors that will eventually span the entire N -space. The only difference between the various CG versions is how these search vectors are generated. In general, the search vectors are chosen such that each new vector is linearly independent of all previous vectors, and the residual error is minimized. The basic CG method is applicable only to symmetric systems and is presented here first, followed by two popular methods for nonsymmetric systems, the modified biconjugate gradient (BCG) and the generalized minimum residual (GMRES) methods. An excellent resource for these and other CG algorithms is the *Templates* book [23], for which associated computer subroutines are readily available.

5.1. CG Algorithm for Complex Symmetric Matrices

The basic CG algorithm for solving the complex symmetric matrix equation $\mathbf{A}\tilde{\mathbf{x}} = \tilde{\mathbf{b}}$ is listed below. A complete derivation is included later in this article. *In the following algorithm the vector products are not Hermitian*, that is, there is no complex conjugation as in (4).

Conjugate Gradient Algorithm 1

Initialization:

$$\tilde{\mathbf{v}} = \frac{\tilde{\mathbf{b}}}{\sqrt{\tilde{\mathbf{b}}^T \mathbf{A} \tilde{\mathbf{b}}}}, \quad \tilde{\mathbf{x}} = 0, \quad \tilde{\mathbf{r}} = \tilde{\mathbf{b}}$$

Iteration:

1. $\tilde{\mathbf{x}} = \tilde{\mathbf{x}} + \alpha \tilde{\mathbf{v}}, \alpha = \tilde{\mathbf{v}}^T \tilde{\mathbf{b}}$
2. $\tilde{\mathbf{u}} = \mathbf{A} \tilde{\mathbf{v}}, \tilde{\mathbf{r}} = \tilde{\mathbf{r}} - \alpha \tilde{\mathbf{u}}$
3. Check $\|\tilde{\mathbf{r}}\|/\|\tilde{\mathbf{b}}\| \leq \epsilon$; if yes, then stop, and $\tilde{\mathbf{x}}$ is a good approximation; if no, then continue.
4. $\tilde{\mathbf{p}} = \tilde{\mathbf{r}} - \beta \tilde{\mathbf{v}}, \beta = \tilde{\mathbf{u}}^T \tilde{\mathbf{r}}$
5. $\tilde{\mathbf{v}} = \tilde{\mathbf{p}}/\sqrt{\tilde{\mathbf{p}}^T \mathbf{A} \tilde{\mathbf{p}}}$
6. Go to step 1.

Each iteration of the CG algorithm involves one matrix–vector multiplication, which is at most an $O(N^2)$ operation. The residual error of the solution is checked in step 3. If it is less than some threshold error ϵ , the iterations are halted. This threshold level determines the accuracy of the solution. For most engineering applications a threshold level in the range 0.0001–0.01 yields sufficient accuracy. Of course, greater accuracy requires more iterations, and it is possible for the algorithm to stall before reaching a given threshold. The convergence properties of the CG method are discussed later in this article.

5.2. Modified Biconjugate-Gradient Method for Nonsymmetric Matrices

In solving the magnetic field integral equation or combined field integral equations or many other RF engineering

applications (such as hybrid finite-element/integral equation formulation), we quite often end up with a nonsymmetric matrix equation $\mathbf{A}\tilde{\mathbf{x}} = \tilde{\mathbf{b}}$, where \mathbf{A} is an $N \times N$ complex nonsymmetric matrix. There are many variants of Krylov-based methods for solving this equation; here we shall list the modified BCG method, followed by the GMRES method. *In the following algorithm the vector products are not Hermitian*; that is, there is no complex conjugation as in (4).

Modified BCG Algorithm for Solving Complex Nonsymmetric Matrix Equations

Initialization:

$$\tilde{\mathbf{x}} = \tilde{\mathbf{x}}_T = 0 \quad \tilde{\mathbf{r}} = \tilde{\mathbf{b}} \quad \tilde{\mathbf{r}}_T = \tilde{\mathbf{b}}$$

$$\begin{aligned} \tilde{\mathbf{p}} &= \tilde{\mathbf{r}} & \tilde{\mathbf{p}}_T &= \tilde{\mathbf{r}}_T \\ \tilde{\mathbf{v}} &= \frac{\tilde{\mathbf{p}}}{\sqrt{\tilde{\mathbf{p}}^T \mathbf{A} \tilde{\mathbf{p}}}} & \tilde{\mathbf{v}}_T &= \frac{\tilde{\mathbf{p}}_T}{\sqrt{\tilde{\mathbf{p}}_T^T \mathbf{A}^T \tilde{\mathbf{p}}_T}} \end{aligned}$$

Iteration:

1. $\tilde{\mathbf{x}} = \tilde{\mathbf{x}} + \alpha \tilde{\mathbf{v}} = \tilde{\mathbf{x}} + \left(\tilde{\mathbf{v}}^T \tilde{\mathbf{b}} \right) \tilde{\mathbf{v}}$
2. Compute $\tilde{\mathbf{u}} = \mathbf{A} \tilde{\mathbf{v}}$
 $\tilde{\mathbf{u}}_T = \mathbf{A}^T \tilde{\mathbf{v}}_T$
3. $\tilde{\mathbf{r}} = \tilde{\mathbf{r}} - \alpha \tilde{\mathbf{u}}$
 $\tilde{\mathbf{r}}_T = \tilde{\mathbf{r}}_T - \alpha \tilde{\mathbf{u}}_T$
4. Check convergence. If $\|\tilde{\mathbf{r}}\|/\|\tilde{\mathbf{b}}\| \leq \epsilon$, then stop and $\tilde{\mathbf{x}}$ is a good approximation; if not, continue.
5. $\tilde{\mathbf{p}} = \tilde{\mathbf{r}} - \beta \tilde{\mathbf{v}} \quad \beta = \frac{\tilde{\mathbf{u}}_T^T \tilde{\mathbf{r}}}{\tilde{\mathbf{u}}_T^T \tilde{\mathbf{p}}}$
 $\tilde{\mathbf{p}}_T = \tilde{\mathbf{r}}_T - \beta \tilde{\mathbf{p}}_T \quad \beta_T = \frac{\tilde{\mathbf{u}}^T \tilde{\mathbf{r}}_T}{\tilde{\mathbf{u}}^T \tilde{\mathbf{p}}_T}$
6. $\tilde{\mathbf{v}} = \frac{\tilde{\mathbf{p}}}{\sqrt{\tilde{\mathbf{p}}^T \mathbf{A} \tilde{\mathbf{p}}}}$
 $\tilde{\mathbf{v}}_T = \frac{\tilde{\mathbf{p}}_T}{\sqrt{\tilde{\mathbf{p}}_T^T \mathbf{A}^T \tilde{\mathbf{p}}_T}}$
7. Go to step 1.

In this BCG algorithm it is noted that two matrix–vector products need to be computed for each iteration, one with the original matrix \mathbf{A} and the other with its transpose \mathbf{A}^T . This makes the BCG methods roughly twice as computationally expensive as the CG method for symmetric systems. The difference between the basic BCG and the modified BCG is that the former uses the Hermitian matrix \mathbf{A}^H (i.e., complex conjugate–transpose) instead of the transpose matrix \mathbf{A}^T .

5.3. GMRES Method for Nonsymmetric Matrix Equations

Another useful Krylov space iterative method for nonsymmetric systems is the generalized minimum residual (GMRES) method [24]. Like the CG method, a sequence of linearly independent search vectors is generated. However, unlike the CG method, the entire set of search vectors is saved in memory. Coefficients are found that give the minimum residual error over the complete set of search vectors. In essence, it is a “brute force” CG method. The advantages are that only one matrix–vector product is computed per iteration and the transpose of the matrix is not needed. Furthermore, the GMRES method truly minimizes the residual at each iteration, so its convergence is monotonic. The disadvantage is that all the previous search vectors must be stored in memory. Therefore, the memory requirement grows with the number of iterations. This may not be a problem for dense system matrices for which the matrix storage is generally much larger than the storage of a set of search vectors (depending, of course, on how many search vectors are stored).

To alleviate the memory requirement, the GMRES algorithm may be restarted after a certain number of iterations. The solution vector after one set of iterations is used as the initial solution for the next set of iterations. However, the restarted version of the GMRES algorithm is not guaranteed to converge because the reduced set of expansion vectors may not span the entire solution space. The GMRES algorithm is listed in the third-edition book by Golub and Van Loan [1] and in *Templates* [23]. A simplified algorithm that is conceptually equivalent to GMRES, the generalized conjugate residual (GCR) method [25], is listed below. *In the following algorithm the vector products are Hermitian*, using complex conjugation as in (4).

Generalized Conjugate Residual Algorithm

Initialization: $x = 0$, $r = b$, $p_1 = b$, $u_1 = \mathbf{A}p_1$

Iteration: $k = 1, 2, \dots$

1. $x = x + \alpha p_k$, $\alpha = u_k r / \|u_k\|^2$.
2. $r = r - \alpha u_k$.
3. Check $\|r\| / \|b\| \leq \epsilon$. If yes, then stop, and x is a good approximation; if no, then continue.
4. $\beta_i = \frac{u_i \mathbf{A}r}{\|u_i\|^2}$, for $i = 1, 2, \dots, k$.
5. $p_{k+1} = r - \sum_{i=1}^k \beta_i p_i$.
6. $u_{k+1} = \mathbf{A}r - \sum_{i=1}^k \beta_i u_i$.
7. Go to step 1.

This algorithm is very similar to the basic conjugate-gradient method. Note that only one matrix–vector product is used per iteration (in step 4) if we store all the vectors p_i and u_i for $i = 1, 2, \dots, k$. It is also helpful to store $\|u_i\|^2$ to avoid repeated computation in step 4. If storage becomes excessive, the algorithm may be restarted after the m th iteration starting with $p_1 = p_m$ and $u_1 = u_m$.

6. PRECONDITIONERS FOR ITERATIVE METHODS

The convergence rate of iterative methods, both classical and conjugate-gradient, can be very slow if the system matrix is not *well-conditioned*. As mentioned in the section on classical iterative methods, the convergence of these methods depends on the spectral radius of the iteration matrix ($\mathbf{M}^{-1}\mathbf{N}$). Similarly, the convergence rate of CG methods depends on the spectral properties of the system matrix (see Section 7 for a discussion). Certain formulations in electromagnetics give rise to poorly conditioned systems, such as the electric field integral equation (EFIE). Sometimes the formulation may be altered to give a better conditioned system, such as by converting the EFIE to the combined field integral equation. The choice of basis functions may also affect the conditioning. Alternatively, one may apply a *preconditioner* matrix \mathbf{M} to the original system as

$$\mathbf{M}^{-1}\mathbf{A}x = \mathbf{M}^{-1}b$$

Clearly, if the inverse of \mathbf{M} approximates the inverse of \mathbf{A} , then the solution of this system should be easier, or, mathematically speaking, the matrix $\mathbf{M}^{-1}\mathbf{A}$ should have better spectral properties than the original matrix. The preconditioner may be implemented in any iterative algorithm by replacing matrix–vector products of the form $\mathbf{A}p$ with $\mathbf{M}^{-1}\mathbf{A}p$, and the excitation vector b with $\mathbf{M}^{-1}b$. There are cleverer ways to do this as described in Section 7.

The preconditioner should improve convergence, while its inverse \mathbf{M}^{-1} (or factorization) must be computed efficiently. It is not a coincidence that the preconditioner matrix \mathbf{M} uses the same symbol as the classical iterative matrix splitting \mathbf{M} . In fact, the \mathbf{M} matrix of all of the classical iteration matrix splittings discussed here and shown in Fig. 2 may be used as a preconditioner, namely, diagonal, block-diagonal, lower or upper triangular, and banded. Classical splittings often mimic wave interactions, which make them useful as preconditioners. From the matrix-splitting point of view, we want the matrix \mathbf{M} to contain the “dominant” portion of the system matrix \mathbf{A} . Then the inverse of \mathbf{M} will approximate the inverse of \mathbf{A} , and the iterative algorithm should therefore converge rapidly.

A very effective preconditioner for the EFIE with subsectional basis functions is described in Ref. 26. The preconditioner \mathbf{M} is a sparse version of \mathbf{A} , which contains the matrix entries corresponding to basis interactions within a specified distance. Incomplete factorization is used to compute a sparse factorization of \mathbf{M} . In fact, there is a large class of preconditioners that use incomplete factorization. Some common preconditioning approaches for iterative algorithms are discussed in Refs. 1 and 23.

7. THEORY OF THE BASIC CG METHOD

The basic CG method is applicable only to symmetric systems. Consider the following complex symmetric matrix equation

$$\mathbf{A}x = b \quad (15)$$

where \mathbf{A} is an $N \times N$ complex symmetric matrix, x is the solution column vector, and b is the RHS excitation column vector. Before we derive the CG method, let us try to answer a few related questions first.

A-Conjugate Condition. Given a set of basis column vectors $\{v_0, v_1, \dots, v_{n-1}\}$ with $n < N$, how to determine the *best* approximate solution

$$\tilde{x}_{\text{app}} = \sum_{i=0}^{n-1} c_i \tilde{v}_i \quad (16)$$

that solves (15). The answer is the Galerkin method, or weighted residual. For each column vector, we shall form a residual column vector

$$\tilde{\mathbf{R}} = \tilde{\mathbf{b}} - \mathbf{A}\tilde{x}_{\text{app}} \quad (17)$$

Note also that equation (16) can be written in matrix form as

$$\tilde{x}_{\text{app}} = \mathbf{V}\tilde{\mathbf{c}} \quad (18)$$

$$\mathbf{V} = [\tilde{v}_0 \quad \tilde{v}_1 \quad \cdots \quad \tilde{v}_{n-1}], \quad \tilde{\mathbf{c}} = \begin{bmatrix} c_0 \\ c_1 \\ \vdots \\ c_{n-1} \end{bmatrix}$$

Subsequently, by requiring that the residual vector $\tilde{\mathbf{R}}$ be orthogonal to all the basis vectors is equivalent to solving the coefficient vector $\tilde{\mathbf{c}}$ through the following reduced matrix equation

$$(\mathbf{V}^t \mathbf{A} \mathbf{V}) \tilde{\mathbf{c}} = \mathbf{V}^t \tilde{\mathbf{b}} \quad (19)$$

Let us take a closer look at Eq. (19). If the reduced matrix $\mathbf{V}^t \mathbf{A} \mathbf{V}$ turns out to be an identity matrix, then the coefficients can be simply computed by

$$c_i = v_i \tilde{\mathbf{b}}, \quad v = (\tilde{v})^t \quad (20)$$

What is more is that, as will be seen later in this section, there is no need to store all these basis vectors in order to find the approximate matrix solution \tilde{x}_{app} . Requiring $\mathbf{V}^t \mathbf{A} \mathbf{V} \equiv \mathbf{I}$ implies that the basis vectors need to satisfy

$$v_i \mathbf{A} \tilde{v}_j = \delta_{ij} \quad (21)$$

which is called the *A-conjugate condition*.

Before moving on to derive the CG methods, let's take a few moments to restate what we have discussed in a more fundamental way. You see, as in many applications, to solve equations, whether infinite dimensional problems (integral equation formulations), or finite-dimensional

problems (like matrix equations), the Galerkin method is a very good method of choice. Once again, in applying the Galerkin method, we shall need to establish what the trial and test function spaces are. When the operators are symmetric, some would argue that they need to be positive definite as well, we can simply have both the trial and test functions be the same. The next logical question will be how to generate these basis vectors that span the trial and test function spaces. As basic linear algebra taught us, these basis vectors at least need to be linearly independent, preferably orthonormal. This is where the *A-conjugate condition* comes in. When the operator is symmetric, we can, with some violation when the operator is not positive definite, define the vector inner product as

$$\langle \tilde{v}_i, \tilde{v}_j \rangle = v_i \mathbf{A} \tilde{v}_j \quad (22)$$

As you shall see, different definitions of the “inner product” lead to different variants of CG methods.

For the matrix equation $\mathbf{A}\tilde{x} = \tilde{\mathbf{b}}$ with a nonzero initial solution \tilde{x}_i , it is always possible to solve for the correction equation $\mathbf{A}\tilde{x}' = \tilde{\mathbf{b}}' (= \tilde{\mathbf{b}} - \mathbf{A}\tilde{x}_i)$, and with $\tilde{x} = \tilde{x}' + \tilde{x}_i$. Therefore, without loss of generality, we shall assume that we will solve $\mathbf{A}\tilde{x} = \tilde{\mathbf{b}}$ with initial guess zero. We shall derive the CG method by induction.

$k=0$: With the initial solution $\tilde{x}^{(0)} = 0$, the residual vector is simply $\tilde{r}^{(0)} = \tilde{\mathbf{b}}$. The trial space for solving the matrix equation can now be established as

$$\mathbf{V}_0 = [\tilde{v}_0] = \text{MGS}_A\{\tilde{r}_0\} \quad (23)$$

The notation $\text{MGS}_A\{\tilde{a}_0 \quad \tilde{a}_1 \quad \cdots \quad \tilde{a}_{n-1}\}$ means making an orthonormal basis from the n column vectors, $\tilde{a}_0 \quad \tilde{a}_1 \quad \cdots \quad \tilde{a}_{n-1}$, through the modified Gram-Schmidt (MGS) process and the inner product is defined by the *A-conjugate condition*:

$$\tilde{v}_0 = \frac{\tilde{r}_0}{\sqrt{r_0 \mathbf{A} \tilde{r}_0}} \quad (24)$$

Notice that, in equation (24), we have an expression $r_0 \mathbf{A} \tilde{r}_0$. If the matrix \mathbf{A} is positive definite, the expression $r_0 \mathbf{A} \tilde{r}_0$ will always be a positive nonzero number, thus Eq. (24) will always be valid. Since in our case \mathbf{A} is a complex symmetric matrix, it is possible that $r_0 \mathbf{A} \tilde{r}_0 \equiv 0$ even though $\tilde{r}_0 \neq 0$. This is referred to as “breakdown” in the CG method. Although, in practical computation, it rarely occurs, but when the matrix \mathbf{A} is poorly conditioned, it is possible that $r_0 \mathbf{A} \tilde{r}_0 \approx 0$ and thus causes slow and even failure to converge in the CG process. It should be emphasized here that many researchers object to the use of CG method to non-positive-definite matrix equations; in reality, with good preconditioners (a topic which is of paramount importance) the CG method may be used to solve complex symmetric matrix equations.

$k=1$: The best solution in the trial space $\mathbf{V}_0 = \text{span}\{\tilde{v}_0\}$, from the Galerkin method, for the matrix equation

$\mathbf{A}\tilde{\mathbf{x}} = \tilde{\mathbf{b}}$ is

$$\tilde{\mathbf{x}}^{(1)} = c_0\tilde{\mathbf{v}}_0, \quad c_0 = \nu_0\tilde{\mathbf{b}} \tag{25}$$

Subsequently, the residual vector $\tilde{\mathbf{r}}^{(1)}$ can be obtained as

$$\tilde{\mathbf{r}}^{(1)} = \tilde{\mathbf{b}} - \mathbf{A}\tilde{\mathbf{x}}^{(1)} = \tilde{\mathbf{r}}^{(0)} - c_0\mathbf{A}\tilde{\mathbf{v}}_0 \tag{26}$$

Since the solution is solved through Galerkin method, and $\nu_0\tilde{\mathbf{r}}^{(1)} = 0$, it is certain that $\tilde{\mathbf{r}}^{(1)}$ is linearly independent with vectors from $\mathbf{V}_0 = \text{span}\{\tilde{\mathbf{v}}_0\}$; therefore it would be a good idea to have

$$\mathbf{V}_1 = \mathbf{V}_0 \cup \text{span}\{\tilde{\mathbf{r}}^{(1)}\} = \text{MGS}_A\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{r}}^{(1)}\} \tag{27}$$

Consequently, our new basis vector is determined through the modified Gram-Schmidt (MGS) process:

$$\begin{aligned} \tilde{\mathbf{w}} &= \tilde{\mathbf{r}}^{(1)} - \beta\tilde{\mathbf{v}}_0, \quad \beta = \nu_0\mathbf{A}\tilde{\mathbf{r}}^{(1)} = \nu_0^{(1)}\mathbf{A}\tilde{\mathbf{v}}_0 \\ \tilde{\mathbf{v}}_1 &= \frac{\tilde{\mathbf{w}}}{\sqrt{\nu_0\mathbf{A}\tilde{\mathbf{w}}}} \end{aligned} \tag{28}$$

It is easy to verify that $\nu_0\mathbf{A}\tilde{\mathbf{v}}_1 = \nu_1\mathbf{A}\tilde{\mathbf{v}}_0 = 0$ and $\nu_0\mathbf{A}\tilde{\mathbf{v}}_0 = \nu_1\mathbf{A}\tilde{\mathbf{v}}_1 = 1$. Moreover, we see from equation (26), $\mathbf{A}\tilde{\mathbf{v}}_0 \in \mathbf{V}_1$. To summarize, at $k=1$, we have the following conditions:

1. $\mathbf{V}_1 = \text{span}\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{v}}_1\} = \text{MGS}_A\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{r}}^{(1)}\}$
2. $\mathbf{V}_1^t\mathbf{A}\mathbf{V}_1 = \mathbf{I}$
3. $\mathbf{A}\tilde{\mathbf{v}}_0 \in \mathbf{V}_1$

***k*th iteration:** At this moment, we have the trial space $\mathbf{V}_{k-1} = \text{span}\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{v}}_1 \quad \dots \quad \tilde{\mathbf{v}}_{k-1}\}$ and it satisfies

1. $\nu_i\mathbf{A}\tilde{\mathbf{v}}_j = \delta_{ij}, i, j = 0, 1, \dots, (k-1)$
2. $\mathbf{A}\tilde{\mathbf{v}}_i \in \mathbf{V}_{k-1}, i = 0, 1, \dots, (k-2)$

The best matrix solution in the trial space $\mathbf{V}_{k-1} = \text{span}\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{v}}_1 \quad \dots \quad \tilde{\mathbf{v}}_{k-1}\}$ is then

$$\begin{aligned} \tilde{\mathbf{x}}^{(k)} &= \sum_{i=0}^{k-1} c_i\tilde{\mathbf{v}}_i = \sum_{i=0}^{k-1} \left(\nu_i\tilde{\mathbf{b}}\right)\tilde{\mathbf{v}}_i \\ &= \tilde{\mathbf{x}}^{(k-1)} + \left(\nu_{k-1}\tilde{\mathbf{b}}\right)\tilde{\mathbf{v}}_{k-1} = \tilde{\mathbf{x}}^{(k-1)} + \alpha\tilde{\mathbf{v}}_{k-1} \end{aligned} \tag{29}$$

and of course, the residual vector is computed through

$$\tilde{\mathbf{r}}^{(k)} = \tilde{\mathbf{b}} - \mathbf{A}\tilde{\mathbf{x}}^{(k)} = \tilde{\mathbf{r}}^{(k-1)} - \alpha\mathbf{A}\tilde{\mathbf{v}}_{k-1} \tag{30}$$

From the Galerkin method it follows that

$$\nu_i\tilde{\mathbf{r}}^{(k)} = 0, \quad i = 0, 1, \dots, (k-1) \tag{31}$$

Since $\mathbf{A}\tilde{\mathbf{v}}_i \in \mathbf{V}_{k-1}, i = 0, 1, \dots, (k-2)$, we also have

$$\nu_i\mathbf{A}\tilde{\mathbf{r}}^{(k)} = 0, \quad i = 0, 1, \dots, (k-2) \tag{32}$$

Subsequently, the next basis vector will be computed by

$$\begin{aligned} \tilde{\mathbf{p}} &= \tilde{\mathbf{r}}^{(k)} - \sum_{i=0}^{k-1} \beta_i\tilde{\mathbf{v}}_i = \tilde{\mathbf{r}}^{(k)} - \sum_{i=0}^{k-1} \left(\nu_i\mathbf{A}\tilde{\mathbf{r}}^{(k)}\right)\tilde{\mathbf{v}}_i \\ &= \tilde{\mathbf{r}}^{(k)} - \left(\nu_{k-1}\mathbf{A}\tilde{\mathbf{r}}^{(k)}\right)\tilde{\mathbf{v}}_{k-1} = \tilde{\mathbf{r}}^{(k)} - \beta\tilde{\mathbf{v}}_{k-1} \end{aligned} \tag{33}$$

and

$$\tilde{\mathbf{v}}_k = \frac{\tilde{\mathbf{p}}}{\sqrt{\nu_0\mathbf{A}\tilde{\mathbf{p}}}} \tag{34}$$

Consequently, $\{\tilde{\mathbf{v}}_0 \quad \tilde{\mathbf{v}}_1 \quad \dots \quad \tilde{\mathbf{v}}_k\}$ is an *A*-conjugate basis for the trial space \mathbf{V}_k . This process continues until $\|\tilde{\mathbf{r}}^{(k)}\|$ is very small at a certain iteration *k*; it then implies, for all practical purposes, that $\tilde{\mathbf{x}}^{(k)}$ is the solution to the matrix equation $\mathbf{A}\tilde{\mathbf{x}} = \tilde{\mathbf{b}}$. Note that the process is extremely simple and the recursive nature of the process makes it possible not to store all the basis vectors.

The detailed induction argument above leads directly to the basic CG algorithm 1 listed earlier in this article.

7.1. Convergence Rate of Conjugate-Gradient Methods

There are two features that can make CG converge fast: (1) eigenvalue clusters and (2), a good condition number of the matrix. To see why eigenvalue clusters are good for CG method, let's look at the following theorem.

Theorem 1. Assume that matrix **A**, which is a diagonalizable $N \times N$ symmetric matrix, has only *k* distinctive eigenvalues, namely

$$\begin{aligned} \lambda(\mathbf{A}) &= \left\{ \overbrace{\lambda_0 \quad \lambda_0 \quad \dots \quad \lambda_0}^{n_0} \quad \overbrace{\lambda_1 \quad \lambda_1 \quad \dots \quad \lambda_1}^{n_1} \quad \dots \quad \overbrace{\lambda_{k-1} \quad \lambda_{k-1} \quad \dots \quad \lambda_{k-1}}^{n_{k-1}} \right\} \\ n_0 + n_1 + \dots + n_{k-1} &= N \end{aligned} \tag{35}$$

then the dimension of the Krylov space

$$K_m(\tilde{\mathbf{v}}_0; \mathbf{A}) = \{\tilde{\mathbf{v}}_0 \quad \mathbf{A}\tilde{\mathbf{v}}_0 \quad \dots \quad \mathbf{A}^{m-1}\tilde{\mathbf{v}}_0\} \tag{36}$$

will always be bounded by *k* regardless of the initial vector $\tilde{\mathbf{v}}_0$ and *m*:

$$\dim[K_m(\tilde{\mathbf{v}}_0; \mathbf{A})] \leq k \tag{37}$$

Proof: Let $\tilde{\mathbf{e}}_{p_i}$ be the *i*th eigenvector corresponding to eigenvalue λ_p of the matrix **A**:

$$\mathbf{A}\tilde{\mathbf{e}}_{p_i} = \lambda_p\tilde{\mathbf{e}}_{p_i}; \quad i = 0, 1, \dots, (n_p - 1) \tag{38}$$

Since these eigenvectors form a complete set of basis vectors, any column vector \tilde{v}_0 can be written as a linear combination of these eigenvectors:

$$\tilde{v}_0 = \sum_{p=0}^{k-1} \sum_{i=0}^{n_p-1} c_{p,i} \tilde{e}_{p,i} = \sum_{p=0}^{k-1} \tilde{v}_0^{(p)} \quad (39)$$

$$\tilde{v}_0^{(p)} = \sum_{i=0}^{n_p-1} c_{p,i} \tilde{e}_{p,i}$$

It then follows that

$$\begin{aligned} \mathbf{A}\tilde{v}_0 &= \sum_{p=0}^{k-1} \sum_{i=0}^{n_p-1} \lambda_p c_{p,i} \tilde{e}_{p,i} = \sum_{p=0}^{k-1} \lambda_p \sum_{i=0}^{n_p-1} c_{p,i} \tilde{e}_{p,i} \\ &= \sum_{p=0}^{k-1} \lambda_p \tilde{v}_0^{(p)} \end{aligned} \quad (40)$$

Moreover, we have

$$\mathbf{A}^n \tilde{v}_0 = \sum_{p=0}^{k-1} \lambda_p^n \tilde{v}_0^{(p)} \quad (41)$$

This means that for any Krylov vector $\mathbf{A}^n \tilde{v}_0$, it can always be written as a linear combination of k independent vectors $\tilde{v}_0^{(0)}, \tilde{v}_0^{(1)}, \dots, \tilde{v}_0^{(k-1)}$. Thus, we conclude that

$$\dim[K_m(\tilde{v}_0; \mathbf{A})] = \dim\{\tilde{v}_0 \quad \mathbf{A}\tilde{v}_0 \quad \dots \quad \mathbf{A}^{m-1}\tilde{v}_0\} \leq k \quad (42)$$

regardless of the initial vector and the iteration number m .

Consequently, in applying the CG method, or any Krylov-based methods, to solve a matrix equation with k distinctive eigenvalues, CG converges in at most k iterations.

Next, let's examine the effect of condition number on the convergence rate of the CG methods. To gain more insight, let us assume further that matrix \mathbf{A} is an $N \times N$ symmetric positive definite (SPD) matrix. With this assumption, we can state a fact that at the m th iteration, the CG method produces the same solution as the following minimization problem.

Minimization: Seek $\tilde{\mathbf{x}}^{(m)} \in K_m(\tilde{\mathbf{b}}; \mathbf{A}) = \{\tilde{\mathbf{b}} \quad \mathbf{A}\tilde{\mathbf{b}} \quad \dots \quad \mathbf{A}^{m-1}\tilde{\mathbf{b}}\}$ such that the quadratic form

$$\left(\mathbf{x} - \tilde{\mathbf{x}}^{(m)} \right) \mathbf{A} \left(\mathbf{x} - \tilde{\mathbf{x}}^{(m)} \right) \quad (43)$$

is minimized.

Since \mathbf{A} is SPD, and its eigenvectors form a complete set of basis vectors, we can express the RHS vector $\tilde{\mathbf{b}}$ as

follows:

$$\tilde{\mathbf{b}} = b_0 \tilde{\mathbf{e}}_0 + b_1 \tilde{\mathbf{e}}_1 + \dots + b_{N-1} \tilde{\mathbf{e}}_{N-1} = \sum_{i=0}^{N-1} b_i \tilde{\mathbf{e}}_i \quad (44)$$

It is easy to show then the exact solution $\tilde{\mathbf{x}}$ is

$$\tilde{\mathbf{x}} = \frac{b_0}{\lambda_0} \tilde{\mathbf{e}}_0 + \frac{b_1}{\lambda_1} \tilde{\mathbf{e}}_1 + \dots + \frac{b_{N-1}}{\lambda_{N-1}} \tilde{\mathbf{e}}_{N-1} = \sum_{i=0}^{N-1} \frac{b_i}{\lambda_i} \tilde{\mathbf{e}}_i \quad (45)$$

Furthermore, a general trial vector in the Krylov space in the m th iteration is of the form

$$\begin{aligned} \tilde{v} &= \sum_{i=0}^{m-1} c_i \left(\mathbf{A}^i \tilde{\mathbf{b}} \right) \\ &= \sum_{i=0}^{m-1} (c_0 + c_1 \lambda_i + \dots + c_{m-1} \lambda_i^{m-1}) b_i \tilde{\mathbf{e}}_i \end{aligned} \quad (46)$$

Subsequently

$$\tilde{\mathbf{x}} - \tilde{v} = \sum_{i=0}^{N-1} \frac{1}{\lambda_i} (1 - c_0 \lambda_i - c_1 \lambda_i^2 - \dots - c_{m-1} \lambda_i^m) b_i \tilde{\mathbf{e}}_i \quad (47)$$

and a quadratic functional $F(\tilde{v})$ can be defined as

$$F(\tilde{v}) = (\mathbf{x} - \tilde{v}) \mathbf{A} (\mathbf{x} - \tilde{v}) \quad (48)$$

Substituting (46) and (47) into Eq. (48), we have

$$\begin{aligned} F(\tilde{v}) &= \sum_{i=0}^{N-1} [1 - c_0 \lambda_i - c_1 \lambda_i^2 - \dots - c_{m-1} \lambda_i^m]^2 \frac{1}{\lambda_i} b_i^2 \\ &\leq \max_{\substack{0 \leq i \leq N-1 \\ \lambda_i}} [1 - c_0 \lambda_i - c_1 \lambda_i^2 - \dots - c_{m-1} \lambda_i^m]^2 \sum_{i=0}^{N-1} \frac{1}{\lambda_i} b_i^2 \\ &= \max_{\substack{0 \leq i \leq N-1 \\ \lambda_i}} [1 - c_0 \lambda_i - c_1 \lambda_i^2 - \dots - c_{m-1} \lambda_i^m]^2 \left| \mathbf{x} \mathbf{A} \tilde{\mathbf{x}} \right| \end{aligned} \quad (49)$$

Since the CG solution is the same as the one that minimizes the quadratic functional, we have

$$\begin{aligned} F(\tilde{\mathbf{x}}^{(m)}) &= \min_{\tilde{v} \in K_m(\tilde{\mathbf{b}}; \mathbf{A})} F(\tilde{v}) \leq \left| \mathbf{x} \mathbf{A} \tilde{\mathbf{x}} \right| \min_{\{c_0 \quad c_1 \quad \dots \quad c_{m-1}\}} \\ &\quad \max_{\substack{0 \leq i \leq N-1 \\ \lambda_i}} [1 - c_0 \lambda_i - c_1 \lambda_i^2 - \dots - c_{m-1} \lambda_i^m]^2 \\ &= \left| \mathbf{x} \mathbf{A} \tilde{\mathbf{x}} \right| \min_{P_m(0)=1} \max_{0 \leq i \leq N-1} |P_m(\lambda_i)|^2 \end{aligned} \quad (50)$$

where $P_m(\lambda)$ is the m th polynomial in λ . If we arrange the eigenvalues of \mathbf{A} in ascending manner, namely, $\lambda_0 \leq \lambda_1 \leq \dots \leq \lambda_{N-1}$, then we can replace the best approximation problem on the discrete set with the best

approximation problem on the interval $[\lambda_0 \ \lambda_{N-1}]$. Note that we have

$$\min_{P_m(0)=1} \max_{\lambda_i} |P_m(\lambda_i)| \leq \min_{P_m(0)=1} \max_{\lambda_0 \leq \lambda \leq \lambda_{N-1}} |P_m(\lambda)| \quad (51)$$

The solution to the minmax problem on an interval is known; namely

$$\min_{P_m(0)=1} \max_{\lambda_0 \leq \lambda \leq \lambda_{N-1}} |P_m(\lambda)| = \frac{1}{T_m\left(\frac{\lambda_{N-1} + \lambda_0}{\lambda_{N-1} - \lambda_0}\right)} \max_{\lambda_0 \leq \lambda \leq \lambda_{N-1}} \left| T_m\left(\frac{\lambda_{N-1} + \lambda_0 - 2\lambda}{\lambda_{N-1} - \lambda_0}\right) \right| \quad (52)$$

where $T_m(x) = \frac{1}{2} \left[(x + \sqrt{x^2 - 1})^m + (x - \sqrt{x^2 - 1})^m \right]$ is the Chebyshev polynomial. Also, since $\max_{-1 \leq x \leq 1} |T_m(x)| = 1$ and $-1 \leq [(\lambda_{N-1} + \lambda_0 - 2\lambda)/(\lambda_{N-1} - \lambda_0)] \leq 1$, we then find

$$\begin{aligned} \min_{P_m(0)=1} \max_{\lambda_0 \leq \lambda \leq \lambda_{N-1}} |P_m(\lambda)| &= \frac{1}{T_m\left(\frac{\lambda_{N-1} + \lambda_0}{\lambda_{N-1} - \lambda_0}\right)} \\ &= 2 \frac{\sigma^m}{1 + \sigma^{2m}}; \\ \sigma &= \frac{1 - \sqrt{\frac{\lambda_0}{\lambda_{N-1}}}}{1 + \sqrt{\frac{\lambda_0}{\lambda_{N-1}}}} \end{aligned} \quad (53)$$

In conclusion, the convergence rate of CG method, measured in A norm is

$$\sqrt{(x - x^{(m)}) \mathbf{A} (x - x^{(m)})} \leq 2 \frac{\sigma^m}{1 + \sigma^{2m}} \sqrt{x \mathbf{A} x} \quad (54)$$

7.2. Preconditioned CG method

We conclude the previous section by observing that CG method works well on matrices that are either well-conditioned or have just a few distinct eigenvalues. For many RF engineering applications (such as the electric field integral equation), the system matrix equations are usually not suitable directly for CG method. However, if a proper preconditioning matrix, $\mathbf{M} = \mathbf{C}^t \mathbf{C}$, can be found, then the system matrix can be transformed into

$$\begin{aligned} \mathbf{A} \tilde{\mathbf{x}} = \tilde{\mathbf{b}} &\Rightarrow \mathbf{A}' \tilde{\mathbf{z}} = \tilde{\mathbf{b}}' \\ \mathbf{A}' &= \left((\mathbf{C}^t)^{-1} \mathbf{A} \mathbf{C}^{-1} \right), \tilde{\mathbf{x}} = \mathbf{C} \tilde{\mathbf{z}}, \\ \tilde{\mathbf{b}}' &= (\mathbf{C}^t)^{-1} \tilde{\mathbf{b}} \end{aligned} \quad (55)$$

Applying the CG algorithm 1 to the transformed matrix equation results in the following algorithm.

CG Algorithm 2

Initialization: $\tilde{\mathbf{v}}' = -\frac{\tilde{\mathbf{b}}'}{\sqrt{\tilde{\mathbf{b}}' \mathbf{A}' \tilde{\mathbf{b}}'}}$, $\tilde{\mathbf{z}} = 0, \tilde{\mathbf{r}}' = \tilde{\mathbf{b}}'$
 Iteration:

1. $\tilde{\mathbf{z}} = \tilde{\mathbf{z}} + \alpha \tilde{\mathbf{v}}', \quad \alpha = \underline{v}' \tilde{\mathbf{b}}'.$
2. $\tilde{\mathbf{u}}' = \mathbf{A}' \tilde{\mathbf{v}}', \quad \tilde{\mathbf{r}}' = \tilde{\mathbf{r}}' - \alpha \tilde{\mathbf{u}}'.$
3. Check $\|\tilde{\mathbf{r}}'\| / \|\tilde{\mathbf{b}}'\| \leq \epsilon$. If yes, then stop, and $\tilde{\mathbf{z}}$ is a good approximation; if no, then continue.
4. $\tilde{\mathbf{p}}' = \tilde{\mathbf{r}}' - \beta \tilde{\mathbf{v}}', \quad \beta = \underline{u}' \tilde{\mathbf{r}}'.$
5. $\tilde{\mathbf{v}}' = \tilde{\mathbf{p}}' / \sqrt{\tilde{\mathbf{p}}' \mathbf{A}' \tilde{\mathbf{p}}'}$.
6. Go to step 1.

Of course, once we have $\tilde{\mathbf{z}}$, then we can obtain $\tilde{\mathbf{x}}$ via $\tilde{\mathbf{x}} = \mathbf{C}^{-1} \tilde{\mathbf{z}}$. However, it is possible to avoid explicit reference to the matrix \mathbf{C}^{-1} by defining $\tilde{\mathbf{p}}' = \mathbf{C} \tilde{\mathbf{p}}, \tilde{\mathbf{z}} = \mathbf{C} \tilde{\mathbf{x}}$ and $\tilde{\mathbf{r}}' = (\mathbf{C}^t)^{-1} \tilde{\mathbf{r}}$ in every CG iteration. Indeed, if we substitute these definitions into CG algorithm 2 and recall $\tilde{\mathbf{b}}' = (\mathbf{C}^t)^{-1} \tilde{\mathbf{b}}$, then we obtain

CG Algorithm 3

Initialization:

$$\mathbf{C} \tilde{\mathbf{v}} = \frac{(\mathbf{C}^t)^{-1} \tilde{\mathbf{b}}}{\sqrt{\tilde{\mathbf{b}} (\mathbf{C}^{-1} (\mathbf{C}^t)^{-1}) \mathbf{A} (\mathbf{C}^{-1} (\mathbf{C}^t)^{-1}) \tilde{\mathbf{b}}}}, \quad \tilde{\mathbf{z}} = 0, \tilde{\mathbf{r}} = \tilde{\mathbf{b}}$$

Iteration:

1. $\mathbf{C} \tilde{\mathbf{x}} = \mathbf{C} \tilde{\mathbf{x}} + \alpha \mathbf{C} \tilde{\mathbf{v}}, \quad \alpha = \underline{v} \tilde{\mathbf{b}}.$
2. $(\mathbf{C}^t)^{-1} \tilde{\mathbf{u}} = (\mathbf{C}^t)^{-1} \mathbf{A} \tilde{\mathbf{v}}, \quad (\mathbf{C}^t)^{-1} \tilde{\mathbf{r}} = (\mathbf{C}^t)^{-1} \tilde{\mathbf{r}} - \alpha (\mathbf{C}^t)^{-1} \tilde{\mathbf{u}}.$
3. Check $\|\tilde{\mathbf{r}}'\| / \|\tilde{\mathbf{b}}'\| \leq \epsilon$. If yes, then stop, and $\tilde{\mathbf{x}}$ is a good approximation; if no, then continue.
4. $\mathbf{C} \tilde{\mathbf{p}} = (\mathbf{C}^t)^{-1} \tilde{\mathbf{r}} - \beta \mathbf{C} \tilde{\mathbf{v}}, \quad \beta = \underline{u} \mathbf{C}^{-1} (\mathbf{C}^t)^{-1} \tilde{\mathbf{r}}.$
5. $\mathbf{C} \tilde{\mathbf{v}} = \mathbf{C} \tilde{\mathbf{p}} / \sqrt{\tilde{\mathbf{p}} \mathbf{A} \tilde{\mathbf{p}}}$.
6. Go to step 1.

Finally, the entire algorithm can be simplified by using the preconditioner $\mathbf{M} = \mathbf{C}^t \mathbf{C}$ directly instead of referring to \mathbf{C} or \mathbf{C}^t . This is then the preconditioned CG algorithm.

Preconditioned CG Algorithm

Initialization: $\tilde{\mathbf{z}} = 0, \tilde{\mathbf{r}} = \tilde{\mathbf{b}}, \tilde{\mathbf{p}} = \mathbf{M}^{-1} \tilde{\mathbf{r}}, \tilde{\mathbf{v}} = \tilde{\mathbf{p}} / \sqrt{\tilde{\mathbf{p}} \mathbf{A} \tilde{\mathbf{p}}}$
 Iteration:

1. $\tilde{\mathbf{x}} = \tilde{\mathbf{x}} + \alpha \tilde{\mathbf{v}}, \quad \alpha = \underline{v} \tilde{\mathbf{b}}.$
2. $\tilde{\mathbf{u}} = \mathbf{A} \tilde{\mathbf{v}}, \quad \tilde{\mathbf{r}} = \tilde{\mathbf{r}} - \alpha \tilde{\mathbf{u}}.$
3. Check $\|\tilde{\mathbf{r}}'\| / \|\tilde{\mathbf{b}}'\| \leq \epsilon$. If yes, then stop, and $\tilde{\mathbf{x}}$ is a good approximation; if no, then continue.
4. $\tilde{\mathbf{p}} = \mathbf{M}^{-1} \tilde{\mathbf{r}} - \beta \tilde{\mathbf{v}}, \quad \beta = \underline{u} \mathbf{M}^{-1} \tilde{\mathbf{r}}.$
5. $\tilde{\mathbf{v}} = \tilde{\mathbf{p}} / \sqrt{\tilde{\mathbf{p}} \mathbf{A} \tilde{\mathbf{p}}}$.
6. Go to step 1.

ITS RADIO SERVICE STANDARDS AND WIRELESS ACCESS IN VEHICULAR ENVIRONMENTS (ITS-WAVE) AT 5.9 GHz

RAMEZ L. GERGES
IEEE-ITSC Standards
Committee
Goleta, California

1. INTRODUCTION

This article describes ongoing activities to create a new family of standards that supports the emerging Intelligent

Transportation Systems (ITS) and telematics wireless markets. ITS-WAVE is a radiocommunication system intended to provide seamless, interoperable services to surface transportation systems. After an initial overview of the ITS-WAVE family of standards, more emphasis will be given to the radio (lower layers) part of the system, and the use of orthogonal frequency-division multiplexing (OFDM) for the physical layer [1].

1.1. ITS, Telematics, and Wireless Interoperability

The Intelligent Transportation Systems (ITS) initiative was created by Congress in the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA) to improve the mobility and safety of the surface transportation system. ITS is defined as those systems utilizing synergistic technologies and systems engineering concepts to develop and improve transportation systems of all kinds. Communication and information technologies are at the core of roadside infrastructure and in-vehicle systems. These technologies promise to enhance mobility by improving the way we monitor and manage traffic flow, clear incidents, reduce congestion, and provide alternate routes to travelers. The telematics industry is focused on driver comfort and safety, and while “telematics” in general has meant the blending of computers and telecommunications, it is used within the ITS community with the connotation of “automotive telematics” or the in-vehicle subsystem of ITS.

In 1999, the Federal Communications Commission (FCC) allocated the 5.850–5.925-GHz band for use by the ITS radio service for both public safety and commercial ITS applications. Many standards development organizations (e.g., IEEE, IETF, ISO) are engaged in the process of achieving an end-to-end ITS wireless interoperability. This article addresses Wireless Access in Vehicular Environments (WAVE), which is currently being developed under the IEEE WG 802.11, WAVE Study Group.

1.2. ITS Radio Services

The proposed ITS-WAVE standard addresses broadband wireless communications that operate in a long range (≤ 1000 m) and at a high data rate [27 Mbps (megabits per second)] for all ITS applications. The proposed lower-layer standard currently addresses communications between roadside units and mostly high-speed, but occasionally stopped and slow-moving, vehicles or between high-speed vehicles. The ITS new spectrum will be used to support multiple applications to enhance public safety and transportation mobility and can be categorized as follows:

1. *Public Safety*: The primary use of this band is to offer services such as emergency vehicle signal preemption and announcements for work zones. While the FCC has allocated the 4.9 GHz for communications between *first responders*, the 5.9-GHz band is expected to allow first responders to communicate with the general driving public on roads and freeways.
2. *Mobility*: Services such as electronic toll, vehicle probes, traveler information, and public transporta-

tion integration are expected to enhance the transportation system performance.

3. *Driver Safety*: New features such as support of collision avoidance and warnings for excessive speed and railroad crossings are expected to improve system performance. More recently, vehicle manufacturers and telematics providers have shown interest in the ITS-WAVE standards. There is no other radiocommunication technology that can support the real-time requirements for vehicle-to-vehicle communications.

1.3. ITS-WAVE Development History

Attempts to develop standards for the wireless ITS environment date back to the early 1990s, when California adopted the Title 21 regulation to achieve a common standard for “toll collections.” The dedicated short-range communications (DSRC) standard at 900 MHz, and Title 21 [2], predated the ITS initiative, and addressed only the electronic toll collection; it was not intended to support a national interoperable wireless ITS standard.

The Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA) funded many research ITS programs. In the mid-1990s, the author (then with the New Technology program at Caltrans) initiated some of the first technical studies to develop an integrated wireless communications system for all ITS applications [3]. In 1996, the U.S. National System Architecture identified wireless communications as one of the critical enabling technologies needed to support many of the ITS services. Later, the USDOT funded more studies, and the California Department of Transportation (Caltrans) established the Testbed Center for Interoperability (TCFI) to study and test end-to-end wireless interoperability. In May 1997, the Intelligent Transportation Society of America (ITSA) filed a Petition for Rulemaking, requesting that the FCC allocate 75 MHz of spectrum in the 5.850–5.925-GHz band on a coprimary basis for DSRC-based ITS services. In 1998 at the IEEE-Vehicular Technology Conference, the author suggested to leverage the economical feasibility of the IEEE 802.11 to achieve wireless ITS interoperability [4]. In 1999, the FCC amended Parts 2 and 90 of the Commission’s Rules to allocate the 5.850–5.925-GHz band to the Mobile Service for Dedicated Short Range Communications of Intelligent Transportation Services.¹ The USDOT funded the American Society for Testing and Materials (ASTM) to initiate the standard writing group for the DSRC at 5.9 GHz. In 2000, TCFI tested the first video relay to a moving vehicle at highway speed using OFDM technology.² The successful test paved the way to use broadband technologies for wireless ITS. Later, the ASTM selected the OFDM Forum proposal to use the IEEE 802.11a [5,6] as the basis for the new standard.³ The new DSRC standard is now being

¹ET Docket 98-95, 14 FCC Record 18221.

²Wireless LAN provided the OFDM equipment at 2.4 GHz; Further information is available at <http://www.wi-lan.com>.

³The OFDM-Forum proposal (802.11 RA) suggested changing the physical layer of the IEEE 802.11 to match the requirements of the “road access” environment. (<http://www.ofdm-forum.com>).

Frequency allocations 4.9-5.9 GHz:

Figure 1. Spectrum allocation at the 5-GHz Band. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

completed within the IEEE WG 802.11. The Study Group (SG) decided to use the ASTM standard [7] as the basis for the ITS-WAVE proposal.⁴ As the proposed standard is not limited to short-range applications, the SG has named it the *Wireless Access in Vehicular Environments (WAVE)* instead of DSRC. This will also avoid any confusion with the single carrier technology in use in the United States (900-MHz band) or in Japan and Europe (at 5.8 GHz but different standards).

On December 17, 2003 the FCC adopted the rules for the ITS band. It is expected that the new standard (possibly 802.11p) will be completed by the end of 2005.

2. ITS RADIO SERVICES SYSTEM-LEVEL DESCRIPTION

2.1. Spectrum Allocation for ITS, Telematics, and Public Safety

The Broadband ITS Radio Service (ITS-RS) establishes a common framework for providing wireless services in the 5.850–5.925-GHz band. This band is allocated for ITS-RS applications by the FCC.⁵ Figure 1 shows the spectrum allocation in the 4.9–5.9-GHz band. The differences between the ITS-WAVE and the IEEE 802.11 WLAN systems stem from the fact that the ITS-WAVE operates in a licensed band, and it establishes reliable communications

between units operating at full vehicle mobility, a different environment than the indoor WLAN.

These communications may occur with other units that are (1) fixed along the roadside or above the roadway, (2) mounted in other high-speed moving vehicles, (3) mounted in stationary vehicles, (4) mounted on mobile platforms (e.g., watercraft, buoy, or a robotic platform), or (5) portable or handheld. In-vehicle communications units are called *onboard units (OBUs)*. Communication units fixed along the freeways, over the road on gantries or poles, or off the road in private or public areas, are called *roadside units (RSUs)*. The WAVE RSUs may function as stations or as access points (APs) and the WAVE OBUs only have functions consistent with those of stations (STAs). The common function between all RSUs is that these stationary units control access to the radiofrequency medium for OBUs in their communication zone or relinquish control to broadcast data only.

The vehicular mobility environment requires that we design a system that can survive both the time-dispersive (frequency-selective) multipath fading and the frequency-dispersive (time-selective) fading environment. Tests conducted at the Testbed Center For Interoperability (TCFI) at UCSB show that we may encounter up to 400 ns of delay spread and up to 2200 Hz of Doppler spread as explained later. Single-carrier transmission, with a time-domain equalizer, has an inherent limitation due to convergence and tracking problems which arises as the number of taps increase. A coded OFDM (COFDM) approach similar to the IEEE 802.11a/g standard offered a more robust, as well as economically feasible solution

⁴The ASTM E2213-02 was approved but not published because of copyright issues with the IEEE.

⁵Title 47, *Code of Federal Regulations (CFR)*, Part 90, Subpart M.

Figure 2. Impact of delay spread. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

based on the success of the WLAN industry. This economic feasibility also made the COFDM approach a better candidate than the single-carrier transmission with a frequency-domain equalizer. Although, the latter has the same complexity and may have some good features [e.g., avoids the PAPR (peak-to-average power ratio) issues].

The 802.11a scheme would not be able to tolerate the delay spread expected in the WAVE environment. Figure 2 shows the impact of delay spread on a 16-QAM signal constellation for a 64-subcarrier OFDM system [1]. The channel has a two-ray multipath; the second ray is 6 dB lower than the first one: (1) delay spread less than guard time (Fig. 2a), (2) delay spread greater than guard time by 3% of the FFT interval (Fig. 2b), and (3) delay spread greater than guard time by 9% of the FFT interval (Fig. 2c).

We proposed to double the guard interval (GI) to be more multipath-tolerant; in principle, using half the master clock should double the GI and scale down the channel bandwidth to 10 MHz, a desired outcome to increase the number of channels within the allocated spectrum. Of course the maximum data rate will be reduced to 27 Mbps, which is still adequate for demanding ITS applications (e.g., video relay). WLAN chips manufacturers (e.g., Intersil and Atheros) confirmed the feasibility of the approach using their current 802.11a implementations.⁶ It is expected that products with the correct front end operating at 5.9 GHz (10 MHz bandwidth) will be available as the market develops.

In order to accommodate the more dynamic vehicle environment with essentially the same radio technology, and provide priority to public safety communications, the ITS community is proposing a complementing set of standards under the IEEE SCC32. These standards address the upper layers including a different channel structure and access mechanism than that of the IEEE 802.11 as explained later.

2.2. System Architecture and SDO Coordination

The International Standards Organization (ISO) and the IEEE are coordinating their standards development

efforts to achieve ITS wireless interoperability. To this end a common CALM/WAVE architecture has been developed as shown in Figs. 3 and 4.

The current scope of the IEEE-WAVE proposed project is to create an amendment of IEEE 802.11 to support communication between vehicles and the roadside and between vehicles while operating at speeds up to a minimum of 200 km/h for communication ranges up to 1000 m. The amendment will support communications in the 5-GHz bands; specifically, the 5.850–5.925-GHz band within North America with the aim to enhance the mobility and safety of all forms of surface transportation, including rail and maritime transportation. Amendments to the PHY and MAC will be limited to those required to support communications under these operating environments within the 5-GHz bands.

The IEEE SCC32 sponsors the IEEE P1556, DSRC Security and Privacy and the ITS-WAVE (upper layers). The WG P1556 is proposing a dual-certificate system for public safety and vehicle safety to balance security and anonymity requirements. The IEEE WG P1609 architecture adopted IPV6 as the method of handling upper-layer applications. It consists of a series of four standards:

1. P1609.4 defines the channelization approach and considers integration issue with the IEEE 802.11e and IEEE 802.11 h.
2. P1609.3 is based on the IPv6 specification and may include a broad range of supporting standards defined by the Internet Engineering Task Force (IETF). It defines IPv6 addressing and configuration issues, network services (e.g., WAVE router advertisement), and all the WAVE management entities needed for registration and “service table” exchanges.
3. P1609.2 defines applications services.
4. P1609.1 defines a resource manager for onboard units (OBUs).

The ISO-Transport Information & Control (TC204) Working Group 16 is developing standards for wide-area wireless communications for transport information and control. ISO-TC204-WG16 is developing the communication air interface for long and medium range (or short media) (CALM) architecture. The CALM scope includes

⁶WLAN products from Intersil are now part of Conexant (<http://www.conexant.com>), Atheros (<http://www.atheros.com>).

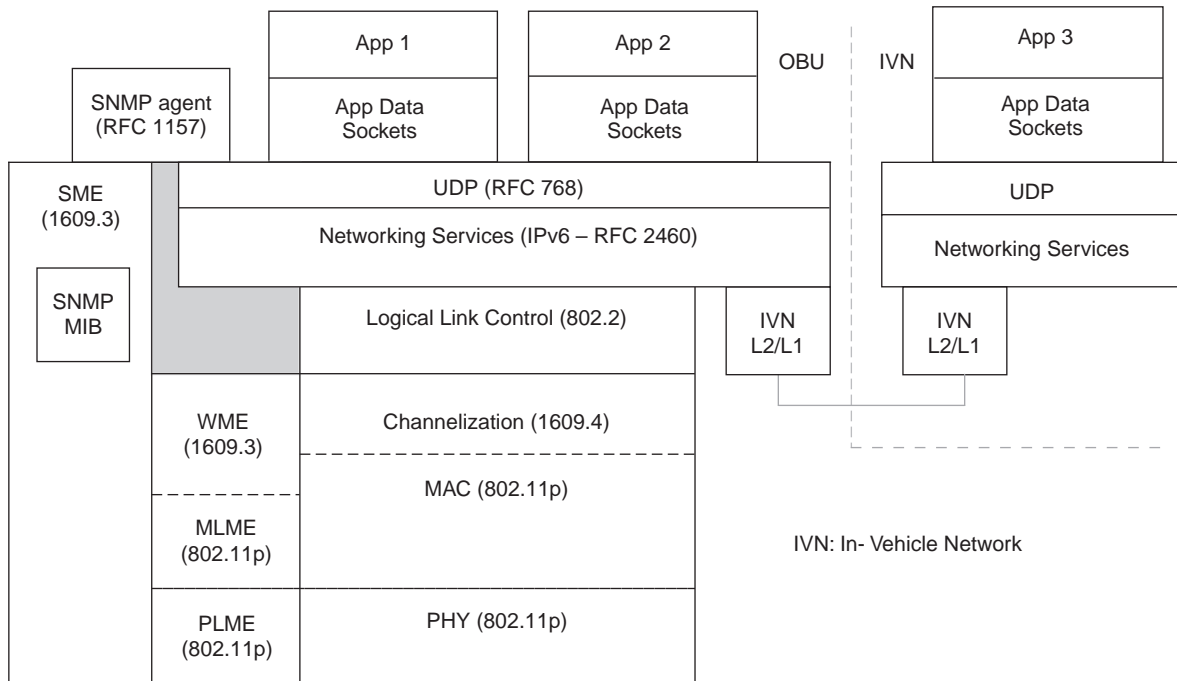

Figure 3. Wave architecture.

communications between fixed sites and switching between communication media (e.g., 3G cellular and WAVE), as well as issues such as handover and mobility management. CALM mandates end-to-end system interoperability at all levels. CALM-M5 is adopting the IEEE-WAVE proposal for the lower layers at 5 GHz.

2.3. Basic Concept of Operation

The ITS-WAVE typically consists of two types of radio devices. The first type is always used while stationary, usually permanently mounted along the roadside, and is referred to as the *roadside unit* (RSU). The second is

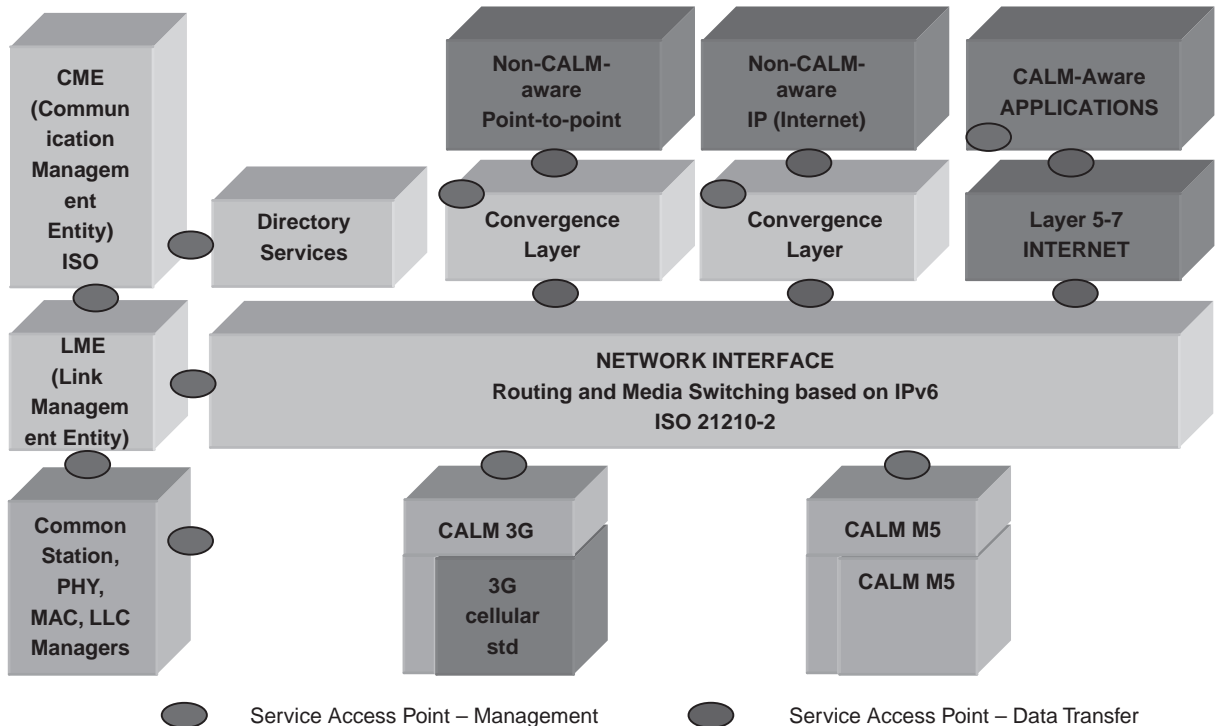

Figure 4. CALM architecture. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

mobile, mounted on board vehicles, and is referred to as the *onboard unit* (OBU). Three types of communication are supported: a command/response type between a service provider and a service user, a broadcast to listener, and a peer-to-peer type that does not identify either device as controlling the actions of the other. OBUs and RSUs can initiate both types of communication. The command/response type includes various forms of transactions between a service provider and a user of that service. To ensure scalable interoperability between ITS-WAVE units, the proposed standards define two levels of implementations. A minimal implementation only supports the lower layers, those below the network layer, and will be referred to as a “WAVE radio.” An implementation that has the full ITS-WAVE protocol stack is referred to as a “WAVE device.” Multiple devices interact with each other through the Networking Services (IEEE P1609).

Figure 5 represents the current ITS-WAVE band plan. The ITS-WAVE uses a “control channel” and any of six “service channels”. Licensing of both roadside RSUs and OBUs are necessary to prevent unauthorized use of the control channel. OBUs should be licensed by rule, since these devices are mobile and can operate nationwide, communicating with any other ITS-WAVE devices within range.

The onboard units (OBUs) are required to listen on the control channel every few hundred milliseconds, in order to check for public safety messages. The messages on the control channel are of variable length, but are generally kept short, to permit maximum access to the channel. Control channel access will be performed via a standard IEEE 802.11a, *Multiple Access with Collision Avoidance* (CSMA/CA). By default, all devices when turned on are tuned to the control channel. If an ITS-WAVE device

desires to transmit, but detects another message being broadcast on the control channel, it must wait before attempting to transmit. A request to send (RTS) is initiated, and time is granted first to high priority (public safety) broadcasts, then to lower-priority transmissions. The same control channel is used for roadside-to-vehicle, vehicle-to-roadside, and vehicle-to-vehicle communications. “Control channel interval” and “service channel interval” are controlled by RSU beacon frames. Since the control channel will be fixed throughout the nation, all ITS-WAVE devices will be able to access those services in an interoperable matter.

A registration process must occur before a WAVE device can be considered “ready for operation”; the RSU broadcasts beacon frames that include the “provider service table” (PST) and the “WAVE router advertisement” (WRA) on the control channel. Application initialization procedures are based on SNMP, and the designated service channel, priority, and power level are indicated in the PST. At the end of the application initialization state, the RSU commands the OBU to switch to the designated service channel. The RSU, now on the service channel, receives UDP datagrams sent by the OBU. The RSU routes datagrams to and from the applications indicated by the global IPv6.

The description above is included to give an idea about the basic concept of operations, with the understanding that the proposed standards are now under development. The P1609.3, 1609.4, and the P1556 are currently the most critical part of the WAVE family of standards as they require integration and coordination with many other standards such as IEEE 802.11e/h/i and many of the IETF recommendations.

Figure 5. ITS-wave band plan. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

It is expected that WAVE radios that implement only the lower layers will develop first, as they leverage the existing IEEE 802.11a standard and chip technology.

3. DESIGNING FOR WIRELESS VEHICULAR ENVIRONMENTS

3.1. Channel Impairments

There is extensive literature on different statistical models of the communication channels at different frequency bands [8]. However, limited data of actual field measurements for vehicle–vehicle and vehicle–roadside communications are available at the ITS-WAVE frequency band. Statistical models include large-scale path loss models and small-scale fading models:

1. Large-scale propagation models characterize the mean received power over large transmitter–receiver separation distances. It is used to estimate radio coverage area of a transmitter.
2. Small-scale (fading) models characterize the rapid fluctuations of the received signal strength and phase over a very short distance. Multipath structure (power delay profile) is used to measure and describe the fading effects.

Both large- and small-scale fading models are needed for packet error rate characterization.

3.1.1. Time-Dispersive (Frequency-Selective) Multipath Fading Channel. A *time-dispersive channel* is defined as a channel for which the delay spread is much wider than the signal duration. The classification of a channel as time dispersive is therefore dependent on the data rate of the system. For a single carrier, high-data-rate systems, time-dispersive channels are commonly encountered. This type of fading is often referred to as *frequency-selective* because the signal may be simultaneously faded at one frequency and not at another. OFDM is robust against delay spread by design because of the longer symbol time and the fact that each subcarrier experiences a flat-fading channel. Similar to the IEEE 802.11a, the insertion of guard interval, and the use of forward error correction (FEC) are essential design elements to the coded OFDM scheme employed in the WAVE physical layer. This multipath rejection capability was one of the main reasons for selecting COFDM instead of a single-carrier system, especially for ITS applications that operate at longer ranges and at high data rates.

Short-range systems typically experience significantly smaller delay spreads than does a longer-range system. Previous studies show that 90% RMS (root-mean-square) delay spread is less than 100 ns for typical short-range applications (e.g., toll collection) in urban environments.⁷ RMS delay spread could be up to 300 ns [9,10] in a non-line-of-sight (NLoS) heavy-multipath environment, as may be expected in a freeway urban environment.

⁷For transmit–receive (Tx/Rx) separation of 30–300 m, both LoS and NLoS (Xiongwen, et.; IEEE JSAC 2002).

In order for subcarriers to perceive a flat-fading channel, the bandwidth (subcarrier spacing) must be less than the “coherence bandwidth” (\mathbf{B}_c) of the channel.⁸ \mathbf{B}_c is the bandwidth of the channel variation in frequency and is defined [8] as

$$\mathbf{B}_c = 1/5 \sigma$$

where σ is the RMS delay spread of the channel. The ITS-WAVE has a subcarrier spacing (bandwidth) of 156 kHz, and each subcarrier will encounter flat fading as long as $\sigma < 100$ ns (for range < 300 m). For long ranges (large delay spread), the pilot channels are available to estimate the channel in the frequency domain if they are well structured. In order to use the pilots for channel estimation, the pilot spacing in frequency has to be less than \mathbf{B}_c (~ 2 MHz for $\sigma = 500$ ns). This may not be the case using the current pilot structure of the IEEE 802.11a (pilot spacing = 14×156 kHz = 2.18 MHz $> \mathbf{B}_c$). Interpolation of pilot subcarrier in the current structure may not be sufficient to track the frequency selective fades. It is expected that the first generation WAVE radios, those using modified 802.11a chips, will be limited in range and may not be suitable for long-range public safety applications.

3.1.2. Frequency-Dispersive (Time-Selective) Fading Channel. Frequency-dispersive channels are classified as channels that have a Doppler spread larger than the channel bandwidth. Doppler spread is a direct result of multiple Doppler shifts which are caused by motion of the transmit and/or receive antenna. Doppler shifts can also result from reflections off of moving objects.⁹ Distortion of the power spectrum of the received signal results from Doppler spread, which can be approximated by the Doppler spread \mathbf{B}_d

$$\mathbf{B}_d = \mathbf{f}_m \cdot \cos \alpha$$

where $\mathbf{f}_m = v \cdot \mathbf{f}_c / c$, where v is the vehicle speed in m/s, \mathbf{f}_c is the carrier frequency in Hz, c is the speed of light in m/s, and α is the angle between the direction of vehicle travel and the ray of the communication path. In the case of the ITS-WAVE where vehicle speeds of ≤ 120 mph (193 km/h) must be supported (public safety), the maximum Doppler shift for a vehicle traveling directly toward the roadside antenna would be about 1100 Hz at 5.9 GHz, and much less for vehicle–vehicle communication (two vehicles heading in the same directions).

Time-selective fading caused by Doppler spread is described by the coherence time (\mathbf{T}_c) of the channel. \mathbf{T}_c represents the duration over which the channel characteristics do not change significantly, and is defined [8] as

$$\mathbf{T}_c = 0.423 / \mathbf{f}_m$$

⁸ \mathbf{B}_c is defined as the bandwidth over which the frequency correlation function is above 0.5.

⁹If a sinusoidal signal is transmitted over a fading channel (commonly referred to as a *constant wave*), the Doppler spread \mathbf{B}_d is defined as the range of frequencies over which the received Doppler spectrum is essentially nonzero.

Figure 6. Subcarrier Orthogonality in OFDM systems. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

At a vehicle speed of 120 mph and a frequency of 5.9 GHz, $T_c = 400 \mu s$. When using pilot symbols at the start of a packet, the assumption is that channel variations during the rest of the packet are negligible. This limits the packet duration to less than T_c , and places an upper limit on the packet size. At a data rate of 3 Mbps, $\frac{1}{2}$ -code-rate BPSK-modulated signal, the maximum packet size¹⁰ is 135 bytes. Although this suggests that higher-order modulation would give better performance, as their transmission time is shorter, these modulation schemes degrade more in the presence of channel impairment.

3.2. The ITS-WAVE Physical Layer

The ITS-WAVE physical layer is based on using the robustness of the coded orthogonal frequency-division multiplexing (OFDM) signal to achieve the required performance in the wireless vehicular environments. OFDM is a special case of multicarrier modulation (MCM), which is the principle of transmitting data by dividing the data-stream into several parallel bitstreams and modulating each bitstream onto individual subcarriers. Each subcarrier is a narrowband signal, resulting in long bit intervals. High data rates are achieved by using multiple orthogonal subcarriers for a single data transmission. The OFDM system differs from traditional MCM in that the spectra of the subcarriers were allowed to overlap under the restriction that they were all mutually orthogonal. An orthogonal relationship between subcarriers is achieved if there are integer numbers of subcarrier frequency cycles over the symbol interval. This orthogonality guarantees that each subcarrier has a null at the center frequency of all other subcarriers as shown in Fig. 6.

Orthogonality is achieved with precision by modulating the subcarriers with a discrete Fourier transform (DFT), which is implemented in hardware with the fast Fourier transform (FFT). By transmitting several symbols in parallel, the symbol duration is increased proportionately, which reduces the effects of intersymbol interference (ISI) caused by the dispersive fading environment. Additional multipath rejection and resistance to intercarrier interference (ICI) is realized by cyclically extending each symbol on each subcarrier. Rather than using an empty guard space, a cyclic extension of the OFDM symbol is used to

¹⁰Packet duration = $[10(16 + 2)(80 + 1)(80 + 135)(8)(2/48)(80)] \times 100 \text{ ns} = 400 \mu s$.

Figure 7. Structure of an Operating Channel.

ensure that delayed replicas of the OFDM symbol will always have an integer number of cycles within the FFT interval. This effectively converts the linear convolution of the channel to a circular one, as long as the cyclic prefix (CP) is longer than the impulse response of the channel. The penalty of using a CP is loss of signal energy proportional to the length of the CP. In order to avoid excessive bit errors on individual subcarriers that are in a deep fade, forward error control (FEC) is typically applied.

The ITS-WAVE physical layer organizes the spectrum into operating channels. Each 10-MHz channel is composed of 52 subcarriers. Four of the subcarriers are used as pilot carriers for monitoring path shifts and ICI, while the other 48 subcarriers are used to transmit data symbols. Subcarriers are spaced 156.25 kHz apart, giving a total bandwidth of 8.8 MHz. The composite waveform, consisting of all 52 subcarriers, is upconverted to one of the seven channels between 5.850 and 5.925 GHz. As shown in Fig. 7, channels are numbered from -26 to 26. Subcarrier 0 is not used for signal processing reasons, and pilot subcarriers are assigned to subcarriers -21, -7, 7, and 21. To avoid strong spectral lines in the Fourier transform, the pilot subcarriers transmit a fixed bit sequence as specified in the IEEE 802.11a using a conservative modulation technique. Table 1 compares the ITS-WAVE and the IEEE 802.11a parameters. Table 2 lists ITS-WAVE baseband modulation values.

3.2.1. Structure of the WAVE Physical Layer. The physical layer is structured as two sublayers: the physical-layer convergence procedure (PLCP) sublayer and the physical-medium-dependent (PMD) sublayer. The PLCP communicates to MAC via primitives through the physical-layer service access point (SAP); it prepares the PLCP protocol data unit (PPDU) shown in Fig. 8. The PPDU provides for asynchronous transfer of the MAC protocol data unit (MPDU) between stations. The PMD provides

Table 1. Comparison of 802.11a and ITS-WAVE Parameters

Parameter	802.11a	ITS-WAVE
Channel bandwidth (MHz)	20	10
Subcarrier spacing (kHz)	312.5	156.25

27	$\frac{3}{4}$	64-QAM	288	216

actual transmission and reception of the physical layer entities via the wireless medium, interfaces directly to the medium, and provides modulation and demodulation of the transmission frame.

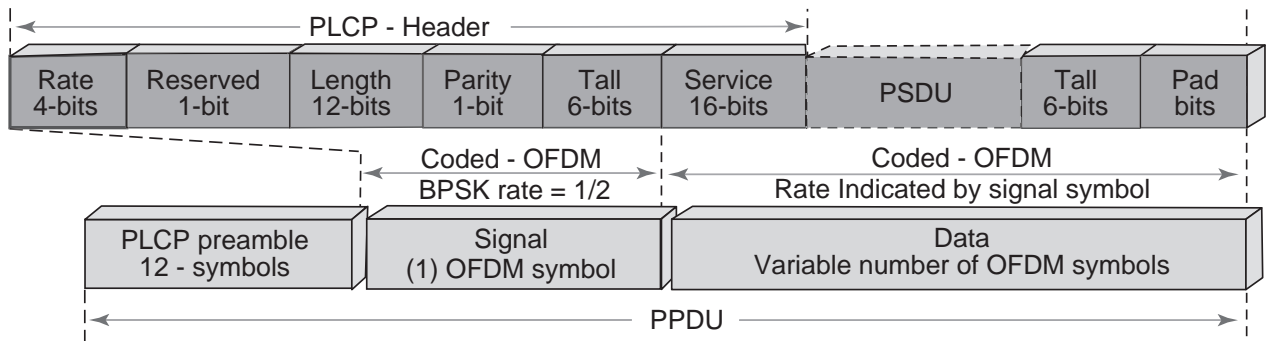

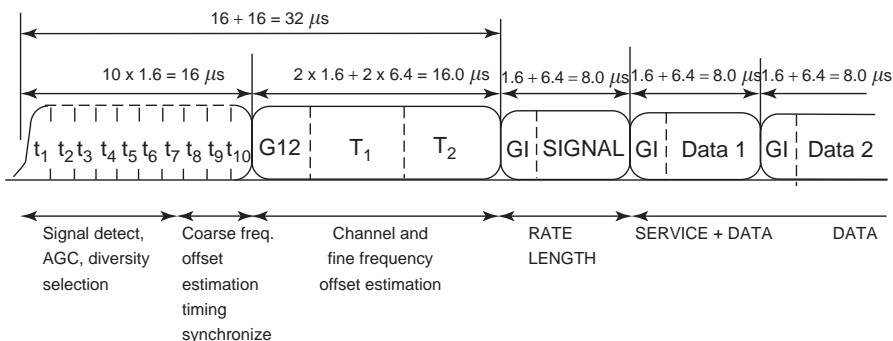

3.2.2. Roles of Preamble, Training Sequences, and Pilots. The ITS-WAVE specifies a preamble at the start of every packet as shown in Fig. 9.

The PLCP preamble consists of 10 short training symbols, each of which is $1.6\ \mu\text{s}$, followed by two long training symbols, each of which is $6.4\ \mu\text{s}$ including a $3.2\text{-}\mu\text{s}$ prefix that precedes the long training symbol. The long training sequence contains a guard interval, T_{GI2} , and two long training symbols, each $6.4\ \mu\text{s}$ in duration. The short symbols are used by the receiver for synchronization [signal detection, AGC (automatic gain control), diversity selection, frequency offset estimation, and timing synchronization]. The long symbols are used to fine-tune the frequency

offset and channel estimates. This training sequence is transmitted over all 52 subcarriers and is QPSK-modulated. In terms of algorithmic complexity, carrier frequency offset and timing recovery are by far the most difficult to determine. The phase-locked-loop (PLL) on the radio subsystem is responsible only for maintaining the 5-ppm voltage-controlled oscillator (VCO) requirement. Digital signal processing is used, independent of the VCO, to remove the carrier frequency offset. It is important to note that once the carrier frequency offset is determined by the digital baseband hardware, there is no time to provide a feedback signal to the WAVE radio's VCO since a PLL network will take too long to eliminate the offset. The training sequences are followed by the SIGNAL symbol, which is a single BPSK-modulated OFDM data symbol containing information about the packet such as data rate.

After preamble transmission, any common frequency offset is tracked via the four pilot subcarriers as shown in Fig. 10. It is not necessary to use pilots to estimate the channel as long as the channel remains fairly stationary over the duration of a single packet. The four pilot signals facilitate coherent detection throughout the duration of the packet. The remaining subcarriers carry the data body of the packet. The pilot spacing is selected to be less than the coherent bandwidth of the channel, as explained later.

3.2.3. ITS-WAVE Performance Issues. The performance of an OFDM receiver is affected by several factors, most of which fall into the categories of hardware limitations and channel impairments. Hardware limitations,

**Figure 8.** PPDU frame.**Figure 9.** ITS-WAVE PLCP structure.

Figure 10. Pilot structure. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

particularly clock accuracy and oscillator stability, affect the synchronization accuracy of the receiver. The channel impairments discussed in Section 3.1 include “delay spread” and “Doppler spread,” which result in frequency-selective fading and time-selective fading, respectively.

OFDM is extremely sensitive to receiver synchronization imperfections, which can cause degradation of system throughput and performance. The overlap between sub-carriers leads to a system that is extremely sensitive to imperfections in carrier frequency synchronization. Also, multiplexing symbols onto multiple subcarriers results in a system that is extremely sensitive to imperfections in timing synchronization. This requires that the receiver architecture be structured to correct for frequency, timing, and sampling. Figure 11 is a simplified block diagram [1] depicting the major processing modules associated with the ITS-WAVE physical layer.

3.2.3.1. Synchronization. Synchronization is a big hurdle in OFDM systems. The ITS-WAVE physical layer uses

the same synchronization scheme as in the IEEE 802.11a; it usually consists of three processes:

1. Frame detection
2. Carrier frequency offset estimation and correction
3. Sampling error correction

Frame detection is used to determine the symbol boundary so that correct samples of the symbol frame can be taken. The first 10 short symbols are identical and are used for frame detection. The received signal is correlated with the known short-symbol waveform that produces correlation peaks. The received signal is also correlated with itself with a delay of one short symbol, which creates a plateau for the length of 10 short symbols. If the correlation peaks are within the plateau, the last peak is used as the position from where the start of the next symbol is determined.

Frequency offset estimation uses the long training symbols, which are two FFT symbols back-to-back. The

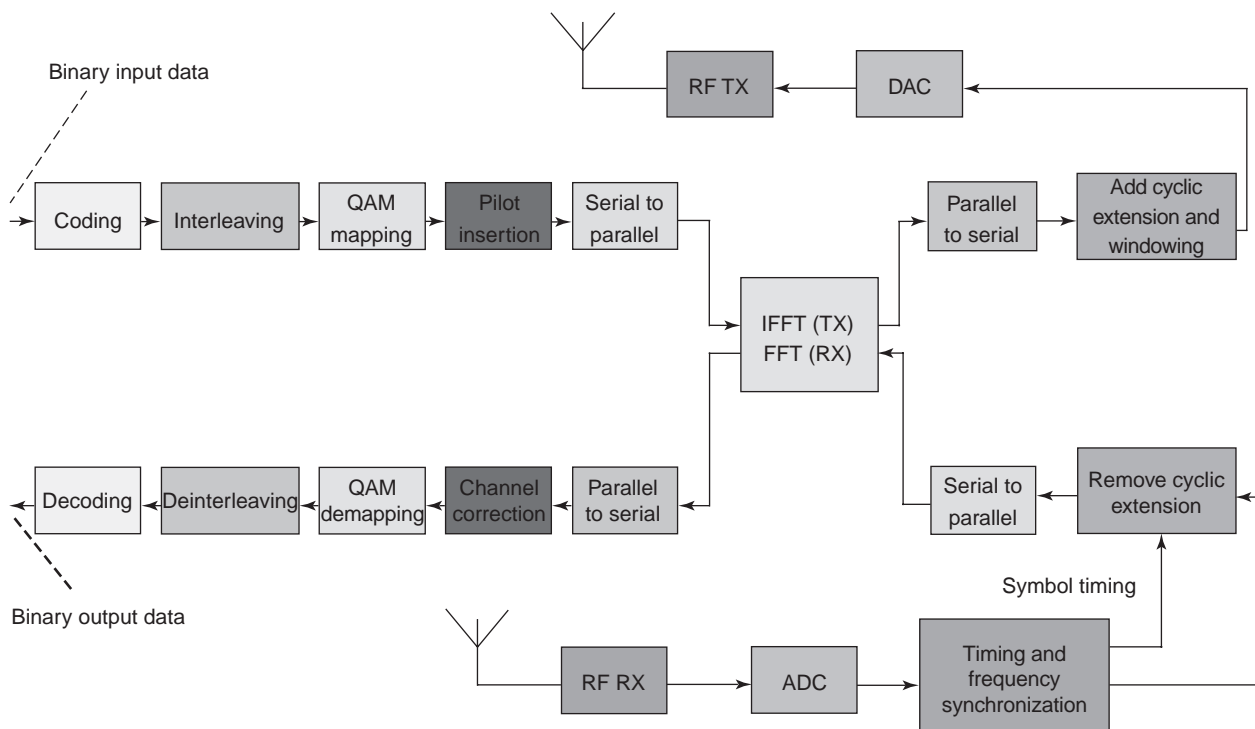

Figure 11. Basic OFDM block diagram.

Figure 12. Carrier frequency offset.

corresponding chips of the two FFT symbols are then correlated to estimate the frequency offset. Channel estimation uses the same two OFDM symbols as the frequency offset estimation. Once the frame start is detected, frequency offset is estimated and signal samples are compensated, the two long symbols are transformed into frequency domain by FFT. After performing FFT on the preambles, the frequency-domain values are compared with the known preamble values to determine the channel response.

3.2.3.2. Carrier Frequency Offset. The ITS-WAVE (like the 802.11a) specifies that the carrier frequency and symbol clock be derived off the same oscillator. This allows the receiver to compute symbol clock drift directly from the carrier frequency offset (e.g., ppm error). Frequency synchronization must be applied before the FFT. Without a carrier frequency offset, the peak of any subcarrier corresponds to the zero crossings of all other subcarriers. When there is a random frequency offset, there is no longer an integer number of cycles over T_{FFT} , resulting in ICI. The degradation in SNR that occurs due to random frequency offset is approximated by D [1] in decibels

$$D \approx \frac{10}{3 \ln 10} (\pi \Delta F T_{\text{FFT}})^2 \frac{E_s}{N_0}$$

ΔF is the frequency offset and W ($= 1/T_{\text{FFT}}$) is the bandwidth of the composite OFDM waveform (subcarrier spacing). In essence, any carrier frequency offset results in a shift of the received signal in the frequency domain. This frequency error results in energy spillover between subcarriers, resulting in loss of their mutual orthogonality. The approximation states that the degradation increases with the square of normalized frequency offset. The major tradeoffs encountered when selecting an appropriate carrier frequency offset correction algorithm include speed, accuracy, and performance under noisy conditions.

Short training symbols can recognize offsets as high as 312.5 kHz [$\frac{1}{2} \times (1/1.6 \mu\text{s})$]. However, their short duration results in reduced accuracy since they produce only 16-point FFT samples per symbol. Although there are 10

short training symbols, 5 or 6 are consumed during RSSI, AGC, and timing recovery. Long training symbols provide a much more accurate estimate of the frequency offset since they produce 4 times as many FFT points compared to the short training symbol. However, their long extent limits the discernable frequency offset to 78 kHz [$\frac{1}{2} \times (1/6.4 \mu\text{s})$] as shown in Fig. 12. Noise imparts variance on the final offset estimate, thereby mitigating its accuracy.

3.2.3.3. Symbol Timing. Errors in symbol timing synchronization manifest as ISI and nonuniform phase shift to the constellation points. Both of these effects naturally lead to degradation of bit error rate (BER). The fast Fourier transform (FFT) demodulation process accumulates over exactly one 6.4- μs OFDM interval. If the start of the symbol time is not accurately established, the FFT demodulation process will operate on two adjacent symbols leading to ISI as shown in Fig. 13. Coarse synchronization can resolve to within half the sampling period and remove ISI. However, the residual sampling time offsets must be identified, or a nonuniform phase shift will be imparted to the constellation points.

The 6.4- μs FFT window is divided up into 64 time instants separated by 100 ns. Each point of the FFT is computed at a rate of 10 Msps (megasamples, i.e., 10,000 samples, per second), which corresponds to 64 discrete frequency-domain samples of the composite 6.4- μs symbol. Since these 64 samples are 100 ns apart [$T_s = 100 \text{ ns}$], the

Figure 13. ISI and sampling-time offset. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

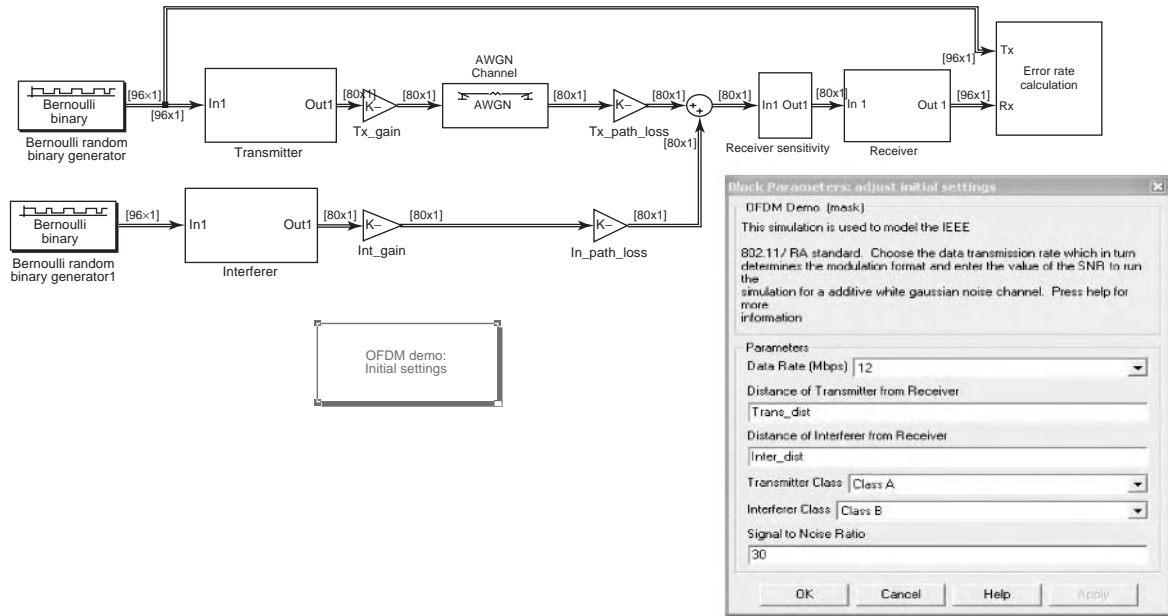

Figure 14. Enhanced simulation model. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

range of the maximum detectable sampling offset ranges from -50 to $+50$ ns. This sampling time offset manifests itself in the frequency domain as a phase shift, which is proportional to the subcarrier frequency. Subcarriers at the high end of the frequency range are affected disproportionately relative to those subcarriers at the low end. The effect of this phase shift on BER can be devastating, as symbols that map to subcarriers at the edges will experience a phase shift that rotates the constellation point out of its reliable detection region.

Sampling frequency offset does not negatively impact performance on a “symbol per symbol” basis. However, it can have harmful effects over large numbers of symbols. The ITS-WAVE proposal calls out a 5 ppm static center frequency offset from the VCO for analog-to-digital/digital-to-analog clocks and carrier VCOs. At 10 MHz, a 5 ppm figure corresponds to a 50 Hz offset, which means that one of the clocks is toggling 50 Hz faster than the other. In the period of one 10-MHz clock (100 ns), one clock will advance past the other by 0.5 psc. If we take into account the number of samples per symbol and the number of symbols in a large packet, we find that over a time span of 50 symbols the sampling instants for symbols will have shifted by 2 ns.¹¹ This timeshift will manifest itself in the frequency domain as a phase shift proportional to the subcarrier frequency. This is clearly a receiver steady-state issue, and can’t be detected during training. During receiver tracking, this offset is taken care of by processing the pilots and feeding back corrections to an interpolator.

3.2.4. ITS-WAVE Adjacent-channel and Cochannel Interference. Effects of adjacent-channel and cochannel interference has been studied using simulation [11], a Simulink

model developed to evaluate these types of interference as shown in Fig. 14.

In the model shown in Fig. 14 we consider the type of the device and apply the corresponding spectrum mask as

Table 3. ITS-WAVE Device Class Spectral Mask

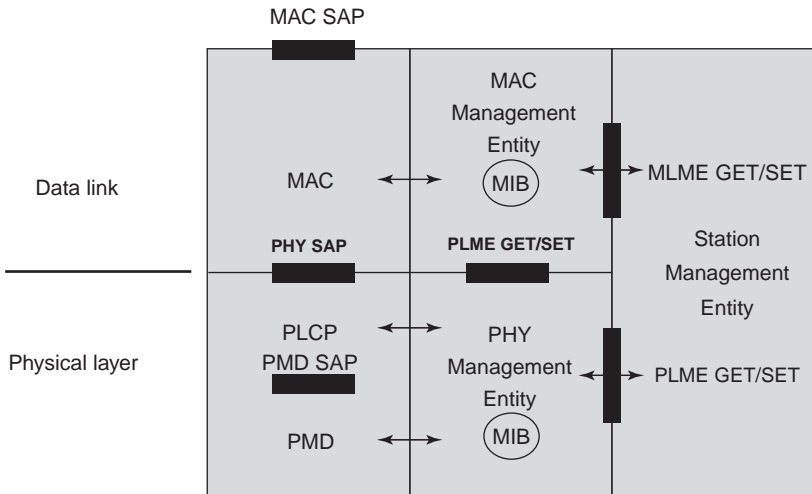

Figure 15. GET and SET operations.

given in Table 3. The model also considers the fact that the devices operate at the maximum power output according to Table 4, which reflects the increase of the out-of-band attenuation for higher power devices. The model takes into account the minimum receiver sensitivity as per Table 5. The channel path loss is modeled according to the two-segment model with a breakpoint of 164 m as given by

$$L(d)_{\text{dB}} = 20 \log(d) + 43.05 \quad (d < 164 \text{ m})$$

$$L(d)_{\text{dB}} = 40 \log(d) - 1.263 \quad (d \geq 164 \text{ m})$$

This is typical for models that use ray tracing [12], where the path loss is generally proportional to $1/d^2$ before the breakpoint and $1/d^4$ after the breakpoint. The breakpoint represents the point at which the first Fresnel zone touches the ground, wherein the reflected ray off the surface of the ground cancels some of the power of the direct ray. The breakpoint is approximated by $d_{\text{bp}} \cong (4h_t h_r)/\lambda$, where h_t is the transmit antenna height and h_r is the receive antenna height.

3.3. The ITS-WAVE MAC Layer

Generally, for reliable system operation, the MAC must be properly designed to match the physical layer so that its impairments do not cause undue degradation at higher layers. The IEEE 802.11 MAC is a very complex protocol; it took over 10 years of development with the support of dozens of corporations developing products for the WLAN market. The ITS-WAVE Study Group intends to use the IEEE 802.11a MAC without modification, except for changes to the management information base (MIB). The management information specific to each layer is represented as a MIB for that layer. The generic model across the management SAPs is to allow the SAP user entity to either GET the value of a MIB attribute, or to SET the value of a MIB attribute. The invocation of a SET.request primitive may require that the layer entity perform

certain defined actions. Figure 15 depicts these generic primitives.

4. CHALLENGES AND FUTURE DEVELOPMENTS

4.1. Validation, Verification, and Testing

Developing the ITS-WAVE family of standards is a complex task, and the fact that these standards will be supporting safety applications makes validation, verification, testing, and system integration critical steps for developing this market. The USDOT has begun this process through funding the Vehicle Safety Communications Consortium (VSCC) and other industry participants. At the Caltrans Testbed Center For Interoperability (TCFI), we have developed lab and field infrastructure [11] in order to support these activities as the standards mature. Figure 16 shows data collected over the air using Agilent's equipment (VSG, VXI, and PSA) at TCFI. In addition, we have demonstrated passing data between the test equipment and the simulation tool (Simulink). Validation of the MAC layer will be a special challenge; currently we are experimenting with Telelogic's TAU G2, which supports both the Specifications and Description Language (SDL) and the Unified Modeling Language (UML).¹² SDL is an ITU formal language that was used to describe the original IEEE 802.11 MAC specifications.

4.2. System Integration: The Santa Barbara Radio Access Network

Beyond the development of the ITS-WAVE family of standards and the availability of telematics products, the development of the ITS wireless market will require reliable roadside infrastructure [13]. This infrastructure requires feeder and backhaul networks that may use both fixed wireless and landline networks. Figure 17 shows one such infrastructure that has passed the planning stage: Santa Barbara's Radio Access Network (RAN) [14]. The RF planning of 28 sites has been completed, and some sites are

¹²Further information is available at <http://www.telelogic.com>.

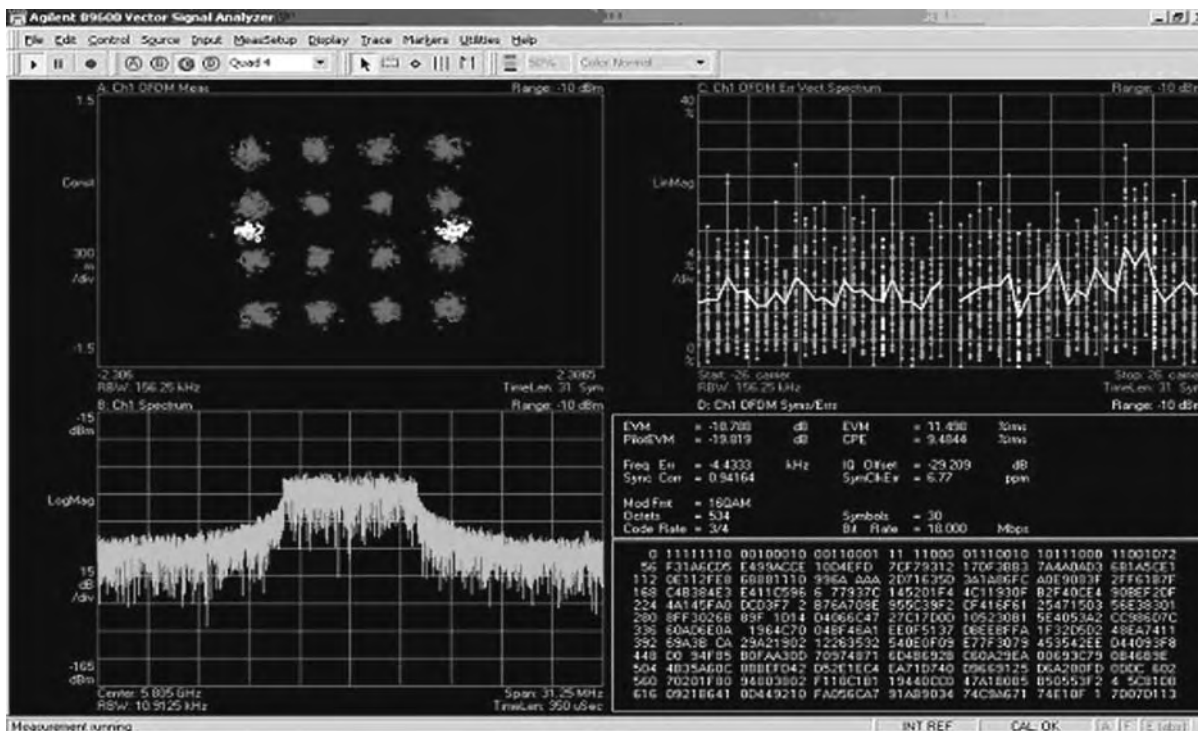

Figure 16. Over-the-air ITS-WAVE signal—18 Mbps. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

being installed through the collaboration of Caltrans, local governments, and the university (UCSB). SB-RAN is currently part of a new proposal to develop a public safety testbed, which addresses wireless infrastructure interoperability (WII) issues for both the “first responder” (4.9 GHz) and the ITS (5.9-GHz) bands.

4.3. Observations and Future Developments

While WAVE standards efforts are progressing within the IEEE, there are remaining questions yet to be answered regarding many issues such as the following:

- Security architecture (P1556 and 802.11i)
- Multiple-channel devices and the current “concept of operations”
- Interference mitigation in a real environment

- MAC extension and its relation to IEEE 802.11e/h
- “Pilot structure” and its impact on dedicated public safety channels
- Fast handover
- IP-based internetworking
- Wireless infrastructure interoperability

As we move from the descriptive phase of the standard development to the performance and testing phases, the need for better protocol development tools will continue to be a challenge.

Roadside system integration issues are rarely addressed in the wireless ITS community. Issues such as cost-effective feeder and backhaul networks to support the wireless infrastructure are considered implementation issues and are outside the scope of the national efforts.

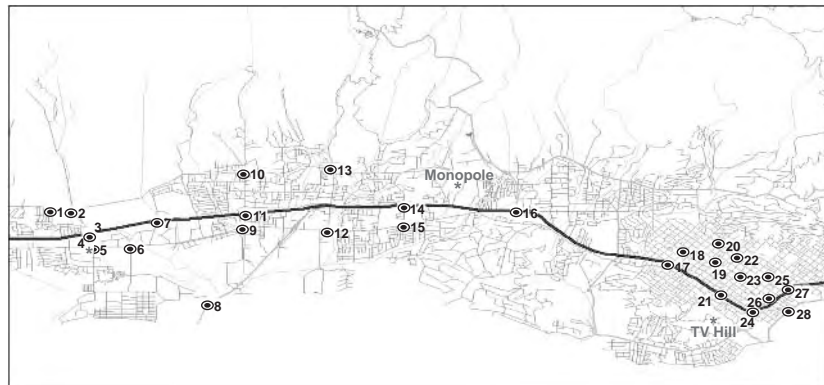

Figure 17. Santa Barbara’s RAN site locations. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Presently, the ITS industry is addressing market-enabling applications such as vehicle safety and toll applications. The more general ITS “public safety” applications such as work-zone safety (WZS), public protection disaster relief (PPDR), and homeland security, are assumed to be the role of public agencies.

The potential gains from considering advanced technologies such as software-defined radios (SDR), and multiple-input/multiple-output (MIMO) systems have not yet been investigated for wireless ITS applications.

5. SUMMARY AND CONCLUSION

This article examined the emerging ITS-WAVE family of standards, with emphasis on the mobile vehicle environment and the lower-layer standard. Our findings confirmed the validity of adopting the IEEE 802.11a as the basis for the broadband wireless ITS standard. The OFDM Forum proposal, originally submitted to the ASTM for wireless road access, is now well understood and it has been accepted by the ITS industry.

The physical-layer, proposal is ready for standardization with the exception of the new pilot structure issue. Long-range dedicated public safety cannot be realized without resolving this issue. The data-link layer proves to be more challenging, as we integrate other IEEE standards (e.g., 802.11e/h/i).

As new devices and systems are introduced, there will be a need for demonstration projects, testing standards, compliance certification, and performance benchmarks.

KLYSTRON

PAUL J. TALLERICO
Los Alamos National Laboratory

The klystron is a very successful high-power microwave amplifier since it has good gain, over 40 dB; good efficiency, above 50%; good life expectancy, above 30,000 h, output power up to 150 MW pulsed for several microseconds, or 1.3 MW CW, and reasonable bandwidth of 5% to 15% (measured at rates slower than the response times of the cavities), but the instantaneous bandwidth is generally under a few percent. The klystron can be designed to operate with a center frequency between 200 MHz and 40 GHz, but the bandwidth of a single klystron is usually small. The lower frequency limit occurs only because of the impracticably large size of the klystron at large wavelengths, and the upper frequency limit arises from the difficulties in scaling the device with wavelength. The optimum frequency range for the high-power (above 100 kW) klystron is from 300 MHz to perhaps 20 GHz, but a few kilowatts of peak power can still be obtained up to 100 GHz. Special versions of the klystron—the extended-interaction klystron and the hybrid klystron–traveling-wave amplifier—can provide several kilowatts power over 100 GHz.

1. OPERATION PRINCIPLE

The klystron is a vacuum electron device for transforming DC energy into RF energy, and it may be either an oscillator or an amplifier. In the past, small reflex klystron oscillators were used as local oscillators in microwave receivers, but these oscillators are not used in modern equipment. Therefore the amplifier klystron is emphasized in this article. The klystron was invented in 1938 by the Varian brothers [1,2] to utilize the finite transit time of electrons in motion (which is a severe impediment to the operation of most electron devices at microwave frequencies) and thereby obtain previously impossible levels of microwave power. The klystron is called a *linear beam device*, since the fields that influence the electron motion are predominantly in the same direction as the electron motion. As the frequency is raised for all electron devices, the transit time of the electrons eventually causes low efficiency and poor operation. The basic idea is to start with an unbunched, moderate velocity electron beam in a magnetic system such that the beam translates along an axis with minimal radial spreading. If two RF cavities are also along this axis, the first one can be driven by an external RF source (the input cavity), and the second can serve as a source (the output cavity) of microwave power. This power is obtained from the kinetic energy of the electron beam, which comes from the DC power supply. Figure 1 shows a simplified drawing of a four-cavity klystron. If we arrange

the various cavity voltages and phases such that the beam is converted in tight bunches that cross the output gap periodically, we would expect to convert a significant portion of the electron-beam energy into microwaves. Tuning the intermediate cavities to frequencies above the operating frequency makes the induced voltage and phase correct to maximize the bunching.

The principle of operation is called *velocity modulation*. The electrons are emitted in a continuous stream at the cathode, and accelerated to a moderate velocity by the DC fields in the electron gun. We want the electrons to arrive at the output gap in short bunches, so these bunches can be slowed down by the fields in the output cavity. In this manner, energy from the power supply is converted into microwave energy in the output cavity. In a gridded vacuum tube, the control grid is used to convert a continuous stream of electrons from a cathode into bunches, but the grid only works well when the time the electrons take to move from the cathode to the grid is small compared to an RF period. The input cavity in the klystron has an RF voltage that makes a field that oscillates with time along the axis. The klystron is designed so that the first electrons in each period are slowed down, and the last electrons in each period are accelerated, while the electrons near the center of the period are left alone (the E field is a cosine wave, in this example). As the initially uniform density beam drifts down the axis, the faster electrons at the rear catch up to the slower electrons from the front, and, if the dimensions are correct, the fast, slow, and average velocity electrons arrive at the output gap center at the same time. Of course, with a continuum of electrons in the bunches cavity, and in the presence of the unavoidable electron repulsion (space charge) effects, the bunched beam is only more temporally concentrated in the output cavity, and the electrons remain distributed in time. Thus, the beam is density modulated at the output gap, and a careful analysis (see below) shows that the velocity and density modulation are cosine and sine waves, respectively.

Several of the reasons for the klystron's importance in RF power generation may be seen from Fig. 1. The major

Figure 1. Simplified sketch of a four-cavity klystron. The klystron body is at ground potential, and a high voltage, negative polarity power supply is attached to the cathode.

advantage is that the klystron is naturally made of three main components: the electron gun (on the left), the RF interaction section, and the collector, on the right. Each component has only a simple function, and can be designed almost independently of the other parts. Thus, there are essentially no RF fields in the electron-gun region, so it is designed to make a good, laminar, and uniform electron beam. Similarly, the RF section is composed of several resonant cavities that are designed to optimize the gain and efficiency of power conversion. Significant heat is developed in the collector area, and this can be designed to safely dissipate large amounts of heat, since there are no DC and only minimal RF fields in this region. When power is expensive, the heat in the collector may be reduced by designing a multiple-stage depressed collector, so that the fields in the collector sort the electrons in the spent beam, and the beam is collected at several potentials, thereby reducing the heat produced and the power consumed. There are mechanical problems introduced by the complexity of the multiple-stage depressed collector, and the power supply becomes more complicated, so this technique is used only where power is expensive, such as satellite and airborne applications. Depressed collectors are also used in UHF television transmitters, where the electrical power costs can be a significant portion of the annual operating costs, since these transmitters operate for 24 h per day with peak output powers at or above 50 kW.

2. APPLICATIONS OF THE KLYSTRON

The major uses of the klystron are in UHF television transmitters, particle accelerators, communication system uplinks, and radar. There are several thousand UHF television transmitters in the world, and a majority of the higher-power ones, above 50 kW, use the klystron as the final amplifier. The more modern UHF television transmitters use either klystrones or depressed-collector klystrons to save energy. The latter are discussed subsequently. The most common particle accelerator is the electron linear accelerator, and about five thousand are used for tumor treatment and medical diagnoses in the world. About half of the newer, higher power medical accelerators are driven by klystrons, while the lower powered half are driven by magnetron oscillators. Particle accelerators for nuclear science are generally powered by klystrons, and a review is given in Ref. 3. Indeed, the modern, high-power klystron [4] was developed to power the Stanford Linear Accelerator, which is the world's highest-energy electron accelerator. The development of the high-power klystron started at Stanford after World War II, and the power levels of pulsed klystrons were increased from 30 kW to over 50 MW over a few decades. The linear particle accelerators for nuclear physics are usually even more powerful than the medical accelerators, and klystrons are the most popular vacuum devices used for these applications. This is especially true for large, high-power accelerators. The largest linear electron accelerator is the Stanford Linear Accelerator, and it uses 320 of the 50 MW peak power klystrons at 2856 MHz and 3 μ s pulses at repetition rates

as high as 360 Hz. The highest powered proton linear accelerator is at the Los Alamos Neutron Science Center, where 44 of the 1.25-MW-peak klystrons operate at 805 MHz with 1 ms pulses at a 120 Hz repetition rate.

The role of the klystron in radar is diminishing, since the klystron is best suited for large, high-power transmitters. However, the air traffic control system use klystrons in airport radar, and klystrons are also used in weather radar. Thus, there are over 2000 radar klystrons in operation, but many radar applications now use many small amplifiers, whose phase can be controlled to electronically steer the radar beam. This combination can still give moderate to large output powers, and the steering can be done electronically, so it is very rapid.

Another market is the satellite uplink transmitters, whose numbers are about 7000. Most of these have klystron amplifiers, but some of the newer ones use traveling-wave amplifiers as their final amplifier. The traveling-wave amplifier has a greater bandwidth, and it can be smaller, so it is becoming the amplifier of choice for this application.

3. DESIGN METHODS

The design methods depend on the klystron component, corresponding to the labels in Fig. 1. Each section of the klystron may be designed almost independently of the other sections, which simplifies the design and optimization processes.

3.1. Electron Gun

The first section is the electron gun, and its design is a DC problem, complicated by large space charge fields. The cathode is space-charge-limited, so the emission follows a Child–Langmuir law, with the current proportional to the 1.5th power of the cathode to anode voltage, and the proportionality constant is called the perveance, P . Thus, the cathode current is given by the expression

$$I = PV_A^{3/2} \quad (1)$$

where V_A is the anode voltage. The modern electron gun was invented by J. R. Pierce [5], but his methods provide only a starting point for the design. A good electron gun has laminar (noncrossing) trajectories, and a relatively uniform cathode current density. The gun must also have the correct current at the design voltage, and the electric fields in the gun must be low enough so that sparking very rarely occurs. The peak and average current density at the cathode must be low enough so the cathode life is satisfactory. The detailed design of the electron gun is accomplished with Poisson equation solvers that solve Poisson's equation for the electric (and magnetic) static fields, and the Lorentz force equations with finite-element or finite difference methods. Three-dimensional computations are sometimes required to account for grids or other nonsymmetric features. Another constraint on the gun design is that the beam radius at the entrance to the RF interaction region must be small

relative to the operating wavelength. For good performance, the normalized radius of the beam $k_r b$ must be in the range of 0.5 to 1.0, where b is the beam radius at the entrance to the RF region, and the radial propagation constant is

$$k_r = \frac{\omega}{u_0 \gamma_0} \quad (2)$$

where ω is the radian frequency of operation, γ_0 is the relativistic mass ratio for the electron, and u_0 is the velocity of the electron beam corresponding to the average beam voltage V_0 . For low-beam currents, the average beam voltage is the anode voltage, but the space charge fields of the beam at higher currents reduce the beam's kinetic energy. The mass ratio is essentially unity for low beam voltages, and in general, is given by

$$\gamma_0 = 1 + \frac{\eta V_0}{c^2} \quad (3)$$

where c is the velocity of light and η is the magnitude of the electronic charge-to-mass ratio. If we assume that the charge density in the beam is constant, we can use Gauss' law to show that the voltage at the beam center V_c is

$$V_A - V_c = \frac{I}{2\pi\epsilon_0 u_0} \left(\frac{1}{2} - \ln(b/a) \right) \quad (4)$$

where a is the radius of the beam tunnel and ϵ_0 is the permittivity of free space.

The simplest klystron electron gun produces a solid cylindrical beam, with the cathode at a negative voltage and the anode at ground potential. This design is best for short-pulse applications, where the high-voltage pulse comes from a pulse transformer. An advantage of this design is that the gun is as simple as possible; it is a diode. This simplicity has two advantages: (1) the parts count is minimum, and this helps cost and reliability; and (2) the fields in the gun region can be minimized for any given peak output power with this design. The second type of electron gun has a modulating anode, and both types are shown in Fig. 2. This electron gun may be called a *triode type*, since there is now a second anode and a second insulator in the gun. In operation, voltage of the modulating anode controls the beam current. The modulating anode is a complication in the design, and it is used either for long-pulse applications for pulses above 0.5 ms (where the pulse transformer becomes very large), or for high-efficiency operation, where the beam current is adjusted to optimize the efficiency for a given operating cathode voltage and output power. The modulation anode becomes the anode of the gun, and the voltage between the modulating anode and the anode forms a lens that must be accounted for in the design. The modulating anode aperture is made thick enough so that when it is at the cathode potential, only negligible current flows in the klystron. The cathode is usually shaped to be a segment of a sphere for a solid beam, but it can have a conical shape to produce a hollow beam. This is the magnetron injection gun, and it also is shown in Fig. 2. Hollow-beam klystrons have some

Figure 2. The three types of klystron electron guns: (a) the diode gun; (b) the modulating-anode gun; (c) the magnetron injection gun. The high-voltage insulators are shown shaded.

advantages, including higher perveance and potentially higher efficiency, but the magnetron injection gun can be noisy, since the electrons circulate around the cathode, and influence the emission.

3.2. RF Cavities

The RF cavities must be designed for a high R/Q ratio (which is a measure of the efficiency of the interaction compared to the stored energy in the cavity), good coupling to the beam, and the correct resonant and harmonic frequencies. The input and output cavities are generally tuned close to the operating frequency, and the remaining cavities are tuned for the desired bandwidth and efficiency, as determined either by experiment, or by specially written, nonlinear, large-signal klystron software. Most of the intermediate cavities are tuned above the operation frequency to maximize efficiency, and the detuning increases towards the output cavity. The cavity shape is called reentrant, since this shape puts most of the electric fields in the beam region. Typical reentrant cavity shapes

are shown in Fig. 1. The cavities are each designed for a particular frequency, but mechanical tuners are usually included to compensate for manufacturing tolerances. Some klystrons, especially those for UHF TV transmitters, are designed so the tuners may be adjusted by the final customer, to change the center frequency (TV channel) on demand. Another subtlety of the cavity design is that it is unwise to make the geometry too similar from cavity to cavity. If the cavities all have the same geometry, the higher order cavity modes are likely to overlap, and this increases the probability of exciting significant harmonic voltages with the harmonics of the beam current. The highest R/Q ratio is when the gap is centered in the cavity, but the gaps are often offset by varying amounts, which slightly reduces the R/Q ratio, but that also significantly alters the harmonic frequencies. Remember that the designer is trying to achieve perfect delta-function bunches of current, and thus the amplitude of all the harmonic currents may be up to twice the DC component. Thus, low impedance at the first few harmonics of the beam current is another requirement on the cavities. Low impedance at the higher harmonics is not important, since the coupling of the cavity fields to the beam is generally small for high harmonics.

3.3. The Magnetic Circuit

The magnetic circuit is designed to keep the beam confined. Most klystrons have an axial magnetic focusing field (supplied by either a solenoid or permanent magnets) that counteracts the radial repulsive force on the electron beam. A focus solenoid is shown schematically in Fig. 1. The focus coils and their return circuits can be heavy and rather expensive in a pulsed klystron, and the power dissipated in the focus coils can be several kilowatts. Research is under way to make short-pulsed, high-power klystrons with permanent magnetic focusing, to eliminate this loss of energy and the weight and expense of the focus coils and their power supplies. Permanent magnet systems are also used with either a single magnet or periodic focusing, and the reader should see TRAVELING-WAVE TUBE for more information on periodic focusing systems. Permanent-magnet focusing is used on several commercial medium power (up to 5 kW) klystrons in the 1.5–3 GHz frequency range.

At the gun end, the magnetic field is designed to be parallel with the electron trajectories, so the trajectories are unchanged by the field. The magnetic field balances the space charge forces, and the magnetic field required by the unbunched beam is given by the relation

$$\omega_c^2 = \frac{2\omega_p^2}{\gamma_0(1-K)} \quad (5)$$

where $\omega_c = \eta B_{z0}$ is the cyclotron frequency, B_{z0} is the axial magnetic field at the entrance to the RF interaction region, where the beam has a minimum diameter

$$\omega_p = \sqrt{\frac{\eta\rho_0}{\epsilon_0}}$$

is the free-space plasma frequency, ρ_0 is the space charge density at the beam minimum, and K is the square of the ratio of the magnetic flux at the cathode to the magnetic flux at the beam minimum. The range of K is from 0 to 1, with $K=0$ being called the Brillouin flow case, after its inventor, and K approaching 1 is the confined flow case, where the electrons follow lines of constant magnetic flux, and no radial motion is possible. The higher values of K make the beam more resistant to radial spreading, and are used at high frequencies. The Brillouin case is difficult to achieve, since flux lines from the focus magnet tend to link the cathode, but it can be achieved approximately with a bucking coil whose excitation is adjusted to null the magnetic field at the cathode surface. As the beam bunches, the radial space charge forces grow, and the axial magnetic field increases by a factor of ~ 2 at its peak near the center of the output gap. The magnetic field then drops quickly to cause the beam to rapidly expand into the collector. With careful design, including use of Poisson equation solvers, all these requirements can be realized with a single set of coils and magnetic pole pieces connected with a single power supply.

It is also possible to transport the electron beam through the klystron with an array of electrostatic lenses. Electrostatic focusing was investigated seriously for satellite transmitters when designers thought that the only solution for satellite broadcasting to earth was with 500–1000-W transmitters on the satellite. Several prototype, lightweight, electrostatic-focused klystrons were designed and built, but improvements in the receiver noise figure rendered these higher-powered transmitters obsolete before they were ever deployed in space.

3.4. Collector

The collector's function is to stop the beam and transfer the heat produced by this action to a cooling media. The most stressful operation for the collector is the case with no RF signal applied to the klystron. In this case, the entire beam power is dissipated in the collector. In its basic form, the collector is a hollow cylinder terminated in a cone, that is part of the overall vacuum envelope. The exterior has a cooling jacket, generally with water as the coolant, and lead shielding is used with the higher powered klystrons, since the electrons produce X rays when they are suddenly stopped. The maximum power density must be limited to 500–1000 W/cm², depending on the cooling method, with the former applying to turbulent flow cooling, and the latter for mixed-phase water cooling, where steam is generated at the outside of the collector, but rapidly condenses in the cooling stream. Copper, because of its high thermal conductivity, is the most common collector material, but key parts of the collector are often made of stainless steel, to strengthen the assembly.

For pulsed klystrons, it is desirable to have the collector capable of being isolated from the rest of the klystron with a ceramic joint. This allows the precise monitoring of the body current, and the body current may be monitored to protect the klystron. Many klystrons dissipate 3–10% of the beam power in the body, and this component is not usually designed to dissipate much power.

3.5. The Depressed Collector

Only the kinetic energy of the moving electrons can be converted into microwave energy. After the beam has gone through the output gap, its remaining energy is converted into heat when the electrons strike the collector surface. However, a majority of this energy may be recovered by designing an array of electrodes at carefully selected potentials to form the collector. This is called a *multistage depressed collector*, and it is used in spaceborne and television transmitters to reduce the energy demands on the power supply. A schematic of a depressed collector is shown in Fig. 3. The voltages on the figure follow the inequality $V_c < V_1 < V_2 < V_3 < V_4$, where V_c is the cathode voltage. In practice, V_4 may be only a few percent of the cathode voltage, thus, when no signal is applied to the klystron, all the current is collected on the lowest collector, and the power supply has to provide only a few percent of the normal beam power. The electrostatic fields in the collector region sort out the electrons by their kinetic energy. Consider a case with three energy levels in the spent beam. The electrons with the most energy are intercepted at potential that is close to the cathode, while the electrons with a lower kinetic energy are intercepted at a potential that is between the cathode and the anode, and those with the lowest kinetic energy are intercepted at the anode potential. The kinetic energy of the high-energy electron classes is reduced by the work done moving to a more negative potential, so the heat produced at the collector is reduced, as is the power from the power supply. In this example klystron, the power supply must produce three more voltages, in between the cathode and anode potential, so the power supply is more complicated. However, when energy must be conserved, the depressed collector can save energy. The energy that can be recovered by the depressed collector increases with the number of stages, or potentials, in the collector, but so does the complexity of the power supply.

There are three practical problems of the depressed collector that should be addressed. First, the collector segments must have a low secondary emission ratio, since secondary electron current will travel to a higher potential, and absorb energy from the power supply. Second, the electrons should all hit the collector segments where the electric field will push any secondary electrons back into

Figure 3. Schematic diagram of a depressed collector with four potentials.

the emitting electrode. Third, the insulators and cooling system must be carefully designed, so only acceptably small amounts of RF radiation are emitted into the space surrounding the collector. The beam in the collector is partially bunched, and it can deliver real RF power to the collector and its circuitry.

High-power (>50-kW), high-efficiency klystrons have not been produced with depressed collectors, since in this type of klystron, some electrons are almost stopped in the output gap, so if there is a potential barrier in the collector, these very slow electrons can be returned to the RF interaction region, and cause the klystron to be unstable. However, depressed collector klystrons are commercially available for the UHF television band to the 50 kW level.

3.6. Mechanical Considerations

The major mechanical requirements are that the klystron have a good vacuum, be strong enough to withstand the stresses of handling and from the water system, and the mechanical design must be repairable. The klystron must also withstand the thermal stresses involved in normal operation and during the bakeout process, which is a 450–600°C bake for 2–3 days for a large klystron. To allow repairs, the klystron often has weld flanges between cavities and at the collector and electron gun. The design must also have no trapped volumes, so it can be outgassed during the bakeout. Materials consistent with high vacuum must also be used, such as oxygen-free, high-conductivity copper, stainless steel, and tungsten and tantalum in the gun area. The RF window is generally made of high-purity aluminum or beryllium oxides, both of which have low losses, and which can be brazed to thin metal membranes for attachment to the klystron.

4. LIMITATIONS OF THE KLYSTRON

4.1. Efficiency

The maximum efficiency obtainable with a klystron remains an open question. For decades, the 58% result mentioned previously was considered the maximum theoretical limit, but numerical calculations involving second harmonic cavities, first published by Lien [6], showed that 70% to 75% efficiencies may be obtainable. The early experimental results [7,8] showed that the new numerical results were essentially correct, but it was several years before the first commercial klystron with over 60% efficiency was produced. The maximum efficiency achieved to date is 76%, in an S-band, 100-kW CW klystron [9] designed for industrial heating. However, for the highest efficiencies, the klystron's bandwidth, gain, and even stability are reduced, due to electrons that are returned from the output gap. Most of the high-efficiency klystrons have a second-harmonic cavity to optimize the shape of the bunch, and the S-band record klystron referred to previously has two second-harmonic cavities. Unfortunately, space charge effects reduce the klystron efficiency, so for high efficiency, the klystron must be designed with low beam current, and low perveance P , which is a geometric factor of the electron gun. Based on results of large signal

calculations and on experimental data, the optimized efficiency of klystron is estimated as [10]

$$\eta_e = 0.82 - 0.228P \cdot 10^6 \quad (6)$$

Thus, it is plausible that 80% efficiencies may be available in the future, provided that the market is large enough to support the necessary research. There will likely be more than one harmonic cavity in 80% efficient klystron. Equation (6) is an expression for the electronic efficiency which neglects the losses in the output cavity, which are also a function of the perveance or the operating voltage. While these losses are usually small, for very low perveance they become proportionately larger, and cannot be neglected.

4.2. Power

The maximum power that may be obtained from the klystron is limited by arcing considerations in the region of the electron gun, the output cavity, or the output window. At the highest peak powers, there is an inverse correlation between maximum peak output power and pulse length, since both pulse voltage and RF breakdown depend on pulsewidth. In the submicrosecond region, klystrons have been made with field-emission cathodes and up to 15 GW [11] output powers. For pulse lengths of a few microseconds, the peak power is limited to about 150 MW [12]. In the CW regime, the record peak power is 1.3 MW [13], and only slow progress has been made in raising this power from the first practical 1 MW CW klystron in 1989 or earlier. The effect of pulselength on the peak power obtainable from a given klystron often varies as the pulselength to the $-\frac{1}{2}$ th power. Representative state-of-the-art peak powers are 150 MW for 3 μ s, 20 MW for 15 μ s, and 5 MW for 1000 μ s. This is typical of short and medium pulsed klystrons.

For the highest peak powers, the output cavity electric fields must be minimized. The first step to reduce these fields is to round the cavity noses more, but this also reduces the interaction impedance. Major improvements in the output fields are obtained by separating the output cavity into two or more coupled cavities, separated by a short drift space. With two cavities, for example, the voltage of each cavity is reduced to 50% of the single cavity value, and so the fields are reduced also by this same 50%. The ohmic losses in the output cavity are proportional to the square of the cavity voltage, so the losses for the two-cavity system will each be only be 25% of the original single cavity, and the total ohmic losses will be 50% for the two-cavity system compared to the single cavity solution.

4.3. Frequency

The beam dynamics allow frequency scaling in the klystron, so that if all the dimensions are changes by a factor k' , the klystron will operate with the same characteristics at a new frequency, f/k' . However, if k' is less than unity, all the current and power densities in the new klystron will be $1/k'^2$ as high, so this limits the power available at high frequency. Both peak and average power then scale as f^{-2} . Hence, the optimum frequency range for the klystron is

from 0.5 to perhaps 20 GHz. Reduced power klystrons are available at up to 100 GHz. The low frequency limit occurs because of the massive size of a low-frequency klystron. With solid beams of ordinary perveance (between 0.75 and 2.0×10^{-6}) the low frequency limit is about 200 MHz. Hollow or multiple beams may permit a reduction in this lower limit, since with higher currents we have a slower electron velocity and therefore a smaller klystron.

The extended interaction klystron uses a set of coupled cavities to replace each cavity in the klystron. Amplifiers can be made with the extended interaction technique at frequencies up to 100 GHz. For even high-frequency operation, the gyroresonant principle must be used, and the gyroklystron is discussed further in the gyrotron section.

4.4. Bandwidth

The bandwidth of the klystron is relatively small, since there are five or more tuned cavities in the klystron. The loaded Q 's of these cavities depend on their shape, the frequency, and the beam current, since the beam loading is the most important factor in determining the cavity loading. The designer has very little control over these variables; the shape is always reentrant, with a gap that does not exceed one radian; the frequency is set by the application, so only the beam current can be controlled. The beam current follows Eq. (1). The output power P_o depends on the electronic efficiency and the power in the klystron beam, $P_o = \eta_e P V_A^{5/2}$. Since the beam loading is proportional to I , one achieves high bandwidth by increasing the beam current, for a given power, but this reduces the overall efficiency. In practice, klystrons with high (above 65%) efficiency tend to have 1 dB bandwidths of about $\pm 1\%$, and if the perveance is increased, the efficiency drops to under 50%, but the 1 dB bandwidth can be increased to 15% [14], even for klystrons at the 1 MW power level. Large bandwidths are easier to obtain in the klystron with high-output powers, since the beam impedance decreases as the operating voltage increases. The DC beam resistance is given by the relation, $R_o = 1/(PP_o^{0.2})$, and this is proportional to the maximum fractional bandwidth. Thus, wideband klystrons must either have high perveance, or high output power. Up to 10 cavities may be used, and optimally tuned to increase the bandwidth, and multiple resonances are designed into the output cavity and its coupling system. The klystron is not suited for wideband low-power applications, and the bandwidth, even for high-power devices, is limited to 15–20%. The cluster cavity concept [15], where each cavity is replaced by a set of closely spaced cavities, has the potential to make improvements in both bandwidth and efficiency, and devices with up to 25% bandwidth should be possible with this concept. A wideband, cluster cavity klystron would have as many as 15 cavities, and it would be more expensive than a conventional klystron, but the bandwidth could be significantly greater.

4.5. Gain

The klystron generally has a gain of 40–60 dB, with the lower gain corresponding to either a few cavities or wide bandwidth. In narrowband applications, gains over 60 dB

are possible, but the stability may suffer. At the higher frequencies, above 10 GHz, gain is more difficult to achieve, since the coupling function to the gap is not favorable.

4.6. Noise

The major noise sources in the klystron are (1) shot noise from the electron beam, (2) resistor noise from the input circuit, and (3) noise from the cathode temperature. The shot noise in a diode is given by the relation

$$\langle i_n^2 \rangle = 2eIBF(\theta) \quad (7)$$

where e is the electronic charge, B is the klystron bandwidth, and

$$F(\theta) = \frac{4}{\theta} [\theta^2 + 2(1 - \cos \theta - \theta \sin \theta)] \quad (8)$$

and the transit angle of the diode is

$$\theta = \frac{2\omega L_d}{u_0} \quad (9)$$

where L_d is the distance from the diode cathode to the anode. This value of the rms noise in the current is reduced by space charge effects, but the noise is proportional to the klystron current. Hence, high-power klystrons often have relatively high noise, with a noise figure of 30 dB being typical. When the klystron is used as a low-noise amplifier, it must be operated at low beam current. Even with low beam current, the klystron typically has a 6 dB noise figure, which is much higher than the few tenths of a dB that is possible with a good solid-state amplifier.

5. KLYSTRON VARIATIONS

Several physical variations of the conventional, solid cylindrical-beam klystron have been studied, including the sheet-beam [16], hollow-beam [17], and the multiple-beam [18] klystron. The cluster klystron [19] is a variation of the multiple beam klystron for very high output power where several beams are put in the same vacuum envelope, but they feed a common output cavity. These designs spread out the beam to reduce the adverse effects of space charge. Both the hollow-beam and multiple-beam klystron have been demonstrated, but the latter is under active development and is discussed here. The fundamental concepts include all klystron cavity gaps have a radial variation of the electric fields, so it is better to have all the electrons at one radius; and by spreading out the electron beam, the potential depression formed by the space charge will be minimized, so the variation in kinetic energy in the beam is minimized. In the interaction with the output gap, only the beam's kinetic energy can be converted to microwave power, the potential energy can be recovered only by using a multiple-stage depressed collector [20], which reduces the energy of the collected electrons. This in turn, reduces

the power from the power supply, but does not increase the output power of the klystron.

Another variant of the klystron is a hybrid of the traveling-wave amplifier (used as the input section) and the klystron output section (or vice versa). This type of amplifier can easily achieve 10–15% bandwidth, high output power, and good gain. The extended-interaction klystron has an RF structure that consists of several coupled cavities, rather than single cavities. With this technology, monotron oscillators can be built to produce 1 kW at frequencies up to 325 GHz, and amplifiers can be made up to 100 GHz.

5.1. Relativistic Klystron

Since the electron has a rest mass of 511 keV, relativistic effects start to appear at only 50 kV, so most high-power klystrons have relativistic effects in their detailed design. However, the term *relativistic klystron* is applied only to those klystrons operating at or above 500 kV, where relativistic effects are extremely important. The relativistic factor for klystron scaling with voltage is $\gamma_0^{3/2}$, so for a given frequency, the length becomes very long for high-voltage operation, or for γ significantly larger than unity. Thus, the relativistic klystrons often exploit a *gating effect* of an electron beam that is very near the space charge propagation limit. The propagation limit occurs when the potential depression because the beam's space charge is so high that all the kinetic energy is converted into potential energy, and the beam stops. This limiting current depends on the geometry of the beam and the surrounding drift tunnel or cavity. The limiting current for a solid beam of radius b in a drift tunnel of radius a is [21]

$$I_{\max} = \frac{4\pi\epsilon_0 mc^3}{e} \frac{(\gamma_0^{2/3} - 1)^{3/2}}{1 + 2 \ln(a/b)} \quad (10)$$

where m is the rest mass of the electron and the first ratio on the right-hand side is the Alfvén current, which is 17.1 kA for electrons.

The beam current in the relativistic klystron is generally a few tenths of this limiting current, while for conventional klystrons the current is often less than one tenth of the limiting current, but it increases with beam voltage. By operating fairly close to the current limit and carefully controlling the transverse geometry, the bunching distances for the relativistic klystron may be drastically reduced from the classic formulas given later, which do not include the gating effect. To obtain such high current, the relativistic klystrons often utilize field emission cathodes, which limits their performance to pulselengths below 1 μ s and limits the repetition rate for the pulse per minute range. The formidable output power of around a gigawatt can be produced, but the efficiency is generally only 20%, because the beam motion during the short pulse is not as uniform and laminar as is possible with lower current beams.

Many variations of the relativistic klystron are possible, and some of the most successful to date have been the virtual cathode or vircator family of devices [22].

5.2. Reflex Klystron

The reflex klystron has a reflector electrode after the first cavity, so the electrons pass through the cavity, are reflected by the electrostatic field from the reflector, and transverse the cavity again in the reverse direction. The beam is velocity modulated by the cavity in the first pass, and the beam will be bunched in $n + \frac{3}{4}$ RF periods, where n is any positive integer, including zero. By varying the potential of the reflector, we can adjust the time the electrons spend in the reflector region, and this changes the frequency of the oscillator. Hence, the device is inherently electronically tunable, so it has been applied primarily as a local oscillator, at the milliwatt power levels. High output powers are possible, but the device has lower efficiency than the conventional klystron, since the bunch geometry cannot be optimized in the reflex case.

5.3. Monotron Oscillator

The monotron is another single-cavity oscillator. The fundamental principle is that the impedance that the unbunched beam presents to a cavity is negative for long-transit angles, and the magnitude of this negative impedance varies linearly with the beam current. Hence, if the cavity and beam are properly designed, the real part of the cavity impedance can be negative and the cavity will oscillate, extracting power from the beam. One pitfall of klystron design is that a cavity, or more often, an inadvertent resonator in the electron-gun region, may start to oscillate at the klystron's design current, due to a monotron oscillation. The designer must know the impedance seen by the beam as a function of frequency, and remove the oscillation possibilities by reducing the Q of the unwanted peaks. This is especially important for high-current beams.

6. THEORY

There are two different limiting small-signal theories of the klystron that are each valid in their own small-signal regions. But the klystron is a very nonlinear device, and one must resort to numerical calculations to predict the efficiency, large-signal gain, and the phase and amplitude transfer functions of the klystron.

6.1. Small-Signal Theory

There are two simple theories of klystron operation, Webster's ballistic theory [23] and the space charge wave theory [24]. The ballistic theory is valid in the limit of small-space-charge forces. The principal result of the theory, when applied to a two-cavity klystron, is that the n th harmonic current amplitude is

$$\left| \frac{i_n}{I_0} \right| = 2\alpha J_n \left(n \frac{\alpha M \theta_d}{2} \right) \quad (11)$$

where I_0 is the DC beam current, J_n is the n th-order Bessel function, α is the ratio of the voltage at the input gap to the DC beam voltage (V_0), M is the gap coupling

coefficient, a number less than 1 that expresses the efficiency of the RF fields in the input gap in coupling to the beam, and $\theta_d = \omega L/u_0$ is the drift distance (in radians of transit time) between the center of the input and output cavities. For the highly idealized case of a gridded planar gap, $M = [\sin(L_g/2)]/[L_g/2]$, where L_g is the distance between the grids, measured in radians. If we assume an output gap with its value of M and α , then the electronic efficiency (the ratio of the RF energy produced to the beam's kinetic energy) may be written as

$$\eta_e = M_2 \alpha_2 J_1 \left(\frac{\alpha M \theta}{2} \right) \quad (12)$$

where the subscript 2 refers to the output cavity. When $M_2 \alpha_2 = 1$, the effective gap voltage experienced by an electron equals the DC beam voltage, and electrons will begin to be reflected from the output gap, and this can cause instabilities due to the electronic feedback. The first maximum of J_1 is approximately 0.584. Thus, the limiting value of klystron efficiency is half the current bunching ratio, or 58%. For several decades after the invention of the klystron, no klystron produced 58% efficiency, but the modern klystron can have an efficiency of up to 76%, and even higher with development.

The bandwidth and frequency response of the klystron was first calculated with the space charge wave theory. The space charge wave theory of the klystron is valid when the gap voltages are small and space charge forces are high. The bunching in the klystron can be explained as a result of two waves carried by the electron beam, a current wave, and a velocity wave. These waves obey a transmission-line equation, and are sinusoidal with distance and time for the usual case of an unaccelerated beam [25]. The voltage at the input gap modulates the velocity of the electrons as they cross the gap (and thus initiates a current wave), and in the drift space the velocity modulation is converted to current modulation. These modulation waves are a result of longitudinal plasma oscillations of the electrons, but it is complicated because the magnetic field and boundary conditions in the drift tubes also affect this plasma frequency. The result of this theory is that each cavity gap in the klystron excites a current and a velocity wave on the beam. The first cavity is driven by an external source (the drive signal), which excites a current wave plus a small velocity wave, due to the finite axial extent of the gap fields. The current wave is a sine wave with distance, so it grows. This wave interacts with the second cavity impedance and produces a larger voltage in the second cavity compared to the input cavity, provided that the second cavity is tuned reasonably close to resonance. This cavity voltage excites a second current and velocity wave, which adds to the original waves from the first cavity, and the process is repeated at each cavity. If we neglect the small velocity waves and concentrate on the current waves, then the standing waves set up by an input gap are of the form [26]

$$\frac{u_1}{u_0} = \frac{\alpha M}{2} \cos Z_1 \quad (13)$$

and

$$\frac{i_1}{I_0} = -j \frac{\alpha M}{2\omega_p/\omega} \sin Z_1 \quad (14)$$

where $Z_1 = (R\omega_p z)/(u_0)$ is the axial distance measured in reduced-plasma radians. The plasma reduction factor R is a measure of the reduction in the plasma frequency by the combined effects of the drift tunnel and the magnetic focus field. The plasma frequency is the free-space oscillation of electron density variations, for a one-dimensional situation. In the klystron, the space charge fields are two-dimensional, and a significant fraction of the space charge electric fields terminate on the drift tunnel walls, rather than on electron scarcity regions. The net result is that the actual plasma frequency, $\omega_q = R\omega_p$, is usually about one-tenth of the free-space value. The value of ω_p/ω is almost always less than unity, and this ratio usually is a few times 0.1. Thus, the current wave is generally 3–10 times larger than the velocity wave, which is often neglected. The small-signal bandwidth of the klystron may be determined by calculating the waves that begin at each cavity, due to the voltage produced in that cavity by the prior cavities. However, the electron beam itself loads down each cavity with a capacitive and a resistive component that are in parallel with the usual L , C , and R parallel elements that represent the cavity at the detuned short plane. If the gaps were gridded, the conductance $G = G_b + jB_b$ supplied by the beam to the gap is calculated from the subsequent relations.

$$\frac{G_b}{G_0} = 1 - \frac{\cos L_g}{L_g^2} - \frac{\sin L_g}{2L_g} \quad (15)$$

and

$$\frac{B_b}{G_0} = \frac{\sin L_g}{L_g^2} - 1 + \frac{\cos L_g}{2L_g} \quad (16)$$

where G_0 is I_0/V_0 , the DC beam conductance. These small-signal equations are easily programmed on small computers, and are widely used to estimate the bandwidth of klystron designs. Note that when designing a wideband klystron, there are frequencies at which the response from the current waves discussed previously is very small. The total response is the sum of the responses from the current waves and from the small velocity waves that have been neglected. Under these conditions, the velocity waves cannot be neglected.

6.2. Large-Signal Simulation

Since the klystron is such a nonlinear device, with many parameters, the linear theories cannot be used to predict the overall efficiency or the power that is intercepted along the klystron body, and large-signal nonlinear computer programs must be used to optimize the efficiency. The first large-signal klystron analysis was performed by Webber in 1958 [27]. For the next decade, the early klystron simulations were not very accurate, with about 10–15%

errors, since the theory was not self-consistent. The force equations were written for both gap and drift regions, with approximate expressions for the space charge. Electrons were tracked through a series of cavities and drift regions, but the amplitudes and phases of the gap fields were estimated by circuit equations that basically came from the linear space charge wave theory, where the beam current is assumed to be unaffected by the cavity fields. These amplitudes and phases were not necessarily correct, since the beam's current at large gap fields is altered by the gap fields. The necessity of iterating this procedure was first published by Kageyama et al. in 1977 [28]. The older methods were still used to estimate the voltages and fields in each cavity, but in addition, for each cavity, the induced current is calculated from Ramo's induced current theorem [29], which states the equivalence of the electrical energy change in a circuit to the work done by the particles on fields. For the klystron, the general form of the induced current is

$$i_i(t) = \frac{\int_V J(t) \cdot E(t) dV}{V_g(t)} \quad (17)$$

where the space charge current is given by J , the electric field E is only that due to the cavity, V_g is the gap voltage, and V is the entire volume over which there are cavity fields. One next takes a Fourier component of this time function to get the appropriate frequency component of the induced current.

Once the last electron leaves a particular gap, the induced current is finally known, and the gap voltage and phase are recalculated, using the Fourier component at the appropriate frequency. The old and new complex gap voltages are averaged, and used for the next iteration of the beam through this gap. After a few such cycles, the new fields and phase are very close to the previous estimates, and the cavity parameters are then established. Then, the next drift space calculation is performed, and the process continues in the next gap, until the output gap is reached. The output gap is special because the output gap voltage is often greater than the beam voltage, and the optimum loading of the cavity is not known a priori. The difference between the beam current at the entrance to the cavity and the induced current in the output cavity is very large, since the output cavity voltage is so great. The optimum coupling between the output cavity and the external load must also be found empirically (with a large-signal computer program), by varying the Q of the output cavity. The output cavity is a parallel RLC circuit (when viewed from the waveguide plane of the detuned short), and the beam is a current source, while the load being driven by the klystron is coupled to the output cavity by an iris, or a loop at low frequencies. This coupling iris can be represented by a transformer. The schematic is shown in Fig. 4. For the simple case where the load is purely resistive, the coupling iris may be ignored, and the combination of the iris and the load resistor can be replaced by a resistor transformed to the primary of the transformer, which is then in parallel with the RLC circuit. Refinements of the

Figure 4. The equivalent circuit for the output cavity (the passive elements on the left of the transformer), the coupling transformer, the klystron's load impedance, and a modulated beam (the current generator) in this cavity.

method include using a wave equation solver to obtain accurate calculations of the cavity field distributions, and iterating over more than one cavity at a time when there are reflected electrons. These calculations must be repeated for each drive level, load on the klystron, and frequency, and so they are time consuming for large-bandwidth klystrons.

One of the most difficult calculations of the large-signal klystron programs is the evaluation of the space charge forces. There are basically two methods for calculating these forces. The earliest method is to calculate the Green function for the charged particle being followed, while accounting for the particular boundary conditions. For example, the Green's function fields at the point r, z for a unit-charged ring of radius r' and position z' , moving with velocity u_0 along the z axis, and contained in a conductive cylinder of radius a are [30]

$$E_r(r, z; r', z') = \frac{\gamma_0}{2\pi\epsilon_0 a^2} \sum_{l=1}^{\infty} \frac{J_0(v_l r) J_0(v_l r')}{J_1^2(v_l a)} e^{(-v_l \gamma_0 |z-z'|)} \quad (18a)$$

$$E_z(r, z; r', z') = \frac{\text{sgn}(z-z')}{2\pi\epsilon_0 a^2} \sum_{l=1}^{\infty} \frac{J_0(v_l r) J_0(v_l r')}{J_1^2(v_l a)} e^{(-v_l \gamma_0 |z-z'|)} \quad (18b)$$

and

$$B_\theta(r, z; r', z') = \frac{u_0}{c^2} E_r(r, z; r', z') \quad (18c)$$

where the eigenvalues are the roots of $J_0(v_l a) = 0$. A finite approximation to the infinite series is only calculated once, at the start of each problem. There are two major difficulties with using these equations in a computer code. The first is that the space charge fields are added in a point-by-point manner, so the time spent calculating the fields grows with n , the number of particles, as n^2 . This places a practical limit of around 100–300 particles with this method, for a personal computer. The other problem is more fundamental; these equations were derived by using a Lorentz transformation of the static fields of a moving charge into the laboratory frame. The γ_0 and u terms in the equations depend on this velocity. For most of the klystron, the particles move with an almost constant velocity, so this approximation is not bad, but in the penultimate and output cavities, there is a large spread of velocity, and Eqs. (18) lose their accuracy.

An alternative method of calculating the space charge fields is to directly integrate Maxwell's equations, with the bunched beam as a driving force. This method is called the particle-in-cell method, and a grid is set up over the klystron interaction area. The beam currents are averaged over the grid, and discretized versions of the curl equations are integrated to find the time derivatives of the fields. The major advantages of this method are that the method is valid for any distribution of particle velocity, and the computation time grows much more slowly, only as $n \log(n)$. A reference to the particle-in-cell method as applied to klystrons is Ref. 31, and a general reference to the particle in cell method is Ref. 32.

LEAKY MODES AND HIGH-FREQUENCY EFFECTS IN MICROWAVE INTEGRATED CIRCUITS

FRANCISCO MESA

University of Seville
Seville, Spain

DAVID R. JACKSON

University of Houston
Houston, Texas

1. INTRODUCTION

This article investigates the high-frequency effects that occur when sources or discontinuities are present on printed-circuit transmission lines. Although many of the conclusions are general, the analysis and the results will focus on microstrip and stripline types of transmission lines, where there is a single-strip conductor that is within a layered structure that may contain either one or two ground planes. Examples include the microstrip structure shown in Fig. 1a, the covered microstrip shown in Fig. 1b, and the stripline structure that has an airgap over the

Figure 1. Cross sections of (a) a microstrip line, (b) a covered microstrip, and (c) stripline with an airgap.

strip conductor, as shown in Fig. 1c. (Later in the article, the analysis will be extended to include coupling between two strip conductors, so that the crosstalk current induced on a passive microstrip line from coupling to an adjacent active microstrip line can be studied.)

The analysis and results will focus on the current and fields that are excited when a gap voltage source is located at the origin ($z=0$) on an infinite structure, where the strip conductor extends from $-\infty$ to ∞ , as shown in Fig. 2. This source model allows for a semianalytical treatment of the problem in the spectral domain, which greatly simplifies the solution. Other types of sources may be considered, however. Many of the conclusions also apply to discontinuities on the line (bends, junctions, etc.), although such discontinuity problems are not specifically treated here.

One of the main goals of the article is to examine the nature of the current on the transmission line that is excited by the gap voltage source, and explore what types of spurious effects occur at high frequency. It is well known that at low frequency, simple transmission line theory may be used to adequately predict the current on the strip conductor. In particular, the current $I(z)$ predicted by simple transmission-line theory is

$$I(z) = \frac{1}{2Z_0} e^{-jk_z^{\text{BM}}|z|} \quad (1)$$

where Z_0 is the characteristic impedance of the line and k_z^{BM} is the propagation wavenumber of the transmission-line mode, which is also called a “bound mode” (BM) of propagation, since the fields of this mode decay transversely away from the structure (in the $\pm x$ direction), and hence are bound to the guiding structure.

At high frequency, simple transmission-line theory is no longer adequate to accurately predict the current excited by the gap source, for various reasons. First, it should be noted that the definition of the characteristic impedance Z_0 is not unique at high frequency [1]. Second, at high frequency, the current on the strip is not solely that of the bound transmission-line mode (as assumed in the above equation), but it also consists of a “continuous spectrum” (CS) part, which is not predicted by transmission-line theory, and which becomes more important as the frequency increases. The analysis presented here allows for an accurate calculation of the bound-mode amplitude that is excited by the gap source at any frequency, even when the bound-mode current is not the dominant current on the line. The bound mode current has the form

$$I(z) = A_{\text{BM}} e^{-jk_z^{\text{BM}}|z|} \quad (2)$$

where the modal amplitude A_{BM} is determined by a residue in the complex plane, as explained later.

The semianalytical treatment presented here allows for a calculation of the CS current, which may become very

important at high frequencies. The method also provides a convenient description of the physics of the CS current. In particular, the CS current includes the effects of leaky modes, which are modes that radiate (leak energy) as they propagate. The leakage may be of two types. In one case the leakage occurs into the fundamental mode of the substrate, which is either a surface-wave mode or a parallel-plate mode, depending on whether there are one or two ground planes. (When only a single ground plane is present, the structure will be called “open,” since the structure is open to free space. When there are two ground planes, the structure will be called “closed.”) Assuming that only a single substrate mode is above cutoff (the usual case), the leakage will occur into the fundamental TM_0 mode of the substrate. In the other case, which only occurs on open structures, the leakage occurs into both the TM_0 substrate mode and into space. In either case, a leaky-mode (LM) current has the form

$$I(z) = A_{LM} e^{-jk_z^{LM}|z|} \quad (3)$$

where the propagation wavenumber $k_z^{LM} = \beta - j\alpha$ of the leaky mode is complex as a result of radiation loss. The excitation of a leaky mode may cause considerable spurious effects, including power loss, interference with the desired bound mode, and crosstalk with neighboring circuit components. The semianalytical treatment presented here allows for a calculation of the excitation of any leaky modes that are part of the CS current. In the representation used here (and explained later), leaky modes appear explicitly as part of the continuous spectrum if the modes are “physical,” meaning that the leakage mechanism of the mode (either into the substrate or into both the substrate and into space) is consistent with the phase constant of the leaky mode.

The analysis also reveals that the CS current on the strip conductor consists not only of leaky modes but also of a component called the “residual-wave current.” The residual-wave (RW) current is the leftover, or residual, part of the CS current that is not representable as a sum of physical leaky-mode (LM) currents. When no physical leaky modes are present, the RW current is identically the same as the CS current. When physical leaky modes are present, the CS current consists of both the LM and the RW currents. In either case, the RW current may become important at high frequency. The analysis further shows that the RW current consists, in general, of two parts. One part is called the “ TM_0 RW current,” and exists for both open and closed structures. The second type, called the “ k_0 RW current,” exists only for open structures. An asymptotic analysis shows that for large distances z from the source, the TM_0 RW current behaves as

$$I_{RW}^{TM_0}(z) = A_{RW}^{TM_0} \frac{1}{|z|^{3/2}} e^{-jk_{TM_0}|z|} \quad (4)$$

where k_{TM_0} is the wavenumber of the TM_0 substrate mode, while the k_0 RW current behaves as

$$I_{RW}^{k_0}(z) = A_{RW}^{k_0} \frac{1}{|z|^2} e^{-jk_0|z|} \quad (5)$$

where k_0 is the wavenumber of free space.

Section 2 provides a detailed description of the semi-analytical method of analysis that is used to calculate the strip current and the consistent BM, LM, and RW components. The analysis shows how the total strip current is representable as a sum of BM and CS currents, and also how the CS current can be represented as a sum of physical LM currents together with RW currents.

In Section 3, results will be presented to show the types of spurious effects that can occur for the various types of printed-circuit transmission-line structures in Fig. 1, due to the LM currents and the RW currents.

Section 4 extends the analysis and the results of the previous sections by considering the calculation of the crosstalk current that is excited on a passive (victim) line, when a gap voltage source is present on an excited line. It is shown that simple transmission-line theory can predict the crosstalk current accurately at low frequency, using an even/odd-mode analysis. However, at high frequency, the CS current becomes important, and the crosstalk current cannot be adequately described by simple transmission-line theory.

Section 5 examines the nature of the crosstalk field that surrounds a printed-circuit transmission line, when it is excited by a gap voltage source. It is seen that at low frequency the field decays away from the line fairly rapidly, but at high frequency this is not the case. When physical leaky modes are present, very strong focused radiation may occur in a specific direction, leading to very high crosstalk fields.

Section 6 concludes the article by summarizing the most important observations and conclusions that are obtained from the study of the printed-circuit transmission line excited by a gap voltage source.

2. ANALYSIS FOR CURRENT EXCITED BY A GAP SOURCE

This section describes the theory underlying the computation of the current excited on the strip conductor of an infinite printed-circuit line by a gap voltage source on the line as shown in Fig. 2. The substrate is a lossless dielectric that can be layered and an optional metallic wall can cover the line (in which case the structure is referred to as a “closed” structure, since it is closed vertically, and radiation into space is prohibited). The line is assumed to be infinite along the longitudinal direction (z) and the conductors are infinitesimally thin and perfectly conducting. (Although only lossless striplike lines will be considered here, the present approach can be extended to lossy and/or slotlike lines with some modifications.) The basic ideas of the theory will be exposed in this section in connection with a single microstrip line. Section 4 will treat the current excited on a pair of coupled microstrip lines.

Figure 2. Geometry of an infinite microstrip line excited by a gap voltage source at $z=0$.

In order to compute the surface current on the strip conductor, $\mathbf{J}_s = J_x \hat{\mathbf{x}} + J_z \hat{\mathbf{z}}$, the following electric field integral equation (EFIE) has to be solved:

$$\mathbf{E}_t[\mathbf{J}_s(x, z)] = \mathbf{E}_t^{\text{gap}}(x, z) \quad (6)$$

where $\mathbf{E}_t^{\text{gap}}$ is the tangential electric field impressed in the gap (where the “t” subscript denotes “tangential”) to model the gap voltage source. This impressed electric field is equated to the field that is computed from the strip current using the transverse part of the corresponding dyadic Green’s function of the layered structure at the strip interface, $\bar{\mathbf{G}}_t(x, z; x', z') = G_{xx} \hat{\mathbf{x}}\hat{\mathbf{x}} + G_{xz}(\hat{\mathbf{x}}\hat{\mathbf{z}} + \hat{\mathbf{z}}\hat{\mathbf{x}}) + G_{zz} \hat{\mathbf{z}}\hat{\mathbf{z}}$, as the following convolution product

$$\mathbf{E}_t(x, z) = \int_{-\infty}^{\infty} \int_{-w/2}^{w/2} \bar{\mathbf{G}}_t(x - x', z - z') \cdot \mathbf{J}_s(x', z') dx' dz' \quad (7)$$

where the translational symmetry of the grounded substrate in the tangential plane has been incorporated. The impressed field is assumed to be

$$\mathbf{E}_t^{\text{gap}}(x, z) = -\frac{1}{\Delta} \text{rect}\left(\frac{x}{w/2}\right) \text{rect}\left(\frac{z}{\Delta/2}\right) \hat{\mathbf{z}} \quad (8)$$

in order to give a uniform gap field that corresponds to homogeneous voltage drop of 1 V along the gap (Δ denotes the longitudinal width of the gap, and $\text{rect}(x) = 1$ if $|x| \leq 1$ and is zero otherwise). For future use it is convenient to note that the z Fourier transform of the impressed gap field, $\tilde{\mathbf{E}}_z^{\text{gap}}(x, k_z)$, of (8) is given by

$$\tilde{\mathbf{E}}_z^{\text{gap}}(x, k_z) = -\text{rect}\left(\frac{x}{w/2}\right) \text{sinc}\left(\frac{k_z \Delta}{2}\right) \quad (9)$$

where $\text{sinc}(x) = \sin(x)/x$. (In the present notation, $\tilde{A}(k_z)$ denotes the Fourier transform of $A(x)$ for any function A .)

Next, the EFIE is solved by means of Galerkin’s method [2], for which the unknown induced current density on the strip has to be expanded in basis functions. First, and for simplicity of explanation, the current density will be expanded using only one basis function. The extension to

include multiple basis function will be discussed afterward.

2.1. Single Basis Function

If only a single basis function is employed to expand the induced current density on the strip, $\mathbf{J}_s(x, z)$ will have only a longitudinal component, J_{sz} , which can be represented by

$$J_{sz}(x, z) = T(x)I(z) \quad (10)$$

where $T(x)$ denotes the transverse profile, which is normalized to give

$$\int_{-w/2}^{w/2} T(x) dx = 1 \quad (11)$$

so that $I(z)$ actually represents the longitudinal current on the line at a distance z from the source. Specifically, the following basis function has been chosen

$$T(x) = \frac{\text{rect}\left(\frac{x}{w/2}\right)}{\pi \sqrt{\left(\frac{w}{2}\right)^2 - x^2}} \quad (12)$$

which will give a good approximation for narrow strips. The EFIE (6) can be then written as

$$\int_{-\infty}^{\infty} \int_{-w/2}^{w/2} G_{zz}(x - x', z - z') T(x') I(z') dx' dz' = \mathbf{E}_z^{\text{gap}}(x, z) \quad (13)$$

The application of the longitudinal inverse Fourier transform

$$I(z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{I}(k_z) e^{-jk_z z} dk_z \quad (14)$$

to the integral equation above (or alternatively, taking the Fourier transform of both sides with respect to z) leads to

$$\begin{aligned} \tilde{I}(k_z) \int_{-w/2}^{w/2} \tilde{G}_{zz}(x - x', k_z) T(x') dx' \\ = \text{rect}\left(\frac{x}{w/2}\right) \tilde{\mathbf{E}}_z^{\text{gap}}(k_z) \end{aligned} \quad (15)$$

The tilde above the Green’s function indicates here a 1D Fourier transform with respect to z . If Galerkin’s method is now applied, (15) can be finally expressed as

$$\begin{aligned} \tilde{I}(k_z) \int_{-w/2}^{w/2} T(x) \int_{-w/2}^{w/2} \tilde{G}_{zz}(x - x', k_z) T(x') dx' dx \\ = \left[\int_{-w/2}^{w/2} T(x) dx \right] \tilde{\mathbf{E}}_z^{\text{gap}}(k_z) \end{aligned} \quad (16)$$

which, after taking into account (11), allows this to be written as

$$\tilde{I}(k_z) = \frac{\tilde{\mathbf{E}}_z^{\text{gap}}(k_z)}{D(k_z)} \quad (17)$$

with

$$D(k_z) = \int_{-w/2}^{w/2} T(x) \int_{-w/2}^{w/2} \tilde{\mathbf{G}}_{zz}(x-x', k_z) T(x') dx' dx \quad (18)$$

It should be noted that $D(k_z)$ actually represents a function whose zeros are the modal propagation constants (k_z^M) of the infinite microstrip line. A careful study of the singularities of this function in the complex k_z plane will be presented later in this section.

Two common techniques have been commonly used in the literature to compute integrals such as $D(k_z)$: the spectral-domain approach (SDA) [3,4] and the discrete complex images technique (DCIT) [5–7]. Each is discussed further below.

2.1.1. Spectral-Domain Analysis. As is well known, the use of the SDA is motivated by the fact that the dyadic Green's function can be obtained in closed form (or by means of certain algorithms) in the spectral domain [8–10]. Thus, assuming that $\tilde{\mathbf{G}}_{zz}(k_x, k_z)$ is known in closed form, $D(k_z)$ can be expressed analytically in terms of a spectral-domain integral involving this Green's function. (The tilde over the Green's function indicates here a 2D Fourier transform of the Green's function.) This is accomplished by first expressing the inner integral in Eq. (18) as an inverse Fourier transform of the Fourier transform (in x), noting the convolutional nature of the integral, and then performing the outer integral in x in closed form, resulting in the Fourier transform of the function $T(x)$. The result is (assuming that $T(x)$ is an even function)

$$D(k_z) = \frac{1}{2\pi} \int_{C_{kx}} \tilde{\mathbf{G}}_{zz}(k_x, k_z) \tilde{T}^2(k_x) dk_x \quad (19)$$

where C_{kx} is an appropriate inverse Fourier transform path from minus infinity to infinity in the complex k_x plane [11–13].

Since the preceding integral has to be computed many times to obtain the current profile given by (14), it is very convenient to minimize as much as possible the intensive numerical effort required to compute (19). Different strategies have been proposed in the literature to speed up the overall computation of similar integrals, and one that has been found particularly efficient is the extraction of an asymptotic behavior that can be further expressed in closed form. This involves splitting the integral (19) into two integrals

$$D(k_z) = D^s(k_z) + D^\infty(k_z) \quad (20)$$

where

$$D^s(k_z) = \int_{C_{kx}} \left[\tilde{\mathbf{G}}_{zz}(k_x, k_z) - \tilde{\mathbf{G}}_{zz}^\infty(k_x, k_z) \right] \tilde{T}^2(k_x) dk_x \quad (21)$$

$$D^\infty(k_z) = \int_{-\infty}^{\infty} \tilde{\mathbf{G}}_{zz}^\infty(k_x, k_z) \tilde{T}^2(k_x) dk_x \quad (22)$$

so that $D^s(k_z)$ can be computed with low computational effort. An asymptotic expression for the spectral-domain Green function is

$$\tilde{\mathbf{G}}_{zz}^\infty(k_x, k_z) = - \left(\frac{j\omega\mu_0}{2} + \frac{1}{2j\omega\epsilon_m} k_z^2 \right) \frac{|k_x|}{k_x^2 + k_0^2} \quad (23)$$

(where k_0 is the free-space wavenumber). Use of this expression leads to a closed-form expression for $D^\infty(k_z)$ [14,15].

2.1.2. Discrete Complex Images Technique. One of the main numerical disadvantages of the spectral-domain technique is that obtaining the longitudinal current profile from Eq. (14) requires numerically evaluating the integral (21) with infinite limits for each value of k_z . This drawback can be considerably alleviated if the discrete complex images technique (DCIT) is used to obtain a closed-form expression for the Green's function in the spatial domain. This procedure has been employed elsewhere [7,16,17] to deal with 2D printed lines when Eq. (6) is posed as a mixed potential integral equation (MPIE) [18]. It is worth mentioning that the integrals to be repeatedly computed are double definite integrals with nonsingular integrands (except at the strip edges) that can be very efficiently computed by low order Gauss–Chebyshev quadratures [17]. Our experience shows that this scheme reduces the CPU time at least 5 times when compared to that required by the SDA.

2.1.3. Multiple Basis Functions. The procedure shown in the previous section is numerically accurate only for those situations where the transverse component of the current density can be neglected (which is usually found at low frequencies and/or for narrow strips). In general, however, an expansion with multiple basis functions is required. For this purpose, the current density on the strip is assumed to be (with q even and p odd)

$$J_z(x, z) = \sum_{q=0}^{N_f} T_q^z(x) I_q^z(z) \quad (24)$$

$$J_x(x, z) = \sum_{p=1}^{N_f} T_p^x(x) I_p^x(z) \quad (25)$$

where $T_p^z(x)$ and $T_q^x(x)$ are, respectively, the basis functions used to expand the transverse profile of the z and x components of the current density, and $I_p^z(z)$ and $I_q^x(z)$ are the corresponding unknown coefficient functions accounting

for the longitudinal profile of the current density. The term N_f denotes the maximum order of the basis functions. The transverse profile is accounted for by the usual Chebyshev polynomials of the first and second kinds [$T_n(\cdot)$ and $U_m(\cdot)$, respectively] weighted by the proper edge condition, namely

$$T_q^z(x) = (2 - \delta_{q0}) \frac{2}{w\pi} \frac{T_q(2x/w)}{\sqrt{1 - \left(\frac{2x}{w}\right)^2}} \quad (26)$$

$$T_p^x(x) = \frac{4}{w\pi} j U_p(2x/w) \sqrt{1 - \left(\frac{2x}{w}\right)^2} \quad (27)$$

where δ_{mn} is the Krönecker delta. The use of this expansion in the EFIE, after using Galerkin's method and applying the longitudinal Fourier transform, leads to the following linear equation system

$$\begin{bmatrix} \Gamma_{pp'}^{xx}(k_z) & \Gamma_{pq'}^{xz}(k_z) \\ \Gamma_{qp'}^{zx}(k_z) & \Gamma_{qq'}^{zz}(k_z) \end{bmatrix} \cdot \begin{bmatrix} \tilde{I}_p^x(k_z) \\ \tilde{I}_q^z(k_z) \end{bmatrix} = \begin{bmatrix} [0] \\ [\tilde{b}_q^z(k_z)] \end{bmatrix} \quad (28)$$

where

$$\Gamma_{pp'}^{xx}(k_z) = \int_{-w/2}^{w/2} [T_p^x(x)] \int_{-w/2}^{w/2} \tilde{G}_{xx}(x, x', k_z) T_{p'}^x(x') dx' dx \quad (29a)$$

$$\Gamma_{pq'}^{xz}(k_z) = \int_{-w/2}^{w/2} [T_p^x(x)] \int_{-w/2}^{w/2} \tilde{G}_{xz}(x, x', k_z) T_{q'}^z(x') dx' dx \quad (29b)$$

$$\Gamma_{qp'}^{zx}(k_z) = \int_{-w/2}^{w/2} [T_q^z(x)] \int_{-w/2}^{w/2} \tilde{G}_{zx}(x, x', k_z) T_{p'}^x(x') dx' dx \quad (29c)$$

$$\Gamma_{qq'}^{zz}(k_z) = \int_{-w/2}^{w/2} [T_q^z(x)] \int_{-w/2}^{w/2} \tilde{G}_{zz}(x, x', k_z) T_{q'}^z(x') dx' dx \quad (29d)$$

$$\tilde{b}_q^z(k_z) = \tilde{E}_z^{\text{gap}}(k_z) \delta_{q0} \quad (29e)$$

The current along the line can be obtained finally as

$$I(z) = \int_{-w/2}^{w/2} J_z(x, z) dx = \sum_{q=0}^{N_f} I_q^z(z) \int_{-w/2}^{w/2} T_q^z(x) dx \quad (30)$$

which can be recognized as simply $I(z) = I_0^z(z)$ because of the normalization condition imposed on the basis functions. Therefore

$$I(z) = \frac{1}{2\pi} \int_{C_{kz}} \tilde{I}_0^z(k_z) e^{-jk_z z} dk_z \quad (31)$$

The coefficients of the Galerkin matrix (29a)–(29d) can be numerically obtained by using the SDA or the DCIT techniques discussed in the previous sections, since the introduction of multiple basis functions does not affect the asymptotic or singular behavior of the corresponding integrals.

2.2. The Complex k_z Plane

It has been shown above that the computation of the current on the strip $I(z)$ requires an inverse Fourier transform given, in general, by Eq. (31). It is well known that the study of the singularities of the integrand of any complex spectral integral gives very valuable information about the integral itself [19]. In this way, references have shown [12,13,20–22] that a study of the integrand of (31) in the complex k_z plane provides a deep and very useful physical insight into the nature of the current excited on the line, and furthermore, how to decompose the current into its constituent parts. Since the $\exp(-jk_z z)$ function is fully analytic in the entire k_z plane, any singularity of the integrand comes necessarily from $\tilde{I}_0^z(k_z) \equiv \tilde{I}(k_z)$, and therefore the present study will focus on the poles and branch points of this latter function.

Looking at the form of $\tilde{I}(k_z)$ given in (17), it can be recognized that the numerator will not show any singularity in the k_z plane since $\tilde{E}_z^{\text{gap}}(k_z)$ is the Fourier transform of a bounded function. Thus, the pole singularities of $\tilde{I}(k_z)$ will come from the zeros of the denominator $D(k_z)$ (for the case of multiple basis functions, this function will be the determinant of the Galerkin matrix), which have been previously identified as the propagation wavenumbers for modes on the infinite line. Also, the branch points of $D(k_z)$ will be the branchpoint singularities of $\tilde{I}(k_z)$.

The discussion above shows that the nature of the complex k_z plane defined by $\tilde{I}(k_z)$ is fully determined by the function $D(k_z)$. This function can be rewritten in general (also for multiple basis functions) as

$$D(k_z) = \int_{C_{kx}} Q(k_x, k_z) dk_x \quad (32)$$

where $Q(k_x, k_z)$ involves the spectral-domain Green function (SDGF). The expression given in Eq. (19) for $D(k_z)$ makes apparent that its singularities are themselves determined by both the singularities of the SDGF and the corresponding integration path C_{kx} in the complex transverse wavenumber plane (k_x).

There are two types of singularities in the complex k_z plane: poles and branchpoints. Poles correspond to guided modes that exist on the printed-circuit transmission line, and the residues at the corresponding pole locations determine the amplitudes of the modes that get launched by the gap voltage source, including both bound and leaky

modes. During a path deformation to the steepest-descent path (discussed later), the bound-mode poles are always captured, and hence the bound-mode currents always appear explicitly in the final expression for the current. Leaky-mode poles may or may not be captured, however. Leaky modes whose poles are captured are said to be “physical” leaky modes, and these currents appear explicitly in the final expression for the current. Leaky modes whose poles are not captured do not appear explicitly in the final expression for the current, and are said to be “nonphysical.” However, these nonphysical poles may still have an influence on the total current, by virtue of their proximity to the steepest-descent path. This will be particularly true when a nonphysical pole is close to being physical, so that the pole is close to the steepest-descent path.

Branchpoints in the k_z plane arise because of a non-uniqueness in the evaluation of the integral (32). In particular, different paths of integration in the complex k_x plane may be used for the path C_{k_x} . These different paths may detour around the pole and/or branchpoint singularities of the SDGF in different ways, resulting in different values for the integral. This corresponds to $D(k_z)$ being a multiple-valued function of k_z . Mathematically, this may be conveniently viewed as the complex k_z plane corresponding to a Riemann surface. On each sheet of the surface a different path of integration is used in the k_x plane to evaluate the integral in Eq. (32).

The SDGF for an open structure such as microstrip has singularities at particular points in the transverse wavenumber k_t plane, where $k_t^2 = k_x^2 + k_z^2$. This results in corresponding singularities at the following locations in the complex k_x plane [13,23–25]:

1. *Branchpoints* at $k_x = \pm k_{xb}$, where $k_t^2 = k_{xb}^2 + k_z^2 = k_0^2$
2. *Proper poles* at $k_x = \pm k_{xp}$, where $k_t^2 = k_{xp}^2 + k_z^2 = k_{sw}^2$, where k_{sw} is the propagation constant for a proper surface wave of the background layered structure
3. *Improper poles* at $k_x = \pm k_{xi}$, where $k_t^2 = k_{xi}^2 + k_z^2 = k_{imp}^2$, where k_{imp} is the propagation constant of an improper mode of the background layered structure

The improper modes of the background layered structure can be classified as either improper surface-wave modes, if the propagation constant k_{imp} is purely real, or as complex leaky modes, if k_{imp} is complex. (An improper surface-wave mode is never regarded as a physical mode. A complex improper leaky mode is regarded as being physical if the phase constant of the mode is less than k_0 , so that the radiating leaky mode is a fast wave with respect to free space [26,27].)

A careful study of the integration paths in the k_x plane, and their evolution as the point k_z moves in the complex k_z plane, reveals that branchpoints in the complex k_z plane occur at the following locations:

1. Branchpoints at $k_{zb}^p = \pm k_{TM_0}$, where k_{TM_0} is the wavenumber of the TM_0 surface-wave (or parallel-plate) mode of the background layered structure (it

is assumed here that only the TM_0 mode is above cutoff).

2. Branchpoints at $k_{zb}^i = \pm k_{imp}$, where k_{imp} is the wavenumber of an improper (improper real or complex leaky) mode of the background layered structure.
3. Branchpoints at $k_{zb}^0 = \pm k_0$, where k_0 is the free-space wavenumber.

The branchpoints at k_{zb}^p and k_{zb}^i give rise to a double-valued function of k_z (corresponding to two sheets of the k_z Riemann surface), since circling these branchpoints twice gives back the original function $D(k_z)$ at the starting point in the k_z plane. Thus, the path of integration in the k_x plane in integral (32) evolves back to the original path when the point k_z moves twice around the branchpoint back to the original path.

The branchpoints at $k_{zb}^0 = \pm k_0$ have a logarithmic character in the sense that there are an infinite number of sheets associated with these branchpoints; that is, each time the branchpoint is circled in the k_z plane, the path of integration in the k_x plane changes, and never returns to the original path after a finite number of encirclements of the branchpoint. The original path of integration lies in the sheet that is denoted as the “zero” sheet, for which the path of integration in the k_x plane stays on the top (proper) sheet of the k_x Riemann surface.

As shown in Ref. 13, the branchpoints corresponding to the improper modes of the background structure at $k_{zb}^i = k_{imp}$ do not appear on the zero sheet of the $\pm k_0$ branchpoints on the k_z Riemann surface (such branchpoints appear only on the odd sheets of the $\pm k_0$ branchpoints). The original path of integration C_{k_z} , which stays on the zero sheet, thus sees the branchpoints only at $k_{zb}^0 = \pm k_0$ and $k_{zb}^p = \pm k_{TM_0}$. The branchpoints at $\pm k_{TM_0}$ appear only on the even sheets of the $\pm k_0$ branch points, including the zero sheet.

The complex k_z plane for the case of an open structure such as microstrip line is shown in Fig. 3. The branchpoints at $\pm k_0$ and at $\pm k_{TM_0}$ are shown. To aid in the understanding of the branchpoints and the k_z Riemann surface, an example is given to connect the location of

Figure 3. The k_z plane showing two pairs of branchpoints at $\pm k_0$ and $\pm k_{TM_0}$, a pair of proper poles at $\pm A$, and two pairs of leaky poles at $\pm B$ and $\pm C$.

the k_z point on the Riemann surface with the corresponding path of integration in the k_x plane. Three points are shown in the complex k_z plane, labeled as A , B , and C . The corresponding paths of integration in the k_x plane are shown in Figs. 4a, 4b, and 4c.

Figure 4. Integration paths in the transverse wavenumber complex plane (k_x) corresponding to (a) point A , (b) point B , and (c) point C in Fig. 6.

Point A is located on the real axis of the k_z plane, and is assumed to be on the zero sheet of the branchpoints at $\pm k_0$ and also the top sheet of the branchpoints at $\pm k_{TM_0}$. (The original path of integration C_{kz} is on this sheet.) This point corresponds to a path of integration that stays along the real axis in the k_x plane, shown in Fig. 4a, without detouring around any pole or branchpoint singularities of the SDGF.

Point B is assumed to lie on the zero sheet of the $\pm k_0$ branchpoints, and the bottom sheet of the $\pm k_{TM_0}$ branchpoints. Such a point is obtained by starting from point A , then moving into the first quadrant of the k_z plane, and then moving down, crossing the real axis between k_0 and k_{TM_0} . In doing so, the branchcut from the k_{TM_0} branchpoint is crossed, to enter the lower sheet of this branchpoint on the k_z Riemann surface. The corresponding path in the k_x plane detours around the TM_0 poles of the SDGF located at $\pm k_{xp}$, but stays on the top sheet of the Riemann surface in the k_x plane.

Point C is assumed to be on the lower (-1) sheet of the k_0 branchpoints on the k_z Riemann surface. Such a point is obtained by starting from point A , then moving into the first quadrant of the k_z plane, and then moving down, crossing the real axis between the origin and k_0 . In doing so, the branchcut from the k_0 branchpoint is crossed, to enter the lower sheet of this branchpoint on the k_z Riemann surface. (As soon as this branchcut is crossed, the branchpoints at $\pm k_{TM_0}$ no longer appear, since these branchpoints appear only on the even sheets of the $\pm k_0$ branchpoints.) The corresponding path of integration crosses through the branchcuts of the SDGF in the k_x plane and lies partly on the improper lower sheet of the k_x Riemann surface. The path also detours around the TM_0 surface-wave poles of the SDGF.

For covered structures such as covered microstrip, the only branchpoints that occur are those at the wavenumbers of the parallel-plate modes of the background structure. Assuming that only the TM_0 parallel-plate mode is above cutoff, there will be one pair of branchpoints on the real k_z axis at $k_{zb} = \pm k_{TM_0}$. There will also be an infinite number of branchpoints on the imaginary axes, corresponding to the wavenumbers of the evanescent parallel-plate modes. The complex k_z plane for a covered structure is shown in Fig. 5.

Figure 5. The k_z plane showing a pair of branchpoints at $\pm k_{TM_0}$, a pair (out of an infinite number) of branchpoints on the imaginary axis, and two pairs of poles.

2.3. Decomposition of the Total Current

When computing the fields of a simple source such as a dipole in the presence of a grounded dielectric slab, the existence of square-root-type branchpoints at $\pm k_0$ in the integrand of the corresponding Fourier integral is related to radiation in the free space, namely, to its continuous spectrum [23,24]. This principle holds for more complicated systems, such as the gap source on the microstrip line, discussed here. The existence of branchpoints is related to mechanisms of radiation. Thus, for the microstrip line under study, the fact that $\tilde{I}(k_z)$ has multiple pairs of branchpoints indicates that radiation can take place by means of different mechanisms (or, in other words, that the continuous spectrum will have different components). Specifically, the $\pm k_0$ branchpoints are related to radiation into free space, and the branchpoints at $\pm k_{\text{TM}_0}$ are related to radiation in the form of surface waves or parallel-plate modes of the background waveguide.

In addition to branchpoints, $\tilde{I}(k_z)$ also has pole singularities that originate from the roots of $D(k_z)$. It is well known that $D(k_z)$ has an infinite number of roots: a finite set corresponding to bound (proper) modes and an infinite set of leaky (improper) modes [28–35]. Specifically, the different poles of $\tilde{I}(k_z)$ are located as follows:

- *Bound modes*—the poles lie on the zero sheet with respect to the $\pm k_0$ branchpoints and on the top (proper) sheet with respect to the $\pm k_{\text{TM}_0}$ branchpoints.
- *Surface-wave leaky modes*—the poles lie on the zero sheet with respect to $\pm k_0$ branchpoints and on the bottom (improper) sheet with respect to the $\pm k_{\text{TM}_0}$ branchpoints.
- *Surface and space-wave leaky modes*—the poles lie on the -1 sheet of the $\pm k_0$ branchpoints.

A typical diagram of the integration path C_{kz} to compute $I(z)$ together with some relevant singularities of $\tilde{I}(k_z)$ is shown in Fig. 6. The path is equivalent to a real-axis path that runs from $-\infty$ to ∞ , detouring around the branchpoint singularities and also the bound mode poles on the real axis.

With an understanding of the complex k_z plane, it is now possible to discuss the physical significance of a

Figure 6. The k_z plane showing the integration path C_{kz} , two pairs of branchpoints at $\pm k_0$ and $\pm k_{\text{TM}_0}$, a pair of proper poles at $\pm k_{\text{TM}_0}^{\text{BM}}$, and a pair of leaky poles at $\pm k_z^{\text{LM}}$.

particular mode. This physical significance can be defined by the degree of excitation of this mode from a realistic source. A mode that is physically significant should be excited by a suitable finite source, which implies that the current $I(z)$ on the line will then have a component that closely resembles the current of the mode. (If a particular mode is excited with a sufficient amplitude, this modal component may dominate the total line current.)

One possible “measure” of the relative significance of each microstrip mode can be obtained by looking at the “distance” from the corresponding pole in the k_z plane to the integration contour C_{kz} on the Riemann surface. The term “distance” here refers to distance on the Riemann surface. For example, two points on the opposite sides of a branchcut, both on the same sheet, will not be “close” to one another, regardless of how geometrically close they are together. Two geometrically close points on either side of a branchcut will be close on the Riemann surface if they are located on different sheets, such that there is a continuous connection between the two points.

Since the k_z^{BM} pole on the real axis corresponding to a bound mode is on the same sheet as the integration path C_{kz} , this pole is always close to the path of integration, and is therefore always physically significant. For the leaky-mode poles, however, the poles may or may not be close to the integration path, depending on which sheet they are located, and the value of the phase constant β of each mode. The physical significance of a leaky mode can be summarized concisely by saying that a mode can have physical significance only if the mode satisfies what is denoted as the *path consistency condition* (PCC). This condition (which was called the “condition of leakage” in Ref. 32) states that the path of integration in the k_x plane used to obtain a particular leaky-mode solution should be *consistent* with the phase constant β of the leaky mode that is obtained by using the given path. For example, if the path in the k_x plane used to obtain a leaky mode is the one shown in Fig. 4b, which corresponds to leakage into the TM_0 mode but not into space, the resulting leaky mode will be physically significant (or “physical”) provided the phase constant of the leaky mode is in the range $k_0 < \beta < k_{\text{TM}_0}$. If the path in the k_x plane used to obtain a leaky mode is the one shown in Fig. 4c, which corresponds to leakage into both the TM_0 mode and into space, the resulting leaky mode will be physically significant (or “physical”) provided the phase constant of the leaky mode is in the range $\beta < k_0$.

This physical significance of a leaky mode is directly related to the closeness of the corresponding pole to the path C_{kz} on the Riemann surface. For example, consider a leaky-mode pole located as shown in Fig. 6, to the left of the branchpoint k_0 ; that is, $\Re(k_{zp}) < k_0$. Such a leaky mode is close to the path C_{kz} if it is on the -1 sheet of the $\pm k_0$ branchpoints. This means that the path of integration in the k_x plane is that shown in Fig. 4c. Similarly, if a leaky-mode pole is located in the region $k_0 < \Re(k_{zp}) < k_{\text{TM}_0}$, the pole is close to the path C_{kz} if the pole is on the zero sheet of the $\pm k_0$ branchpoints, and the bottom sheet of the $\pm k_{\text{TM}_0}$ branchpoints.

A more mathematical way of determining the physical significance of the leaky modes, which also provide

additional insight into the nature of the current and fields excited by the source, is to deform the original integration path C_{kz} to a vertical set of steepest-descent paths (SDPs) [23,24,36]. Figure 7 illustrates this for the case of an open structure such as microstrip (for $z > 0$).

Figure 7a shows how the original C_{kz} path may be first deformed into a path C_{BC} detouring around all the branchcuts (the TM_0 and k_0 branchcuts) and a set of residue contributions C_{BM} from paths that encircle all of the bound-modes poles on the positive real axis (in the figure only one bound mode is assumed). The total current (TC) on the strip can be decomposed as

$$I(z) = -j \operatorname{Res}\{\tilde{I}(k_z^{BM})\}e^{-jk_z^{BM}z} + \frac{1}{2\pi} \int_{C_{BC}} \tilde{I}(k_z) e^{-jk_z z} dk_z \quad (33)$$

$$= I_{BM}(z) + I_{CS}(z) \quad (34)$$

where the residue contribution around C_{BM} accounts for the launching amplitude of the bound-mode (BM) current from the gap source and the integral around C_{BC} defines the continuous-spectrum (CS) current on the line that is induced by the gap source. It is interesting to note that standard transmission-line theory only predicts the BM

Figure 7. (a) Complex k_z plane showing the integration path C_{kz} , an integration path C_{BC} around the branch cuts, and a residue path C_{BM} around the BM pole; (b) complex k_z plane showing the path deformation of C_{kz} to a set of vertical SDPs, a residue path around the captured LM pole k_z^{LM} , and a residue path C_{BM} around the BM pole.

current and not the CS current, which is a consequence of the full-wave modeling of the complete current spectrum due to the gap source. This latter current usually increases with frequency and is responsible for spurious effects observed in the line current, as shown later.

The CS current can be further decomposed by deforming the C_{BC} path to a set of vertical SDPs as shown in Fig. 7b. In this deformation some leaky-mode (LM) poles may be captured and therefore will appear explicitly in the final decomposition of the strip current. In particular, a leaky-mode pole will be captured if the leaky mode is a physical one, satisfying the path consistency condition described previously. The residue contribution of the captured LM poles will define the launching amplitude of the *physical* leaky modes. Nonphysical leaky-mode poles will not give an explicit contribution to the leaky-mode current (defined from the residues of the captured poles), but the possible influence of such poles is automatically included in the calculation of the “residual wave” (RW) currents, which are the contributions from the path integrations along the two vertical SDP paths. The RW currents represent that part of the CS current that is not represented explicitly by the sum of the physical LM currents. The total strip current can therefore be expressed as

$$I(z) = I_{BM}(z) + I_{LM}(z) + I_{RW}^{TM_0}(z) + I_{RW}^{k_0}(z) + \sum_i I_{RW}^i(z) \quad (35)$$

where

$$I_{BM}(z) = -j \operatorname{Res}\{\tilde{I}(k_z^{BM})\}e^{-jk_z^{BM}z} \quad (36a)$$

$$I_{LM}(z) = -j \operatorname{Res}\{\tilde{I}(k_z^{LM})\}e^{-jk_z^{LM}z} \quad (36b)$$

$$I_{RW}^{TM_0}(z) = \frac{1}{2\pi} \int_{SDP_{TM_0}} \tilde{I}(k_z) e^{-jk_z z} dk_z \quad (36c)$$

$$I_{RW}^{k_0}(z) = \frac{1}{2\pi} \int_{SDP_{k_0}} \tilde{I}(k_z) e^{-jk_z z} dk_z \quad (36d)$$

$$I_{RW}^i(z) = \frac{1}{2\pi} \int_{SDP_i} \tilde{I}(k_z) e^{-jk_z z} dk_z \quad (36e)$$

The first term represents the currents of the bound modes that are launched by the gap source. Usually there is only one, and this is the desired transmission-line mode. The second term represents the sum of all physical leaky modes, from the residues of the captured poles. In general, there may be two types of physical leaky modes, those that leak into only the TM_0 mode, and those that leak into both the TM_0 modes and into space. The next term is the TM_0 RW current, arising from the path integration along the vertical SDP path that descends downward from the branchpoint at $k_{zb} = k_{TM_0}$. The next term is the k_0 RW current that arises from the path integration along the vertical SDP path that descends downward from the branchpoint at $k_{zb} = k_0$. The last series term is a set of

RW currents that comes from SDP paths (not shown in Fig. 7b) that descend from branchpoints associated with improper complex modes of the background structure. These RW currents are included whenever the phase constants of the corresponding improper modes of the background structure are less than k_0 , so that the branchpoints are intercepted by the path deformation. These RW currents are usually negligible because of the large imaginary part of the corresponding branchpoints.

Although the TM_0 and k_0 RW currents do not have closed-form expressions, it is possible to evaluate their asymptotic behaviors for large z [21,36]. The calculation shows that the TM_0 RW current behaves as

$$I_{RW}^{TM_0}(z) \sim A_{RW}^{TM_0} \frac{e^{-jk_{TM_0}z}}{(k_{TM_0}z)^{3/2}} \quad (37)$$

and the k_0 RW current as

$$I_{RW}^{k_0}(z) \sim A_{RW}^{k_0} \frac{e^{-jk_0z}}{(k_0z)^2} \quad (38)$$

3. RESULTS FOR THE CURRENT EXCITED BY A GAP SOURCE

In this section results will be presented for the three structures shown in Fig. 1, to illustrate the types of spurious effects that may be observed in the current excited by a gap voltage source on a printed-circuit transmission line. The three structures are microstrip, covered microstrip, and stripline with an airgap. In each case plots of the total current are presented, along with plots of the bound mode and continuous-spectrum currents. When physical leaky modes are present, the continuous-spectrum (CS) current is decomposed into the leaky-mode (LM) and residual-wave (RW) parts, and these are shown.

3.1. Microstrip

For the microstrip structure of Fig. 1a, the current excited by the gap source consists of a BM current and a CS current. The CS current consists of any physical leaky modes that exist at the frequency of interest, together with a RW current, which consists of both the TM_0 RW current and the k_0 RW current.

In all the cases presented, the only physical leaky mode that is found to exist is one that leaks into the TM_0 surface-wave mode, and not into space. Such a leaky mode is physical, and hence is included in the composition of the CS current, if $k_0 < \beta < k_{TM_0}$. Results are presented for both a moderate-permittivity substrate and a high-permittivity substrate [21].

Results are first presented for the case of a moderate permittivity substrate, $\epsilon_r = 2.2$, for several different values of w/h , corresponding to different characteristic impedances. The substrate thickness is $h = 1.0$ mm in all cases.

Figure 8 shows the dispersion plot for a narrow line, with $w/h = 0.333$. For this dimension, the low-frequency characteristic impedance is 145.8 Ω . A plot of the normal-

Figure 8. Normalized phase constants (normalized by k_0) versus frequency, for a microstrip line with a moderate substrate permittivity ($\epsilon_r = 2.2$) and a small strip width ($w = 0.333$ mm, $h = 1.0$ mm). The bound mode (BM) is shown along with the leaky mode (LM) and the TM_0 and TE_1 surface-wave modes. At low frequency there is no leaky mode, only a pair of improper real modes (RIM). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ized phase constant of the bound mode is shown, along with a plot for the leaky mode. Also, for reference, a plot of the normalized phase constants for the TM_0 and TE_1 surface-wave modes of the grounded substrate are included. It is observed that leakage begins at 30 GHz. Above this frequency a leaky mode with a complex propagation wavenumber exists on the microstrip line. The leaky mode leaks into the TM_0 surface-wave mode of the grounded substrate. The leaky mode is an EH_0 mode, meaning that the transverse profile of the current closely resembles the expected quasi-TEM shape function. Below 30 GHz there is no leaky mode, only a pair of improper real modes (modes that are improper, but with a real propagation wavenumber). The leaky mode becomes physical above about 35 GHz, where it crosses the TM_0 dispersion line to become a fast wave with respect to the TM_0 surface wave.

Figure 9 shows the total current on the strip versus normalized distance from the source, for various frequencies. In this figure, and in all subsequent results, the length of the gap source is taken as $\Delta = 0.1\lambda_0$. It is seen in Fig. 9 that the total current is increasingly oscillatory as the frequency increases. This is due to the interference between the BM and CS currents. At low frequency, only the BM current is significant, and the current level is essentially flat with distance from the source. As the frequency increases, the amplitude of the CS current also increases, resulting in a stronger interference effect.

Figure 10 shows the dispersion plots for the case of a moderate strip width, $w/h = 1$. For this case the low-frequency characteristic impedance is 95.2 Ω . Comparing with Fig. 8, it is seen that leakage begins at a lower frequency for this wider strip, although the lowering in frequency is not dramatic. The leakage starts at about 27 GHz, with the leaky mode becoming physical at about 33 GHz, where the phase constant crosses the TM_0 dispersion curve. The leaky mode is not physical between approximately 47 and 70 GHz, where the dispersion curve

Figure 9. The total strip current versus distance from the source, for the case of Fig. 8. Results are shown for various frequencies.

is below the unity line, so that $\beta < k_0$. In this frequency range a physical leaky mode would be one that leaks into both the TM_0 surface-wave mode of the substrate and into space. However, no such physical leaky mode is found.

Figure 11 shows the current on the strip at various frequencies, for the case of moderate strip width. Comparing with Fig. 9, it is seen that the level of spurious oscillations is roughly the same, although the overall level of the current is higher for the wider strip case, because a wider strip corresponds to a smaller characteristic impedance, and hence the bound mode is excited with a larger amplitude. However, the CS current is also excited with a larger amplitude, giving roughly the same level of oscillations in the total current.

Figure 12 gives the dispersion behavior for a wide-strip case, where $w/h = 3$. For this case the low-frequency characteristic impedance is 51.1Ω . It is seen that the trend of a lower leakage frequency continues, with leakage now

Figure 10. Normalized phase constants (normalized by k_0) versus frequency, for a microstrip line with a moderate substrate permittivity ($\epsilon_r = 2.2$) and a moderate strip width ($w = 1.0$ mm, $h = 1.0$ mm). The bound mode (BM) is shown along with the leaky mode (LM) and the TM_0 surface-wave mode. At low frequency there is no leaky mode, only a pair of improper real modes (RIM). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 11. The total strip current versus distance from the source, for the case of Fig. 10. Results are shown for various frequencies. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

beginning at about 23 GHz, and the leaky mode becoming physical at about 27 GHz. The leaky mode is once again nonphysical in a particular high-frequency region, from about 33 to 64 GHz.

The current plots in Fig. 13 for the wide-strip case show a continuing increase in the overall current level, as expected. As with the other cases, the level of the spurious oscillations increases with frequency. However, for this wider strip case an interesting new effect is also observed. At a high frequency of 70 GHz, the oscillations decay extremely slowly with distance from the source. In fact, out to eight wavelengths from the source, there is no noticeable decay in the oscillation amplitude of Fig. 13. This is because the CS current decays very slowly with distance in this case. The effect has been examined in detail in Ref. 22, where it is shown that the effect is due to a leaky-mode pole

Figure 12. Normalized phase constants (normalized by k_0) versus frequency, for a microstrip line with a moderate substrate permittivity ($\epsilon_r = 2.2$) and a large strip width ($w = 3.0$ mm, $h = 1.0$ mm). The bound mode (BM) is shown along with the leaky mode (LM) and the TM_0 and TE_1 surface-wave modes. At low frequency there is no leaky mode, only a pair of improper real modes (RIM). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 13. The total strip current versus distance from the source, for the case of Fig. 12. Results are shown for various frequencies. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

approaching the branchpoint at k_0 in the complex k_z plane. The frequency at which this effect occurs is given approximately for wide strips by the following empirical formula [22]:

$$k_0 \sqrt{\epsilon_r} w = 2\pi \quad (39)$$

In Fig. 14, the current is investigated in more detail for the case of moderate strip width ($w/h = 1$), at a frequency of 20 GHz. Part (a) of this figure shows the total current and its constituent parts, the BM and CS currents; part (b) shows the CS current resolved into its constituent components, the k_0 RW current and the TM_0 RW current. There is no physical leaky mode at this frequency (see Fig. 10), so the CS current is simply the sum of the two RW currents. The TM_0 RW current is the stronger of the two residual waves, although the amplitudes are somewhat comparable. At 40 GHz the situation changes in that a physical leaky mode now exists (see Fig. 10). At this higher frequency the oscillations in the total strip current are larger, as seen in Fig. 15a, because the magnitude of the CS current is larger at this higher frequency. In Fig. 15b, the CS current is shown with its three components, the leaky-mode current, the k_0 RW current, and the TM_0 RW current. Close to the source, the LM current is the strongest. However, because the LM current decays exponentially with distance, the two RW currents become dominant for larger distances. The TM_0 RW current is the more dominant of the two, as for the 20-GHz case. The presence of the physical leaky mode causes the level of spurious oscillation to be quite significant close to the source in the 40-GHz case, much larger than in the 20-GHz case. Farther away from the source the level of spurious oscillation is still slightly larger in the 40-GHz case, but the increase is not as dramatic.

Figure 16 shows the dispersion behavior for a microstrip with a high-permittivity substrate ($\epsilon_r = 10.2$) and a moderate strip width ($w/h = 1$). (The leaky-mode solution is plotted up to 37.5 GHz, which is already well within the

Figure 14. Strip currents for the case of a moderate substrate permittivity ($\epsilon_r = 2.2$) and moderate strip width ($w = h = 1.0$ mm) at 20 GHz: (a) total current and its constituent parts, the bound-mode and continuous-spectrum currents; (b) continuous-spectrum current and its constituent parts, the TM_0 residual-wave current and k_0 residual-wave currents.

nonphysical region.) Comparing with Fig. 10, it is seen that the higher permittivity has lowered the frequency at which leakage begins. At about 24 GHz a second surface-wave mode, the TE_1 mode, begin to propagate, and the dispersion curve for this mode is included in the plot. Above this frequency, there will be a third propagating RW current, corresponding to the TE_1 branchpoint on the real axis in the complex k_z plane.

Figure 17 shows the current versus distance from the source for this high-permittivity case. The level of spurious oscillations in the strip current increases with frequency, as for the moderate-permittivity case of Fig. 11. Figure 18a shows the total strip current at 20 GHz for the case of Fig. 16 along with its components, the BM and CS currents. In Fig. 18b it is seen that a physical leaky mode dominates the CS current near the source, although the k_0 RW and TM_0 RW currents are not negligible, even near the source. Because of the exponential decay of this leaky mode, the oscillations in the total strip current die out fairly quickly with distance.

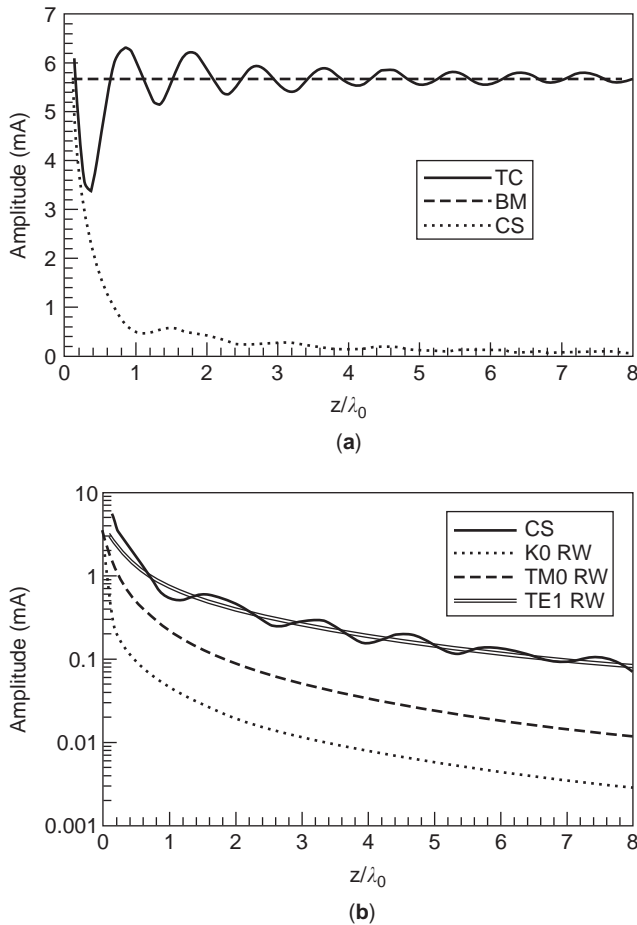

Figure 19. Strip currents for the high-permittivity case of Fig. 16 at 40 GHz: (a) the total current and its constituent parts, the bound-mode and continuous-spectrum currents; (b) the continuous-spectrum current and its constituent parts—a leaky mode current together with TM_0 residual-wave, TE_1 residual-wave, and k_0 residual-wave currents.

At 40 GHz, the oscillations become stronger, as seen in Fig. 19. As before, the CS current is responsible for the oscillations, as seen in Fig. 19a. However, the strong CS current is not due to the excitation of a leaky mode, as was the case for the moderate-permittivity substrate at 40 GHz (Fig. 15). For the higher-permittivity substrate at 40 GHz, the leaky mode shown in Fig. 16 is not physical, since its dispersion curve is lower than that of the TE_1 surface-wave dispersion curve (while this leaky mode has leakage only into the TM_0 surface-wave mode). Furthermore, no physical leaky mode that leaks into both the TM_0 and TE_1 surface-wave modes is found at this frequency. Figure 19b shows that the strong CS current is due to the TE_1 RW current. The TE_1 RW current is very strong because the dispersion curve for the leaky mode is only slightly below that for the TE_1 surface-wave mode. The leaky mode is therefore only slightly into the nonphysical region. Mathematically, this means that even though the LM pole is not captured by the path deformation to the steepest-descent paths from the branchpoints, the LM pole is close to the TE_1 branch point, and thus makes its influence felt in the TE_1 RW current.

3.2. Covered Microstrip

In practice, microstrip lines are often used in microwave circuits that are placed into packages of some type. It is therefore important to determine the influence of the top and sidewalls of a package on the possible leakage behavior of various transmission lines. The effects of a top cover, as shown in Fig. 1b, is investigated here. The addition of a top cover still allows the same method of analysis to be used as for the open microstrip structure, as discussed in Section 2. Because of the cover, leakage may only occur into the TM_0 parallel-plate substrate mode, and not into free space (it is assumed here that only the TM_0 substrate mode is above cutoff). Furthermore, there is only one type of residual current, the TM_0 RW current.

One of the most important conclusions, demonstrated from the results below, is that the presence of the top cover lowers the frequency at which leakage begins. This is because the top cover significantly raises the dispersion plot of the TM_0 mode, while influencing the dispersion plot of the guided mode to a lesser degree. Hence, physical leakage begins at a lower frequency with the top cover.

Furthermore, it is demonstrated that the top cover also increases the overall amplitude of the CS current. Hence, spurious effects significantly increase due to the presence of the top cover.

Figure 20 presents a dispersion plot for a moderate permittivity substrate ($\epsilon_r = 2.2$) and a strip-width:substrate-height ratio of $w/h = 1$, for uncovered microstrip. This result is the same as that shown in Fig. 10, except that the result is plotted in a normalized form, versus the electrical thickness of the substrate h/λ_0 . (Although the result in Fig. 10 is plotted against frequency using fixed dimensions in millimeters instead of plotting versus normalized electrical substrate thickness, the result is just as general, since it can be directly converted into a result for normalized substrate thickness, following the style of Ref. 37.) For the uncovered microstrip, the splitting point (the frequency at which leakage first begins as a nonphysical leaky mode) is at about $h/\lambda_0 = 0.09$, and the frequency at which the leaky mode enters the physical fast-wave region is at about $h/\lambda_0 = 0.11$. Clearly, physical leakage on

Figure 20. Dispersion plot showing the normalized phase constant versus normalized frequency for an open microstrip line ($w/h = 1.0$, $\epsilon_r = 2.2$).

Figure 21. Dispersion plot showing the normalized phase constant versus normalized frequency for a covered microstrip line ($w/h = 1.0$, $\epsilon_r = 2.2$). The cover heights are (a) $h_c/h = 2.0$, (b) $h_c/h = 1.0$, and (c) $h_c/h = 0.5$.

typical microstrip lines occurs only for high frequencies or thicker substrates.

Figures 21a–21c show the dispersion curves for cover heights of $h_c/h = 2.0$, 1.0, and 0.5, respectively, showing the changes in the dispersion plots as the top cover is brought successively nearer to the strip.

For a cover height $h_c/h = 1.0$, the frequency at which leakage begins is approximately $h/\lambda_0 = 0.02$. When the cover height is reduced still further to $h_c/h = 0.05$, leakage now occurs at all frequencies. These results clearly demonstrate that for smaller cover heights the potential exists for spurious effects such as crosstalk and power loss due to the leaky mode. An investigation into the current excited on the strip by a gap voltage source, presented next, will confirm this.

Figure 22 shows a plot of the current for the uncovered case of Fig. 20, at a moderate frequency ($h/\lambda_0 = 0.04$). At this frequency we may note from Fig. 20 that there is no leaky mode, so that the continuous spectrum consists only of the residual wave. From Fig. 22 it is seen that the CS current is very small, and that the total strip current is essentially the same as that of only the bound mode. The residual wave is therefore very small. At this moderate frequency the continuous spectrum is small enough that no serious spurious effects are observed. Of course, significant spurious effects will be observed at higher frequencies, as demonstrated in Section 3.1, but at this relatively low frequency the spurious effects are quite small.

Figure 23 shows a plot of the current for the same moderate-permittivity case as in Fig. 22, but for a cover height of $h_c/h = 1.0$. The normalized frequency is $h/\lambda_0 = 0.02$ (half of the value used in Fig. 22). Even though the frequency is half that used in the uncovered case, the spurious oscillations are clearly much more severe. From Fig. 21b it is seen that the leaky mode is not physical at this frequency, so the CS current consists entirely of the RW current. Hence, one conclusion is that the presence of a top cover increases the amplitude of the RW current.

Figure 22. Plots of the total current, BM current, and CS current on an uncovered microstrip line versus normalized distance from the delta gap voltage source at $h/\lambda_0 = 0.04$ ($w/h = 1.0$, $\epsilon_r = 2.2$).

Figure 23. Plots of the total current, BM current, and CS current on a covered microstrip line versus normalized distance from the delta gap voltage source at $h/\lambda_0 = 0.02$ ($h_c/h = 1.0$, $w/h = 1.0$, $\epsilon_r = 2.2$).

Figure 24a shows the current for the case of a smaller cover height, $h_c/h = 0.5$, at the same normalized frequency of $h/\lambda_0 = 0.02$. All other parameters remain the same as in Fig. 23. (See Fig. 21c for a dispersion plot.) This figure reveals two important aspects about the effects of reducing the cover height:

1. The level of oscillation in the total current has increased significantly, compared to that in Fig. 23, which corresponds to the same frequency. This is partly because lowering the cover height has decreased the amplitude of the bound mode, but even more importantly, it has dramatically increased the amplitude of the CS current. Part (b) of Fig. 24 shows that the leaky mode is now the main component of the CS current.
2. Comparing Figs. 24b and 23, it is also seen that the RW current is somewhat stronger for the lower cover height. (In Fig. 23 there is no physical leaky mode at this frequency, so the RW current is the same as the CS current.) However, the main reason why the CS current is significantly larger in Fig. 24 is the presence of the very strong leaky mode. Hence, lowering the top cover both increases the amplitude of the RW current and also results in the excitation of a strong LM current.

3.3. Stripline with an Airgap

The stripline structure is one of the most well known and widely used printed-circuit transmission-line structures. A homogeneous stripline structure will support only a TEM mode of propagation, and no leaky modes. This is because the substrate between the two ground planes is homogeneous. However, during manufacture, an airgap may be inadvertently introduced, resulting in the airgap

Figure 24. (a) Plot of the total current, BM current, and CS current on a covered microstrip line versus distance from the delta gap voltage source, for $\epsilon_r = 2.2$, $w/h = 1.0$, and a cover height of $h_c/h = 0.5$, with normalized frequency $h/\lambda_0 = 0.02$; (b) the CS current is shown along with its constituent parts: the LM current and the TM_0 RW current.

stripline structure shown in Fig. 1c. It has been known for some time that airgaps within stripline packages can degrade the performance of the stripline, although the fundamental reasons were perhaps not clear. It is shown here that the airgap lowers the phase constant of the dominant quasi-TEM stripline mode below that of the TM_0 parallel-plate mode of the (now inhomogeneous) background structure. This causes the stripline mode to become a physical leaky mode. This means that the stripline mode used for signal transmission will suffer from power loss due to leakage, as well as crosstalk and other effects due to leakage into the TM_0 mode.

When a small airgap is present, it is shown that there is a bound mode present, as well as the leaky mode. However, the bound mode is one that has the field characteristics of a parallel-plate type of mode. In fact, as the airgap thickness tends to zero, the bound mode evolves into a TEM parallel-plate mode. A conventional stripline feed

would predominantly excite the leaky mode, since this is the mode that resembles the TEM stripline mode that would exist with no airgap. However, a practical feed will also excite the bound-mode field to some extent, more so as the airgap thickness increases, since the fields of the leaky and bound modes tend to become less distinct as the airgap thickness increases. The fact that both a leaky mode and a bound mode are excited means that spurious oscillations will occur in the strip current, as was observed in the results presented for the previous two structures, microstrip and covered microstrip. This interference explains the experimental observation in Ref. 11, which was subsequently investigated more thoroughly in [20], where a very sharp and pronounced spurious dip in the transmission (S_{21}) response was observed at a specific frequency, using the airgap stripline. The spurious dip that was observed was attributed to interference between the bound mode and the leaky mode, and this is proved by an examination of the currents excited by a gap voltage source.

Figure 25. (a) The normalized phase constants of the bound mode, leaky mode, and TM₀ mode of the parallel-plate background structure, versus airgap thickness at 3.0 GHz; (b) the normalized attenuation constant of the leaky mode ($h = 1.0$ mm, $w = 1.0$ mm, $\epsilon_r = 2.2$).

The normalized phase and attenuation constants at 30 GHz are plotted with respect to the airgap thickness in Figs. 25a and 25b, respectively. It is seen from part (a) that the LM will be a physical mode (a fast-wave solution with respect to the TM₀ parallel-plate mode) for an airgap thickness less than 0.5 mm. The physical validity of the leaky mode is gradually lost as the airgap thickness increases beyond this value.

For an airgap thickness of $\delta = 0.3$ mm, plots of the total current as well as the BM and CS currents are shown in Fig. 26a. Figure 26b shows the CS current and its two constituent parts, the LM current and the RW current. For this airgap thickness, Fig. 26a shows that the CS current is much more strongly excited than the BM current. Moreover, the curves in Fig. 26b show that the CS current is almost entirely accounted for by the LM current. This is because the leaky mode is physical for this airgap thickness, and because the field of the leaky mode resembles that of the usual TEM stripline mode, and hence is excited quite strongly by the gap voltage source. The dip in the

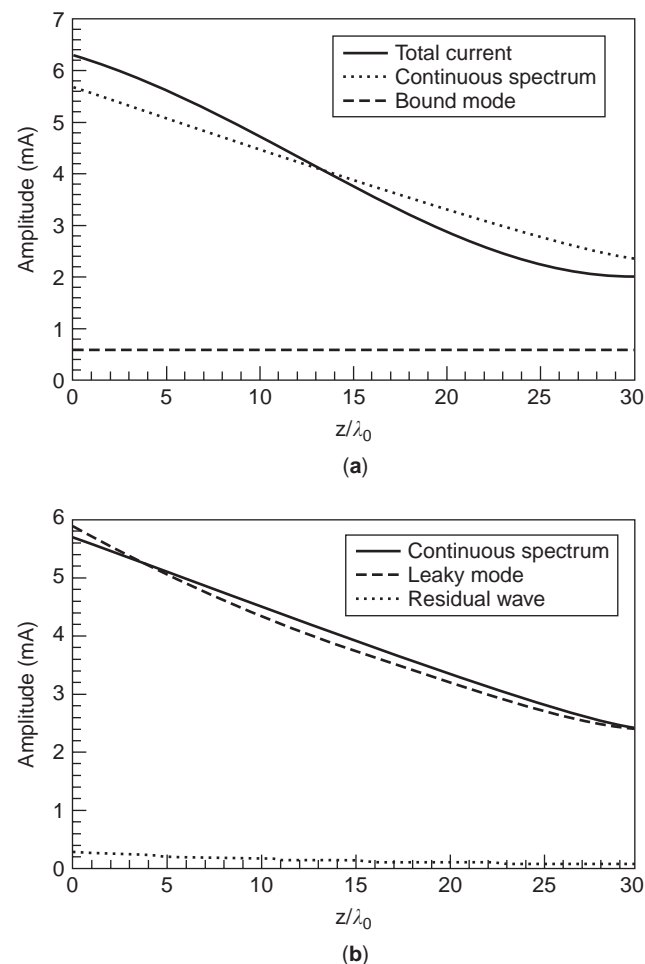

Figure 26. Plots of the total current, bound-mode current, and continuous-spectrum current versus distance from the delta gap source for the structure of Fig. 25 with an airgap thickness of 0.3 mm; (b) plots of the continuous-spectrum, leaky-mode, and residual-wave currents.

Figure 27. The same type of plot as in Fig. 26a but for an airgap thickness of 0.353 mm, which results in an almost a perfect destructive interference between the bound-mode and continuous-spectrum currents at $z \approx 32\lambda_0$.

amplitude of the total current at about 25 wavelengths from the source is due to the destructive interference between the BM and CS currents, which have an approximate 180° phase difference at this distance. Because the LM current dominates the CS current, it is concluded that the dip in the total current magnitude is due to a destructive interference between the bound and leaky modes that are excited by the source.

At the point of destructive interference, the amplitudes of the leaky and bound modes are not necessarily equal, and this explains why the dip in the total current does not extend completely to zero in Fig. 26a at $z = 25\lambda_0$. However, by correct selection of the airgap thickness, the amplitudes of the two modes can be made equal, resulting in an essentially complete destructive interference. A smaller airgap thickness will cause the amplitude of the leaky mode to dominate the amplitude of the bound mode at the point of destructive interference, while a larger airgap thickness will cause the amplitude of the bound mode to dominate. A critical airgap thickness thus exists that equalizes the two amplitudes at the interference point. This is demonstrated in Fig. 27 for airgap thickness of $\delta = 0.353$ mm. For this case there is an almost perfect cancellation of the total current on the strip at $z = 32\lambda_0$, pointing out how the simultaneous presence of the LM and the BM currents can significantly distort the expected transmission behavior of the line.

Figure 28. Top view of a pair of coupled microstrip lines. Line 1 is fed by a gap voltage source, causing a crosstalk current in line 2.

4. CROSSTALK BETWEEN TWO MICROSTRIP LINES

This section investigates the current excited on a pair of coupled microstrip lines when one of the lines (the source line, i.e., line 1) is excited by a gap voltage source (see Fig. 28) [38]. The *crosstalk current* is defined as the current induced on line 2 (the victim line, which is passive). At low frequency the current on the two lines is well predicted by standard transmission-line theory, which gives the following expressions for the current on each strip

$$I_1^{\text{TLT}}(z) = \frac{1}{4} \left(\frac{1}{Z_0^e} e^{-jk_z^e z} + \frac{1}{Z_0^o} e^{-jk_z^o z} \right) \quad (40)$$

$$I_2^{\text{TLT}}(z) = \frac{1}{4} \left(\frac{1}{Z_0^e} e^{-jk_z^e z} - \frac{1}{Z_0^o} e^{-jk_z^o z} \right) \quad (41)$$

where Z_0^e and Z_0^o are the frequency-dependent even-mode and odd-mode characteristic impedances and k_z^e and k_z^o are the corresponding wavenumbers. However, simple transmission-line theory fails to predict the effects of the continuous spectrum, and ignores all radiation effects. It will be seen that the CS current can be predominant at high frequency, and can thus be a source of undesirable spurious effects that can ruin the performance of microwave circuitry involving neighboring printed-circuit lines.

4.1. Formulation for the Currents

The same concepts presented in Section 2 apply to the present case, with some extension to account for the fact that currents now exist on two lines. One important feature of the present structure is that the currents do not show any symmetry about the center of either line, and thus a multiple-basis function expansion is necessary in practice to model these currents. Thus, the surface current can be expanded, similarly to (24) and (25), as

$$J_z^{(l)}(x, z) = \sum_{q=0}^{N_f} T_{l,q}^z(x) I_{l,q}^z(z) \quad (42)$$

$$J_x^{(l)}(x, z) = \sum_{p=1}^{N_f} T_{l,p}^x(x) I_{l,p}^x(z) \quad (43)$$

where the subscript $l = 1, 2$ is now added to denote the strip conductor (the integers q and p are no longer even and odd, respectively, as they were for the case of a single strip).

However, with the aim of keeping the explanation of the problem as simple as possible, only a single longitudinal basis function will be used on each line in the following explanation. This implies that the surface current on each line is expanded as $J_z^{(1)}(x, z) = T_1(x)I_1(z)$ and $J_z^{(2)}(x, z) = T_2(x)I_2(z)$ and thus the EFIE can be written as

$$E_z^{(1)}[T_1(x)I_1(z)] + E_z^{(1)}[T_2(x)I_2(z)] = E_z^{\text{gap}}(z) \quad (44)$$

$$E_z^{(2)}[T_1(x)I_1(z)] + E_z^{(2)}[T_2(x)I_2(z)] = 0 \quad (45)$$

The Galerkin testing procedure combined with the application of the inverse longitudinal Fourier transform leads to the following system of equations

$$\begin{aligned} \tilde{I}_1(k_z) \int_{w_1} T_1(x) E_z^{(1)} [T_1(x) e^{-jk_z z}] dx + \tilde{I}_2(k_z) \\ \int_{w_1} T_1(x) E_z^{(1)} [T_2(x) e^{-jk_z z}] dx = \tilde{E}_z^{\text{gap}}(k_z) e^{-jk_z z} \end{aligned} \quad (46)$$

$$\begin{aligned} \tilde{I}_1(k_z) \int_{w_2} T_2(x) E_z^{(2)} [T_1(x) e^{-jk_z z}] dx + \tilde{I}_2(k_z) \\ \int_{w_2} T_2(x) E_z^{(2)} [T_2(x) e^{-jk_z z}] dx = 0 \end{aligned} \quad (47)$$

which can be rewritten as

$$\begin{bmatrix} Z_{11}(k_z) & Z_{12}(k_z) \\ Z_{21}(k_z) & Z_{22}(k_z) \end{bmatrix} \begin{bmatrix} \tilde{I}_1(k_z) \\ \tilde{I}_2(k_z) \end{bmatrix} = \begin{bmatrix} \tilde{E}_z^{\text{gap}}(k_z) \\ 0 \end{bmatrix} \quad (48)$$

where the $Z_{ij}(k_z)$ coefficients ($i, j = 1, 2$) have the following form:

- *Space Domain:*

$$Z_{ij}(k_z) = \int_{w_i} \int_{w_j} T_i(x) \tilde{G}_{zz}(x - x'; k_z) T_j(x') dx' dx \quad (49)$$

- *Spectral Domain:*

$$Z_{ij}(k_z) = \frac{1}{2\pi} \int_{C_{kx}} \tilde{T}_i(-k_x) \tilde{G}_{zz}(k_x, k_z) \tilde{T}_j(k_x) e^{-jk_x s(1-\delta_{ij})} dk_x \quad (50)$$

The form given in (49) will be used when the DCIT is used with the corresponding MPIE in the space domain, and expression (50) is used when the EFIE is solved using the SDA approach.

Following the same rationale as in Section 2, the total current on the lines is given by $I_1(z) = I_{1,0}^z(z)$ and $I_2(z) = I_{2,0}^z(z)$, which are given in terms of their corresponding longitudinal Fourier transforms as

$$I_l(z) = \frac{1}{2\pi} \int_{C_{kz}} \tilde{I}_{l,0}^z(k_z) e^{-jk_z z} dk_z, \quad l = 1, 2 \quad (51)$$

4.2. Results

The theory presented above (using multiple basis functions) has been implemented in a computer code to study the crosstalk current in line 2, $I_2(z)$, for a pair of coupled microstrip lines when line 1 is excited by a 1-V gap voltage source.

Figure 29 shows the crosstalk current for two microstrip lines at various frequencies (low, medium, and high frequencies) and a wide separation between the lines

Figure 29. Crosstalk current $I_2(z)$ versus z/λ_0 for $\epsilon_r = 2.2$, $s/h = 10.0$, $w_1 = w_2 = h = 1.0$ mm. Both the total current and the transmission-line theory (TLT) currents are plotted for three different frequencies.

($s/h = 10$). The crosstalk current is plotted versus distance z from the origin (the source is at $z = 0$ on line 1). Both the total current (TC) numerically obtained from (51) and the transmission-line theory (TLT) current given by (41) are shown. The curves show that, at the low frequency of 1 GHz ($h/\lambda_0 \approx 0.003$), transmission-line theory predicts very accurately the crosstalk current. At 20 GHz ($h/\lambda_0 \approx 0.065$) there is overall agreement, but the exact crosstalk current shows a noticeable oscillation, which is due to the presence of the CS current. At 40 GHz ($h/\lambda_0 \approx 0.13$) the CS current has become strong enough that there is no agreement at all between the exact and the TLT currents.

It is interesting to note that at low frequency, for a large line separation, the crosstalk current exhibits an almost perfectly linear growth with distance z . This is explainable from Eq. (41), which may be rewritten as

$$\begin{aligned} I_2^{\text{TLT}}(z) = \frac{1}{4} \left(\frac{1}{Z_0^e} - \frac{1}{Z_0^o} \right) e^{-jk_z^a z} \\ + \frac{j}{2Z_0^o} e^{-jk_z^a z} \sin(\Delta k_z z / 2) \end{aligned} \quad (52)$$

where $k_z^a = (k_z^e + k_z^o)/2$ is the average of the two bound-mode wavenumbers and $\Delta k_z = k_z^e - k_z^o$ is their difference. As the line separation increases, the even- and odd-mode characteristic impedances and wavenumbers approach each other, making the first term in Eq. (52) negligible and the second term approximately linear.

To explore the nature of the spurious behavior of $I_2(z)$ at high frequency (40 GHz), Fig. 30 shows the decomposition of this current in terms of its constituent parts, the BM and the CS currents. The TLT current predicted by Eq. (52) is also shown for comparison. It is seen that the CS current is significantly stronger than the BM current, confirming that the CS current is responsible for the spurious effects. It is also interesting to note that the TLT current predicts fairly accurately the actual BM current

Figure 30. Total crosstalk current $I_2(z)$ and its constituent parts versus z/λ_0 for $\epsilon_r = 2.2$, $s/h = 10.0$, $w_1 = w_2 = h = 1.0$ mm at 40 GHz.

on the line. Thus, transmission-line theory predicts accurately the amplitude of the BM currents on the line, which in the exact theory comes from the residues at the two BM poles in the complex k_z plane. Transmission-line theory does not account for the CS current, however, so the TLT current is far from the actual current on the line.

It is also interesting to note from Fig. 29 that for low to moderate frequencies, the crosstalk current *decreases* as the frequency increases. This is because the even- and odd-mode wavenumbers become more nearly equal as the frequency increases. As seen from Eq. (52), this results in the crosstalk current $I_2(z)$ becoming smaller. However, when the frequency becomes very high, the crosstalk current increases with frequency, due to the increase of the CS current. This is illustrated by Fig. 31, which shows that at 80 GHz the crosstalk current has significantly increased from 40 GHz.

For large line separations, the CS current strongly dominates the crosstalk current at high frequencies. This is illustrated by Fig. 32, which shows that at 80 GHz, the total crosstalk current and the CS component

Figure 31. Comparison of the total crosstalk current $I_2(z)$ versus z/λ_0 for $\epsilon_r = 2.2$, $s/h = 10.0$, $w_1 = w_2 = h = 1.0$ mm at 40 and 80 GHz.

Figure 32. Total crosstalk current $I_2(z)$ and its constituent parts versus z/λ_0 for $\epsilon_r = 2.2$, $s/h = 10.0$, $w_1 = w_2 = h = 1.0$ mm at 80 GHz. The TC and CS curves are indistinguishable, while the BM curve is essentially zero.

of the crosstalk current are essentially indistinguishable. Physically, this is because for large line separation and high frequency, the crosstalk current is due mainly to radiation from the source line into the TM_0 parallel-plate mode, as opposed to quasistatic coupling. Radiation from the source line mainly induces a CS current on the victim line, instead of a bound mode, since the bound modes have wavenumbers that are larger than that of the TM_0 parallel-plate mode, and hence cannot couple to the TM_0 parallel-plate radiation.

The behavior of the high-frequency crosstalk current for various line separations is shown in Fig. 33. For a small line separation ($s/h = 2$), the crosstalk current is well accounted for by TLT model, but this good agreement worsens as the line separation increases. This fact can be added to the predominant quasistatic nature of the crosstalk coupling for small separation between the lines, which is accounted for by the TLT model. As the frequency

Figure 33. Total crosstalk and transmission-line theory (TLT) currents versus z/λ_0 for various line separations: $s/h = 2, 5, 10$; $\epsilon_r = 2.2$, $w_1 = w_2 = h = 1.0$ mm, frequency = 40 GHz.

increases, the TLT model loses accuracy as the CS current becomes stronger. It is clear by comparing Figs. 29 and 33 that as the line separation increases, the frequency at which the CS current becomes appreciable decreases. Hence, simple transmission-line theory loses accuracy at lower frequencies when the line separation is larger.

5. CROSSTALK FIELDS

In this section, the fields radiated by the currents on the strip conductor of a printed-circuit transmission line are examined, to see how crosstalk fields may be produced, especially at high frequency, due to the radiation from the currents that are induced on the strip conductor excited by a gap voltage source [39,40].

The structure that is examined is the covered microstrip structure of Fig. 1b. The currents on this structure that are produced by a gap voltage source have already been examined in some detail in Section 3.2, where it was shown that the total current consists of a bound-mode (BM) transmission-line mode together with a continuous-spectrum (CS) current. The CS current consists of a physical leaky-mode (LM) current, when such a mode exists, together with a TM₀ residual-wave (RW) current. Hence, there are a maximum of three different types of currents on the line, the BM, LM, and RW currents.

The BM current is normally regarded as a nonradiating type of current, since the fields are bound to the guiding structure. Indeed, for such a mode propagating on an infinite line, there would be no radiation and no power loss (assuming lossless conductors and dielectric). However, the 1-V gap voltage source at $z=0$ is a discontinuity, and radiation in general occurs from discontinuities. In particular, the current in Eq. (2) has a slope discontinuity (a discontinuity in the derivative) at $z=0$. Because of this discontinuity, the BM current will produce a radiation field, with radiation occurring into the TM₀ parallel-plate substrate mode. As shown in the results below, the level of this radiation increases with frequency.

The RW current increases with frequency, as demonstrated in Section 3.2. This current is a rather complicated function of distance z from the source, although asymptotically it propagates with a wavenumber of k_{TM_0} , as shown in Eq. (4). For this reason, the radiation from this current is somewhat endfire directed, concentrated more toward the direction of the strip axis, as will be shown in the results below. However, the radiation is somewhat diffuse, since the current is actually composed of a continuous spectrum of wavenumbers.

When a physical LM current exists on the line, the radiation from this current is typically directive, in the form of a beam, since the LM current has a single wavenumber β that is less than k_{TM_0} . The LM current may thus be responsible for significant crosstalk fields in the direction of this beam. This will be demonstrated in the results presented below.

5.1. Calculation of Crosstalk Fields

To calculate the crosstalk field, it is first assumed that only radiation into the TM₀ parallel-plate mode is significant.

All of the other higher-order parallel-plate modes are assumed to be sufficiently far below cutoff that these fields decay very rapidly away from the strip current, and hence are negligible at any significant distance away from the strip (in practice, more than a half-wavelength or so). Hence, the crosstalk field is assumed to be the field of the TM₀ parallel-plate mode that is produced by the current on the strip conductor. To calculate this field, the field of a unit amplitude infinitesimal electric dipole in the z direction on top of the substrate at $x=0, z=0, y=h$ is considered. The TM₀ field from the dipole has the following form in cylindrical (ρ, ϕ, y) coordinates:

$$E_y(\rho, \phi, y) = Af(y)H_1^{(2)}(k_{TM_0}\rho) \cos \phi \tag{53}$$

where, for $0 < y < h$, we obtain

$$f(y) = \cos(k_{y1}y) \tag{54}$$

with

$$k_{y1} = (k_1^2 - k_{TM_0}^2)^{1/2} \tag{55}$$

where k_1 is the wavenumber in the substrate. The constant A can be determined by spectral-domain techniques, but the value is not important here.

The field from the strip current is found by integrating over the strip current, using the above mentioned dipole field as a Green's function. Assuming the line width to be small relative to a wavelength, the integral has the following form

$$E_y(x, y, z) = Af(y) \int_{-\infty}^{\infty} I(z')H_1^{(2)}(k_{TM_0}\rho') \cos \phi' dz' \tag{56}$$

where

$$\rho' = \sqrt{x^2 + (z - z')^2} \tag{57}$$

$$\tan(\phi') = \frac{x}{z - z'} \tag{58}$$

Integrating across the substrate height, the voltage drop between the strip and the ground plane at any point is

$$V_h(x, z) = -Ah \operatorname{sinc}(k_{y1}h) \int_{-\infty}^{\infty} I(z')H_1^{(2)}(k_{TM_0}\rho') \cos \phi' dz' \tag{59}$$

The integral can be accelerated by using a technique such as the Shanks transform [41].

5.2. Results

All the cases presented in this section are for a covered microstrip with $\epsilon_r = 2.2$ and $w = h$, with a cover height $h_c = h$. The dispersion plot for this structure is shown in

Figure 34. Dispersion plot showing the normalized phase constants (β/k_0) versus normalized frequency (h/λ_0) for a covered microstrip ($h_c = h$, $w = h$, $\epsilon_r = 2.2$)

Fig. 34. This figure shows three distinct regions of behavior. In the first region, $h/\lambda_0 < 0.021$, there is no leaky mode; only a pair of nonphysical improper real modes exist, in addition to the bound mode. In the region $0.021 < h/\lambda_0 < 0.052$, a leaky mode exists, but it is nonphysical (since the wavenumber of the leaky mode is larger than that of the TM_0 parallel-plate mode). In the region $h/\lambda_0 > 0.052$ the leaky mode is physical. Results will be shown for each region to illustrate how the field surrounding the strip behaves.

The first case is that for $h/\lambda_0 = 0.005$. For this low-frequency case, the operating point is well inside the nonphysical spectral-gap region in the dispersion plot of Fig. 34. As a result of the low frequency, the continuous-spectrum current is very small, as shown in Fig. 35. The

Figure 35. Strip current for a covered microstrip at a normalized frequency of $h/\lambda_0 = 0.005$ ($h_c = h$, $w = h$, $\epsilon_r = 2.2$).

Figure 36. Normalized substrate voltage for the covered microstrip of Fig. 35. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

oscillations in the total current due to the interference between the BM and CS currents are apparent, although they are small in amplitude, since the CS current is quite small compared with the BM current. Figure 36 shows a plot of the field surrounding the strip for this case. The field is fairly diffuse away from the strip, with noticeable oscillations close to the strip as the observation distance z increases. This oscillation is due to an interference between two components that make up the overall field produced by the BM current. One component is the field due to a bound mode propagating on an infinite line. This field propagates in the z direction with the wavenumber of the bound mode, and decays exponentially away from the line. The second component is a radiation type of field that propagates radially with a wavenumber k_{TM_0} and decays as $1/\sqrt{\rho}$, and arises because of the slope discontinuity of the BM current at the origin.

Figure 37 shows the current components at a higher frequency of $h/\lambda_0 = 0.04$. At this frequency the leaky mode exists, but is nonphysical. Figure 37 shows that at this higher frequency the CS current has become significant, because of the strong RW current that now exists. Figure 38 shows that the field surrounding the strip has begun to become more directive in shape, although the field is still somewhat diffuse.

Figure 39 shows the current components at a still higher frequency of $h/\lambda_0 = 0.08$. At this frequency the leaky mode exists and is physical. Because of the physical LM current, the CS current is now quite strong. Figure 40

Figure 37. Strip current for a covered microstrip at a normalized frequency of $h/\lambda_0 = 0.04$ ($h_c = h, w = h, \epsilon_r = 2.2$).

shows that the field surrounding the strip has begun to assume a beamlike shape, due to the radiation of the LM current. The overall level of the field is also higher. Clearly, significant crosstalk could occur with circuit components that are placed within the beamlike region of strong leakage fields. The angle of leakage of the leaky mode,

Figure 39. Strip current for a covered microstrip at a normalized frequency of $h/\lambda_0 = 0.08$ ($h_c = h, w = h, \epsilon_r = 2.2$).

measured from the strip axis, is given approximately (for small attenuation constants) as

$$\phi_0 = \cos^{-1}\left(\frac{\beta}{k_{TM_0}}\right) \tag{60}$$

Figure 38. Normalized substrate voltage for the covered microstrip of Fig. 37. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 40. Normalized substrate voltage for the covered microstrip of Fig. 39. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

where β is the phase constant of the leaky mode. This equation actually predicts the leakage angle for a leaky mode existing by itself on an infinite line, with a small attenuation constant. The predicted leakage angle from this equation is $\sim 13.5^\circ$, whereas the actual beam angle in Fig. 40 is $\sim 18^\circ$. The discrepancy is caused by several factors: (1) the attenuation constant of the leaky mode is not zero, as is assumed in Eq. (60); and (2) the total field consists of the BM and RW fields in addition to the LM field. Finally, the direction of maximum radiation for the field radiated by the LM current of Eq. (3) is not the same as the direction of leakage for a leaky mode on an infinite line, since the field radiated by the LM current of Eq. (3) consists of a source discontinuity radiation term due to the slope discontinuity of the current at the origin.

6. CONCLUSIONS

This article has examined the nature of the current and fields excited by gap voltage source on an infinite printed-circuit transmission line, in order to ascertain the nature of the current and to show what types of spurious effects may be produced at high frequency. Three particular structures have been examined: microstrip, covered microstrip, and stripline with an airgap above the strip conductor.

A semianalytical method for determining the strip current has been used, based on a Fourier transform of the current in the longitudinal (z) direction. The strip current is thus expressed as an inverse Fourier transform integral in the complex longitudinal wavenumber (k_z) plane. This method provides an accurate calculation of the strip current, as well as physical insight into the nature of the current on the strip. In particular, deforming the original path of integration in the k_z plane allows for a convenient decomposition of the total strip current into a sum of constituent parts.

It was shown that the total current consists of a bound-mode (BM) current together with a continuous-spectrum (CS) current. The BM current corresponds to the usual transmission-line mode, whose fields are bound to the strip region, decaying away from the strip in the transverse (x) direction. The amplitude of the BM current is accurately calculated at any frequency by taking the residue in the k_z plane at the BM pole. The amplitude of the BM current obtained this way is accurate even for high frequencies, where the definition of the characteristic impedance becomes ambiguous. The CS current is, generally speaking, a high-frequency radiation type of current whose existence cannot be predicted by simple transmission-line theory.

The CS current consists of two types of current. The first is a set of any physical leaky-mode currents. A "physical" leaky mode is defined here as one that satisfies a "path consistency condition," meaning that the nature of the leakage (as determined by the path of integration in the transverse wavenumber (k_x) plane used to calculate the wavenumber of the leaky mode) is consistent with the phase constant of the leaky mode. For open structures such as microstrip, there are two types of leaky modes that

may in principle be physical. One type has leakage into only the TM_0 surface-wave mode of the grounded substrate (assuming here that only the TM_0 mode is above cutoff). This type of leaky mode is physical when the phase constant of the leaky mode is less than the wavenumber of the TM_0 surface-wave mode, and greater than the wavenumber of free space. The second type of leaky mode, which can exist on open (uncovered) structures, has leakage into both the TM_0 surface-wave mode and also into space. This type of leaky mode is physical when the phase constant of the leaky mode is less than the wavenumber k_0 of free space. For the cases presented here, only the first type of physical leaky mode has been found to exist for the parameters used in the results. For closed structures (meaning that a ground plane exists both above and below the structure) such as covered microstrip, only the first type of leaky mode can exist.

The second type of current that makes up the CS current is the "residual-wave" (RW) current. This current physically represents the current that is left over when the physical leaky-mode currents are removed from the CS current. For open structures such as microstrip, the RW current consists of a sum of two different RW currents: a TM_0 RW current and a k_0 RW current. Mathematically, these currents arise from the corresponding branchpoints in the complex k_z plane, at the locations of the TM_0 surface-wave wavenumber and the k_0 wavenumber, respectively. Although there is no closed-form expression available for these currents, an asymptotic analysis reveals how they behave for large distances z from the source. The TM_0 RW current propagates with the wavenumber of the TM_0 surface-wave mode, and decays with distance along the strip as $z^{-3/2}$. The k_0 RW current propagates with the wavenumber k_0 of free space, and decays with distance along the strip as z^{-2} . For a closed structure such as covered microstrip, only the TM_0 RW current exists.

Hence, for an open structure such as microstrip, the strip current produced by the gap voltage source consists of a sum of five possible current waves:

1. The bound-mode (transmission-line mode) current
2. A physical leaky mode (if any) that leaks into the TM_0 substrate mode
3. A physical leaky mode (if any) that leaks into both the TM_0 substrate mode and into space
4. A TM_0 residual-wave current, which asymptotically propagates with the wavenumber of the TM_0 mode and decays as $z^{-3/2}$
5. A k_0 residual-wave current, which asymptotically propagates with the wavenumber of free space and decays as z^{-2}

For a closed structure such as covered microstrip, only currents 1, 2, and 4 exist.

For microstrip, only the desired BM current exists at low frequency. However, as the frequency increases, the CS current becomes increasingly important. For moderate frequencies, the CS increases in amplitude as the frequency increases because the RW current increases in

amplitude with frequency. For high frequencies a leaky mode (having leakage into the TM_0 surface-wave mode) becomes physical, and the CS current becomes very significant above this frequency. This frequency occurs roughly when the substrate is a tenth of a wavelength thick electrically in the dielectric. As the frequency increases, a significant oscillation is observed in a plot of the strip current versus the distance z from the source. This oscillation is due to an interference between the desired BM current and the CS current.

For covered microstrip, the oscillations in the strip current also increase with frequency, since the CS current increases with frequency. However, the effect of the top cover also significantly increases the magnitude of the spurious oscillation. This is due to two effects: (1) as the top cover is lowered toward the microstrip line, the amplitude of the RW current increases; and (2) even more importantly, as the top cover is lowered, the frequency at which a physical leaky mode exists is lowered. In fact, for a sufficiently small cover height, a physical leaky mode exists at all frequencies. Therefore, even at low frequencies, a significant oscillation in the strip current may be observed when the cover height is sufficiently small, due to the leaky mode. For a certain value of the cover height, a complete destructive interference will occur between the leaky mode and the bound mode at some distance from the source; that is, the two currents will have an equal amplitude and a 180° phase difference at some distance z from the source. At this point on the line the total current will essentially have a complete null.

Homogeneous stripline supports only the desired TEM mode of propagation. However, during manufacture, an airgap may be inadvertently introduced above the strip conductor. It has been known for many years that such an airgap may lead to poor performance, although the reasons were, perhaps, not completely clear. It was shown here that the presence of the airgap causes the TEM stripline mode to become a leaky mode. For a small airgap the leaky mode still resembles the usual TEM stripline mode, but the mode now has a complex wavenumber due to leakage loss (leakage into the TM_0 parallel-plate mode of the background airgap structure). This results in power loss as the mode propagates, which is in addition to any attenuation due to conductor or dielectric loss. In addition to the quasi-TEM leaky mode, there is also a bound mode that exists on the structure with a small airgap, but the bound mode has a field configuration that resembles that of a parallel-plate mode, and is thus only weakly excited by the gap source (or by a conventional stripline connector, in practice). The bound mode does not attenuate with distance from the source, however, and thus a significant interference may occur between the quasi-TEM leaky mode and the bound mode at some distance from the source. This results in a spurious dip in the observed transmission response (S_{12}) of the transmission line at a particular distance from the source (or at a particular frequency, if the distance is fixed).

The analysis and results were extended to the case of two coupled microstrip lines, where a gap voltage source was placed on one line (the source line) and the current that was produced on the second line (the victim line) was

examined. It was concluded that at low frequency, an even/odd-mode transmission-line analysis is sufficient to determine the crosstalk current on the victim line. Interestingly, for larger line separation, and low frequency, the crosstalk current displays an almost linear behavior, growing linearly with distance z on the line away from the origin (where the gap source is placed on the source line). This is explainable from simple transmission-line theory. At higher frequency, the CS current becomes important, and simple transmission-line theory is no longer adequate to predict the crosstalk current. For large line separation and higher frequencies, the main component of the crosstalk current is in fact the CS current.

Finally, the field surrounding a printed-circuit transmission line that is excited by a gap voltage source was examined, and results were shown for the case of a covered microstrip line (with a moderate cover height). The nature of this field is important for understanding the crosstalk that may occur with other circuit components placed in the package near the printed-circuit transmission line. At low frequency, it is mainly the bound mode that is excited on the line. However, because of the discontinuity in the derivative of the current (slope discontinuity) at the source location, there is radiation from the BM current. The total field from the BM current, when plotted along the z direction parallel to the strip, is an oscillatory one. This is because the field from the BM current physically consists of two parts: (1) the field of the bound mode itself, which decays exponentially away from the strip, and (2) the radiation from the slope discontinuity in the BM current at the origin.

As the frequency increases, the RW current becomes appreciable, and the crosstalk fields become stronger and extend out to distances farther from the line. The crosstalk field is fairly diffuse, however. As the frequency increases past the point where a leaky mode becomes physical, the crosstalk field begins to assume a beamlike shape, due to radiation from the leaky-mode current, which is directed at a particular leakage angle. At these higher frequencies, crosstalk may be especially severe for circuit components that are in the direction of the leakage radiation.

1. FUNDAMENTAL CONCEPTS

1.1. Definition

According to the IEEE Standard 145-1993, a *leaky-wave antenna* (LWA) is "an antenna that couples power in small increments per unit length either continuously or discretely, from a traveling wave structure to free space."

The basic behavior of LWAs can efficiently be described by means of a particular type of wave, that is the *leaky wave*, which can propagate in open waveguiding structures and describes a gradual loss of power towards the external environment (*leakage*).

1.2. Basic Radiation Features

LWAs belong to the class of traveling-wave antennas for which the illumination is produced by a wave that propagates along a guiding structure [1–3]. If compared with the wavelength, a single LWA typically is *long* in the propagation direction (z), while its cross section usually is of the order of the wavelength (see, as reference, the first two examples in Fig. 1). Therefore, a LWA radiates along its length and is generally excited from one input of an open

Figure 1. Basic structures of leaky-wave antennas (LWAs): (a) uniform LWAs—geometry derivable by a partially open metallic rectangular waveguide; (b) periodic LWAs—geometry derivable by a strip-loaded dielectric-rod waveguide; (c) LWA arrays—a printed topology based on microstrip.

guiding structure by a traveling wave, which propagates mainly in a longitudinal direction (e.g., $+z$) and is attenuated due to the power leakage toward the external (air) region, thus leaving a negligible field at the termination of the line. In a harmonic regime [assuming an $\exp(j\omega t)$ time dependence], the longitudinal behavior of such a wave can be characterized by a complex propagation constant of the type $k_z = \beta_z - j\alpha_z$ [3–5], where β_z is the *phase constant* and α_z is the *attenuation constant* of the *leaky wave* (when only power loss due to radiation is taken into account, α_z is also termed *leakage constant*). As discussed later, the knowledge of the complex propagation constant of this leaky wave allows for a straightforward description of the main radiation features of LWAs.

Usually the radiation pattern of a single LWA excited at one end has a typical *fan* shape; in the *elevation* (or *zenith*) plane it presents a *narrow beam* scannable by varying the *frequency*, while in the *cross* (or *azimuth*) plane usually it presents a wider beam due to a smaller transverse aperture. Multidirectional excitation is also possible, as can occur in planar dielectric structures excited by local sources (dipoles or slots) able to produce conical beams.

In general, *beamshaping* is achievable by means of suitable longitudinal variations of the structure (and of the consequent equivalent aperture distribution); the proper modulation of geometric parameters (*tapering*) allows for flexible control of the *radiation pattern*. In some cases, in order to obtain a particular beam shaping or a physical matching with mounting curved surfaces, LWAs can be designed with certain amounts of *curvature* along their lengths [6]. *Broadbeam* LWAs have also been proposed using *straight* lengths with suitable longitudinal modulation of both phase and leakage constants [7].

For ordinary LWAs the *frequency-dependent scanning* properties in the elevation plane are related to the kind of the waveguiding structure employed, which can be classified as either of *uniform* (Fig. 1a) or of *periodic* type (Fig. 1b) [1,2]. In LWAs derived by waveguides that are longitudinally *uniform*, the structure maintains a fixed transverse geometry (with possible continuous smooth modulation of the shape in the z direction); this type of radiators typically allows for angular scanning in one quadrant, from around broadside toward one endfire (i.e., the "forward" one, concordant with the wave propagation direction). In LWAs derived by waveguides that are longitudinally *periodic*, the structure along z is periodically loaded with suitable modifications or discontinuities, at intervals that are usually short with respect to the wavelength; this type of radiator allows for a wider angular scanning, in both the forward and backward quadrants. However, for different reasons, limitations in such scanning ranges generally exist for both the types of structures. A scan range in both quadrants may also be accomplished by properly using nonreciprocal anisotropic media.

When a *pencil beam* is desired with possible *two-dimensional* (2D) scanning, both in elevation and cross planes, a *linear phased array* of juxtaposed LWAs may be employed, capable to furnish a wider equivalent aperture also in the transverse direction [8,9] (see Fig. 1c). LWA arrays are in general constituted by a linear configuration

of sources (i.e., one-dimensional elements), instead of planar ones of standard arrays (i.e., two-dimensional elements). For such LWA arrays the pointed-beam scanning is achievable by varying both the *frequency* for the *elevation* plane and the usual *phase shift* between elements for the *cross* plane.

1.3. Applications

Since LWAs are derived by partially open waveguides, they present a number of distinctive features as radiators, including (1) capability of designing a wide variety of aperture distributions and consequent flexibility for beam shaping through tapering; (2) possible use as wideband radiators that allow for large angular scanning by varying frequency instead of using mechanical or electronic means; (3) achievement of very narrow beams, often with good polarization purity; (4) simplicity of feeding and economy for 2D scannable pencil-beam arrays, due to the reduced number of phase shifters; (5) handling of high-power amounts at microwaves, particularly for structures derived by metallic waveguides; (6) easy integration of planar LWAs with microwave integrated circuit (MIC) technology; (7) reduction of some bulk problems, due to usual small profiles in the cross sections; and good physical matching with unconventional mounting geometries.

LWAs are used mainly for microwaves and millimeter waves. The fundamental studies were presented during the 1940s and 1950s, basically for aerospace control applications; since then, a wide number of different solutions for LWAs have been proposed in connection with changing requirements and constraints. Also the applicability of this type of antennas has been widened, involving various aspects of monitoring, remote sensing, wireless local area network (WLAN) communications, and so forth.

2. OPERATION PRINCIPLES

2.1. Leaky Waves in Open Structures

It is known that, in order to describe radiation of a source from an open waveguiding structure, the evaluation of the field through a *spectral representation* (i.e., including a sum of a finite number of guided modes and an integral contribution of the *continuous spectrum*) can be very difficult and cumbersome to quantify in many practical circumstances. In well-designed LWAs the radiation field can be evaluated accurately in much a simpler fashion by considering the contribution due to the presence of just one mode of *complex* type, that is a *leaky wave* of the open guide.

In general, the *characteristic dispersion equation* for a waveguide (whose solution furnishes the propagation constants k_z of the *modes* as a function of *geometry* and *frequency*) presents discrete eigenvalues, which in open waveguides can also assume complex values, thus giving rise to solutions of the type $k_z = \beta_z - j\alpha_z$. It is seen that these complex solutions are in general *nonspectral*, that is the relevant modal fields violate the radiation condition (they attenuate along the propagation direction but exponentially increase in a transverse direction away from the

structure). Actually, when properly excited by a source at a finite section, such a complex wave assumes its physical validity within an angular sector close to the equivalent aperture of the open guiding structure, and the relevant field distribution is able to furnish a fundamental contribution to the evaluation of the near field. Since the far field is achieved by a simple Fourier transform of the field on the aperture, a *leaky wave* can definitively furnish a highly convergent and efficient quantification of the *radiation of the open structure*, as an advantageous alternative to a continuous spectrum evaluation.

When a leaky wave exists and can also be efficiently excited by a source in a structure based on an open waveguide, it therefore can describe simply but accurately the radiation phenomena of the structure, which is therefore termed a *leaky-wave antenna*.

2.2. Phase and Leakage Constants

Evaluation of the *complex eigensolutions* for open waveguides depends on the physical parameters involved (frequency and geometry) and is generally achievable with *numerical methods*. Among them, the transverse resonance technique [10] is one of the most used approaches for either rigorous or approximate evaluations, according to the antenna topology. When separation of variables does not strictly hold, other numerical methods can anyway be employed to accurately determine the complex eigensolutions of the involved open waveguides. The most appropriate choice depends on several factors related to the computational features of the methods, the geometry of the open-type structures, and other variables. Among the various possibilities, integral equation techniques (such as boundary element method, or spectral-domain approaches for planar structures) are well suited to calculate complex eigensolutions also for involved topologies.

A typical behavior of the real and imaginary parts of the longitudinal wavenumber k_z of a leaky wave supported by an open guide is illustrated in Fig. 2, specifically with respect to the dispersion curves of the normalized parameters β_z/k_0 (Fig. 2a) and α_z/k_0 (Fig. 2b) versus frequency f (where k_0 is the free-space wavenumber). Radiation of LW structures can occur approximately inside the frequency range where the wave becomes fast ($\beta_z/k_0 < 1$), and power can therefore leak out from the guiding structure toward the outside air region in the typical form of an inhomogeneous plane wave [4,5]. The valid frequency range for effective LWA applications is actually where, as the frequency decreases, β_z/k_0 diminishes monotonically from unity toward rather low values; in this region, to have an efficient directive beam, α_z/k_0 should assume rather limited values (e.g., typically α_z/k_0 varies from about 10^{-1} to 10^{-3} , as will be discussed further). As the frequency decreases further, a sudden rise of α_z/k_0 can generally be found, which describes the predominance of reactive phenomena instead of radiative ones, while β_z/k_0 can present a flat zone with approximately constant low values before showing a further steep rise as frequency goes to zero: in these ranges, radiative effects can no longer be represented by the leaky wave and the structures usually cannot work well as antennas.

Figure 2. Typical dispersion behavior of the leaky-mode complex wavenumber: (a) normalized phase β_z/k_0 and (b) leakage α_z/k_0 constants versus frequency f for an open waveguide (microstrip operating the EH_1 mode).

It is worth remembering that in planar structures that are also transversely open, a different type of leakage can occur, too, associated with the propagation of complex waves that carry away power from a source in the *lateral* region inside the substrate (*surface waves*), instead of toward the upper-air region (*space waves*); the waves in the substrate do not give useful contributions to a LWA far-field radiation but describe power that leaks out in the stratified structures and accounts for typical *interference* and crosstalk effects in planar circuits [8,11].

2.3. Behavior of a Leaky-Wave Antenna

As stated above, LWAs are described by an inhomogeneous fast wave, which propagates on an equivalent aperture losing power towards free-space with a leakage amount that is usually rather limited for a sufficiently directive beam. The simplest LWA geometry for this purpose is

derivable by a closed metallic waveguide in which a suitable “small” aperture is introduced longitudinally in order to calculate a continuous power loss along its length, as shown in Fig. 3a for a rectangular guide with a slit cut on a sidewall. This structure, besides having a historical importance as the first proposed LWA in 1940 [1–3], can be taken as a reference structure for explaining the basic behavior of LWAs in terms of a waveguide description.

In fact, in this structure a leaky wave can be considered as excited by a standard incident mode for the closed rectangular waveguide, that is, the dominant TE_{10} , which travels in the $+z$ direction with a known phase constant β_{0z} for a fixed choice of the physical parameters (geometry and frequency). For a sufficiently small geometric perturbation due to the slit, the phase constant is changed just “slightly” to a value represented by β_z , and a “low” leakage rate α_z also originates; as mentioned, this accounts for the longitudinal attenuation due to the wave that is no longer confined and flows also in the outside region. The propagating field inside the waveguide and in the proximity of its aperture is therefore described by the complex longitudinal wavenumber $k_z = \beta_z - j\alpha_z$, whose specific quantification depends on the physical parameters of the structure.

In this case the leakage phenomenon is assumed along $+z$ ($\beta_z > 0$ and $\alpha_z > 0$), and by supposing that the vertical field variations are almost negligible ($k_y \cong 0$), it is easily seen that, from the general separation condition for waveguides ($k_0^2 = \omega^2 \mu_0 \epsilon_0 = k_t^2 + k_z^2 \cong k_x^2 + k_z^2$), the horizontal wavenumber is also complex

$$k_x = \beta_x - j\alpha_x, \quad (1)$$

with $\beta_x > 0$ and $\alpha_x < 0$, since $\beta_x \alpha_x = -\beta_z \alpha_z$ results. Therefore a plane wave of inhomogeneous type exists, having a complex propagation vector \mathbf{k} of the type

$$\begin{aligned} \mathbf{k} &= \boldsymbol{\beta} - j\boldsymbol{\alpha} \\ \boldsymbol{\beta} &= \beta_x \mathbf{x}_0 + \beta_z \mathbf{z}_0 \\ \boldsymbol{\alpha} &= \alpha_x \mathbf{x}_0 + \alpha_z \mathbf{z}_0 \end{aligned} \quad (2)$$

with the phase vector $\boldsymbol{\beta}$ directed at an angle that describes the outgoing of power from the guide to the external, and the attenuation (leakage) vector $\boldsymbol{\alpha}$ that is perpendicular to $\boldsymbol{\beta}$, and represents attenuation along z and amplification along x . Consequently, the field has a spatial dependence of the type

$$\exp[-j(\beta_x x + \beta_z z)] \exp[|\alpha_x| x - \alpha_z z] \quad (3)$$

Therefore, this plane wave travels at an angle $\theta = \sin^{-1}(\beta_z/|\boldsymbol{\beta}|)$ with respect to broadside carrying out power, and its amplitude is transversely increasing as expected in a leaky wave. It should be noted that the pointing direction angle θ of the leaky wave is usually expressed under the approximate form $\theta \cong \sin^{-1}(\beta_z/k_0)$, since in general the leakage constant is numerically negligible with respect to the phase constant. The nature of the propagation vector is sketched in Fig. 3b, while the

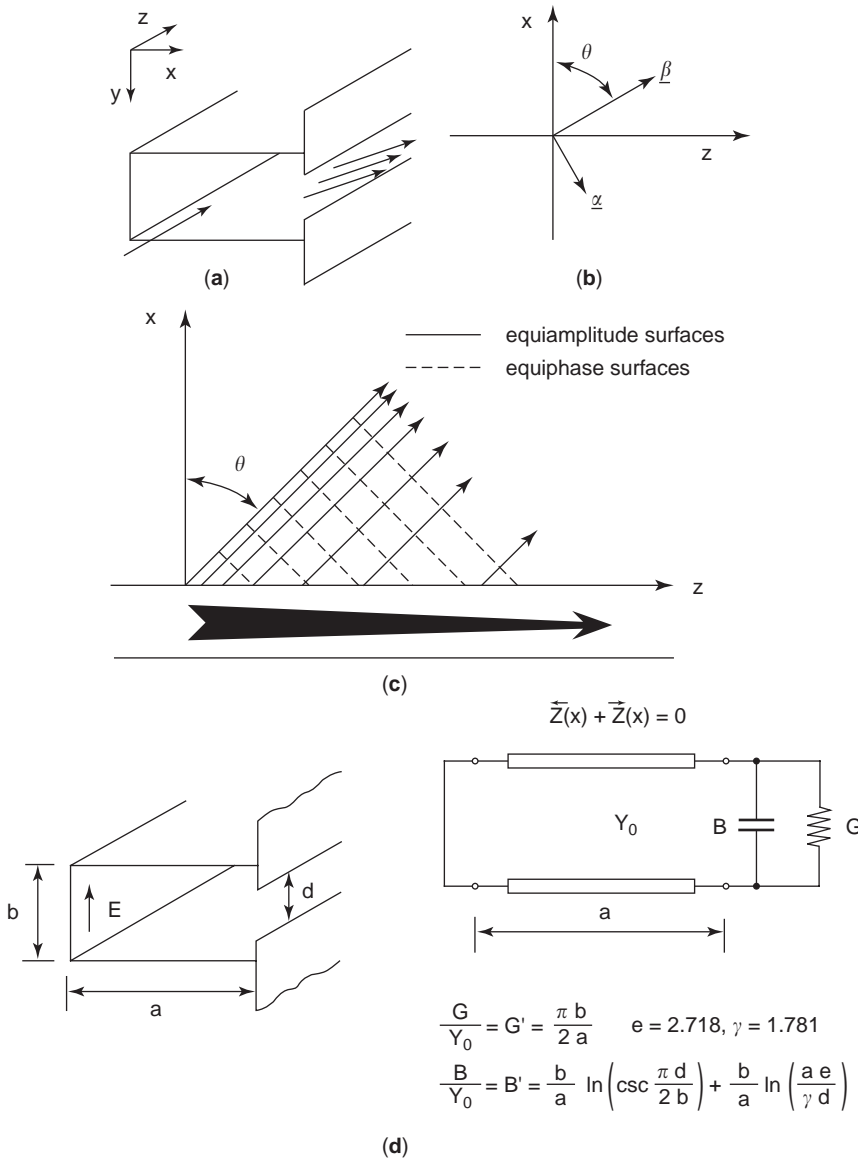

Figure 3. LWA derived by a sidewall slit rectangular waveguide; (a) geometry of the structure; (b) nature of the propagation vector of the inhomogeneous plane leaky wave (phase and attenuation vectors); (c) equiphas and equiamplitude planes of the leaky wave with the relevant leakage phenomenon along the guide; (d) equivalent transverse-resonance network, resonance conditions, and network parameters for evaluation of leaky-wave complex wavenumbers as a function of the physical parameters involved.

distribution of equiphas and equiamplitude surfaces with the decreasing power flow along the guide is represented in Fig. 3c. It should be recalled that, even though the leaky wave has a nonspectral nature, the field generated from a source located at a finite distance along z still satisfies the radiation condition, since the field increases transversely only in a limited sector given by angles greater than the θ value describing the direction of power leakage [4,5].

A quantitative description of the behavior of this LWA can be achieved with a simple evaluation of the complex eigenvalue derivable as a modification of the dominant mode by employing, for example, a transverse resonance technique. To this aim, it is required a characterization of the slit aperture in the sidewall as a circuit element in the equivalent transmission line. For the quantification of such discontinuities, a great deal of work has been deve-

loped, basically through variational methods [8,10]. The solution of the relevant resonance equation in the complex plane for the perturbed dominant mode describes the leaky-wave behavior; for example, in Fig. 3d the equivalent network for the LWA considered here is shown, through which k_z is determined as a function of the physical parameters of the antenna.

3. DESIGN PROCEDURES

3.1. Basic Radiative Features

For a basic LWA constituted by a single nontapered open guiding structure, the fundamental parameters given by pointing direction and beamwidth are simply determined as a function of k_z and other few basic quantities. In

$$\vec{Z}(x) + \vec{Z}(x) = 0$$

$$\frac{G}{Y_0} = G' = \frac{\pi b}{2 a} \quad e = 2.718, \gamma = 1.781$$

$$\frac{B}{Y_0} = B' = \frac{b}{a} \ln \left(\csc \frac{\pi d}{2 b} \right) + \frac{b}{a} \ln \left(\frac{a e}{\gamma d} \right)$$

(d)

particular, as seen before, the beam maximum *direction* θ_m is mainly related to the normalized phase constant according to the simple relationship:

$$\sin \theta_m \cong \beta_z/k_0 \tag{4}$$

Since β_z has a dispersive behavior, as is typical of waveguiding structures, a change in the frequency yields a beam scanning. Typically, as the frequency is increased from the cutoff, the pointing angle varies its direction from around the broadside ($\theta_m = 0^\circ$), toward the forward endfire ($\theta_m = 90^\circ$).

Regarding the *beamwidth*, we recall that the leakage constant α_z quantifies the rate of power loss along the line due to the radiation, thus influencing primarily the effective dimension of the equivalent aperture for the line source; in fact, the more α_z increases, the more the actual illumination length reduces (and the less the beamwidth is focused). A basic link between the leakage constant and the antenna length L derives from the specification of the radiation efficiency η , expressible in LWAs as $\eta = [P(0) - P(L)]/P(0)$, where $P(0)$ is the input power delivered to the structure and $P(L)$ is the output power left at the end section. The link between leakage rate and length is generally dependent on the desired radiation pattern and therefore on the aperture distribution. Referring to a uniform-section LWA, where α_z is independent of z , we obtain $\eta = 1 - \exp(-2\alpha_z L)$. It should also be noted that, for narrowbeam applications, a very high increase in efficiency should require an extreme prolongation of the line source; actually, in LWAs it typically radiates around 90% or at most 95% of the input power, where the remaining power at the termination is absorbed by a matched load to avoid a backlobe of radiation due to the reflected wave. Once the efficiency is chosen, a fixed link therefore exists between the relative length in terms of wavelengths L/λ_0 and the normalized leakage constant α_z/k_0 . For a uniform-section LWA, an inverse proportionality relationship between L and α_z is found to be of the type:

$$\begin{aligned} L/\lambda_0 &\cong c/(\alpha_z/k_0) \\ c &= (1/4\pi) \ln [1/(1 - \eta)] \end{aligned} \tag{5}$$

where c is related to the value of the desired efficiency (e.g., for 90% of efficiency it is $c = 0.185$). For a tapered section, since α_z depends on z , the link between efficiency, length, and leakage rate is related to the chosen illumination and is more complicated.

In order to achieve narrow beams in the elevation angle, the effective longitudinal aperture has to be sufficiently wide (usually several wavelengths), and this implies a rather low leakage rate. The half-power (-3 -dB) beam-width $\Delta\theta$ is directly linkable to the normalized antenna length L/λ_0 through an approximate relationship, which also takes into account the contribution of the scan angle [1]

$$\Delta\theta \cong a/[L/\lambda_0 \cos \theta_m] \text{ (rad)} \tag{6}$$

where the proportionality factor a is dependent on the aperture distribution. It has the most reduced value for a constant aperture distribution ($a \cong 0.88$) and increases for tapered distributions (typically, more than unity) [1]. From the previous expression, it is seen that, since $\cos \theta_m \cong k_t/k_0$, the beamwidth can also be expressed as $\Delta\theta \cong 2\pi/(k_t L)$. This means that the beamwidth is, at first approximation, practically constant when the beam is scanned away from broadside by varying the frequency for air-filled LWAs (where k_t is independent of frequency), while it changes for dielectric-filled LWAs (where k_t depends on frequency). The effective aperture is nevertheless reduced for a fixed antenna length as the beam approaches endfire (where the previous expression becomes inaccurate), and $\Delta\theta$ anyway tends in practice to enlarge. It can be seen that for an ideal semiinfinite uniform structure, that is, an antenna aperture from $z = 0$ to $z = L \rightarrow \infty$, the beamwidth is determined by the leakage rate only, since in this case it can be found that $\Delta\theta \cong 2\alpha_z/k_t$. Moreover, in this situation the radiation pattern depends only on β_z and α_z and does not present sidelobes:

$$R(\theta) \approx \frac{\cos^2 \theta}{(\alpha/k_0)^2 + (\beta/k_0 - \sin \theta)^2} \tag{7}$$

For finite antenna lengths, sidelobes are produced and the expression for $R(\theta)$ is more involved. In general the specifications on the sidelobe level are related to the choice of the aperture distribution, whose Fourier transform allows for the derivation of the radiation pattern.

3.2. Scanning Properties

It is seen that, for LWAs derived by partially open air-filled metallic waveguides, the beams scan in theory an angular region from around the broadside ($\beta_z/k_0 \cong 0$) toward one endfire ($\beta_z/k_0 \cong 1$). In practice, around broadside the structure works near the cutoff region of the closed waveguide where reactive effects are increasingly important. Nevertheless, the leaky-wave values for β_z/k_0 cannot be extremely low, and at the same time α_z/k_0 tends to increase too much, adversely affecting the possibility of focusing radiation at broadside. Regarding the behavior at endfire it is seen that, since β_z/k_0 tends to unity asymptotically as the frequency increases, in the unimodal range (where these structures are usually employed) the beam cannot reach so closely the endfire radiation in an air-filled LWA.

A way of improving the angular scanning is to fill these structures with dielectric materials. Thus, since in this case the normalized phase constant approaches the square root of the relative permittivity as the frequency is increased ($\beta_z/k_0 \rightarrow \epsilon_r^{1/2}$), the $\beta_z/k_0 = 1$ value can actually be approached in a much more restricted frequency range. It should be noted that for such dielectric-filled structures the beamwidth may change strongly as a function of frequency and therefore as the pointing angle varies [see comments to Eq. (6)]. Moreover, it should be noted that in many leaky structures (such as the dielectric and printed ones), as the frequency is increased, the leaky-mode solution changes into a guided-mode solution

through an involved “transition region” [2]; in this frequency range, also called the “spectral gap,” the contribution of the leaky wave to the accurate determination of the field tends progressively to decrease, and generally the structure does not work well as a LWA.

As mentioned, while the uniform LWAs usually radiate only in the forward quadrant, with the limits specified above, the LWAs derived from periodically modulated slow-wave guides can start to radiate from the backward endfire in the lower frequency range. The design principles of periodic LWAs are in most part similar to those of uniform LWAs [1,2]. The main difference lies in the characterization of the fast wave that is now associated with a Floquet space harmonic of the periodic guide [1,2]. One can see that if a uniform guide is considered whose operating mode is slow [$\beta_z/k_0 > 1$, e.g., a dielectric waveguide], and a longitudinally periodic discontinuity is properly added (e.g., an array of metal strips or notches, placed at suitable distances p), such periodicity furnishes a field expressible in an infinite number of space harmonics ($\beta_{zn}p = \beta_{z0}p + 2n\pi$), where β_{z0} is the phase constant of the fundamental harmonic, which is slightly varied with respect to the original value β_z of the unperturbed guide. With proper choices of the physical parameters, it is in general possible to make only one harmonic fast (typically, the $n = -1$ one), so that it can radiate as a leaky wave (presence of an additional attenuation constant α_z).

In this case, the phase constant of this fast harmonic can assume both positive and negative values ($-1 < \beta_z/k_0 < 1$), as a function of the parameters involved; in particular, as frequency is increased, the beam starts to radiate from backward endfire toward the broadside. In general, also periodic LWAs can have difficulties in working well in the broadside region, since usually for periodic structures there exists an “open stopband” [1], where the attenuation constant rapidly increases, resulting in a widening beamwidth. As the frequency is further increased after broadside, the beam is then scanned also in the forward quadrant. In periodic LWAs, depending on the choice of the design parameters, additional limitations in the forward scanning behavior could exist when a second harmonic also starts to radiate before the first harmonic reaches its endfire, thus limiting the scanning range of the single beam [1,3].

3.3. Leaky-Wave Arrays

If an increase of directivity in the cross-plane is desired, a simple improvement for LWAs based on long radiating slots can be achieved by a physical enlargement of the transverse aperture (e.g., with a flared transition to enlarge the effective cross-aperture). As said before, a more efficient way to increase directivity in the cross-plane is to use a number of radiators placed side-by-side at suitable lateral distances, thus constituting a linear array: it is then possible to achieve radiation with a focused pencil beam. In addition, if properly phased, these arrays of LWAs allow a 2D scanning of the beam; in the elevation plane, as is typical for LWA's, the scanning is achievable by varying the frequency, while in the cross-plane the scanning is achievable with phase shifters that vary the phase

difference among the single-line sources. As noted, in LWAs only a one-dimensional number of phase shifters is therefore necessary, with particular structural simplicity and economic advantage if compared to all the usual radiators requiring a two-dimensional number of shifters for the scanning. Additional desirable features of such arrays are in general the absence of blindspots and good polarization properties [8,9].

For the analysis of such LW arrays, an efficient method is that one based on the “unit cell” approach [8,9]. In this way, it is possible to derive the behavior of the global structure by referring to a single radiator taking into account the mutual effects due to the presence of all the others. In the equivalent network this is achievable by changing only the description of the radiation termination for a periodic-type array environment (infinite number of linear elements); in particular, an ‘active admittance’ can be quantified, which describes the external radiating region as a function of the geometry and of the scan angle. More sophisticated numerical techniques also allow for accurate analyses of arrays by taking into account the mutual couplings for a finite number of elements.

3.4. Pattern Shaping

In the basic requirements of the LWAs radiation pattern, in addition to the specification for the maximum of the beam direction and for its half-power width, the sidelobe behavior also has a primary importance. In general, it is required to derive the properties of the source in connection with a desired radiation pattern. Since LWAs can be viewed as aperture antennas with a current distribution having a certain illumination $A(z)$, it is possible to obtain the far field through a standard relationship [1–3]:

$$E(\theta) = G(\theta) \int_0^L |A(z')| e^{j \text{Arg}[A(z')]} e^{jk'z' \sin \theta} dz' \quad (8)$$

The radiation pattern for E is expressed in terms of a Fourier transform of the line-source complex current distribution on the aperture multiplied by the pattern of the element current G (e.g., a magnetic dipole).

It is easily seen that if the LWA geometry is kept longitudinally constant, the amplitude distribution has an exponential decay of the type $\exp(-\alpha_z z)$. As is known, this behavior furnishes a quite poor radiation pattern for the sidelobes that are rather high (around -13 dB). It therefore derives that, in conjunction with the choice of a fixed illumination function $A(z)$ giving a desired sidelobe behavior (cosine, square cosine, triangular, Taylor, etc.), the leakage rate has to be modulated along the direction z of the line source: in practice this is achievable by properly modifying the cross section of the LWA structure along z with the so-called tapering procedure. Considering that, for a smoothly tapered antenna, the power radiated per unit length from the antenna aperture is simply related to the aperture distribution [viz., $-dP(z)/dz = 2\alpha_z(z)P(z) = c|A(z)|^2$], a useful analytical expression for $\alpha_z(z)$ as a function of the amplitude $A(z)$, of the line-source length

L , and of the efficiency η is obtainable [1–3]:

$$\alpha_z(z) = \frac{1}{2} \frac{|A(z)|^2}{\frac{1}{\eta} \int_0^L |A(z')|^2 dz' - \int_0^z |A(z')|^2 dz'} \quad (9)$$

From Eq. (9) it is also seen that the more the efficiency is desired high (around unity), the more α_z has to increase towards extremely high values around the terminal section (as mentioned, efficiency in common practice does not exceed 90–95%).

For narrowbeam applications, in the tapering procedure the longitudinal modification of the geometry should be made in an appropriate way in order to affect only the leakage constant, taking into account the fact that the phase constant should conversely be maintained the same (β_z should not depend on z in order to have the correct pointing angle for each elementary current contribution on the aperture).

The pattern shaping procedure requires therefore the knowledge of the phase and leakage constants as a function of the geometric parameters of the chosen structure, and this is achievable, as mentioned, by finding the suitable complex eigensolution with numerical methods. In general, for beam shaping, either when it is required a proper α_z distribution with β_z constant (for narrow beams) or when α_z and β_z have to assume suitable longitudinal patterns (for wide beams), the procedure is strongly simplified if it is possible to find geometric parameters through which the leakage and phase constants are varied as independently as possible. This property is related to the topology characteristics of the waveguiding structure [1,12].

4. REALIZATION

4.1. Types of Leaky-Wave Antennas

The various LWAs topologies that have been investigated in the literature are based on different solutions derived by waveguiding structures. We briefly survey the main classes proposed in the applications:

1. Some LWAs based on *partially open metallic* waveguides are presented in Fig. 4. Figure 4a shows a top wall slitted rectangular guide LWA; Fig. 4b, a stub-loaded rectangular guide LWA; and Fig. 4c, a “stepped” rectangular guide LWA [12]. Many other solutions have been proposed for this class of radiators, based on groove guide, ridge guide, and so on [1].
2. Examples of structures based on *hybrid metallic/dielectric* guides are given in Fig. 5; a basic configuration of nonradiative dielectric (NRD) waveguide can be suitably modified to obtain a foreshortened (Fig. 5a) and asymmetric (Fig. 5b) NRD LWAs [1].
3. Configurations of *printed-circuit* LWAs are shown in Fig. 6; a basic uniform microstrip LWA operating on a leaky higher-order mode is shown in Fig. 6a, a

Figure 4. Metallic-guide LWAs: (a) top-wall slitted rectangular guide LWA; (b) stub-loaded rectangular guide LWA; (c) stepped rectangular guide LWA.

periodically loaded microstrip LWA is in Fig. 6b, and a periodical meander microstrip LWA is in Fig. 6c [1].

4. In basic *dielectric* guides, a periodic loading is required in order to isolate a suitable fast-wave space harmonic from the intrinsically slow-wave guiding structure. The most usual periodic perturbation is represented by grating of grooves or metal strips, usually placed in the top surface of the guide (Fig. 7a); also lateral metal patches can be used in hybrid forms (dielectric/microstrip) (Fig. 7b); the reduction of the beamwidth in the cross plane with flared horns has also been employed (Fig. 7c) [1]. All these topologies are good candidates, particularly for

Figure 5. Hybrid metallic/dielectric LWAs: (a) foreshortened nonradiative dielectric (NRD) LWA; (b) asymmetric NRD LWA.

high-frequency applications (millimeter and submillimeter waves), where the use of dielectric instead of metal for the guidance can reduce losses.

- It has to be noted that in uniform planar dielectric LWAs based on a single layer usually present quite high leakage values, with consequent weak capability in focusing radiation. A significant improvement is achievable by properly dimensioning a substrate/superstrate structure (Fig. 8a), where a simple element (dipole or slot) is able to excite a leaky wave giving a conical highly directive beam. This basic topology can be arranged to allow for a very focused pencil beam with a limited number of radiating elements in form of widely spaced array (Fig. 8b).

Feed, Losses, and Manufacture

Feeding LWAs is often quite simple; in particular, for LWAs derived by metal guides, the feed is represented by a continuous transition from the closed structure acting on a suitable guided mode to the related open one acting on a perturbed (leaky) mode. Tapered transitions from the closed to the open structures can be realized to reduce the discontinuity effects and the possible excitation of spurious modes that could arise from abrupt transitions. At the output termination, the introduction of a matched load can strongly decrease the remaining power that, if reflected, should give rise to a backlobe in a direction symmetric to the mainbeam with respect to the broadside. The use of dielectric structures as LWAs can present more difficulties for efficient feeding and coupling, particularly in planar configurations. Attention has to be paid to obtain a “good launching” of the desired leaky wave, avoiding the excitation of additional guided and leaky modes. For planar guides, such as microstrip or layered dielectrics, local coupling elements (such as slot or dipoles) are usually employed to excite the leaky mode from an input line toward the radiating line [9].

Ohmic losses seldom affect the radiative performance of LWAs significantly, since the attenuation due to the leakage of radiated power is generally more influent than the attenuation due to dissipated power in the practical guiding structure. However, since power loss can be excessive as frequency increases, particularly for LWAs based on quasi-closed metal guides, the choice of open guides with dielectrics and a limited use of metal is naturally advisable for millimeter-wave applications.

The general simplicity of LWA structures makes their manufacture usually easy to perform, even though different construction problems can arise depending on the chosen topology and the frequency range. Simple structures are particularly desirable at millimeter waves, due to the

Figure 6. Printed-line LWAs: (a) uniform higher-mode microstrip LWA—space-wave radiation can be associated, for instance, with the strip current distribution of the EH_1 mode, which is leaky in a suitable frequency range; (b) a pair of periodically loaded microstrip LWAs; (c) a pair of periodical meander microstrip LWAs.

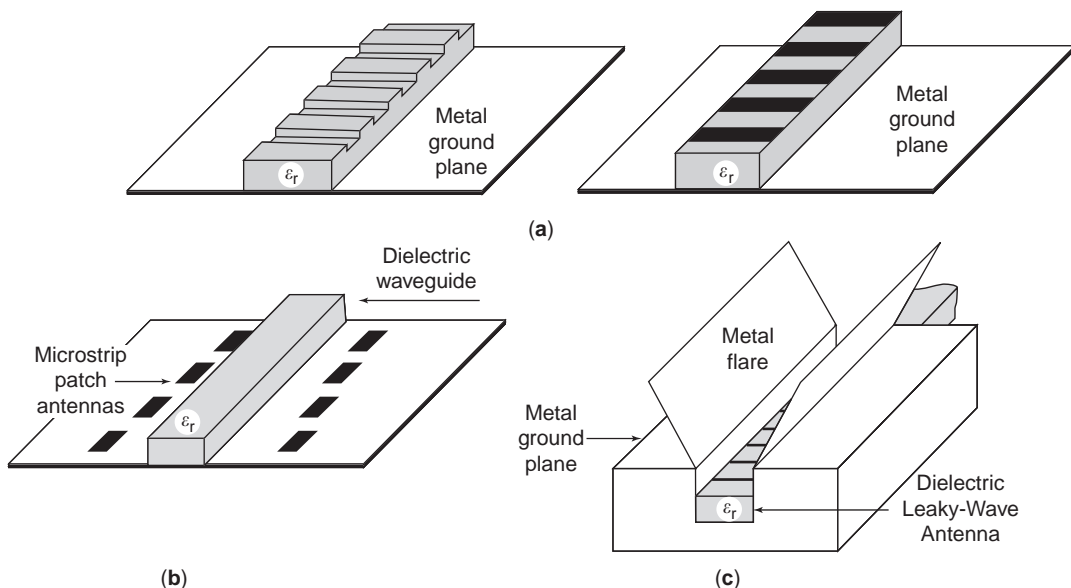

Figure 7. Dielectric-guide LWAs: (a) a pair of periodically loaded dielectric LWAs; (b) dielectric insular guide LWA with metallic patches; (c) dielectric LWA with a flared horn to reduce the cross-plane beamwidth.

reduced dimensions. On the other hand, oversimplified shapes seldom allow good control of radiation performance. In particular, a delicate aspect concerns the usually small longitudinal modifications of the geometry related to tapering for beam control. In this case, an accurate determination of the fabrication inaccuracies and tolerances has particular importance to avoid overwhelming the required geometric variations for tapering, thus degrading the improvements of the pattern shaping. Finally, in specific applications, the practical effects of radomes for environmental protection have to be taken into account.

4.2. Measurement Techniques

The radiation properties of LWAs can be tested experimentally through different types of measurement, most of them applicable to aperture antennas. Some basic parameters, such as efficiency and mismatching effects, can be measured directly through the transmission and/or reflection scattering parameters with a network analyzer. Radiation patterns and directivity properties as a function of the observation angles (θ and ϕ in the zenith and azimuth planes, respectively) can be measured for various frequency values with different techniques, on the aperture, in the radiating near field (Fresnel region), and in the far field (Fraunhofer region). In particular, measurements on the aperture are quite easy to perform. A measurement of the field in the close proximity of the aperture can be achieved with a small pickup element (e.g., an electric dipole probe placed parallel to the aperture electric field). Amplitude and phase of the signal received by the probe are thus measurable through a network analyzer, with possible compensation techniques related to the mutual coupling between the current distribution on the aperture and the current probe element. As said, from the determination of

these basic parameters, a complete knowledge of the radiative characteristics is easily achievable in LWAs.

LEFT-HANDED MATERIALS FOR MICROWAVE DEVICES AND CIRCUITS

CLIFFORD M. KROWNE
Naval Research Laboratory
Washington, DC

1. INTRODUCTION

The use of so-called left-handed materials in the construction of components for physics instruments or electronic devices is an extremely new area to blossom. The materials themselves display a different property of matter compared to ordinary matter relative to the propagation or motion of electromagnetic waves through them. In ordinary matter, through which one sends light, the

energy flow or power travels in the same direction as the phase front or phase motion of the wave. This is not unlike what one would see after dropping a pebble in a pond of water and then observing the ripples. The motion started by initially dropping the pebble in the pond tends to spread out from the point of initial impact where the pebble entered the water surface. As anyone who has seen this phenomenon can attest to, ripples emanate from the initial entry point, and continue in time to spread out, producing increasingly large circles, whose radial distance from the initial entry point increases. One can see that the power flows radially away from the initial point. Also, the phase front of the wave, measured by following a wave crest or trough, also flows radially away from the initial point. So at any given location, the direction of both the power flow and the wave front are the same, or codirectional, and perpendicular to the wave crest, which is in the shape of a circle. If we represent the power flow by a vector, called the *Poynting vector* \mathbf{P} and the phase front by another vector \mathbf{k} at any given location in coordinate space \mathbf{r} , we can say that $\mathbf{P} \cdot \mathbf{k} > 0$, where the dot indicates the multiplication of two vectors, called the *dot product*. Of course, for our example of the pebble in the pond, the problem in computing the dot product is trivial because for any \mathbf{r} location, which in rectilinear coordinates is specified by x , y , and z , \mathbf{P} and \mathbf{k} point in the same direction, and when this occurs, the dot product must both be positive and have a maximum value (Fig. 1a). A more complex situation would be when these two vectors do not point in the same direction (Fig. 1b). This is still not a problem, because we still know how to compute the dot product of two noncollinear vectors. One simply projects one vector onto the other vector, a process that produces the answer $Pk \cos \theta$. Here P is the magnitude of the vector \mathbf{P} , k the magnitude of the vector \mathbf{k} , and θ the angle between them. The cosinusoidal function of θ creates the dot product.

Left-handed materials do not produce positive dot products between the power and phase vectors. Rather, they have $\mathbf{P} \cdot \mathbf{k} < 0$, in apparent contradiction to what we

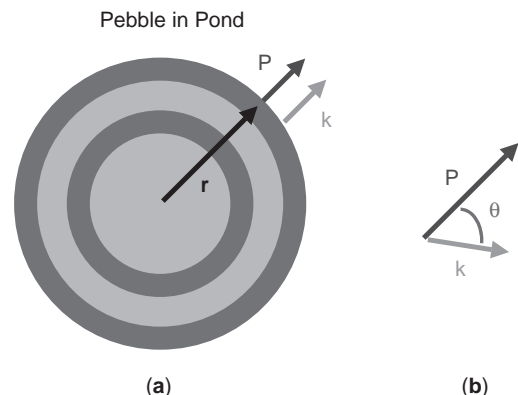

Figure 1. (a) Example of relationship between the power flow vector \mathbf{P} and the phase vector \mathbf{k} for a pebble dropped into a pond at its center—red denotes the location of the crests in the waves emanating from the pond center; (b) nonparallel power \mathbf{P} and phase \mathbf{k} vectors, with an angle θ between them. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

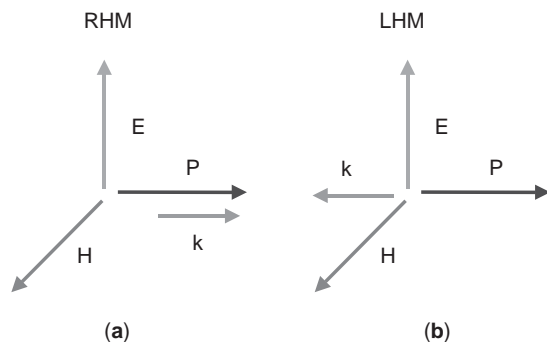

Figure 2. Orientation of the electric \mathbf{E} , magnetic \mathbf{H} , power \mathbf{P} , and phase \mathbf{k} vectors in (a) a right-handed material (RHM) and (b) a left-handed material (LHM). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

understand to be normal behavior. However, there is nothing fundamental that dictates, on the basis of Maxwell's equations, that the product must always be positive. Since it is known that the Poynting vector is equal to the cross-product of the electric \mathbf{E} and magnetic \mathbf{H} fields, or $\mathbf{E} \times \mathbf{H}$, in normal matter it can be demonstrated that \mathbf{E} , \mathbf{H} , and \mathbf{k} form a right-handed system (see Fig. 2a). Clearly, if \mathbf{k} points oppositely to \mathbf{P} , the triad \mathbf{E} , \mathbf{H} , \mathbf{k} must form a left-handed system (see Fig. 2b); this is how the term "left-handed material" arose. Sometimes left-handed material is abbreviated LHM. Similarly, for ordinary matter, or right-handed material, we can use RHM. Left-handed materials have also been variously referred to as negative-index-of-refraction materials (NIMs or NIRMs), negative-phase-velocity materials (NPVs or NPVMs), backward wave materials (BWMs), and negative permittivity and permeability materials (DNMs or NMs). In the latter acronym, the "D" indicates double because both the permittivity and permeability are simultaneously negative. To see that the dual assignment of negative constitutive parameters of a materials leads to a left-handed arrangement of the vector triad, it is sufficient to examine Maxwell's two curl equations. Index of refraction is a concept arising from optics, and merely gives the ratio between the speed of light in the material in comparison to free space or a vacuum. It is usually denoted by the letter "n."

Interest in left-handed media (LHM) originally arose because of its purported ability in combination with right-handed (RHM) or ordinary media to allow unusual focusing of waves, with possible applications in subwavelength control of optical imaging and negative-index-of-refraction (NIR) behavior leading to new radar uses [1]. Definite proof of NIR has occurred in several laboratories, and there is little question that focusing possibilities exist in the much lower frequency microwave/millimeter wavelength regimes compared to the optical regime, although it is now known that imperfect focusing is the best that can be expected. However, this should present no fundamental stumbling block as long as we do not require perfect focusing performance of imaging systems. Thus, applications can be foreseen in the radiocommunication bands. As far as providing focusing capability at the much higher optical frequencies, that is still an unresolved

question. One unusual property of the LHM in conjunction with RHM is the ability to take diverging or parallel rays of light and focus them with a flat plate of LHM. A normal concave lens will now cause rays of light hitting it from a source to diverge, but a convex lens will focus the light rays. These unusual behaviors of LHM were pointed out in the late 1960s in the Russian physics literature [2]. However, the possibility of backward wave behavior has been known since the 1950s and is available in both the American and British physics and electronics literature. So for half a century or so, something has been known about LHM. The earliest work involved backward wave propagation in traveling-wave tubes [3,4] or microwave or millimeter-wave devices and models using nonreciprocal materials [5] or higher-order modes. This earliest work generally involved propagation in one dimension, or dimensions lower than three, as opposed to the left-handed phenomena occurring in any wave direction. When left-handed behavior occurs in any direction, the property is called *isotropic*, meaning that the behavior is seen for any arbitrary propagation direction. Isotropy is what allows the unlimited focusing property that was discussed in the Russian literature in the late 1960s, and which generated the tremendous interest in the physics community worldwide in the late 1990s.

In contrast to the imaging and radar applications stemming from LHM, potential electronic uses may also exist because new physics of propagation in left-handed media occur in structures compatible with integrated circuits. Treating the LHM as intrinsic with microscopic properties that may be described by constitutive relations relating the displacement field or electric flux density \mathbf{D} and electric field intensity \mathbf{E} (i.e., $\mathbf{D} = \epsilon\mathbf{E}$) and relating the magnetic flux density \mathbf{B} to magnetic field intensity \mathbf{H} , (i.e., $\mathbf{B} = \mu\mathbf{H}$), the electromagnetic fields within guided-wave structures employed in integrated circuits can be studied. Completely new dispersion diagrams and electromagnetic field configurations have been found, and it has been proved that propagation in these devices enables regions of forward and backward waves to exist [6]. Such new propagation behavior is in agreement with more recent macroscopic realizations using lumped/distributed circuit elements to make backward wave circuits [7]. These circuits show that various transmission lines, couplers, and other circuit elements with different or improved characteristics may be produced. It is expected that the same could be done for filters, producing devices with new properties or improved characteristics, since propagating and evanescent frequency bands exist in the dispersion diagram. Additionally, the new electromagnetic field distributions strongly imply that improved isolators and circulators [8] could be constructed using LHM in combination with nonreciprocal materials based on carrier cyclotron motion or spin precession. New control components using reciprocal media are also possible by teaming up LHM with ferroelectric materials [9], for example.

The knowledge that backward waves can be produced from discrete inductor and capacitor arrangements configured as unit cells in a transmission system has been known for a long time, and standard textbooks date back to 1967 [10]. This is the origin of the lumped/distributed

elements mentioned above and employed in circuits made using ordinary materials to obtain the backward wave behavior. Dating even further back is the idea that periodic waveguiding structures, with finite-sized unit cells, require the superposition of an infinite set of discrete modes to determine the field at any given location in the repetition direction, call it z . The result of the superposition is to create what is sometimes referred to as “space harmonics,” a coupled system of modes that together satisfy the periodic boundary conditions of the structure. But what also occurs from this superposition with repetition distance d is a k -frequency f diagram repeated infinitely in reciprocal space of period size $2\pi/d$. If we call k_0 the phase behavior within the basic reciprocal unit cell, then the general phase solution includes all the harmonics, stated mathematically as $k_n = k_0 + 2\pi n/d$, $n = 0, \pm 1, \pm 2, \dots, \pm\infty$ [11]. Thus all periodic circuits and structures have an equal number of forward and backward space harmonics.

We will direct our attention in this article, therefore, to the most original area of left-handed materials and devices, those that utilize intrinsic crystalline properties of the material, as opposed to those using lumped elements consisting of capacitive or inductive sections, or RHM transmission lengths, which has been the approach of more recent work producing backward wave devices and circuits. The easiest way to produce intrinsic LHM crystal-

line properties in a guided-wave device is to choose metallic rods and split rings with gaps and to repeat them in a lattice where the repeat distance is much shorter than the effective wavelength. This arrangement is shown schematically in Fig. 3a, and was used in a different context to produce some of the initial results giving rise to the hope in the physics community that optical focusing could be possible given the proof of principle at microwave frequencies (on the order of 5–15 GHz) [12]. But ideally, one would like to have a single-crystalline substrate of material as in Fig. 3b, at the microscopic level. Barring this possibility, another way to make LHM is to combine a layer of crystalline material that has the desired negative permittivity $\epsilon < 0$ with another layer of crystalline material which has the desired permeability $\mu < 0$. This two-layered structure is shown in Fig. 3c. It is even possible that these uniform layers of material could be amorphous and not crystalline. All that would be needed for this concept to work is that each individual layer be substantially less than the wavelength sampling the combination in the vertical direction [13]. This sampling may be evaluated by hitting the two-layered combination by an incident wave as in Fig. 4a and comparing the reflected and transmitted response to the single-layer case in Fig. 4b. It might even be desirable to make multilayered combinations as in Fig. 3d with alternating layers of negative permittivity $\epsilon < 0$ with

Figure 3. Various arrangements of matter to form intrinsic crystalline double-negative material (DNM) or left-handed material (LHM) from (a) inclusions of metallic rods and split resonator rings in a normal RHM or double-positive material (DPM) host, (b) a single-crystalline substance or a single amorphous substance, (c) a bilayer combination of two materials with one having $\epsilon < 0$ but $\mu > 0$ and the other having $\mu < 0$ but $\epsilon > 0$, (d) multiple stacked bilayers, and (e) a heterostructure or superlattice, which creates one of the two bilayers (or both) from (c). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Bilayer Equivalency to Single Layer

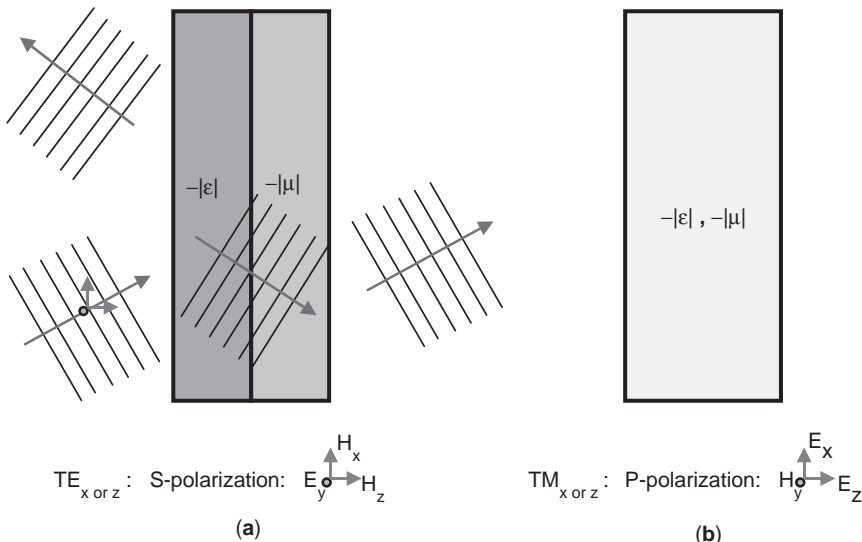

Figure 4. Equivalency of a bilayer and a single DNM or LHM layer is demonstrated using wave transmission (and reflection) of transverse electric (*s*-polarization) or transverse magnetic (*p*-polarization) waves. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

negative permeability $\mu < 0$. Finally, in an extension of the idea in Fig. 3d, heterostructure or superlattice repetitions of layers could be made on the scale of nanometers to produce to the simultaneous $\epsilon < 0$ and $\mu < 0$, as in Fig. 3e. Fig. 5 shows an ϵ/μ plot for DNM or LHM (in the elliptical region) in comparison to other materials already characterized in terms of their basic physical properties. Roughly speaking, electromagnetic waves can propagate in the first and third quadrants of the chart whereas the waves are evanescent or nonpropagating in the second and fourth quadrants. What material processes will be utilized to combine some of the other materials in the chart into DNM, or what new developments will occur to produce completely new materials for DNM await the future.

Next, the electromagnetic field theory and physics of the DNM will be combined into a governing equation

describing the guided-wave DNM problem. Once the governing equation is found, mathematics is done to cast the problem in terms of a Green's function solution. The Green's function approach finds the solution to the DNM structure as if it were hit by a singularity forcing function (in our case it is actually currents on the guiding strip conductor) on an infinitely narrow strip (such as a wire in two dimensions that forms a point), and then uses this simplified and general function to find the actual solution. From the Green's function for the DNM structure, the electromagnetic fields formulas can be found, and the fields can be computed by using a computer code employing numerical techniques.

2. GOVERNING EQUATION FOR GUIDED-WAVE DNM SUBSTRATE MATERIALS

Maxwell's time-varying equations describe the electromagnetic field behavior in a medium if they are combined with constitutive relationships embedding the physical properties of the medium in them. Maxwell's two curl equations are

$$\nabla \times \mathbf{E}(t, \mathbf{x}) = -\frac{\partial \mathbf{B}(t, \mathbf{x})}{\partial t}; \tag{1}$$

$$\nabla \times \mathbf{H}(t, \mathbf{x}) = \frac{\partial \mathbf{D}(t, \mathbf{x})}{\partial t} + \mathbf{J}(t, \mathbf{x})$$

Constitutive relationships are

$$\mathbf{D}(t, \mathbf{x}) = \bar{\bar{\epsilon}} \mathbf{E}(t, \mathbf{x}) + \bar{\bar{\rho}} \mathbf{H}(t, \mathbf{x}); \tag{2}$$

$$\mathbf{B}(t, \mathbf{x}) = \bar{\bar{\rho}} \mathbf{E}(t, \mathbf{x}) + \bar{\bar{\mu}} \mathbf{H}(t, \mathbf{x})$$

Here $\mathbf{x} = (x_1, x_2, x_3) = (x, y, z)$. Most general NPV medium can have all constitutive tensors in (2) nonzero, including the magnetoelectric or optical activity tensors $\bar{\bar{\rho}}$ and $\bar{\bar{\rho}}'$, as they are sometimes denoted. The formulation is therefore kept

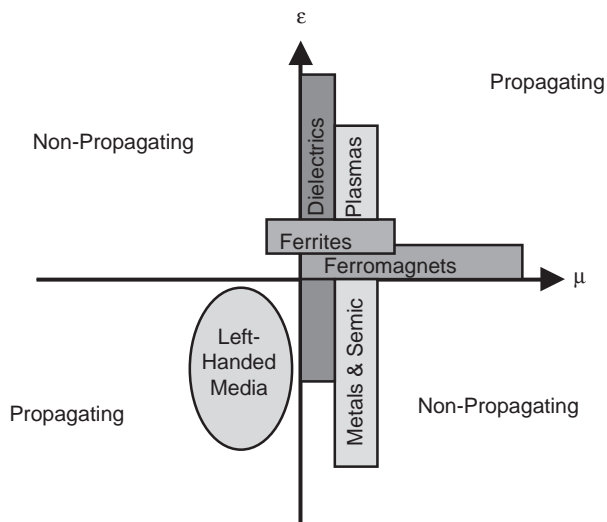

Figure 5. Permittivity ϵ -permeability μ chart showing where DNM or LHM lie in relation to other materials. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

general in order to retain the most flexibility for studying materials with widely varying physical properties. Because many problems are often transparent in the frequency domain, and because nonharmonic problems can be resolved into a superposition of time-harmonic components, we elect to study here time-harmonic electromagnetic wave propagation through the solid-state LHM-RHM structure (RHM = right-handed-medium, or ordinary medium). Taking the time harmonic variation to be of a form $e^{i\omega t}$, Maxwell's equation become

$$\nabla \times \mathbf{E}(\mathbf{x}) = -i\omega \mathbf{B}(\mathbf{x}); \quad \nabla \times \mathbf{H}(\mathbf{x}) = i\omega \mathbf{D}(\mathbf{x}) + \mathbf{J}(\mathbf{x}) \quad (3)$$

with the constitutive relationships dropping the explicit t dependence

$$\begin{aligned} \mathbf{D}(\mathbf{x}) &= \bar{\bar{\epsilon}}(\omega) \mathbf{E}(\mathbf{x}) + \bar{\bar{\rho}}(\omega) \mathbf{H}(\mathbf{x}); \\ \mathbf{B}(\mathbf{x}) &= \bar{\bar{\rho}}'(\omega) \mathbf{E}(\mathbf{x}) + \bar{\bar{\mu}}(\omega) \mathbf{H}(\mathbf{x}) \end{aligned} \quad (4)$$

Dependence of the constitutive parameters on radian frequency is a well recognized fact, and that is why explicit variation on ω is shown. However, for the study to be conducted here at specific frequencies, we do not need to call out this dependence explicitly. We will be setting, for example, $\bar{\bar{\epsilon}}(\omega) = v$ for $\omega = \omega_v$. Therefore, we set

$$\mathbf{D}(\mathbf{x}) = \bar{\bar{\epsilon}} \mathbf{E}(\mathbf{x}) + \bar{\bar{\rho}} \mathbf{H}(\mathbf{x}); \quad \mathbf{B}(\mathbf{x}) = \bar{\bar{\rho}}' \mathbf{E}(\mathbf{x}) + \bar{\bar{\mu}} \mathbf{H}(\mathbf{x}) \quad (5)$$

and understand it means (2).

Curl equations (1) may be combined into a single governing equation [14]

$$L_T(\mathbf{x}) \mathbf{V}_L(\mathbf{x}) = i\omega \mathbf{V}_R(\mathbf{x}) \quad (6)$$

where the matrix partial differential operator acting on the \mathbf{E} - \mathbf{H} column vector is

$$L_T(\mathbf{x}) = \begin{bmatrix} 0 & L_q(\mathbf{x}) \\ -L_q(\mathbf{x}) & 0 \end{bmatrix} \quad (7)$$

where the quadrant operator is

$$L_q(\mathbf{x}) = \begin{bmatrix} 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} & 0 & -\frac{\partial}{\partial x} \\ -\frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0 \end{bmatrix} \quad (8)$$

Vectors in (6) are

$$\mathbf{V}_L(\mathbf{x}) = \begin{bmatrix} E_x \\ E_y \\ E_z \\ H_x \\ H_y \\ H_z \end{bmatrix} = \begin{bmatrix} \mathbf{E} \\ \mathbf{H} \end{bmatrix}; \quad \mathbf{V}_R(\mathbf{x}) = \begin{bmatrix} D_x \\ D_y \\ D_z \\ B_x \\ B_y \\ B_z \end{bmatrix} = \begin{bmatrix} \mathbf{D} \\ \mathbf{B} \end{bmatrix} \quad (9)$$

Restricting ourselves to a guided-wave structure with the wave traveling in a uniform crosssection in the z direction, that is, where the wave has the form $e^{i\omega t - \gamma z}$, $\gamma = \gamma(\omega)$, simplifies (6)–(8) to

$$L_T(x, y) \mathbf{V}_L(x, y) = i\omega \mathbf{V}_R(x, y) \quad (10a)$$

$$L_T(x, y) = \begin{bmatrix} 0 & L_q(x, y) \\ -L_q(x, y) & 0 \end{bmatrix} \quad (10b)$$

$$L_q(x, y) = \begin{bmatrix} 0 & \gamma & \frac{\partial}{\partial y} \\ -\gamma & 0 & -\frac{\partial}{\partial x} \\ -\frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0 \end{bmatrix} \quad (10c)$$

Finally, there are certain advantages for approaching the problem in the Fourier transform domain, not the least of which is that real-space convolution integrals reduce to products, and so for the integral equation technique to be applied to a finite enclosed region in the x direction, with layering in the y direction, the finite Fourier transform pair

$$\mathbf{F}(k_x, y) = \int_{-b}^b \mathbf{F}(x, y) e^{-ik_x x} dx; \quad (11a)$$

$$F_i(k_x, y) = \int_{-b}^b F_i(x, y) e^{-ik_x x} dx$$

$$\mathbf{F}(x, y) = \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} \mathbf{F}(k_x, y) e^{ik_x x}; \quad (11b)$$

$$F_i(x, y) = \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} F_i(k_x, y) e^{ik_x x}$$

is applied to the fields, converting (10) into

$$L_T(k_x, y) \mathbf{V}_L(k_x, y) = i\omega \mathbf{V}_R(k_x, y) \quad (12a)$$

$$L_T(k_x, y) = \begin{bmatrix} 0 & L_q(k_x, y) \\ -L_q(k_x, y) & 0 \end{bmatrix} \quad (12b)$$

$$L_q(k_x, y) = \begin{bmatrix} 0 & \gamma & \frac{\partial}{\partial y} \\ -\gamma & 0 & -ik_x \\ -\frac{\partial}{\partial y} & ik_x & 0 \end{bmatrix} \quad (12c)$$

Constitutive relationships (2) can be combined into a supertensor

$$\mathbf{V}_R(t, \mathbf{x}) = \mathbf{M} \mathbf{V}_L(t, \mathbf{x}); \quad \mathbf{M} = \begin{bmatrix} \bar{\bar{\epsilon}} & \bar{\bar{\rho}} \\ \bar{\bar{\rho}}' & \bar{\bar{\mu}} \end{bmatrix} \quad (13)$$

and using the harmonic transformation leading to (5)

$$\mathbf{V}_R(\mathbf{x}) = \mathbf{M}(\omega)\mathbf{V}_L(\mathbf{x}) \quad (14)$$

Characterization of the wave by the complex propagation constant reduces (14) to

$$\mathbf{V}_R(x, y) = \mathbf{M}(\omega)\mathbf{V}_L(x, y) \quad (15)$$

When the finite Fourier transform is applied to (15), we obtain

$$\mathbf{V}_R(k_x, y) = \mathbf{M}(\omega)\mathbf{V}_L(k_x, y) \quad (16)$$

Inserting this formula describing the material physics into electromagnetic equation yields, after eliminating \mathbf{V}_R , the following equation:

$$L_T(k_x, y)\mathbf{V}_L(k_x, y) = i\omega\mathbf{M}(\omega)\mathbf{V}_L(k_x, y) \quad (17)$$

This matrix equation can in principle be solved for the normal-mode eigenvectors and eigenvalues $\gamma = \gamma(\omega)$, realizing that the 1×6 column vectors and the 6×6 operator and material tensor square matrices use the full electromagnetic field component set. However, because we will restrict ourselves to canonical layered structures (layered in the y direction—see in Fig. 6 cross-sectional and top-side views of a DNM or LHM multilayered structure), it is very convenient to extract the perpendicular field components from (17) using rows 2 and 5, which do not possess differential operator $\partial/\partial y$:

$$-\gamma V_4 - ik_x V_6 = i\omega \sum_{i=1}^6 m_{2i} V_i \quad (18a)$$

$$\gamma V_1 + ik_x V_3 = i\omega \sum_{i=1}^6 m_{5i} V_i \quad (18b)$$

Solution of the pair of equations in (18) is

$$V_i = \sum_{j=1}^6 a_{ij}(1 - \delta_{2,j})(1 - \delta_{5,j})V_j; \quad i = 2, 5 \quad (19)$$

where $\delta_{i,j}$ is the Kronecker delta function, or

$$E_y = a_{21}E_x + a_{23}E_z + a_{24}H_x + a_{26}H_z \quad (20a)$$

$$H_y = a_{51}E_x + a_{53}E_z + a_{54}H_x + a_{56}H_z \quad (20b)$$

Here a_{ij} are given by

$$a_{ij} = \frac{a'_{ij}}{D_a} \quad (21)$$

$$D_a = m_{22}m_{55} - m_{25}m_{52} \quad (22)$$

$$a'_{21} = m_{25} \left(m_{51} + \frac{i\gamma}{\omega} \right) - m_{21}m_{55} \quad (23a)$$

$$a'_{23} = m_{25} \left(m_{53} - \frac{k_x}{\omega} \right) - m_{23}m_{55} \quad (23b)$$

$$a'_{24} = m_{25}m_{54} - m_{55} \left(m_{24} - \frac{i\gamma}{\omega} \right) \quad (23c)$$

$$a'_{26} = m_{25}m_{56} - m_{55} \left(m_{26} + \frac{k_x}{\omega} \right) \quad (23d)$$

$$a'_{51} = m_{52}m_{21} - m_{22} \left(m_{51} + \frac{i\gamma}{\omega} \right) \quad (23e)$$

$$a'_{53} = m_{52}m_{23} - m_{22} \left(m_{53} - \frac{k_x}{\omega} \right) \quad (23f)$$

$$a'_{54} = m_{52} \left(m_{24} - \frac{i\gamma}{\omega} \right) - m_{22}m_{54} \quad (23g)$$

$$a'_{56} = m_{52} \left(m_{26} + \frac{k_x}{\omega} \right) - m_{22}m_{56} \quad (23h)$$

Here \mathbf{M} consists of the set $\{m_{ij}\}$ of elements.

The governing equation of the problem can be acquired by realizing that rows 1, 3, 4, and 6 of (17) contain first-order linear differential equations:

$$\gamma V_5 + \frac{dV_6}{dy} = i\omega \sum_{i=1}^6 m_{1i} V_i \quad (24a)$$

$$-\frac{dV_4}{dy} + ik_x V_5 = i\omega \sum_{i=1}^6 m_{3i} V_i \quad (24b)$$

$$-\gamma V_2 - \frac{dV_3}{dy} = i\omega \sum_{i=1}^6 m_{4i} V_i \quad (24c)$$

$$\frac{dV_1}{dy} - ik_x V_2 = i\omega \sum_{i=1}^6 m_{6i} V_i \quad (24d)$$

With the help of (19) to remove V_2 and V_5 from (24), we obtain

$$\frac{d\Phi}{dy} = i\omega \mathbf{R}\Phi \quad (25)$$

$$\Phi = \begin{bmatrix} V_1 \\ V_3 \\ V_4 \\ V_6 \end{bmatrix} = \begin{bmatrix} E_x \\ E_z \\ H_x \\ H_z \end{bmatrix} \quad (26)$$

$$r_{1j} = m_{60} + a_{50}m_{65} + a_{20} \left(m_{62} + \frac{k_x}{\omega} \right) \quad (27a)$$

$$r_{2j} = - \left\{ m_{40} + a_{50}m_{45} + a_{20} \left(m_{42} - \frac{i\gamma}{\omega} \right) \right\} \quad (27b)$$

$$r_{3j} = - \left\{ m_{30} + a_{20}m_{32} + a_{50} \left(m_{35} - \frac{k_x}{\omega} \right) \right\} \quad (27c)$$

$$r_{4j} = m_{10} + a_{20}m_{12} + a_{50} \left(m_{15} + \frac{i\gamma}{\omega} \right) \quad (27d)$$

Here the $\theta(j)$ index on a_{ij} is defined by

$$\theta(j) = \begin{cases} \frac{3}{2}j; & j=2,4 \\ \frac{3j-1}{2}; & j=1,3 \end{cases} \quad (28)$$

Here \mathbf{R} consists of the set $\{r_{ij}\}$ of elements.

The Green's function problem is posed by placing a Dirac delta forcing function

$$\mathbf{J}_{s\delta}(x) = (\hat{x} + \hat{z})\delta(x - x') \quad (29)$$

on the strip conductor (which could be an ordinary metal or a superconductor) and solving the partial-differential equation system in space subject to appropriate boundary and interfacial conditions. Equation (29) says that a surface current of unit delta magnitude is impressed in the x and z directions. This is consistent with the strip having width w in the x direction, infinitesimal extent in the y direction, and extending infinitely in the z direction corresponding to a uniform cross section. Because we have Fourier-transformed the problem into the spectral domain, the impressed delta current now appears as

$$\mathbf{J}_{s\delta}(k_x) = (\hat{x} + \hat{z}) \int_{-b}^b \delta(x - x') e^{-ik_x x'} dx' = (\hat{x} + \hat{z}) e^{-ik_x x'} \quad (30)$$

where $2b$ is the finite width of the enclosure bounding the x extent. Of course, the actual current is a continuous superposition of weighted contributions over the following

strip width:

$$\begin{aligned} \mathbf{J}_s(x) &= \int_{-w/2}^{w/2} [\mathbf{J}_{s,x}(x')\hat{x} + \mathbf{J}_{s,z}(x')\hat{z}] \delta(x - x') dx \\ &= \int_{-w/2}^{w/2} \mathbf{J}_s(x') \delta(x - x') dx \end{aligned} \quad (31)$$

Here we have been using the fact that current exists only on the strip. Equation (31) merely states that scanning the extent of the strip (with the delta function) will reproduce the correct current distribution function. Now one can state that (3) and (14) having assumed a time-harmonic variation, or (10a) and (15) assuming a z -directed propagation constant also, form a complete set of partial-differential equations subject to the interfacial conditions

$$\hat{y} \times (\mathbf{H}^+ - \mathbf{H}^-) = \mathbf{J}_s(x) \quad (32)$$

$$\mathbf{E}_t^+ = \mathbf{E}_t^- \quad (33)$$

and boundary conditions

$$E_y(x, y) = E_z(x, y) = 0; \quad x = \pm b \quad (34a)$$

$$E_x(x, y) = E_z(x, y) = 0; \quad y = 0, h_T \quad (34b)$$

Equation (32), which arose from curl equation (3), says that the tangential \mathbf{H} field above the interface minus that below is related to the surface current at that interface. If we take this interface to be where there are conductor strips, then, $\mathbf{J}_s(x) \neq 0$, but at other interfaces without strips, $\mathbf{J}_s(x) = 0$ and tangential \mathbf{H} field continuity occurs. Equation (33) assures tangential electric field \mathbf{E} continuity at any interface. Equation (34a) enables the finite Fourier transform, and (34b) constrains the device to be fully enclosed with actual (or computational) walls, where h_T is the total vertical structure thickness.

3. GREEN'S FUNCTION FOR DNM MATERIALS

In the Green's function construction, (29) is impressed on the system through (32), which creates the field solution

$$\overline{\overline{\mathbf{G}}}(x, y; x') = F_L[\delta(x - x')] \quad (35)$$

Here the system linear operator F_L takes the delta function $\delta(x - x')$ applied in either the \hat{x} or \hat{z} direction and determines the field component responses, making a two-indexed tensor (dyadic) of size 6×2 . Equation (35) implicitly assumes that a single interface has the delta function source, and this is acceptable because later on when numerical field plots are shown, that will be the situation for the multilayered structures examined. But there is no reason in principle why this formula cannot be extended to multiple forcing function interfaces (this has been done for ordinary media problems in the literature). Multiplying (35) on the right by $\mathbf{J}_s(x')$ and integrating, and because F_L is a linear operator, the current vector along

with the integral operator may be pulled inside it, giving

$$\int_{-b}^b \overline{\overline{\mathbf{G}}}(x, y; x') \cdot \mathbf{J}_s(x') dx' = F_L \left[\int_{-b}^b \mathbf{J}_s(x') \delta(x - x') dx' \right] \quad (36)$$

The left-hand side is the field solution of the problem $\mathbf{F}(x, y)$, and because the argument of the linear operator by (31) is the total vector surface current, (36) yields

$$\mathbf{F}(x, y) = F_L[\mathbf{J}_s(x)] \quad (37)$$

Therefore, with knowledge of $\overline{\overline{\mathbf{G}}}(x, y; x')$, the field solution is immediately known:

$$\mathbf{F}(x, y) = \int_{-b}^b \overline{\overline{\mathbf{G}}}(x, y; x') \cdot \mathbf{J}_s(x') dx' \quad (38)$$

Considering \mathbf{J}_s as a form of a field, as well as \mathbf{F} as a field, makes (36) an integral equation of the homogeneous Fredholm type of the second kind. Neither \mathbf{J}_s nor \mathbf{F} is known. They must be found by solving (38), with the understanding that the kernel $\overline{\overline{\mathbf{G}}}(x, y; x')$ can be acquired before finding the unknowns. Because we will be working in the spectral domain, the integral equation of problem (38) must be converted to this domain also. There are several ways to find the entire field solution, and one effective way, which does not require obtaining the dyadic Green's function over the whole cross-sectional spatial domain, utilizes the fact that the strip is a perfect conductor with

$$\mathbf{E}_t(x, y) = 0 : \quad |x| < w_p, \quad y = y_I \quad (39)$$

A smaller piece of the $\overline{\overline{\mathbf{G}}}$ must be used, $\overline{\overline{\mathbf{G}}}_{EJ}^{xz}$, which relates the driving surface current to the two tangential electric field components. At the $y = y_I$ interface, (38) is then cast into the form

$$\mathbf{E}(x, y_I) = \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x - x'; y_I) \cdot \mathbf{J}_s(x') dx' \quad (40)$$

Form (40) of the integral equation is a convolution integral of the kernel and the driving surface current. It has the wonderful property that transformation into the spectral domain removes the integral operation. The solution procedure employed requires us to take a finite

Fourier transform of (40)

$$\begin{aligned} \int_{-b}^b \mathbf{E}(x) e^{-ik_x x} dx &= \int_{-b}^b e^{-ik_x x} dx \left\{ \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x - x') \cdot \mathbf{J}_s(x') dx' \right\} \\ &= \int_{-b}^b \left\{ \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x - x') e^{-ik_x x} dx \right\} \cdot \mathbf{J}_s(x') dx' \\ &= \int_{-b}^b \left\{ \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x'') e^{-ik_x(x' + x'')} dx'' \right\} \cdot \mathbf{J}_s(x') dx' \\ &= \int_{-b}^b \left\{ \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x'') e^{-ik_x x''} dx'' \right\} \cdot \mathbf{J}_s(x') e^{-ik_x x'} dx' \\ &= \left\{ \int_{-b}^b \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(x'') e^{-ik_x x''} dx'' \right\} \cdot \left\{ \int_{-b}^b \mathbf{J}_s(x') e^{-ik_x x'} dx' \right\} \\ &= \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(k_x) \cdot \mathbf{J}_s(k_x) \end{aligned} \quad (41)$$

or

$$\mathbf{E}(k_x) = \overline{\overline{\mathbf{G}}}_{EJ}^{xz}(k_x) \cdot \mathbf{J}_s(k_x) \quad (42)$$

In (41) $x'' = x - x'$, $dx'' = dx$, led to the third step and (11a), to the final step. $\overline{\overline{\mathbf{G}}}_{EJ}$ is given by [15]

$$\begin{aligned} \tilde{\mathbf{G}}_{xx}(k_x, \gamma) &= \frac{P_{13}^{(1)} [P_{24}^{(21)} P_{14}^{(2)} - P_{14}^{(21)} P_{24}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \\ &\quad + \frac{P_{14}^{(1)} [P_{13}^{(21)} P_{24}^{(2)} - P_{23}^{(21)} P_{14}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \end{aligned} \quad (43a)$$

$$\begin{aligned} \tilde{\mathbf{G}}_{xz}(k_x, \gamma) &= -\frac{P_{13}^{(1)} [P_{24}^{(21)} P_{13}^{(2)} - P_{14}^{(21)} P_{23}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \\ &\quad - \frac{P_{14}^{(1)} [P_{13}^{(21)} P_{23}^{(2)} - P_{23}^{(21)} P_{13}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \end{aligned} \quad (43b)$$

$$\begin{aligned} \tilde{\mathbf{G}}_{zx}(k_x, \gamma) &= \frac{P_{23}^{(1)} [P_{24}^{(21)} P_{14}^{(2)} - P_{14}^{(21)} P_{24}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \\ &\quad + \frac{P_{24}^{(1)} [P_{13}^{(21)} P_{24}^{(2)} - P_{23}^{(21)} P_{14}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \end{aligned} \quad (43c)$$

$$\begin{aligned} \tilde{\mathbf{G}}_{zz}(k_x, \gamma) &= -\frac{P_{23}^{(1)} [P_{24}^{(21)} P_{13}^{(2)} - P_{14}^{(21)} P_{23}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \\ &\quad - \frac{P_{24}^{(1)} [P_{13}^{(21)} P_{23}^{(2)} - P_{23}^{(21)} P_{13}^{(2)}]}{P_{14}^{(21)} P_{23}^{(21)} - P_{13}^{(21)} P_{24}^{(21)}} \end{aligned} \quad (43d)$$

with

$$\begin{aligned} P^{(1)} &= P^{(1)}(h_1); \quad P^{(2)} = P^{(2)}(h_2); \\ P^{(21)} &= P^{(2)}(h_2)P^{(1)}(h_1) \end{aligned} \quad (44)$$

$$P(y) = e^{i\omega R y} \quad (45)$$

where h_i is thickness of the i th layer.

4. ELECTROMAGNETIC FIELDS FOR DNM

Formulas (43) were found utilizing (25), which has a solution in the i th layer of

$$\Phi_i = \Phi(y_i) = P^{(i)}(y_i)\Phi_i(h_{T,i}) \quad (46)$$

using the global y coordinate. It is very convenient to convert to the local coordinates y' where for the i th layer now the local coordinate ($h_0 \equiv 0$) is

$$y_i' = y_i - h_{T,i}; \quad h_{T,i} = \sum_{k=0}^{i-1} h_k \quad (47)$$

where $h_{T,i}$ is the total thickness of all the layers prior to the i th layer. In the local coordinate system, (46) appears as

$$\Phi_i = \Phi(y_i') = P^{(i)}(y_i')\Phi_i(0) \quad (48)$$

This equation is applied repeatedly to each layer throughout the structure, exercising caution to impose (32)–(34) in the spectral domain

$$\hat{y} \times [\mathbf{H}^+(k_x, y) - \mathbf{H}^-(k_x, y)] = \mathbf{J}_s(k_x); \quad y = y_I \quad (49)$$

$$\mathbf{E}_t^+(k_x, y) = \mathbf{E}_t^-(k_x, y); \quad y = h_i + h_{T,i} = \sum_{k=0}^i h_k \quad (50)$$

and boundary conditions

$$E_x(k_x, y) = E_z(k_x, y) = 0; \quad y = 0, h_T \quad (51)$$

Boundary conditions on the sidewalls (34a) are converted to the spectral domain in a process that generates the discretization of k_x . The detailed derivation will be given since the whole technique hinges on it.

By (11b), the spatial electric field components $E_{y,z}$ are expressed as

$$E_{y,z}(x, y) = \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \quad (52)$$

Consider first the case where $E_{y,z}(x, y)$ has even symmetry with respect to the x axis. (Symmetry choices will be covered in more detail after the derivation of the discre-

tization k_x values.) For even symmetry, we obtain

$$E_{y,z}(x, y) = E_{y,z}(-x, y) \quad (53)$$

Invoking (52), this becomes

$$\begin{aligned} \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} &= \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{-ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=+\infty}^{-\infty} E_{y,z}(-k_x, y) e^{ik_x x} \end{aligned} \quad (54a)$$

$$\frac{1}{2b} \sum_{k_x=-\infty}^{\infty} [E_{y,z}(k_x, y) - E_{y,z}(-k_x, y)] e^{ik_x x} = 0 \quad (54b)$$

Equation (54b) is valid for any x if the bracketed term is zero, namely, if

$$E_{y,z}(k_x, y) = E_{y,z}(-k_x, y) \quad (55)$$

Now we must insert this back into the expansion (52), obtaining

$$\begin{aligned} E_{y,z}(x, y) &= \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=-\infty}^{0^-} E_{y,z}(k_x, y) e^{ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=+\infty}^{0^+} E_{y,z}(-k_x, y) e^{-ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{-ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) [e^{-ik_x x} + e^{ik_x x}] + E_{y,z}(0, y) \\ &= \frac{1}{b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) \cos(k_x x) + E_{y,z}(0, y) \end{aligned} \quad (56)$$

In (56), Eq. (55) was used for the third step. Imposition of boundary condition (34a) forces (56) to obey

$$\frac{1}{b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) \cos(k_x x) + E_{y,z}(0, y) = 0 \quad (57)$$

or

$$\cos(k_x b) = 0; \quad E_{y,z}(0, y) = 0 \quad (58)$$

The first constraint in (57) restricts k_x to

$$k_x = \frac{2n-1}{2} \pi; \quad n = 0, \pm 1, \pm 2, \dots \quad (59)$$

showing that $k_x \neq 0$, allowing us to drop the second (57) constraint. For odd symmetry, we obtain

$$E_{y,z}(x, y) = -E_{y,z}(-x, y) \quad (60)$$

Invoking (52), this becomes

$$\begin{aligned} \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} &= -\frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{-ik_x x} \\ &= -\frac{1}{2b} \sum_{k_x=+\infty}^{-\infty} E_{y,z}(-k_x, y) e^{ik_x x} \end{aligned} \quad (61a)$$

$$\frac{1}{2b} \sum_{k_x=-\infty}^{\infty} [E_{y,z}(k_x, y) + E_{y,z}(-k_x, y)] e^{ik_x x} = 0 \quad (61b)$$

Equation (61b) is valid for any x if the bracketed term is zero, namely, if

$$E_{y,z}(k_x, y) = -E_{y,z}(-k_x, y) \quad (62)$$

Now we must insert this back into the expansion (52), obtaining

$$\begin{aligned} E_{y,z}(x, y) &= \frac{1}{2b} \sum_{k_x=-\infty}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=-\infty}^{0^-} E_{y,z}(k_x, y) e^{ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= \frac{1}{2b} \sum_{k_x=+\infty}^{0^+} E_{y,z}(-k_x, y) e^{-ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \\ &= -\frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{-ik_x x} + E_{y,z}(0, y) \\ &\quad + \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) e^{ik_x x} \end{aligned}$$

$$\begin{aligned} &+ \frac{1}{2b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) [-e^{-ik_x x} + e^{ik_x x}] + E_{y,z}(0, y) \\ &= \frac{i}{b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) \sin(k_x x) + E_{y,z}(0, y) \end{aligned} \quad (63)$$

In (63), Eq. (62) was used in the third step. Imposition of boundary condition (34a) forces (63) to obey

$$\pm \frac{i}{b} \sum_{k_x=0^+}^{\infty} E_{y,z}(k_x, y) \sin(k_x b) + E_{y,z}(0, y) = 0 \quad (64)$$

or

$$\sin(k_x b) = 0; \quad E_{y,z}(0, y) = 0 \quad (65)$$

The first constraint in (65) restricts k_x to

$$k_x = \frac{n}{b} \pi; \quad n = 0, \pm 1, \pm 2, \dots \quad (66)$$

Since the first constraint allows $k_x = 0$, technically the first summation in (64) does not have $n = 0$ in its domain, but by widening its domain to cover $k_x = 0$, the second constraint may be dropped; that is, (64) becomes

$$\pm \frac{i}{b} \sum_{k_x=0}^{\infty} E_{y,z}(k_x, y) \sin(k_x b) = 0 \quad (67)$$

and rule (66) is exact.

Next we treat the origin of the symmetry choices. Go to the harmonic equations (3), and expand them out by components for the simplest case of isotropic DNM, obtaining

$$\begin{aligned} \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} &= i\omega \epsilon_{\text{DNM}} E_x + J_x; \\ \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} &= i\omega \epsilon_{\text{DNM}} E_y; \end{aligned} \quad (68a)$$

$$\begin{aligned} \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} &= i\omega \epsilon_{\text{DNM}} E_z + J_z \\ \frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} &= -i\omega \mu_{\text{DNM}} H_x; \\ \frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x} &= -i\omega \mu_{\text{DNM}} H_y; \\ \frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} &= -i\omega \mu_{\text{DNM}} H_z \end{aligned} \quad (68b)$$

Setting $J_z(x, y) = \text{even}$ for the impressed current, we find that (68a) requires that $E_z(x, y) = \text{even}$, $H_y(x, y) = \text{odd}$, and $H_x(x, y) = \text{even}$ in its third equation; $H_z(x, y) = \text{odd}$

and $E_y(x,y)$ = even in its second equation; and $E_x(x,y)$ = odd and $J_x(x,y)$ = odd in its first equation. These selections are consistent with (68b). For $J_z(x,y)$ = odd, all the selections are reversed. Care must be exercised in this process, and one can show that for biaxial DNM, where the $\bar{\epsilon}$ tensor is biaxial, the $\bar{\mu}$ tensor is biaxial, or both, the symmetry choices still hold. This is the case whether the biaxial tensors are principle axis and diagonal, or the crystal is rotated, producing a nondiagonal tensor(s). However, pure symmetry choices are rarely allowed for nonreciprocal materials such as materials employing precessional spin behavior (as in a ceramics with magnetic ions) or cyclotron carrier motion (as in semiconductors with free electrons or holes), which require the superposition of the even and odd symmetry choices.

The surface currents that drive the problem self-consistently can be chosen in a number of ways, as it is necessary to prepare complete sets only of basis functions that are used to construct them. They are selected in the real-space domain to display some advantageous properties, for example, edge singularity behavior due to charge repulsion. For the complete set of cosinusoidal basis functions modified by the edge condition, we have for a strip with even-mode symmetry (determined by the z -component symmetry as just discussed above)

$$J_{zm}(x) = \zeta_{em}(x) = \begin{cases} \frac{\cos\left(\frac{\pi x}{w}[m-1]\right)}{\sqrt{1-(x/w)^2}}; & |x| \leq w \\ 0; & w < |x| \end{cases} \quad (69a)$$

$$J_{xm}(x) = \eta_{em}(x) = \begin{cases} \frac{\sin\left(\frac{\pi x}{w}m\right)}{\sqrt{1-(x/w)^2}}; & |x| \leq w \\ 0; & w < |x| \end{cases} \quad (69b)$$

and for odd-mode symmetry

$$J_{zm}(x) = \zeta_{om}(x) = \begin{cases} \frac{\sin\left(\frac{\pi x}{2w}[2m-1]\right)}{\sqrt{1-(x/w)^2}}; & |x| \leq w \\ 0; & w < |x| \end{cases} \quad (70a)$$

$$J_{xm}(x) = \eta_{om}(x) = \begin{cases} \frac{\cos\left(\frac{\pi x}{2w}[2m-1]\right)}{\sqrt{1-(x/w)^2}}; & |x| \leq w \\ 0; & w < |x| \end{cases} \quad (70b)$$

Superposition of the complete set forms the total surface current [and constitutes the method of moments (MoM) when unknown currents or fields are expanded using basis sets and inner products with weights taken on the structure-governing equation to derive a linear system to

be solved]:

$$J_{x,e}(x) = \sum_{m=1}^{n_x} a_{e,m} \eta_{e,m}(x); \quad J_{z,e}(x) = \sum_{m=1}^{n_z} b_{e,m} \zeta_{e,m}(x) \quad (71a)$$

$$J_{x,o}(x) = \sum_{m=1}^{n_x} a_{o,m} \eta_{o,m}(x); \quad J_{z,o}(x) = \sum_{m=1}^{n_z} b_{o,m} \zeta_{o,m}(x) \quad (71b)$$

Fourier transforming (71) according to (11a) gives

$$J_{x,e}(n) = \sum_{m=1}^{n_x} a_{e,m} \eta_{e,m}(n); \quad (72a)$$

$$J_{z,e}(n) = \sum_{m=1}^{n_z} b_{e,m} \zeta_{e,m}(n)$$

$$J_{x,o}(n) = \sum_{m=1}^{n_x} a_{o,m} \eta_{o,m}(n); \quad (72b)$$

$$J_{z,o}(n) = \sum_{m=1}^{n_z} b_{o,m} \zeta_{o,m}(n)$$

with

$$\zeta_{e,m}(n) = \zeta_{e,m}(k_x[n]) = \frac{\pi w}{2} \{J_0(k_x w + [m-1]\pi) + J_0(k_x w - [m-1]\pi)\} \quad (73a)$$

$$\eta_{e,m}(n) = \eta_{e,m}(k_x[n]) = -\frac{i\pi w}{2} \{J_0(k_x w + m\pi) - J_0(k_x w - m\pi)\} \quad (73b)$$

$$\zeta_{o,m}(n) = \zeta_{o,m}(k_x[n]) = -\frac{i\pi w}{2} \left\{ J_0\left(k_x w + [2m-1]\frac{\pi}{2}\right) - J_0\left(k_x w - [2m-1]\frac{\pi}{2}\right) \right\} \quad (74a)$$

$$\eta_{o,m}(n) = \eta_{o,m}(k_x[n]) = \frac{\pi w}{2} \left\{ J_0\left(k_x w + [2m-1]\frac{\pi}{2}\right) + J_0\left(k_x w - [2m-1]\frac{\pi}{2}\right) \right\} \quad (74b)$$

An exact solution is obtained only when n_x and $n_z \rightarrow \infty$. However, a finite number of them may be used, depending on the propagating eigenmode modeled, to find a reasonably accurate numerical result. In (73) and (74), J_0 denotes the Bessel function of the first kind.

Eigenvalues γ and eigenvectors of the propagating problem can now be found from (42), the interfacial strip equation (drop all interfacial indexes, and use subscripts to label elements)

$$E_x(n, \gamma) = G_{xx}(\gamma, n) J_x(n, \gamma) + G_{xz}(\gamma, n) J_z(n, \gamma) \quad (75)$$

$$E_z(n, \gamma) = G_{zx}(\gamma, n) J_x(n, \gamma) + G_{zz}(\gamma, n) J_z(n, \gamma)$$

by substituting for the surface currents using expression (72a) or (72b) depending on the mode symmetry to be

studied (we drop the explicit mode symmetry type notation since we will treat only one or the other type of pure symmetry solution here):

$$E_x(n, \gamma) = G_{xx}(\gamma, n) \sum_{i=1}^{n_x} a_i \eta_i(n) + G_{xz}(\gamma, n) \sum_{i=1}^{n_z} b_i \zeta_i(n) \quad (76)$$

$$E_z(n, \gamma) = G_{zx}(\gamma, n) \sum_{i=1}^{n_x} a_i \eta_i(n) + G_{zz}(\gamma, n) \sum_{i=1}^{n_z} b_i \zeta_i(n)$$

Next multiply the first equation of (76) by η_j and the second by ζ_j , then summing over the spectral index n (this is the inner product part of the MoM method)

$$\begin{aligned} \sum_{n=-\infty}^{\infty} \eta_j(n) E_x(n, \gamma) &= \sum_{n=-\infty}^{\infty} \left[\eta_j(n) G_{xx}(\gamma, n) \sum_{i=1}^{n_x} a_i(n) \eta_i(n) \right] \\ &+ \sum_{n=-\infty}^{\infty} \left[\eta_j(n) G_{xz}(\gamma, n) \sum_{i=1}^{n_z} b_i(n) \zeta_i(n) \right] \end{aligned}$$

$$\begin{aligned} \sum_{n=-\infty}^{\infty} \zeta_j(n) E_z(n, \gamma) &= \sum_{n=-\infty}^{\infty} \left[\zeta_j(n) G_{zx}(\gamma, n) \sum_{i=1}^{n_x} a_i(n) \eta_i(n) \right] \\ &+ \sum_{n=-\infty}^{\infty} \left[\zeta_j(n) G_{zz}(\gamma, n) \sum_{i=1}^{n_z} b_i(n) \zeta_i(n) \right] \end{aligned} \quad (77)$$

Interchanging the order of the basis function and spectral summations in (77), we obtain

$$\begin{aligned} \sum_{n=-\infty}^{\infty} \eta_j(n) E_x(n, \gamma) &= \sum_{i=1}^{n_x} a_i(n) \left[\sum_{n=-\infty}^{\infty} \eta_j(n) G_{xx}(\gamma, n) \eta_i(n) \right] \\ &+ \sum_{i=1}^{n_z} b_i(n) \left[\sum_{n=-\infty}^{\infty} \eta_j(n) G_{xz}(\gamma, n) \zeta_i(n) \right] \end{aligned}$$

$$\begin{aligned} \sum_{n=-\infty}^{\infty} \zeta_j(n) E_z(n, \gamma) &= \sum_{i=1}^{n_x} a_i(n) \left[\sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zx}(\gamma, n) \eta_i(n) \right] \\ &+ \sum_{i=1}^{n_z} b_i(n) \left[\sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zz}(\gamma, n) \zeta_i(n) \right] \end{aligned} \quad (78)$$

Examine the left-hand sides of this paired set of equations (78):

$$\begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix} \sum_{n=-\infty}^{\infty} \begin{Bmatrix} \eta_{e,oj} \\ \zeta_{e,oj} \end{Bmatrix} (n) E_{x,z}(n, \gamma)$$

$$\begin{aligned} &= \sum_{n=-\infty}^{\infty} \begin{Bmatrix} \eta_j^* \\ \zeta_j^* \end{Bmatrix} (n) E_{x,z}(n, \gamma) \\ &= \sum_{n=-\infty}^{\infty} \left[\int_{-b}^b \begin{Bmatrix} \eta_j \\ \zeta_j \end{Bmatrix} (x) e^{-ik_x x} dx \right]^* E_{x,z}(n, \gamma) \\ &= \sum_{n=-\infty}^{\infty} \int_{-b}^b \begin{Bmatrix} \eta_j^* \\ \zeta_j^* \end{Bmatrix} (x) e^{ik_x x} dx E_{x,z}(n, \gamma) \\ &= \sum_{n=-\infty}^{\infty} \int_{-b}^b \begin{Bmatrix} \eta_j \\ \zeta_j \end{Bmatrix} (x) e^{ik_x x} dx E_{x,z}(n, \gamma) \\ &= \int_{-b}^b \begin{Bmatrix} \eta_j \\ \zeta_j \end{Bmatrix} (x) \left[\sum_{n=-\infty}^{\infty} E_{x,z}(n, \gamma) e^{ik_x x} \right] dx \\ &= 2b \int_{-b}^b \begin{Bmatrix} \eta_j \\ \zeta_j \end{Bmatrix} (x) E_{x,z}(x, \gamma) dx \\ &= 0 \end{aligned} \quad (79)$$

where the first and second rows in the left-hand side matrix correspond, respectively, to even and odd symmetry. Right-hand equalities in the first, second, fourth, sixth, and last lines used, respectively, (73) and (74), (11a), (69) and (70), (11b), and (40) with (69) and (70). Equation (79) amounts to a Parseval theorem [16] for the problem at hand. Enlisting this theorem, we can rewrite (78) as

$$\begin{aligned} \sum_{i=1}^{n_x} a_i(n) \left[\sum_{n=-\infty}^{\infty} \eta_j(n) G_{xx}(\gamma, n) \eta_i(n) \right] \\ + \sum_{i=1}^{n_z} b_i(n) \left[\sum_{n=-\infty}^{\infty} \eta_j(n) G_{xz}(\gamma, n) \zeta_i(n) \right] &= 0 \\ \sum_{i=1}^{n_x} a_i(n) \left[\sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zx}(\gamma, n) \eta_i(n) \right] \\ + \sum_{i=1}^{n_z} b_i(n) \left[\sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zz}(\gamma, n) \zeta_i(n) \right] &= 0 \end{aligned} \quad (80)$$

Since (80) is valid for any j th basis test function, it may be condensed into the form

$$\begin{aligned} \sum_{i=1}^{n_x} a_i(n) X_{xx}^{ji}(\gamma) + \sum_{i=1}^{n_z} b_i(n) X_{xz}^{ji}(\gamma) &= 0; \quad j = 1, 2, \dots, n_x \\ \sum_{i=1}^{n_x} a_i(n) X_{zx}^{ji}(\gamma) + \sum_{i=1}^{n_z} b_i(n) X_{zz}^{ji}(\gamma) &= 0; \quad j = 1, 2, \dots, n_z \end{aligned} \quad (81)$$

where (this is referred to as the *Galerkin technique* since $\{\eta_i, \zeta_i\} = \{\eta_j, \zeta_j\}$)

$$\begin{aligned} X_{xx}^{ji}(\gamma) &= \sum_{n=-\infty}^{\infty} \eta_j(n) G_{xx}(\gamma, n) \eta_i(n) \\ X_{xz}^{ji}(\gamma) &= \sum_{n=-\infty}^{\infty} \eta_j(n) G_{xz}(\gamma, n) \zeta_i(n) \\ X_{zx}^{ji}(\gamma) &= \sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zx}(\gamma, n) \eta_i(n) \\ X_{zz}^{ji}(\gamma) &= \sum_{n=-\infty}^{\infty} \zeta_j(n) G_{zz}(\gamma, n) \zeta_i(n) \end{aligned} \quad (82)$$

In matrix form, (81) appears as

$$\begin{aligned} \begin{bmatrix} X_{xx} & X_{xz} \\ X_{zx} & X_{zz} \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = 0; \quad \mathbf{X} \begin{bmatrix} a \\ b \end{bmatrix} = 0; \quad \mathbf{X}\mathbf{v} = 0 \\ \mathbf{X} = \begin{bmatrix} X_{xx} & X_{xz} \\ X_{zx} & X_{zz} \end{bmatrix}; \quad \mathbf{v} = \begin{bmatrix} a \\ b \end{bmatrix} \end{aligned} \quad (83)$$

Once system of equations (83) is solved, then vector \mathbf{v} containing the coefficients needed to construct the surface current, and from them the electromagnetic field, is known, which is the problem eigenvector. The eigenvalue γ is determined from this system also (from the determinant of \mathbf{X} set to zero). From (72), the total vector surface current is obtained:

$$\mathbf{J}(x, y) = \frac{1}{2b} \sum_{n=-n_{\max}}^{n_{\max}} \mathbf{J}(n; y) e^{i\alpha_n x} \quad (84)$$

Once the total surface current is available, the total eigenvector field solution follows from $\overline{\mathbf{G}}_{EJ}^{xz}(x-x'; y_I)$ in

(40) [17]:

$$\begin{aligned} \mathbf{E}(x, y) &= \frac{1}{2b} \sum_{n=-n_{\max}}^{n_{\max}} \mathbf{E}(n; y) e^{i\alpha_n x}, \\ \mathbf{H}(x, y) &= \frac{1}{2b} \sum_{n=-n_{\max}}^{n_{\max}} \mathbf{H}(n; y) e^{i\alpha_n x} \end{aligned} \quad (85)$$

Spectral expansion is truncated at the same maximum number of terms $n = n_{\max}$ for all vector components. Basis function summation limits n_x and n_z for the x and z components ($m = m_{\max}$) [see (72) for the surface current expansion] can be truncated at different values. Current and fields are real physical quantities, so they must be converted through

$$\begin{aligned} \mathbf{J}_p(x, y, z) &= \text{Re}[\mathbf{J}(x, y) e^{i\omega t - \gamma z}], \\ \mathbf{E}_p(x, y, z) &= \text{Re}[\mathbf{E}(x, y) e^{i\omega t - \gamma z}], \\ \mathbf{H}_p(x, y, z) &= \text{Re}[\mathbf{H}(x, y) e^{i\omega t - \gamma z}] \end{aligned} \quad (86)$$

which reasserts both the time and z dependence down the guiding structure. At a particular z plane, say, $z=0$, we may drop the explicit z dependence. And if we don't wish to watch the time evolution of the harmonic wave, which is sufficient for plotting purposes, we may further set $t=0$, and write (86) as

$$\begin{aligned} \mathbf{J}_p(x, y) &= \text{Re}[\mathbf{J}(x, y)]; \\ \mathbf{E}_p(x, y) &= \text{Re}[\mathbf{E}(x, y)]; \\ \mathbf{H}_p(x, y) &= \text{Re}[\mathbf{H}(x, y)] \end{aligned} \quad (87)$$

5. NUMERICAL DETERMINATION OF THE FIELDS FOR DNM

Let us, for the sake of discussion, consider a possible use of DNM or LHM in a combination structure as in Fig. 6, which could indicate where the future may lie with such materials under appropriate development. Figure 6a is a

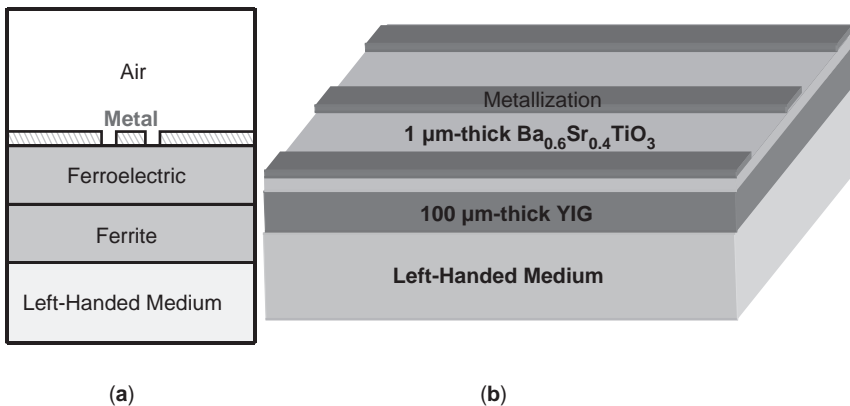

Figure 6. (a) Cross section of a multilayered coplanar structure possessing a ferroelectric material, a ferromagnetic material, and a DNM or LHM; (b) perspective drawing of the structure with possible substances and thicknesses for ferroelectric and ferromagnetic materials. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

cross-sectional view of metallization in what is commonly referred to as a *coplanar microstrip pattern*. The electric fields go from the inner metal strip to the edges of the wider strips of metal. The wider strips attach to the metal enclosure and so act as ground planes on the surface between the layers of materials and the air above them. The RF electric field tends to go from the inner strip to the outer ground planes. Because the fields are close to the ferroelectric–air interface using this metallization pattern, control of the ferroelectric material’s properties using a static DC voltage bias between the strip and the ground planes allows control component capabilities. In particular, the static DC voltage bias will change the ferroelectric material’s dielectric constant, which will affect the RF propagation. Below the ferroelectric layer is a layer of ferromagnetic material that can be controlled with a static magnetic field bias. The ferromagnetic material’s magnetic properties, through its permeability tensor, are altered by changing the magnetic field bias. Finally, on the bottom is the DNM or LHM, which allows one to change the field line patterns of the prior two layers, thereby adding a further degree of design capability to the structure’s RF performance. Because device impedance varies as $Z = \sqrt{\mu_{\text{eff}}/\epsilon_{\text{eff}}}$, where μ_{eff} and ϵ_{eff} respectively are the effective permeability and permittivity of the device structure, we may express the impedance as $Z = \sqrt{\mu_{\text{eff}}(fm)/\epsilon_{\text{eff}}(fe)}[\text{DNM}]$, which serves to indicate where the major effect of each material is. Clearly, the DNM affects the whole field pattern, and that is why it is to the right of the radical sign, altering the field patterns in both ferroelectric and ferromagnetic materials. Figure 6b shows a topside view of the same structure, with some specific possible materials labeled for the ferroelectric and ferromagnetic substances. Although this structure has been neither built nor modeled, it shows where the research and development could go in the future. However, an experimental structure containing a ferroelectric layer and a ferromagnetic layer was fabricated and tested in 2000 [18].

Before examining a structure compatible with integrated planar circuit technology, the material will be

made less general and complex by eliminating the optical activities (magnetolectric coefficients) in Section 2. Then the factors needed to reconstruct the y components of the transverse electric E_y and magnetic H_y fields become $D_a = \epsilon_{22}\mu_{22}$, $a_{21}' = -\epsilon_{21}\mu_{22}$, $a_{23}' = -\epsilon_{23}\mu_{22}$, $a_{24}' = \mu_{22}i\gamma/\omega$, $a_{26}' = -\mu_{22}k_x/\omega$, $a_{51}' = -\epsilon_{22}i\gamma/\omega$, $a_{53}' = \epsilon_{22}k_x/\omega$, $a_{54}' = -\epsilon_{22}\mu_{21}$, and $a_{56}' = -\epsilon_{22}\eta_{23}$. One notices that the first two factors contain off-diagonal constitutive permittivity tensor elements, the next four contain only diagonal constitutive tensor elements, and the last two contain off-diagonal constitutive permeability tensor elements. Because the discussion below will be limited to biaxial electric and magnetic crystals utilized in the principal axis system, off-diagonal-element-dependent factors will become null, making $a_{21}' = 0$, $a_{23}' = 0$, $a_{54}' = 0$, and $a_{56}' = 0$.

Since microstrip is one of the fundamental building blocks of RF hybrid and integrated circuits, actual numerically determined results will be shown for a structure with a single substrate material, that of a DNM or LHM, and a single microstrip conductor strip. The structure to be modeled is shown in Fig. 7. Figure 7a shows a cross-sectional view, indicating that the device is surrounded by a perfect conducting wall (electric wall), and Fig. 7b shows a perspective view without the obstruction of the enclosure walls. The enclosure walls can be thought of as a computational vehicle for using the numerical procedure described in Sections 2–4, even if the actual device is not inside a conductor box. Since, in general, the LHM or DNM can be anisotropic, the permittivity and permeability of the material are characterized by tensors $\bar{\epsilon}$ and $\bar{\mu}$ (or $[\epsilon]$ and $[\mu]$ in the figure). For our actual DNM study device, however, isotropy will be assumed, making $\bar{\epsilon} = \epsilon I$ and $\bar{\mu} = \mu I$, where $I = \text{identity tensor}$. Because the material is DNM, $\bar{\epsilon} = \epsilon I = -|\epsilon|I$ and $\bar{\mu} = \mu I = -|\mu|I$, where $|\epsilon| = \epsilon_{m,r}\epsilon_0$ and $|\mu| = \mu_{m,r}\mu_0$. Here the subscript “r” denotes relative values to free space, where ϵ_0 and μ_0 are the free-space values of, respectively, the permittivity and permeability. Substrate relative permittivity and permeability magnitude values are set to $\epsilon_{m,r} = 2.5$ and $\mu_{m,r} = 2.5$. Structure dimensions are height $h_T = 5.5$ mm, substrate thickness

Figure 7. (a) Single microstrip structure using a DNM or LHM substrate—a perfect conductor (electric wall) encloses the device; (b) perspective drawing of the structure, without the encumbrance of the enclosing walls. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 8. Magnitude plot of electric field E with an overlay of electric field lines of the \mathbf{E} vector is shown for the structure of Fig. 7 at 5 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$h_s = 0.5$ mm, air region thickness $h_a = 5$ mm, box width $B = 2b = 5$ mm, and strip width $w_s = 2w = 0.5$ mm.

Figure 8 shows the electric field magnitude $E = |\mathbf{E}|$ in a color scale plot with the color scale shown below the figure at the frequency of 5 GHz. (This figure and the others to follow, including the associated propagation constants γ , were obtained using $n_x = n_z = 1$ number of surface current basis functions, $n = 200$ Fourier terms, and over 8000 gridpoints for magnitude plots from a computer code. A larger number of n_x , n_z , and n have been examined for plots and propagation constants, but are not discussed here [4,19].) It is a linear scale. Strip location is indicated by a solid dark line at $y = 0.5$ mm, $x = \pm 0.25$ mm. Overlaid on the magnitude plot is a line drawing of \mathbf{E} vector shown in white lines. Electric field direction is also noted by the arrows attached to the lines. The next figure (Fig. 9) shows the magnetic field magnitude $H = |\mathbf{H}|$ in a color scale plot with the color scale again shown below the figure. Once again a line drawing of \mathbf{H} vector is overlaid in white lines on top of the magnitude plot, with \mathbf{H} -field direction indicated by the arrows attached to the lines. In Figs. 9 and 10, we have shown only a limited number of field lines, since in principle one can draw an infinite number of them. In addition, for the electric field lines, we have drawn lines only from the strip, although electric field lines exist elsewhere in the device cross section. Figure 10 extracts from Figs. 9 and 10 the field lines in order to observe them better. Electric field emanation from the strip conductor in terms of the orientation of its vector depends on how the charge resides on the strip, and will vary depending on the

Figure 9. Magnitude plot of magnetic field H with an overlay of magnetic field lines of the \mathbf{H} vector is shown for the structure of Fig. 7 at 5 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

mode propagating. Magnetic field-line circulation around the strip conductor is contrary to what one normally expects for ordinary materials. For ordinary materials, the circulation would be either clockwise or counterclockwise, depending on whether the current was flowing,

Figure 10. Electric \mathbf{E} and magnetic \mathbf{H} field lines for the structure of Fig. 7 at 5 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 11. Electric field magnitude E and an overlaid arrow plot giving the electric field vector \mathbf{E} at 15 GHz for a ordinary media structure. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

respectively, out of or into the paper. But for DNM or LHM in the structure, the behavior changes, as clearly evidenced in Fig. 10.

The propagation constant for the structure at 5 GHz turns out to be entirely real, that is, $\gamma = \alpha + i\beta = i\beta$, where α is the attenuation constant and β is the phase propagation constant, the same quantity that was denoted k in Section 1. Its value at 5 GHz is $\beta = 2.22663$ (relative to the free-space value), and gives the phase behavior in the z direction, perpendicular to the structure cross section. To provide a comparison to other frequencies for this structure, its value at 10 GHz becomes complex and is $\gamma = \alpha + i\beta = 0.939414 + i2.13414$ [17,20]. At 40 GHz it is still complex, ($\gamma = 1.01830 + i1.33370$ [17,20]) and at 80 GHz, it reverts again to being purely a phase, but with two lowest-order fundamental solutions, $\beta = 1.17765$ and $\beta = 1.78861$. Complex γ values at the intermediate millimeter wavelength frequencies mean that the wave is evanescent, or decaying as the wave propagates down the structure. For $\alpha \approx \beta$, it will not take many wavelengths of distance down the guiding structure for the wave to be completely attenuated. However, such wave reduction amplitude control can provide the basis for filtering functions. Now let us return to the discussion of field plots.

For a comparison to an ordinary media structure, Fig. 11 shows the E -field magnitude and an overlaid arrow plot giving the electric field vector \mathbf{E} (arrow length gives the magnitude, while its orientation indicates its direction) at 15 GHz for a somewhat anisotropic device. Its dimensions are total height $h_T = 4.5$ mm, substrate thickness $h_s = 1.5$ mm, air region thickness $h_a = 3$ mm, box width $B = 2b = 8.5$ mm, and strip width $w_s = 2w = 1.5$ mm. The material is pyrolitic boron nitride with diagonal permittivity tensor elements $\epsilon_{xx} = \epsilon_{zz} = 5.12$ and $\epsilon_{yy} = 3.4$. The crystal is oriented so that the structure coordinates and the principal crystal axes match. Although the material's permittivity anisotropy is 33.6% referenced to the dominant diagonal elements, the overall field behavior is indicative of a normal media structure, enough to enable us to

compare it to our demonstration DNM device. Note how the majority of the field magnitude is below the interface. This structure's propagation constant $\gamma = 1.77882$.

This is not the case for our demonstration LHM device, numerically evaluated at 10 GHz and shown in Fig. 12 for the electric \mathbf{E} field. Much of the field is above the interface and to the sides of the strip. Figure 13 shows the magnetic \mathbf{H} field. This figure seems remarkable because the field appears large away from the strip. The ability of the

Figure 12. Magnitude plot of the electric field E , with an overlaid arrow plot giving the electric field vector \mathbf{E} , is shown for the structure of Fig. 7 at 10 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 13. Magnitude plot of the magnetic field H , with an overlaid arrow plot giving the magnetic field vector \mathbf{H} , is shown for the structure of Fig. 7 at 10 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

LHM-RHM combination structure to expel the field from the usual regions it is found in and to place it in other regions signals its potential application toward reconfiguring fields in ordinary devices and designing completely new devices.

6. CONCLUSION

There are many fascinating aspects of double-negative materials (DNM) or left-handed materials (LHM) in relation to their physics in guided-wave structures. Likewise, the electronic aspects of using DNM or LHM as substrates based on the new physics of this material could lead to many new devices, modified old ones with additional functionality, or improved old devices. Many microwave components come to mind that could be affected by the use of this new DNM, including transmission lines [21], phase shifters, couplers, power dividers, isolators, circulators, and filters, to name just a few.

LENS ANTENNAS

J. A. G. MALHERBE
University of Pretoria
Pretoria, South Africa

1. LENSES AS ANTENNAS

There are certain, very specific reasons why a lens antenna would be chosen for a given application, and also very specific disadvantages associated with it. They have high directivity and low sidelobe patterns. Lenses are fed from the rear, and consequently there is no aperture blockage. Furthermore, they can be designed to have a minimum of aberrations for off-axis operation, and are therefore ideally suited to multibeam applications. In some instances, extremely wide scan angles can be achieved. Two-dimensional scanning lenses are well suited in application as linefeeds for cylindrical parabolic reflectors for scanning in a single plane.

At the same time, lenses suffer from internal dielectric losses, as well as reflection losses at the surface interfaces. They are often bulky, and have to be mounted by the edges of the antenna. But this disadvantage is a result of the advantage that they have no aperture blockage. These disadvantages are not typical of, for instance, reflector antennas. In spite of the disadvantages, the positive properties of lens antennas make that they are the chosen solution especially where wide scan angles are needed. At the higher microwave and millimeterwave frequencies, size ceases to be a major consideration in the application of lenses.

1.1. Optics and Dielectrics

The electromagnetic spectrum extends from the very low radiofrequencies through the microwave and millimeterwave frequencies to beyond the visible spectrum of light.

All of these wave phenomena can be described by the same set of wave equations, and there is no reason why the principles applicable to optics cannot be extended downward to cover the RF–microwave spectrum. Together with the physical principles and theory, follows devices resulting from the application of the theoretical principles.

Lenses that make use of the refractive phenomena associated with wave motion can be used to collimate electromagnetic radiation in exactly the same way as they do in optical systems.

In optical systems, extensive use is made of the principles of geometrical optics, where propagation is represented as taking place along a straight line or ray, and the same principles will be applied in understanding electromagnetic lenses in the RF and microwave areas. The principles of reflection, refraction, and diffraction are central to the development of lens antennas, although the latter lies beyond the scope of this article.

Two important principles of optics are basic to lens action:

1. The propagation (phase) velocity for wave propagation differs between various media with different relative permittivity. The relative permittivity is directly related to the refractive index of the material, $n = \epsilon_r^{1/2}$. The index of refraction for *natural homogeneous dielectric materials*, is always $n > 1$. It varies from about just over 1 for foam-type plastic dielectrics to between 2 and 4 for plastics, through a wide range from 2 to 80 for mixtures that contain various ceramics.
2. When rays are obliquely incident on the interface between two media, the wave is partially reflected, and partially refracted. Refraction takes place as shown in Fig. 1. Rays will be refracted towards the surface normal PP' at oblique incidence when traveling from a less to a more dense material, and vice versa. This is known as *Snell's law*; it sets the relationship between the angles of incidence and refraction for known values of n . Snell's law is stated as

$$\sin \phi_i = n \sin \phi_t \quad (1)$$

Figure 1. Refraction at an interface between two media.

The statement on natural dielectrics needs expansion. Clearly, most of the materials mentioned, are not *natural* materials in the true sense of the word, but they perform in the same way as natural materials, so we will use the term. There are also a large number of other, constructed and artificial media, for which $n < 1$. Figure 2a, shows a plane wave incident on the interface between free space and a set of *parallel conducting plates*, with the E field parallel to the plates. Providing that the plate separation lies between λ and $\lambda/2$ of the free-space wave, a single mode, the transverse electric (TE) mode, will propagate, with a phase velocity *larger* than that of light in free space.

In effect, this constitutes a medium with $n < 1$, and can be used to construct a lens. If the wave is *not* polarized with the E -field parallel to the plates, as in Fig. 2b, the wave will propagate between the plates in the transverse electromagnetic (TEM) mode, which has the same phase velocity as free space. This is clearly not useful. In the first case, Snell's law is obeyed.

In cases where the wave has a component of velocity normal to the conducting plates, as depicted in Figs. 2c and 2d, the behaviour of the wave in the x - y plane is as described above. In the x - z plane, though, the wave is forced to propagate between the parallel plates. This is termed a constrained wave. In this plane, Snell's law is *not* obeyed.

Waveguides also exhibit the property of a phase velocity different from that of free space. By closely packing waveguides of particular cross section, a synthetic

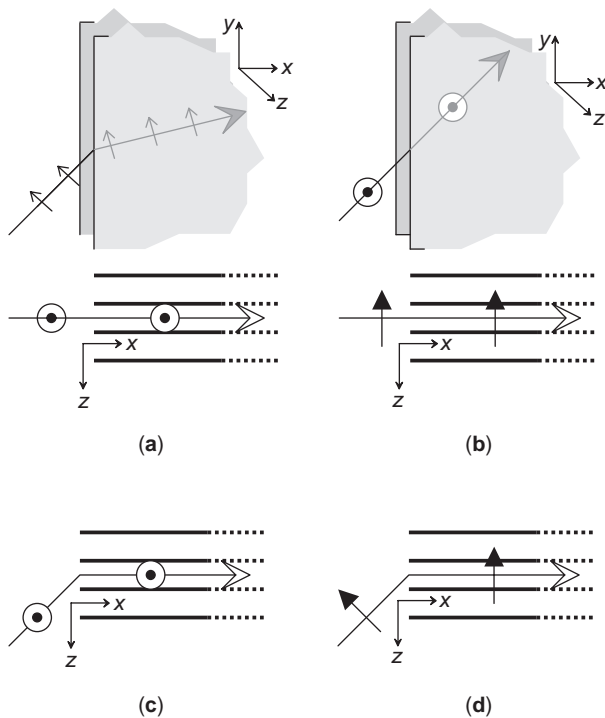

Figure 2. Electromagnetic wave passing through parallel conducting planes: (a, b): Incidence parallel to the plane of the conductors for an E field polarized parallel and normal to the conductors, respectively; (c,d) incidence at an angle to the conductors.

material is created that will have a controlled value of n , and can be applied to the construction of lens antennas. In fact, any device or medium that can be employed to control the phase of a wave over a surface, can be applied as an artificial dielectric medium. In a later section we shall see that even coaxial transmission lines can be applied for this purpose.

A number of synthetic dielectrics have also been developed. They consist variously of plastic bases that have been impregnated with regular lattices of metal spheres, wires, and strips of various cross sections. In some instances, the inclusions are dielectric spheres, or voids such as holes.

In the interest of clarity, we shall discern between *natural dielectrics* when the refractive index $n > 1$, and *artificial dielectrics* if $n < 1$. Synthetic dielectrics will not be treated as examples, and the above definitions will suffice.

1.2. Single-Surface Dielectric Lens

The function of a lens antenna is to collimate all energy radiated from a source. Traveling from the source, all electrical paths to the lens aperture must be of the same length for the rays to add constructively.

In Fig. 3a, the simplest lens is illustrated, where one surface has been chosen to be plane, and the refractive index is $n > 1$. The electrical pathlength of a ray traveling the path FPP' must be the same for P anywhere on the lens surface. Refraction occurs only at the curved surface P , and the rays exit in a direction normal to the plane surface of the lens at P' . The body that satisfies this condition is readily described mathematically, and it turns out that the curved surface of the lens is a hyperbola, with the focus at the origin [1]. Inspection of Fig. 3a leads to the conclusion that the lens can be gainfully increased in size only until the angle subtended by the lens approximates the asymptotes of the hyperbola, and this limits the practical size of the lens.

Because no refraction occurs at plane P' , such lenses are termed *single-surface*. Note that the position of the plane at P' does not enter into any equation, and we are free to make the lens as thick as we like (not that that would be of any advantage). The point being that the lens

Figure 3. (a) Single-surface dielectric lens with one flat surface; (b) lens with circular arc surface $n > 1$.

Figure 4. Single-surface lens, with $n < 1$, as for parallel-plate waveguide lenses.

in effect collimates radiation from a less to a denser medium.

An alternative single-surface lens is shown in Fig. 3b. Here the surface P' is chosen to describe an arc of a circle; thus, P' is an equiphase surface with radius ρ_1 , and no refraction occurs there, because incidence is normal to the surface. Once again, we are free to choose the radius as large or as small as we like, because no refraction occurs, and any additional path in the dielectric material is common to all rays. In fact, we may choose the radius to be so small that F lies within the dielectric, and an observer to the right of P will not be able to determine whether F lies in free space, or whether the body to the left of P' is also immersed in the dielectric. For the waves arriving at QQ' to be in phase across the surface, the electrical pathlength $P'PQ$ must be constant. The solution is once again readily found to be that the curve P' must be described by an ellipse, with the focus of the lens at the focal point of the ellipse farthest from QQ' . This lens is the complement of the planoconvex lens described above. It collimates radiation from a dense to a less dense medium.

In Section 1.1, *parallel plates* and *waveguides* as synthetic dielectrics were discussed. Bearing in mind the fact that for these cases the index of refraction, $n < 1$, the wave travels in effect from a more to a less dense material if we keep one surface plane (equiphase). It should therefore not come as a surprise to find that the locus of points describing a parallel-plate lens with one equiphase surface, is an ellipse, as shown in Fig. 4. Note that Snell's law is automatically satisfied in the case of all single-surface lenses.

1.3. Zoned Lenses

The lenses described above present a problem, insofar as that for the practical ranges of refractive index, they are going to be extremely bulky. In order to alleviate both the bulkiness and the dissipation loss through the lens associated with it, the surface of the lens can be *zoned*, that is, subdivided into sections for which the electrical pathlength through each section, is equal *within a wavelength* (or integral number of wavelengths). Waves that travel an integral number of wavelengths further or less, will, of

Figure 5. Single-surface lens, $n > 1$, zoned on the planar side (a) and on the convex side (b); artificial dielectric lens with $n < 1$ (c).

course, combine in phase with each other. This is achieved if the steps are equal to $\lambda/(n - 1)$. This is shown in Fig. 5a for zoning on the flat surface of a natural dielectric lens, and in Fig. 5b, where the curved surface of the same lens has been zoned. Zoning for an artificial dielectric lens is shown in Fig. 5c.

In the latter case, each zone is a section of a different ellipse, because as the zoned sections are stepped, the focal distance changes. The zoning exercise is therefore not a simple geometric shift of the lens surface, but a separate lens design for each zone. Fortunately, the mathematics is not complicated, and is given in the next section. Note that this is a frequency-dependent solution, and zoning immediately restricts the useful bandwidth of the antenna.

1.4. Lenses with Two Refracting Surfaces

If the lens has two refracting surfaces (neither of which is equiphase), not only does the equal electrical length

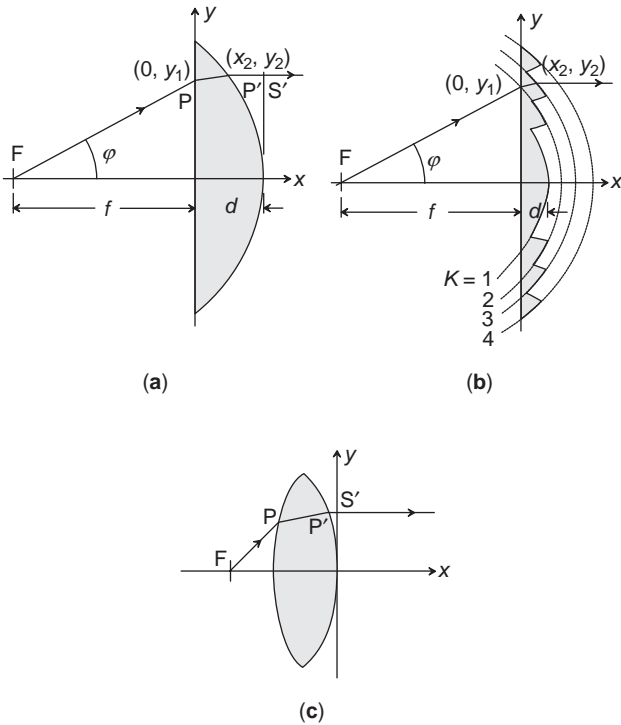

Figure 6. Lenses with two refracting surfaces: (a) one surface plane; (b) the same lens, zoned; (c) both surfaces curved.

condition need to be satisfied, but also Snell's law, at each of the refracting surfaces. In the mathematical analysis for such lenses, it will be found that there are more variables than equations, and it becomes necessary to make assumptions to obtain solutions.

In the lens in Fig. 6a, one of the surfaces has been fixed as planar. This immediately removes one degree of freedom, causing a unique solution to exist, in spite of the fact that also Snell's law needs to be satisfied at both surfaces. The zoned version of the same lens is shown in Fig. 6b. In all other instances (where both surfaces are free, as in Fig. 6c), it is found that there is no unique solution for the surfaces, and a practical design involves choices determined by other considerations [2]. Specific design procedures are discussed in a later section.

1.5. Three-Dimensional Lenses

Up to this point, the lenses studied were described by ray optics and were two-dimensional. In practice, three-dimensional structures are needed, often with specific properties in orthogonal planes. Neglecting the fact that there are end effects when a cylindrical structure is finite, the solution for a cylindrical is identical in cross section to that of the two-dimensional solution. Fig. 7a shows the geometry for a cylindrical lens, fed by a line source, which could typically be a slotted waveguide. The illuminating wavefront is cylindrical.

The rigor of deriving the equations for the geometric surfaces in structures that have some symmetry in a spherical coordinate system can be avoided by simply

Figure 7. Cylindrical lens fed by a line source (such as a slotted waveguide) and (b) spherical lens fed by a point source, such as a small horn.

rotating the two-dimensional solution about its axis to obtain solutions with rotational rather than translational symmetry. For convenience, these lenses will be called *spherical*, although they are, of course, not spheres. A spherical lens fed by a point source is shown in Fig. 7b. The illuminating wavefront is spherical.

Both these lenses would be constructed of a natural dielectric, $n > 1$, because of their plano-convex shape. For 3D structures with $n < 1$, parallel-plate lenses are popular because of their light weight and low loss, and two possible structures are shown in Fig. 8; dielectric spacers would be used to hold the conducting sheets in place. The structure for a cylindrical lens with the conducting planes in the x - y plane, is shown in Fig. 8a; the E field is also polarized in this plane, and Snell's law is satisfied over the concave area of the lens. In the lens of Fig. 8b, the conducting planes lie in the x - z plane, as does the E field. It is, however, a constrained lens, and Snell's law is not satisfied over the concave face of the lens. For both examples, an appropriate slotted waveguide for forming a linear source is shown.

Figure 9 shows a spherical lens constructed of parallel plates, and fed by a point source. As with lenses constructed from natural dielectrics, the principles of zoning can be applied to the parallel-plate lenses. Arrays of closely packed waveguides of round, rectangular or hexagonal cross section are used as a constraining medium in the construction of waveguide lenses. When the operating frequency of the lens lies within the frequency band of the

Figure 8. Cylindrical lenses constructed of parallel plates: (a) lens not constrained; (b) lens constrained. An appropriate waveguide linefeed is shown in each case.

Figure 9. Spherical lens constructed from parallel plates.

waveguide, lenses can be constructed that can be zoned in the same way as the dielectric or parallel plate lenses, and Fig. 10 shows schematically the structure of a zoned rectangular waveguide lens with one planar surface and one concave surface. If the correct dimensions are chosen for the elemental waveguides, the appropriate TE mode will propagate as discussed above, and ensure the correct phase delay through the lens. Waveguide lenses constrain the wave in at least one of the major axes [3]. The major advantage of this type of lens is that, because the elemental waveguides are symmetric about the major axes of the lens, the incident wave can be circularly polarized, without any loss of lens action.

Integrated dielectric lenses, with the source embedded in the dielectric of the lens, have found application in integrated systems, where the lens is mounted directly on top of the stripline or microstrip board that feeds the lens and carries the rest of a microwave circuit. Figure 11 shows an example of such a lens.

1.6. Other Lens Systems

In the areas of application where lenses offer the best solution, it is because of their ability to scan a narrow

Figure 10. Cross sections through zoned lens of rectangular waveguide.

Figure 11. Integrated dielectric lens: (a) the lens is shown on a substrate; (b) thin lens with the same focal length.

beam over a relatively wide angle, that they find regular application. In many instances, substantially more complex lens systems satisfy this need. While a more extensive treatment will be given in Section 3, a brief qualitative description is given here. It will be seen that specific conditions need to be met for a lens to properly collimate the radiation of a source that lies off the focus of the lens. One way to ensure a larger focal area is to design a lens with a multiplicity of focal points. This makes it possible to feed the lens from a number of different points, each corresponding to a new position of the beam of the lens.

1.6.1. Constrained Lens. The constrained lens shown in Fig. 12 has two perfect off-axis focal points, from where the radiation will be collimated in a direction off the main axis of the lens. A source illuminating the lens from anywhere on a circular arc with radius f , and centered at the origin O , will cause the lens to scan in a different direction for each position. Because of these points are not foci, the collimation of the beam will not be perfect, but it will be good enough, provided the source lies between F and F' . By arranging a number of sources on the feed arc, a different beam can be scanned for each of the sources illuminating the lens.

A geometric analysis shows that for two symmetric foci the inner surface of the lens must be an ellipse, with the

Figure 12. Constrained lens with two symmetric focal points.

Figure 13. Rotman lens: layout and ray geometry.

Figure 14. Beam cavity of Rotman lens.

two focal points F and F' on the foci of the ellipse. The construction of the lens would be either as in Fig. 8b, of parallel plates, or of stacked waveguides. The choices that will determine the specific shape of the outer surface of the lens, and other design parameters coupled to it, are discussed in Section 3.2.

1.6.2. The Rotman Lens. In the Rotman lens shown in Fig. 13, the lens consists of a structure that does not have a dielectric per se, not even parallel plates. Each of the two lens surfaces consists of a number of antennas, connected one on one by means of a section of coaxial line. The lengths of the lines determine the phase delay that would normally be associated with the delay through a lens section. The lens is fed from a series of points on a curve FF' as for the constrained lens discussed above; the structure makes it possible to change the outer lens surface shape arbitrarily.

The Rotman lens, of course, is a constrained lens, and originally the lens was constructed of parallel plates that bound the wave between the beam ports (the lens illuminating radiators) and the element ports (the inner surface of the lens). Currently, the most popular form of realization has the beam and element ports constructed of etched tapers, with the inner beam cavity area of stripline, as is shown in Fig. 14.

Because of the stringy transmission lines that connect the two faces of the lens, these lenses are also known as “bootlace lenses”.

1.6.3. The R-2R Lens. Another type of bootlace lens is the R-2R lens shown in Fig. 15. In this lens the feeding curve (the beam port) and the inner face of the lens (the element port) both lie on the same circle of radius R , while the array port containing the radiating elements of the array lie on a circle of radius $2R$. The array elements are connected to the element port elements by transmission lines of equal length, and the lens can scan over a wide angle, free of any distortion.

1.6.4. The Luneburg Lens. A unique and interesting lens, first described by Luneburg [4], is shown in Fig. 16.

The Luneburg lens is a spherically symmetric lens with variable index of refraction, given by $n = (2 - r^2)^{1/2}$ for a sphere of unit radius. When the lens is fed at any point on the surface, it produces a plane wave in a direction diametrically opposite to the feedpoint. In view of the symmetry, moving the feedpoint about the surface results in a scanned beam from a direction diametrically opposite the feedpoint.

Because of the problem of manufacturing a body with a predetermined variation of the dielectric, a number of approximations consisting of discrete shells of fixed dielectric constant are used; these are described in Section 3.4.

1.6.5. Fresnel Zone Plate Lenses. The concept of the Fresnel lens dates from the middle of the nineteenth century, but was until recently (as of 2004) seen as an optical rather than an RF or microwave device. It differs radically from the other lenses described in this article, insofar as it does not make use of the principle of refraction, but rather uses reflection and diffraction.

In its simplest form, the Fresnel lens consists of properly spaced concentric rings of alternately transparent

Figure 15. R-2R lens.

Figure 16. Luneburg lens.

and opaque or reflective material. The sizes of the rings are so chosen that the pathlength from the outside diameter to the focus is one-half wavelength longer than the pathlength to the focus from the inside diameter, as shown in Fig. 17. Energy is reflected and diffracted from the rings in such a way that the forward-scattered components add nominally in phase at the focal point of the plate—at least, their phases will differ by less than half a period. Because of very poor aperture efficiency, practical Fresnel lenses have been developed that are constructed from alternate rings of different dielectrics. Zone plate lenses are attractive solutions when low material weight, low absorption loss and flat lens surfaces are relevant design factors.

Figure 17. Fresnel lens. Basic structure is shown in (a); shadowing is illustrated in (b). Use of dielectric annuli is illustrated in (c).

2. LENS DESIGN CONSIDERATIONS

This section addresses a number of practical considerations pertaining to the operation of lens antennas, as well as aspects that have to be taken into consideration with the design of such structures.

2.1. Lens Design Equations

The design equations for the lenses described in Section 1, are derived readily from first principles [1,2]:

For the simple planoconvex lens of Fig. 3a

$$\rho = \frac{(n - 1)f}{n \cos \varphi - 1} \tag{2}$$

$$y = \sqrt{(n^2 - 1)x^2 + 2(n - 1)fx} \tag{3}$$

The maximum thickness of the lens is given by

$$d = \frac{1}{(n + 1)} \left(\sqrt{f^2 + \left(\frac{n + 1}{n - 1}\right)a^2} - f \right) \tag{4}$$

For the elliptical lens (Fig. 3b),

$$\rho_1 = f - d \tag{5}$$

$$\rho_2 = \frac{(n - 1)f}{n - \cos \varphi} \tag{6}$$

$$y_1 = \sqrt{(f - t)^2 - (x_1 + f)^2} \tag{7}$$

$$y_2 = \sqrt{-2 \left[\frac{n - 1}{n} \right] fx_2 - \left[\frac{n^2 - 1}{n^2} \right] x_2^2} \tag{8}$$

The central thickness of the lens given by

$$d = \frac{2\rho_1 - \sqrt{4\rho_1^2 - d^2}}{2(n - 1)} \tag{9}$$

For the concave lens with $n < 1$, as shown in Fig. 4, we obtain

$$r = \frac{(1 - n)f}{1 - n \cos \varphi} \tag{10}$$

$$y = \sqrt{2(1 - n)(-x)f - (1 - n^2)x^2} \tag{11}$$

2.2. Zoning: Equations and Effects

The usefulness and purpose of zoning has been discussed in Section 1. Johnson and Jasik [2] give equations that describe the surfaces of zoned lenses.

Referring to the zoned lens of Fig. 5b, we have

$$\rho = \frac{(n-1)f_1 - (K-1)\lambda}{n \cos \varphi - 1} \quad (12)$$

$$y = \sqrt{(n^2-1)x^2 + 2(n-1)f_1x + 2(K-1)\lambda nx + 2f_1(K-1)\lambda + (K-1)^2\lambda^2}$$

$$K = 1, 2, 3, 4, \dots \quad (13)$$

For the zoned concave lens of Fig. 5c, we obtain

$$r = \frac{(1-n)f_1 + (K-1)\lambda}{1 - n \cos \varphi} \quad (14)$$

$$y = \sqrt{2(1-n)(-x)f_1 - (1-n^2)x^2 - 2(K-1)(-x)n\lambda + 2(K-1)f_1\lambda + (K-1)^2\lambda^2},$$

$$K = 1, 2, 3, 4, \dots \quad (15)$$

The lens shown in Fig. 6b has two surfaces, and its zoning equations are given by

$$x_2 = \left\{ \frac{(K-1)\lambda + (n-1)d + f - \sqrt{f^2 + y_1^2}}{n - \sqrt{1 - \frac{y_1^2}{n^2(f^2 + y_1^2)}}} \right\} \quad (16)$$

$$\times \sqrt{1 - \frac{y_1^2}{n^2(f^2 + y_1^2)}}$$

$$y_2 = y_1 \left[1 + \frac{x_2}{\sqrt{n^2(f^2 + y_1^2) - y_1^2}} \right] \quad (17)$$

$$K = 1, 2, 3, 4, \dots$$

Unfortunately, zoning has some disadvantages; Fig. 18a illustrates one of them. If the lens is a zoned single surface, there will be a solid-angle section in which the energy is not refracted into the lens path. This represents loss. On the other hand, for the zoned two-surface lens shown in Fig. 18b, no energy will be lost, but a section of the aperture will not be illuminated. This will cause degradation of sidelobe performance. If the zoning is done in the plane surface of a single-surface lens, it is possible to achieve a situation with no loss or shadowing. However, this represents the more unattractive case, where the lens retains the shape of the large, curved surface, which is mechanically much more difficult to handle (Fig. 18c). A similar situation arises with lenses where $n < 1$, as shown in Fig. 18d. Ultimately, the decision on the shape of the lens will be determined by practical considerations.

The other major disadvantage of zoning affects bandwidth, in that the zoned lens is inherently frequency-sensitive. But as will be seen in Section 2.5 on bandwidth, there can also be an upside to zoning when applied to parallel-plate or waveguide lenses.

Figure 18. Effects of zoning. Energy in the shaded solid angle in (a) is lost. In (b) there is no loss, but the aperture is shaded. For the stepped lens in (c) there is no loss or shading. Shading in a concave lens is shown in (d).

2.3. Gain and Sidelobe Level

The illumination of the radiating aperture is the primary variable in determining the gain and sidelobe level of an antenna. In certain instances, such as with antenna arrays, extremely intricate field distributions are possible, making for very specific sidelobe performance; associated directly with the sidelobe performance is the gain. Lower sidelobes generally mean a broader beamwidth, and a decrease in gain. Consequently the field in the aperture of the lens is of primary concern.

In the case of a lens with a hyperbolic surface, it has already been pointed out that the maximum size of the lens is limited by the asymptotes. Silver [1] derives an expression for the amplitude distribution over the lens aperture. If the distance from a point on the lens surface to the axis of a spherical lens is given by $r = a \sin \varphi$, and if the source radiates an amplitude of $A(\varphi)$, then the ratio of amplitudes between the source and aperture is given by

$$\frac{A(r)}{A(\varphi)} = \sqrt{\frac{(n \cos \varphi - 1)^3}{f^2(n-1)^2(n - \cos \varphi)}} \quad (18)$$

For the cylindrical hyperbola, the ratio of source to aperture fields is given by

$$\frac{A(y)}{A(\varphi)} = \sqrt{\frac{(n \cos \varphi - 1)^2}{(n-1)f(n - \cos \varphi)}} \quad (19)$$

As the amount of power per unit solid angle radiated from the source is constant, and as the projected area of the lens becomes substantially larger, there will be a severe dropoff of illuminating field toward the edges. In this case, the low edge illumination implies low sidelobe levels and not much can be done to increase the illumination around the edges.

For the lens with an elliptic contour, the corresponding amplitude ratios are

$$\frac{A(r)}{A(\varphi)} = \sqrt{\frac{(n - \cos \varphi)^3}{f^2(n-1)^2(n \cos \varphi - 1)}} \quad (20)$$

and

$$\frac{A(y)}{A(\varphi)} = \sqrt{\frac{(n - \cos \varphi)^2}{(n-1)f(n \cos \varphi - 1)}} \quad (21)$$

For this lens, the limiting variable occurs on the secondary (radiating) side of the lens; the lens cannot be made larger than the largest dimension of the ellipse. In this case, the illumination is substantially stronger at the edges of the lens. Here edge illumination is naturally reduced by practical feeds, such as horns or linear waveguide arrays.

Radiation from the source antenna in any complex antenna system is always designed to illuminate the secondary element with the largest possible portion of the available power. Spillover from the primary radiator represents a loss of gain, and it is usually attempted to ensure that spillover is as small as possible, by choosing an appropriate element or elements for the purpose.

2.4. Reflections and Loss

In the qualitative discussion on lenses so far attention has been given only to the direct ray paths that contribute to the formation of the radiation properties of the antenna. Unfortunately, at each interface between two materials, reflection occurs; such reflections in general do not add in a way that enhances the performance of the antenna.

Consider, for instance, the lens in Fig. 3a. The wave striking the plane interface between the lens and air is partially reflected back into the lens, to retrace along the same path on which it had entered the lens, and is concentrated at the focal point, causing a substantial mismatch at the feedpoint. Similarly, at the circular surface in Fig. 3b, where the first circular wavefront strikes the lens, the wave is partially reflected straight back at the source.

Referring to Fig. 1, for perpendicular polarization, (i.e., the electric field perpendicular to the plane of incidence), the coefficient of reflection at an interface is given by

$$\rho_{\perp} = \frac{E_r}{E_i} = \frac{\cos \varphi_i - \sqrt{n^2 - \sin^2 \varphi_i}}{\cos \varphi_i + \sqrt{n^2 - \sin^2 \varphi_i}} \quad (22)$$

and for parallel polarization

$$\rho_{\parallel} = \frac{E_r}{E_i} = \frac{n^2 \cos \varphi_i - \sqrt{n^2 - \sin^2 \varphi_i}}{n^2 \cos \varphi_i + \sqrt{n^2 - \sin^2 \varphi_i}} \quad (23)$$

where E_r is the reflected field strength and E_i is the incident field.

At perpendicular incidence, the magnitude of the reflected field could be of the order of the surface reflection coefficient for a plane wave. For a dielectric constant of 2.56, $n = 1.6$, this could be as high as -12.7 dB, corresponding to a loss in gain of 0.24 dB.

As in optical instruments, the lens may be coated in a quarter-wavelength layer of index of refraction, $n_l = n^{1/2}$ to ensure a match between the two media. Application at a plane surface is obviously relatively easy, but at a slope the effective thickness in the direction of the incident wave must be used. Certain other devices are employed to either cancel the reflected power, or to concentrate it elsewhere. A slight offset of the feed from the lens axis will focus the reflections at a point outside the feed antenna. In a method similar to zoning, the lens may be split and half of it displaced axially by a quarter-wavelength in the lens medium, causing the reflected power from the two halves to cancel. The two halves will, of course, have focal lengths that differ by a quarter-wavelength in the medium. Other reflections that do not add constructively at the feedpoint may not cause mismatch, but will, of course, represent a loss of power, and thus reduced gain. Johnson and Jasik [2] describe a number of different surface treatments that can be applied to the lens surface in order to affect a quarter-wave match.

Although not caused by reflection, dielectric losses can be lumped conveniently with reflection losses. In the case of natural dielectrics, all materials are lossy to some extent. In some parallel-plate lenses, a dielectric is used to separate the conducting plates; in such arrays both conductive loss and dielectric loss will occur inside the lens. For a zoned dielectric lens, the attenuation through the dielectric is given [2] approximately by $27.3 (\tan \delta) n/(n-1)$ dB, and for a stepped polystyrene lens at 10 GHz, with $\epsilon' = 2.54$ and $\tan \delta = 4.3 \times 10^{-4}$ is about 0.02 dB.

2.5. Bandwidth

A simple dielectric lens would theoretically have infinite bandwidth, and in practice the bandwidth is in fact very large. This is obviously dependent on the material, and if the latter is not dispersive (v is not a function of frequency), the lens will be wideband. On the other hand, parallel-plate and waveguide lenses are extremely dispersive, and will exhibit narrow bandwidth.

As soon as the lens is zoned, though, the structure becomes frequency-dependent, and the effective bandwidth is a function of the number of zones. Conventionally, it is assumed that if an antenna has been designed for a specific radiation pattern, then degradation of the pattern will be acceptable only up to the point where the phase error across the aperture of the antenna amounts to 22.5° or $\lambda/8$. Silver [1] derives that a lens with K zones separated by steps of one wavelength will have a bandwidth of approximately $25/(K-1)$ percent. A lens with six zones (five steps) will have a bandwidth of 5%.

The lenses with $n < 1$ are all dispersive, as discussed in Section 1.1. In practice, the bandwidth limitation caused by the dispersiveness of the lens material is much higher than that caused by zoning. With the same $\lambda/8$ error allowed across the width of the lens, the bandwidth is

given by approximately

$$B \approx \frac{25n_0}{(1+n_0)} \frac{\lambda_0}{(1-n_0)t} \quad (24)$$

where n_0 , λ_0 are, respectively, the refractive index and wavelength at the center frequency and t is the difference in thickness of the lens between the edge and the center.

Because the waveguide or parallel-plate medium is so dispersive, reducing its length by zoning actually increases the useful bandwidth. For K zones, the bandwidth is given approximately by [1]

$$B \approx \frac{25}{(K-1) + \frac{(1+n_0)(1-n_0)t}{n_0 \lambda_0}} \quad (25)$$

Under the assumption that $(1-n_0)t$ is approximately one wavelength at the thickest sections of the lens, we have

$$B \approx \frac{25n_0}{1+Kn_0} \quad (26)$$

Proctor [5] analyses and describes methods of constructing lenses from slot-loaded ridged waveguides. The structures make it possible to improve the scanning ability, and also eliminates the discontinuities associated with zones. The spacing of the plates in a waveguide lens has a critical aspect, in that at each of the plates, diffraction occurs. In order to avoid the diffracted fields adding constructively, the plate spacing must be kept below the value determined by the inequality $\lambda_0/d > 1 + \sin \varphi$, where φ is the angle of incidence of the wave.

2.6. Natural and Artificial Dielectrics

A wide variety of dielectric materials, specifically manufactured for application in microwave applications, are available in the market. These can be divided in a number of classes. Materials with very low dielectric constant are usually some type of foam with a plastic base. Materials with a dielectric constant in the region of 2–4 are mainly plastics. Examples are Teflon ($\epsilon_r = 2.04$), Teflon fiberglass ($\epsilon_r = 2.7$), Plexiglas ($\epsilon_r = 2.56$), and polystyrene ($\epsilon_r = 2.54$). Ceramic materials such as BaZnTa ($\epsilon_r = 30$), BaTiO₃ (barium titanate, $\epsilon_r = 30$), and BaTiO₉ (barium tetratitanate, $\epsilon_r = 38$), [6] are often mixed with plastics. One example of a commercial product is described as a ceramic-filled cross-linked plastic, with dielectric constants available as $\epsilon_r = 3, 4, 5, 6, 7, 8, 9, 10, 12, 15, 20$.

In Section 1, the use of parallel plates as an artificial dielectric was discussed. For the transverse electric (TE) wave (E field parallel to conducting plates), the propagation velocity varies rapidly as the wavelength approaches double the plate spacing:

$$v = \frac{c}{\sqrt{(1 - \lambda/\lambda_c)^2}} \quad (27)$$

In the TE mode, the refractive index is given by

$$n = \sqrt{1 - (\lambda/\lambda_c)^2} \quad (28)$$

where the cutoff wavelength $\lambda_c = 2a$ for a plate separation of a .

For waveguides operating in the TE mode, Equation (28) holds for parallel plates. In this instance, a rectangular waveguide of width a has $\lambda_c = 2a$; a regular hexagon with a between parallel sides has $\lambda_c = 1.792a$, and a circular waveguide with radius a has $\lambda_c = 1.705a$. The application of waveguides in lens design is comprehensively discussed by Rudge [3].

Brown [7] gives an extensive theoretical treatment of artificial dielectrics. They are categorized into two classes—“delay dielectrics” and “phase advance dielectrics”—the derivation of which is self-explanatory. Parallel plates or waveguides are obviously in the second group, because of the value of the refractive index. Also in this group of structures are arrays of metallic rods, as well as perforated metallic plates that are held in position by means of a dielectric supporting medium such as a dielectric foam. Among the delay dielectrics are metallic strips or metallic disks suspended in a substrate. Jasik [8] provides comprehensive information on a wide variety of structures, including those mentioned above. An interesting variation is described by Milne [9], who uses the phase shift (negative below resonance and positive above) of a wave traveling through an array of dipoles, to design the necessary delay structure. Other authors treat the general problem of composite dielectric materials [10,11].

2.7. Aberrations

In optical systems, the main purpose is usually to form an image, either real or virtual. In the functioning of lens antennas, this is not relevant, except to the extent that an image is composed of a collection of points that do not all lie on a single focal point. In a lens antenna the equivalent is that there are sources that illuminate the lens, that lie off the focal point, as well as nonideal characteristics in lens design and performance. Analogous to the aberrations that occur in optical systems, equivalent aberrations occur in lens antennas, and a number of different types of aberration exist; these are comprehensively treated by Lo and Lee [12]. The source of aberrations in lens antennas is a phase error with respect to a reference plane in the aperture of the lens. The phase error could be caused by inherent properties such as the lens not meeting the equal phase path condition or the source being located away from the focus of the lens.

If the phase error across the aperture is linear, it results in the beam squinting off boresight. In practice this is not a problem with lens antennas. Many examples exist in antenna theory of where a quadratic phase error is introduced to an aperture, and the effect of such errors is well known (see, e.g., Ref. 1, Chap. 6.7; Ref. 2, Chap. 2.8; and Ref. 9).

In lens antennas, the most important aberration is coma, because it relates the formation of a properly

Figure 19. The Abbe sine condition.

collimated beam by a point lying off the focal point. In an 1873 paper, E. Abbe postulated that in order for any optical system to form an image, it must satisfy the condition that the principal surface, defined as the *locus of intersections of the initial and final paths of rays*, is spherical. An optical system satisfying this condition thus acts as a simple spherical lens, and the “Abbe sine condition” is satisfied. Referring to Fig. 19, $h/\sin \varphi = f$. The circular curvature of radius f satisfies the condition, as does the lens shown, because the initial and final rays intersect on the radius f . It is now also clear that the simple planoconvex lens of Fig. 3(a) cannot satisfy this condition.

Note that a simple parabolic mirror does not satisfy the Abbe sine condition, either, since the principal surface is the paraboloid itself. Paraxial rays (rays incident on the mirror and parallel to the optical axis) will focus at a point, but off-axis sources will not. It is possible to meet the Abbe sine condition with two refracting surfaces, as discussed in Section 3.1.

3. WIDE-ANGLE AND SCANNING LENSES

3.1. Wide-Angle Dielectric Lenses

The inability of the lens to collimate properly the radiation from a source offset from the focal axis of the lens is a key element in the performance of a lens designed for wide-angle scanning, and a variety of approaches to improve the scanning properties of dielectric lenses have been developed. The simple hyperboloidal lens is not suitable for substantially displaced feeds in order to scan the mainbeam, and the effects on the lens performance with feed displacement have been analyzed by Kreutel [13]. For small values of the ratio between focal length and diameter f/D and small values of n , coma dominates; with increase in these parameters, astigmatism gradually becomes the dominant aberration.

Making use of thin-lens theory, Rotman [14] develops an analysis in which the zoned lens is approximated by an ideally thin spherical shell. This is applied to evaluate the phase aberrations in the aperture plane of the lens, which are caused by off-axis scanning and deviations from the

design frequency. A set of universal curves, that predict the decrease in directive gain of the lens as function of scan angle and frequency is developed from this theory.

By shaping the lens for aperture distribution control, specific radiation patterns can be achieved through use of the procedure described by Lee [15]. For multiple-beam applications, the design procedure makes it possible to reduce the phase error for off-axis beams by means of coma correction zoning.

A dielectric lens with two refracting surfaces introduces an additional variable, which makes it possible to design a lens with two conjugate off-axis focal points. Peebles [16] describes a procedure for design and analysis of a bifocal dielectric lens with these properties. The lens provides good off-axis performance, and a high-gain radiation pattern over a large field of view. Quadratic phase error is reduced if the feed is constrained along an optimized focal arc. The method of generic curve series has been used [17] to obtain profiles for antennas that have a predetermined aperture amplitude distribution from a given source distribution, or for agreement with the Abbe sine condition.

3.2. Wide-Angle Waveguide Lenses

As has been pointed out for the family of dielectric lenses above, it is possible to obtain wide scan angle performance by ignoring the Abbe sine condition, if two perfect, symmetric off-axis foci are chosen, and illumination of the lens is along a circular path between the two foci. The approach was first proposed by Ruze [18]. For the lens to collimate the radiation, it is found that the inner surface of the lens must be an ellipse, with the foci of the ellipse lying on the chosen focal points of the lens. The problem has three variables (inner and outer surfaces of the lens, and index of refraction), and two variables are fixed by choosing the two foci. This leaves a choice of either the shape of the outer surface, with n to be determined, or, if n is chosen, the outer surface to be determined. It is also possible to choose a third focal point that lies on the axis of the lens.

If the on-axis focal point is chosen, it is chosen such that second-order phase deviation is zero. It is then found that points that lie on an arc of a circle of radius f , centered at the origin O , as shown in Fig. 12, will have good scan performance. Different source antennas, all lying on the arc FF' , will cause beams to be radiated from the lens in different directions.

For the case of a single focal point, the inner surface is described by a circle of radius f ; this forms a sphere when the lens is changed to a 3D body. The outer surface is an ellipsoid described by

$$\frac{y_2^2}{f^2} + \left[\frac{x_2 - d - fn/(1-n)}{fn/(1-n)} \right]^2 = 1 \quad (29)$$

where f is the focal length, n is the refractive index, and d is the minimum thickness of the lens.

If the lens is bifocal, the inner surface is an ellipsoid with focal points at the lens foci, and the surface described

by

$$\frac{y_1^2}{f^2} + \left[\frac{x_1 + f \cos \psi}{f \cos \psi} \right]^2 = 1 \quad (30)$$

The outer surface is also an ellipsoid, described by

$$\frac{y_2^2}{f^2} + \left[\frac{x_2 - d - (nf \cos \psi)/(\cos \psi - n)}{(nf \cos \psi)/(\cos \psi - n)} \right]^2 = 1 \quad (31)$$

The design of a conventional waveguide lens is based on the principle of equal phase delay for the different rays. However, the rays at the edge of the lens have substantially farther to travel than will those in the center, and this inevitably means that, if the frequency changes from the center frequency, the time delay through the lens changes, leading to phase error, and decreased bandwidth. As was pointed out earlier, this situation is alleviated by zoning. Ajioka and Ramsey [19] describe a design procedure that combines constant group delay characteristics with wideband performance.

3.3. Bootlace Lenses

3.3.1. The Rotman Lens. The Rotman lens [20] is one of a family of lenses popularly known as “bootlace lenses”, because of the multitude of transmission lines connecting the inner and outer surfaces of the lens. A brief description of the basic operation of the Rotman lens (as it is usually referred to) was given in Section 1.6. The Rotman lens has two off-axis conjugate focal points and one on-axis focal point. The fact that the shape of the outer surface of the lens can be, in effect, arbitrarily chosen makes it possible to choose four independent conditions to determine the lens parameters. Rotman and Turner select the straight front face of the lens, the two off-axis focal points, and the on-axis focal point. The ray geometry of the lens is shown in Fig. 20. They discuss the merits of different choices for the position of the on-axis focal point.

The lens illustrated is two-dimensional (2D), and cylindrical versions can be constructed by stacking a number of the lenses. Note that the area between the beam and element ports is often referred to as “the lens.” Strictly speaking, the lens comprises the elements in the element port (the inner surface of the lens), the connecting transmission lines, and the radiating array (the outer surface of the lens). The region between the beam port that illuminates the lens, and the element port that forms the inner surface, will be termed the *beam cavity*, and it can be constructed in a variety of media. For the beam and element ports as waveguide horns, the beam cavity can be parallel plates. If the elements of beam and element ports are wideband tapers, stripline or microstrip would be indicated, as is currently common practice. The lens can also be used as a linear scanning feed for a cylindrical reflector, as described by Rotman and Turner.

Musa and Smith [21] describe factors that limit the performance of microstrip lenses compared to parallel-plate lenses. Amongst others, it is necessary to pay specific attention to the design of the beam cavity area. Also, the

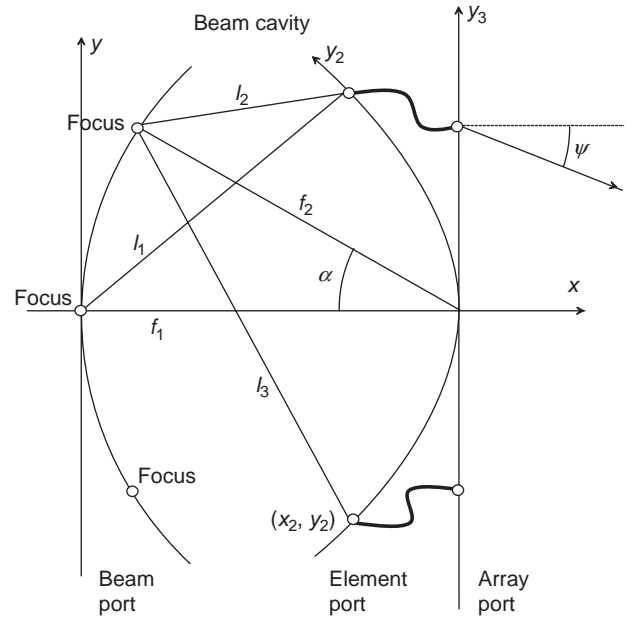

Figure 20. Definitions in the design of a Rotman lens, after Hansen [28]. (With permission, copyright © 1991; IEEE).

direction in which the elements in both ports point should be considered.

A modification to the Rotman lens by Archer [22] has the beam cavity area filled with dielectric. This has the effect of reducing the linear dimensions of the lens by a factor of $n = (\epsilon_r)^{1/2}$. Referring to Fig. 20, if the angle subtended between the focal point and the axis is α and the beam points in a direction ψ , then the ratio of sine of the angles, $\gamma = \sin \psi / \sin \alpha$. For $\gamma > 1$, a design would give large scan angles, while for $\gamma < 1$ the lens will be physically small.

As with any antenna design, the radiation pattern of the antenna is an important parameter, and it is possible to design for predetermined sidelobe patterns. Thomas [23] describes a design in which -30 -dB sidelobe levels were achieved over a 10% bandwidth by the superposition of multiple orthogonal beams; it is shown that the Taylor line source distribution can be described as just such a superposition. Only three beams were sufficient to provide a good approximation to the exact Taylor distribution; the design, however, necessitates a substantial increase in the complexity of the feeding system.

Two or more beams are orthogonal if a signal input to the beam port of one beam gives rise to an output in only that beam, with no signal appearing in any of the other beam patterns or ports. The Rotman and other wide-angle lenses being lenses with multiple beams, this is an important consideration in the design of an antenna, and Hansen [24] explains the effects of nonorthogonality, such as loss of efficiency and changes in sidelobe pattern.

A Rotman lens feed network for a beam forming network implementation employing a 2D stack of Rotman lenses to produce multiple overlapping beams that are scanned in both elevation and azimuth directions is described by Chan and Rao [25]. They present the

development of a compact beamforming network using multiple Rotman lenses having identical design and producing multiple beams with a hexagonal grid. The design of the lens employs dual-port excitations for the beam ports in order to minimize the spillover losses within the lens.

Three-dimensional lenses with two, three, and four perfect focal points are described by Rao [26]. Lenses with more focal points can be scanned to much larger angles in one plane; a tradeoff with the scanning ability in the orthogonal plane exists. In the design procedure described, the lens cross section in the plane in which the focal points lie is first obtained as a 2D solution, and then extended to a three-dimensional (3D) solution by rotating the lens profile around the focal point axis of the lens. In the design procedure proposed in Ref. 27, the planar feed locus of a 2D design is replaced by a curved feed locus optimized to minimize pathlength errors. The design procedure can be extended to a quadrifocal lens with four foci on a circular arc in the plane of the 2D design.

Hansen [24] shows that rotating a Rotman lens to form a symmetric lens does not yield good results and that a circular focus is not possible. The four perfect foci cannot be located with quadrantal symmetry.

3.3.2. Design Procedure. A very substantial body of research and development has been established on the Rotman lens. However, Hansen [28] has published an efficient design procedure that very clearly sets out what the interrelationships between the various choices in the design of Rotman lenses are. The same optical pathlength equality condition as before is applied to the structure of Fig. 20. Note that the position of the focal arc, which contains the three focal points, is not yet specified at this stage. The design equations are repeated here in Hansen’s nomenclature, in order to simplify use of his paper for design purposes.

The problem is defined in terms of the relationship between six basic design parameters, namely, the focal angle α , the focal ratio $\beta = f_2/f_1$, which is the ratio between upper and central focal lengths, the beam angle to ray angle ratio $\gamma = \sin \psi / \sin \alpha$, the maximum beam angle ψ_m , focal length f_1/λ and array element spacing d/λ .

All the dimensions are normalized to the principal focal length, f_1 . The ratio of the upper to central focal length is given by

$$\beta = \frac{f_2}{f_1} \tag{32}$$

as defined previously

$$\gamma = \frac{\sin \psi}{\sin \alpha} \tag{33}$$

A convenient parameter that relates the distance y_3 of any point on the array axis to the principal focal length f_1 is given by

$$\zeta = \frac{y_3 \gamma}{f_1} \tag{34}$$

This parameter controls the portion of the phase and amplitude error that the lens experiences. For a lens with NE radiating elements, spaced a distance d apart, the maximum value that y_3 can have is given by $y_{\max} = (NE - 1)d/2$. Substituting gives

$$\zeta_{\max} = \frac{(NE - 1)\gamma d}{2f_1} \tag{35}$$

An upper limit on ζ occurs when the tangent to the element port curve is vertical; this coincides with $w = 0$. This value of ζ is given by

$$\zeta_{w=0} = \frac{2\sqrt{1 - \beta C}}{S} \sqrt{1 - \frac{1 - \beta C}{S^2}} \tag{36}$$

where $C = \cos \alpha$, $S = \sin \alpha$.

The linelength w that connects the elements on the element port to the array elements is given by the quadratic lens equation

$$a \left(\frac{w}{f_1} \right)^2 + b \frac{w}{f_1} + c = 0, \tag{37}$$

where the coefficients of the equation involve the parameters α , β , and γ and are given by

$$a = 1 - \frac{(1 - \beta)^2}{(1 - \beta C)^2} - \frac{\zeta^2}{\beta^2} \tag{38}$$

$$b = -2 + \frac{2\zeta^2}{\beta} + \frac{2(1 - \beta)}{1 - \beta C} - \frac{\zeta^2 S^2 (1 - \beta)}{(1 - \beta C)^2} \tag{39}$$

$$c = -\zeta^2 + \frac{\zeta^2 S^2}{1 - \beta C} - \frac{\zeta^4 S^4}{4(1 - \beta C)^2} \tag{40}$$

If the maximum beam angle is given by ψ_m , then the maximum allowable array element spacing that will avoid the creation of grating lobes is given by

$$\frac{d}{\lambda} = \frac{1}{\sqrt{2 + \sin \psi_m}} \tag{41}$$

The task at hand is to determine the optimum values for α , β , γ , and f_1/λ .

Hansen sets out the design procedure that amongst others considers the following:

1. The useful range for ζ is roughly from 0.5 to 0.8, and from this a value of β for a given α follows.
2. Six charts in Hansen’s paper [28] show the effect of the choice of variables. It has a bearing on lens width, which in turn affects spillover loss, transmission line loss, amplitude errors, and other parameters.
3. A value of α is chosen that makes the two surfaces of the beam cavity approximately the same height. β has a similar effect to α , and tabulated values for pairs of these two variables are given.

4. Changing γ leaves the port curves relatively unaffected, but the relative positions of the foci change.
5. Changing values of ψ_m spreads the beam ports apart, and determines the maximum element spacing.
6. Changing the focal length changes the separation between the ports, as well as all spacings.
7. Curves showing the effect of parameter choices on phase and amplitude errors are given.
8. Finally, the gain of the lens array can be calculated from [3, Chap. 9]

$$G = \frac{\left| \sum_{n=1}^N A_n \right|^2}{\sum_{n=1}^N \sum_{m=1}^N A_n A_m^* \sin c(n-m)2\pi d/\lambda} \quad (42)$$

where A_n , is the excitation of the array elements.

With the performance parameters frequency range, number of beams, and maximum scan known, the number and spacing of the radiating elements is determined. The maximum value of beam element spacing is limited by the maximum scan angle, and occurs when $d/\lambda = 1/(2 + \sin \psi_m)$. At the center frequency, making use of the guidelines given, α , β , and γ are selected to ensure that the lens meets certain practical and realistic criteria of size and proportion. Once the design parameters have been determined, the gain of the lens can be calculated. It is also possible to make the beam port arc elliptical rather than circular, but Hansen points out that this is not usually warranted, except for very large lenses. The design procedure also includes an evaluation of phase and amplitude errors.

Hansen [24] points out that in practice, bootlace and other lenses are not designed with discrete foci. Rather, the optimum design is a minimax solution for circles of least confusion; that is, aberrations are minimized over the aperture in a sense such as least mean squares. The resultant design produces slightly undefined foci, but better performance. The use of determining the foci, lies in classifying lenses, and developing a sense of how errors are related to lens geometry.

3.3.3. Analysis. The design procedure described above yields the basic dimensions of the lens. However, there are many other aspects that pertain to the physical realization of any given design and make it almost impossible to do a complete design as the result of a sequence of steps. Once the basic design has been achieved, the practical realization of the design needs to be brought into the picture, and to this purpose, analysis methods are very important.

Peterson and Rausch [29] describe an analysis procedure that takes into consideration aspects of the lens design such as the cavity sidewall and port widths, which are parameters not specified by the design procedure. These parameters substantially affect the sidelobe level and insertion loss. The effect of mutual coupling is also included in the analysis procedure. As an example, they quote measured sidelobe levels of -17 dB with straight sidewalls for the beam cavity, while with triangular side-

walls, the sidelobe level improved to -32 dB for a lens with 34 array ports and 19 beam ports. The design sidelobe level was -40 dB, Taylor $n = 3$.

Yuan et al. [30] describe an analysis procedure for Rotman lenses based on a hybrid least-squares finite/transfinite-element method. They point out that most design procedures are based on ray optics, and neglects the effects of port reflections, mutual coupling between elements, and multiple scattering between ports. The procedure used yields the distribution of the electromagnetic fields in the lens, as well as the scattering parameters. They illustrate their procedure by comparing the calculated and measured results for a microstrip Rotman lens with nine beam ports and eight array ports.

3.3.4. The R-2R Lens. The R-2R lens is a bootlace lens in which the radiators on the beam port and element port lie on a circle of diameter R , and where the element ports are connected by equal-length radiators. The properties of the lens are readily derived from the geometry of Fig. 21. If the line OP is extended to intersect the circle $2R$ at Q , then Q defines the position that the array element must have that is connected to the element port at P . If OP subtends an angle of φ with the x axis, then the radius to P will subtend an angle of 2φ . It is clear that, even if the beam port and element port radiators were coincidental, the antenna could not scan more than $\pm 90^\circ$.

In practice, in order to locate the beam and element radiators, the antenna has a restricted scan angle. For cases where extremely wide scan angles are necessary, Clapp [31] has developed a solution making use of four or six physical lenses and hybrid junctions to provide up to 360° scanning.

3.4. The Luneburg Lens

Luneburg [4] solves the problem of determining the index of refraction for a spherical lens that collimates the radiation from any point on the surface of the lens in a direction diametrically opposite. As stated in the introduction, the index of refraction needs to vary as $n = (2-r^2)^{1/2}$. The chief advantages of the Luneburg lens are its ability to scan multiple beams over wide angles, as well as the inherently wide bandwidth. The main disadvantages lie in its bulkiness, and associated weight, and the practical difficulty of manufacturing the varying index of refraction.

Figure 21. R-2R lens geometry.

The two-dimensional analysis of the Luneburg lens is given by Peeler and Archer [32]. The relationship between the feed pattern and the aperture field is found to be proportional to $(\sec \psi)^{1/2}$, where ψ is the angle subtended with the axis of the lens, inferring that the lens has a very high edge illumination. They describe the performance of a lens constructed by filling the cavity between two parallel-plates with dielectric, and propagating the TE_{10} waveguide mode, which is also a parallel-plate mode. The separation between the plates is varied to obtain the desired variation in effective index of refraction.

The two-dimensional Luneburg lens finds application as source for a parabolic reflector in a scanning antenna [33]. A variety of other structures, all making use of the dispersive properties of propagation between sets of (not parallel) plates function as Luneburg lenses with 2D radiation patterns [34].

Braun [35] derives expressions for the radiation pattern, beamwidth, sidelobe level, and gain of the spherically symmetric Luneburg lens. Because of the high edge illumination of the aperture, the lens has a high gain, and high sidelobe level, typically at -17 dB.

The fact that the index of refraction has to change with radius, presents a problem. If a choice is made that the lens shall have a single index of refraction, then it is possible to have only one point on the lens surface that will support a ray of the same electrical length as the ray through the center, as well as its mirror image. For a lens of diameter 20 wavelengths, and the point of equal electrical length chosen at 30° from the axis of the lens, it is found that the phase error across the lens is 0.1λ , which is quite acceptable [2, Chap. 18-2]. An increase in the lens diameter will increase the phase error.

An alternative is to construct the lens from shells and an inner sphere of different dielectrics [36]. However, the discrete quantization of the lens into steps in the vicinity of a wavelength or more, causes the appearance of grating lobes in the radiation pattern, and should be guarded against.

In a procedure described by Mosallaei and Rahmat-Samii [37], an optimized design procedure is described that strives to minimize the number of dielectric shells. In a radially uniform design, reduction of the number of shells decreases the gain and increases the occurrence of grating lobes. They make use of a genetic algorithm optimizer to determine the optimum layer thickness and permittivity for the desired gain and sidelobe envelope.

Rondineau et al. [38] describe the design, construction, and performance of a spherical lens constructed by slicing the spherical body into $2N$ disks. Each disk then has to approximate the relevant varying index of refraction; this is achieved by drilling holes through the disks. A larger number of holes along the periphery of each disk approximates the low values of n toward the outside of the lens, while toward the center of each disk, the number of holes are reduced, until, for the central disks, the innermost area is left unpenetrated. In the example cited, there were 20 disks constructed of Teflon with $\epsilon_r = 2.04$. The lens diameter was 150 mm, and at 27.5 GHz had a gain of 28.5 dB. The authors provide full information on determining the thickness of the disks, and the number and spacing of the holes.

An interesting variation on the spherical Luneburg lens is the cylindrical Luneburg lens [39]. In instances where the scanning capabilities of the conventional lens are not needed, a cylindrical lens of finite-length forms a useful lens antenna. The lens can be designed to have a focal point on its surface, and is constructed from a number of concentric cylinders; in the example cited, the lens was constructed by including cylindrical voids to obtain the varying dielectric constant.

A study of the Luneburg lens would be incomplete without mentioning its properties as a radar reflector [2,40]. If the lens is partially capped, then energy incident from a direction opposite to the cap will be reflected back from the cap and reradiated in the same direction, functioning as a very effective radar reflector, which has a large radar cross section over a wide angle.

4. INTEGRATED AND PLANE LENSES

4.1. Integrated Dielectric Lenses

Dielectric lenses are very well suited to integration directly onto millimeter and submillimeterwave circuits, but with the growing application of local and indoor wireless networks, are becoming more relevant at microwave frequencies. Typically, the dielectric lens is mounted directly on the microwave integrated circuit substrate that carries the active microwave network, as shown in Fig. 11a [41]. Feeding is done directly by means of dipoles or slots or pairs of slots [42] etched in a metallized area. Typically, this would be a lens that radiates from a more to a less dense dielectric material, and is therefore an ellipsoid of revolution, as was discussed for the dielectric lenses in Section 1.2.

In its most elemental form, the lens is a solid dielectric, and the source is mounted at the far focus of the ellipsoid. This makes for a lens that is very easily mounted, and it eliminates the reflections that occur when the inner surface of the lens is spherical. However, at the same time a new source of serious mismatch is introduced at the source antenna. In the event that the inner surface of an elliptical lens lies between the two foci of the ellipse that describes the outer lens surface, the phenomenon of doubly reflected rays occurs; of this, the "solid" dielectric lens is an example. A ray leaving the source focus point is partially reflected at the lens surface; this reflected energy travels through the second focal point, strikes the surface once again, and is reflected back to the source. This happens for all possible paths in the lens; because of the properties of the ellipse, all rays thus reflected arrive at the source in phase, causing a mismatch. Neto et al. [43] have analyzed the effects of multiple reflections inside an elliptical dielectric lens operating in the millimeterwave area, and make use of physical optics to derive an expression for the input admittance to the lens. As a matter of interest, Fig. 11b illustrates the condition with the inner surface beyond the two foci.

It is possible to alleviate to an extent the effects of multiple reflections by applying a matching layer to the lens surface, bearing in mind that it needs to be tapered away from the apex of the lens. The problems associated

with the analysis of lenses in the millimeterwave and submillimeterwave-region, are addressed by van der Vorst et al., and use is made of a combination of geometric and physical optics in an efficient body of revolution finite-difference time-domain methods [44]. Integrated lenses can be designed to have multiple beams [45].

Indoor wireless communications are becoming increasingly important as technology expands and the cost of integrated microwave circuits drop. Dielectric lenses that produce shaped beams for the reduction of multipath phenomena and predetermined coverage patterns have been designed and evaluated [46].

4.2. Fresnel Zone Plate Lenses

Unfortunately, the simple Fresnel lens described in Section 1.6 has very poor efficiency; figures of 8–15% are common for lenses with alternate opaque and transparent rings. Consequently the reflective or opaque rings are replaced by rings that serve to reverse the phase. Black and Wiltse [47] achieve this phase reversal by making use of annular rings cut into a single dielectric, or by means of layers of different dielectrics, as shown in Fig. 17a. Lenses with annular slots suffer from shadow blockage as depicted in Fig. 17b. Petosa and Ittipiboon [48] describe a lens constructed in such a fashion, and measured an aperture efficiency of 63% for a lens of 194 mm diameter and f/D of 0.25. Note that the diameter of the lens is determined by the number of Fresnel rings, 12 in this case. The gain was 23 dBi.

A method of construction with each full-wave zone of the lens consisting of four quarter-wave subzones, in turn consisting of concentric dielectric rings of equal thickness, but different permittivity, is described by Hristov and Herben [49]. They constructed practical lenses with an aperture efficiency of more than 50% at 60 GHz. In order to achieve the correct phase shift through the rings, the dielectric constants have to be, respectively, $\epsilon_{r1} = 1$, $\epsilon_{r2} = 6.25$, $\epsilon_{r3} = 4$, and $\epsilon_{r4} = 2.25$. This corresponds to phase shifts of $\Delta\Phi_t = 0^\circ, 90^\circ, 180^\circ, 270^\circ$. Full design information is provided in Ref. 49.

An alternative method of constructing a lens without grooves is proposed by Petosa and Ittipiboon [50], who constructed a lens from a single slab of dielectric. The appropriate dielectric constants are realized by perforating the dielectric material. The lens then consists of a slab of dielectric material with annular rings where the material is penetrated by a lattice of holes. The effective dielectric constant for such a medium is given by

$$\epsilon_{\text{eff}} = \epsilon_r(1 - \alpha) + \alpha \quad (43)$$

where α is the filling factor, given by

$$\alpha = \frac{\pi}{2\sqrt{3}} \left(\frac{d}{s} \right)^2 \quad (44)$$

The holes have a diameter of d and lattice spacing s .

Analysis procedures for determining the performance of lenses include the *uniform and geometrical theory of diffraction* for metal ring lenses on dielectric, and in the

case of the quarter-wave planar lens antenna, ray tracing combined with diffraction theory is used.

LINEAR ANTENNAS

ASOKE K. BHATTACHARYYA
Lincoln University

Historically, using a piece of radiating straight wire as an aerial, or antenna, was a natural choice for wireless communications. This radiating piece of straight wire without curvature is the linear antenna. A simple example of a linear antenna is a two-wire transmission line carrying equal currents in opposite directions and hence no resultant radiation. A two-wire transmission line may be bent to create an efficient radiator such as a dipole. The linear antennas have been treated in numerous references. Some of them are in Refs. 1–13. We will describe key features of linear antennas in this article.

1. SOME RELEVANT TERMS

Before we proceed to discuss linear antennas, we need to define and discuss certain terms in accordance with the Institute of Electrical and Electronics Engineers (IEEE) standard definitions of antenna terminology.

LINEAR ANTENNAS

ASOKE K. BHATTACHARYYA
Lincoln University

Historically, using a piece of radiating straight wire as an aerial, or antenna, was a natural choice for wireless communications. This radiating piece of straight wire without curvature is the linear antenna. A simple example of a linear antenna is a two-wire transmission line carrying equal currents in opposite directions and hence no resultant radiation. A two-wire transmission line may be bent to create an efficient radiator such as a dipole. The linear antennas have been treated in numerous references. Some of them are in Refs. 1–13. We will describe key features of linear antennas in this article.

1. SOME RELEVANT TERMS

Before we proceed to discuss linear antennas, we need to define and discuss certain terms in accordance with the Institute of Electrical and Electronics Engineers (IEEE) standard definitions of antenna terminology.

1.1. Power Radiated, Radiation Intensity, and Radiation Resistance

Electromagnetic waves, by virtue of their transverse nature, propagate in a direction perpendicular to the plane containing the electric field \mathbf{E} and magnetic field \mathbf{H} . The instantaneous Poynting vector \mathbf{P} , which is a measure of the power density associated with the electromagnetic wave, is given by

$$\mathbf{P} = \mathbf{E} \times \mathbf{H} \quad (1)$$

where \mathbf{P} , \mathbf{E} , and \mathbf{H} are instantaneous Poynting vector in watts per square meter, electric field in V/m, and magnetic field in amperes per meter.

The total power P crossing a sphere enclosing the source (antenna/scatterer) at its center is obtained by integrating the power density over the sphere and is given by

$$P = W \hat{n} \cdot dS = W da \quad (2)$$

where W is the instantaneous power crossing the sphere per unit area held perpendicular to the direction of the flow, \hat{n} is the positive outwardly drawn at the point of incidence, and dS is the unit area arbitrarily oriented at the point of incidence. With $\exp(j\omega t)$ variation assumed, the average power density is given by the time-average Poynting vector \mathbf{P}_{av} :

$$\mathbf{W}_{av}(u, v, w) = \frac{1}{2} \text{Re}(\mathbf{E} \times \mathbf{H}^*) \quad (3)$$

The average radiated power is given by

$$\mathbf{P}_{av} = \frac{1}{2} \iint \text{Re}(\mathbf{E} \times \mathbf{H}^*) da \quad (4)$$

The radiation intensity U is defined by the product of power density \mathbf{P}_{rad} and the square of the far-field range (r) and is expressed as

$$U = r^2 P_{rad} \quad (5)$$

The radiation resistance (R_r) is defined as the positive resistance across which the real power radiated (P_{rad}) can be thought of as being dissipated. The relationship between P_r , R_r , the input resistance, and the current I is

$$R_r = \frac{P_r}{I^2} \quad (6)$$

The input resistance of an antenna is a sum of radiation resistance plus the positive resistance due to ohmic losses.

1.2. Radiation Intensity, Directivity, and Gain

The antenna radiates real power in the far zone in space over a solid angle of 4π radians. The radiation intensity $U(\theta, \phi)$, the real power radiated per unit solid angle, is a product of the radiation intensity P_{rad} , the real power per unit solid area on the surface, multiplied by the square (r^2)

of the distance and is given by

$$U(\theta, \phi) = r^2 P_{rad}(\theta, \phi) \quad (7)$$

The total power can be estimated by integrating the radiation over a large sphere enclosing the antenna over 4π radians:

$$P_{rad} = \int_S U d\Omega = \int_{\theta=0}^{\pi} \int_{\phi=0}^{2\pi} U \sin \theta d\theta d\phi \quad (8)$$

An isotropic source, such as an ideal point source, radiates uniformly in all directions and is independent of θ and ϕ , and the radiation intensity U_0 is related to the real power radiated by the simple formula:

$$U_0 = \frac{P_{rad}}{4\pi} \quad (9)$$

The directivity is a measure of how efficiently the antenna is directing the radiation in space, according to the 1983 IEEE standard [14]. The directivity D , a dimensionless quantity, of an antenna is given by

$$D = \frac{U}{U_0} = \frac{4\pi U}{P_{rad}} \quad (10)$$

The directivity is dependent on the direction. If the direction is not specified, the default is the direction of maximum radiation intensity.

The dimensionless maximum directivity D_{max} , denoted by D_0 , is expressed as

$$D_0 = \frac{U_{max}}{U} = \frac{4\pi U_{max}}{P_{rad}} \quad (11)$$

Many practical antennas work with dual polarizations in mutually perpendicular directions, and then the directivity is defined in that particular direction; the total maximum directivity is a sum of directivities in mutually perpendicular directions and is expressed as

$$D_0 = D_{\parallel} + D_{\perp} \quad (12)$$

The mathematical expressions for D_{\parallel} and D_{\perp} are

$$D_{\parallel} = \frac{4\pi U_{\parallel}}{P_{rad\parallel} + P_{rad\perp}} \quad (13a)$$

$$D_{\perp} = \frac{4\pi U_{\perp}}{P_{rad\parallel} + P_{rad\perp}} \quad (13b)$$

1.3. Antenna Gain and Radiation Efficiency

An antenna is a passive device, but it can be designed to radiate more energy in a desired direction. The gain (G) of

an antenna is defined as

$$G = \frac{\text{radiation intensity in maximum direction of radiation } (U_0)}{\text{radiation intensity of a lossless isotropic source with same input}} \quad (14)$$

All practical antennas have losses, and therefore efficiencies of practical antennas are less than 100%. The antenna efficiency (η) is defined as the ratio of the real power radiated in space by the antenna to the real power input at its feed terminals:

Radiation efficiency (η)

$$= \frac{\text{real power radiated by test antenna } (P_{\text{rad}})}{\text{total real input at antenna feed terminals } (P_{\text{in}})} \quad (15)$$

The antenna efficiency η is related to the directivity D and the gain G through the relationship

$$G = \eta D \quad (16)$$

1.3.1. The Vector and Scalar Potentials and Field Calculations Using Potentials. Most of the time a direct solution of Maxwell's equations subject to the boundary conditions for a practical problem becomes difficult. Therefore, it is customary to use intermediary (or auxiliary) functions, called *potential functions*, to obtain solutions of electromagnetic problems. There are four such functions; two of them are scalar (one electric and one magnetic) and two of them are vector (one electric and one magnetic) potentials.

The magnetic vector potential \mathbf{A} is related to the magnetic flux density through the relation $\mathbf{B} = \nabla \times \mathbf{A}$ and the electric scalar potential V is related to \mathbf{E} and \mathbf{A} through the relation $\mathbf{E} = -\nabla V - \dot{\mathbf{A}}$.

The steps to determine the fields at any point due to the linear antenna are as follows: (1) define the current distribution on the dipole; (2) find expressions for the four potentials; (3) transfer the Cartesian components of the magnetic vector potentials to those in spherical polar coordinates; (4) once the magnetic vector potential is determined, the magnetic field at any point is obtained; and (5) what remains to be done is to use Maxwell's equation to determine the electric fields at any point from the magnetic field obtained.

Before we proceed to determine radiated fields, let us discuss the four potentials for this example. The magnetic current I_m is equal to zero since the wire carries a filamentary electric current and hence the electric vector potential F is zero since it is a function of magnetic current only. In this situation, the magnetic vector potential \mathbf{A} is given by

$$\mathbf{A} = \frac{\mu_0}{4\pi} \int_{-dl/2}^{+dl/2} \mathbf{J}(x', y', z') \frac{\exp(-jkR)}{R} dz' \quad (17)$$

where (x', y', z') are source coordinates, (x, y, z) are the field coordinates, R is the distance between the observation point and any point on the source (Fig. 1). \mathbf{J}_z is the z -directed electric current element, and the linear path C is along the length of the source.

Figure 1. (a) The infinitesimal dipole and (b) its coordinate system. This figure geometrically shows how the field at any observation point from an infinitesimal dipole, which is a building block, can be estimated.

2. THE INFINITESIMAL, OR HERTZIAN, DIPOLE

Before we do the analysis for a practical antenna, namely, a linear antenna, let us establish the analysis procedure for an infinitesimal, elementary, or Hertzian dipole. These are building blocks for more complex antenna systems. Since the dipole is infinitesimal, the current is assumed to be constant.

For the infinitesimal dipole (Fig. 1), the current on the infinitesimal dipole is given by

$$\mathbf{J}_e(x', y', z') = \hat{z} \mathbf{J}_0 \quad (18)$$

where

$x' = y' = 0$, since the length of the dipole is infinitesimal and of length dl

$$R = \sqrt{[(x - x')^2 + (y - y')^2 + (z - z')^2]} \\ = \sqrt{(x^2 + y^2 + z^2)} = r(\text{let})$$

With these, the magnetic vector potential A is given by

$$\begin{aligned} A(x, y, z) &= \hat{z} \frac{\mu_0}{4\pi} \exp(-jkr) dz' \\ &= \hat{z} \frac{\mu_0 I_0 dl}{4\pi r} \exp(-jkr) \text{ for } r \neq 0 \end{aligned} \quad (19)$$

(excluding the source)

The components of A are given by

$$A_r = A_z \cos \theta = \frac{\mu_0 I_0 dl}{4\pi r} \exp(-jkr) \cos \theta \quad (20a)$$

$$A_\theta = -A_z \sin \theta = -\frac{\mu_0 I_0 dl}{4\pi r} \exp(-jkr) \sin \theta \quad (20b)$$

$$A_\phi = 0 \quad (20c)$$

Due to symmetry of the radiating dipole, we have $\partial/\partial\phi = 0$; thus we obtain

$$H = \phi \frac{1}{4\pi r} \left[\frac{\partial}{\partial r}(rA_\phi) - \frac{\partial A_r}{\partial \theta} \right] \quad (21)$$

The expressions for magnetic fields are given by

$$\begin{aligned} H_r &= H_\theta = 0 \\ H_\phi &= j \frac{k_0 I_0 dl}{4\pi r} \left[1 + \frac{1}{jkr} \right] \sin \theta \exp(-jkr) \end{aligned} \quad (22)$$

The electric field can be found from a curl relationship:

$$\mathbf{E} = \frac{1}{j\omega\epsilon} \nabla \times \mathbf{H} \quad (23)$$

This gives the three longitudinal and transverse electric field components as

$$E_r = \frac{\mu_0 I_0 dl}{2\pi r^2} \left[1 + \frac{1}{jkr} \right] \cos \theta \exp(-jkr) \quad (24a)$$

$$E_\theta = j\eta_0 \frac{k_0 I_0 \sin \theta}{4\pi r} \left[1 + \frac{1}{jkr} - \frac{1}{(kr)^2} \right] \exp(-jkr) \quad (24b)$$

$$E_\phi = 0 \quad (24c)$$

2.1. Near and Far Fields

The near-field region are at a close enough distance such that $kr \ll 1$:

$$E_r = -j\eta_0 I_0 dl \frac{\exp(-jkr)}{2\pi k_0 r^3} \cos \theta \quad (25a)$$

$$E_\theta \cong -j\eta_0 I_0 dl \frac{\exp(-jkr)}{4\pi k_0 r^3} \sin \theta \quad (25b)$$

$$H_\phi \cong I_0 dl \frac{\exp(-jkr)}{4\pi r^2} \sin \theta \quad (25c)$$

$$E_\phi = H_r = H_\theta = 0 \quad (25d)$$

Several observations are in order. E_r and E_θ have $(1/r^2)$ variation as distance and therefore decays very fast. These are induction components and die down rapidly with distance. The electric field components E_r and E_θ are in time phase, but the magnetic field component H_ϕ is in time quadrature with them. Therefore, there is no time-average power flow associated with them. Hence, the average power radiated will be zero, and the Poynting vector is imaginary. This can easily be verified by integrating the average power density over a sphere in the near region.

The space surrounding the antenna can be divided into three regions, namely, induction, near-field (Fresnel), and far-field regions. The induction region has $1/r^3$ space variation, the near field has $1/r^2$ variation, and the far field has a $1/r$ variation with distance r .

2.2. Far Field

The far-field expression can be obtained with $kr \gg 1$ and by extracting the $(1/r)$ term and is given by

$$E_\theta = j\eta_0 k_0 I_0 dl \frac{\exp(-jkr)}{4\pi r} \sin \theta \quad (26a)$$

$$E_r = E_\phi = H_r = H_\theta = 0 \quad (26b)$$

$$H_\phi = jk_0 I_0 dl \sin \theta \frac{\exp(-jkr)}{4\pi r} \quad (26c)$$

The intrinsic impedance Z_m of the medium is defined as the ratio of the tangential electric and magnetic fields and is given by

$$Z_m = \frac{E_\theta}{H_\phi} = \eta_m \quad (27)$$

2.3. Intermediate-Field Region

For expression for field components in the intermediate region ($kr > 1$), the reader is referred to any standard text on antennas [1].

2.4. Directivity

The radiation intensity U is given by

$$U = r^2 W_{av} \tag{28}$$

where

$$W_{av} = \frac{1}{2} \text{Re}(\mathbf{E} \times \mathbf{H}^*) \tag{29}$$

and

$$U = \frac{r^2}{2\eta_0} |E_\theta(r, \theta, \phi)|^2 \tag{30}$$

The maximum directivity D_0 turns out to be equal to 1.5.

2.5. Radiation Resistance

The radiation resistance is obtained by dividing total power radiated by the lossless antenna by $|I_0|^2/2$ and is given by

$$R_r = 80\pi^2 \left(\frac{dl}{\lambda}\right)^2 \tag{31}$$

3. THE THIN LINEAR ANTENNA

This section deals with the analysis and properties of a finite-length dipole. The wire is considered to be thin such that tangential currents can be neglected and the current can be considered as only linear. The thin linear antenna and its geometry are shown in Fig. 2. The boundary conditions of the current are that the currents are zero at the two ends and maximum at the center. There is experimental evidence that the current distribution is sinusoidal. The current distributions are for a dipole l and for length varying from $\lambda/2$ to λ . Thick dipoles will be treated in a subsequent section.

3.1. The Current Distribution

The current distribution on the thin dipole is given by

$$\mathbf{I}_x(x' = 0, y' = 0, z') = \begin{cases} \hat{z}I_0 \sin[k(l/2 - z')], & 0 \leq z' \leq l/2 \\ \hat{z}I_0 \sin[k(l/2 + z')], & -l/2 \leq z' \leq 0 \end{cases} \tag{32}$$

The current distributions on the linear dipoles for different lengths are shown in Fig. 3, and Fig. 4 shows the current distributions on a half-wave dipole at different times.

3.1.1. Fields and Radiation Patterns. To determine the field due to the dipole, it can be subdivided into small segments. The field at any point is a superposition of the contributions from each of the segments. Since the wire is

Figure 2. (a) Thin linear antenna and (b) its coordinate system. This figure geometrically shows how the field at any observation point can be formulated using the basic building block, namely, the infinitesimal dipole.

very thin, we have $x' = 0$ and $y' = 0$. The electric and magnetic field components due to the elementary infinitesimal dipole segment of length dz' at an arbitrary point are given by

$$dE_0 = j\eta_0 k_0 I_z(x', y', z') \frac{\exp(-jkR)}{4\pi R} \sin \theta dz' \tag{33a}$$

$$dE_r \cong dE_\phi = dH_r = dH_\theta = 0 \tag{33b}$$

$$dH_\phi \cong jk_0 I_z(x', y', z') \frac{\exp(-jkR)}{4\pi R} \sin \theta dz' \tag{33c}$$

where

$$R = \sqrt{x^2 + y^2 + (z - z')^2} = \sqrt{(r^2 - 2rz' \cos \theta + z'^2)}$$

with

$$r^2 = x^2 + y^2 + z^2, \quad z = r \cos \theta$$

The expression for R can be expanded binomially as

$$R = r - z' \cos \theta + \text{higher-order terms decaying very fast with } r \gg z' \tag{34}$$

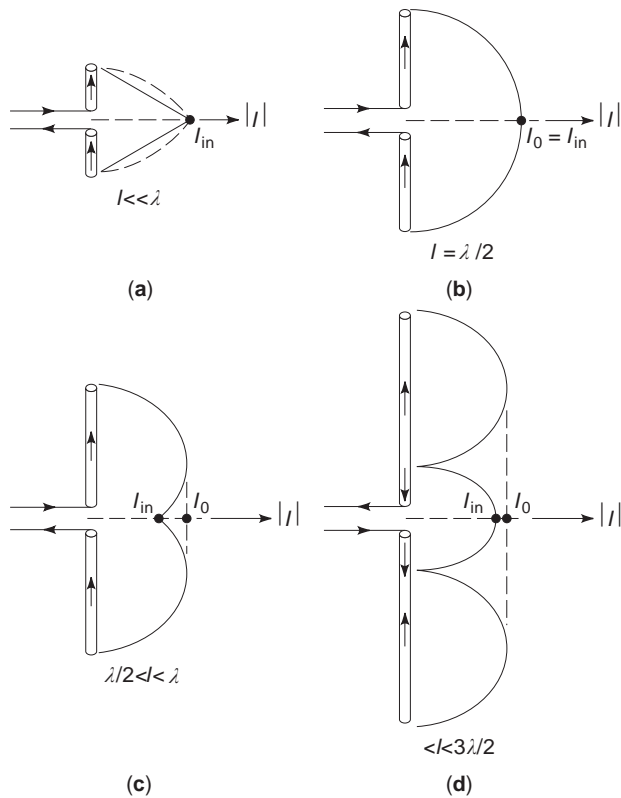

Figure 3. Current distribution on dipoles of different lengths. Different physical lengths of the dipole support different current distributions with varying number of half-sinusoids. This is because at the two ends of the wire, the boundary condition that the current must be zero has to be satisfied.

The total field due to the dipole is obtained by integrating over the whole length. Omitting the straightforward steps, it turns out that the field components E_θ and H_ϕ are given by

$$E_\theta \cong \frac{j\eta_0 I_0}{2\pi} \frac{\exp(-jkr)}{r} \left[\frac{\cos(kl/2 \cos \theta) - \cos(kl/2)}{\sin \theta} \right] \quad (35a)$$

$$H_\phi = E_\theta / \eta_0 \quad (35b)$$

where η_0 is the intrinsic impedance of free space.

To save space we will not describe the derivation of power radiated, which involves $C_i(x)$, $S_i(x)$, and $C_{in}(x)$ functions.

3.1.2. The Radiation Resistance. The resistance can be shown to be given by

$$\begin{aligned} R_r = & \frac{\eta}{2\pi} \{C + \ln(kl) - C(kl) \\ & + \frac{1}{2} \sin(kl) \cdot [S(2kl) - 2S(kl)] \\ & + \frac{1}{2} \cos(kl)[C + \ln(kl/2) \\ & + C(2kl) - 2C(kl)]\} \end{aligned}$$

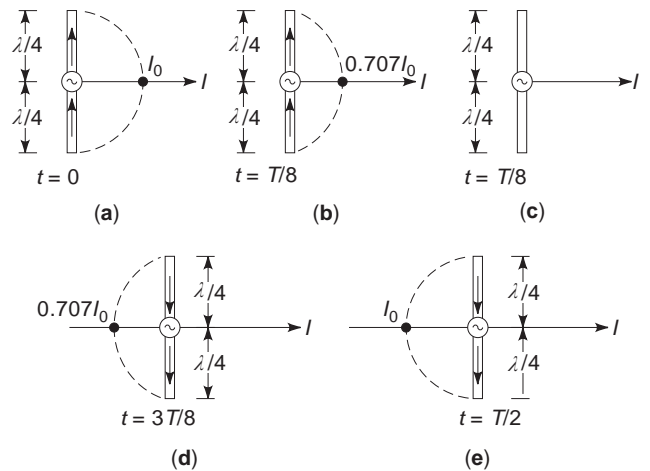

Figure 4. Current distribution on a $\lambda/2$ wire antenna for different times. The current, which is alternating, changes with time. This figure shows the current changes on a half-wavelength wire antenna at different time instants.

where $C(X)$ and $S(X)$ are well-known functions constituting Fresnel integrals (see App. IV in Ref. 1).

4. THE METHOD-OF-MOMENTS SOLUTION

For many practical antennas and scatterers, including linear antennas, the desired current distribution is obtained by numerically solving the integral equations. The method of moments (MoM) is a technique to convert an integral equation to a matrix equation and hence solve the linear system by standard matrix inversion techniques. The MoM is very well documented in the literature [15], and only the basic steps will be briefly discussed below.

The magnetic field integral equation (MFIE) for the unknown current density can be rewritten as an inhomogeneous equation in operator form as follows

$$L(\mathbf{J}_s) = 2\mathbf{n} \times \mathbf{H}(\mathbf{r}) \quad (36)$$

where the right-hand side is a known quantity and $L(\mathbf{J}_s)$ is an integrodifferential linear operator defined as

$$L(\mathbf{J}_s) = \mathbf{J}_s \hat{\mathbf{n}} \times \frac{1}{2\pi} \int_C \mathbf{J}_s(\mathbf{r}') \times \nabla' \mathbf{G} ds' \quad (37)$$

where \mathbf{J}_s is the electric current on the wire and \mathbf{G} is the free-space Green function.

Let us discuss the solution of inhomogeneous scalar equation given by

$$L(f) = g \quad (38)$$

where $f=f(x)$ is the unknown function to be determined, $g(x)$ is a known function and L is a linear operator. The seven steps [16] in obtaining the solution of Eq. (38) are the same as the steps for the solution of Eq. (37).

The steps are as follows:

1. Expand f as

$$f = \sum_{n=1}^N \alpha_n f_n \tag{39}$$

where the α_n values are the unknown coefficients, and the f_n values are known functions of x , known as *expansion*, or *basis*, functions.

2. Using Eq. (38) in Eq. (37), we get

$$\sum_{n=1}^N \alpha_n L(f_n) = g \tag{40}$$

3. Define a suitable inner product $\langle f, g \rangle$ defined in the range L of x :

$$\langle f, g \rangle = \int_D f(x)g(x) dx \tag{41}$$

4. Define a set of testing or weighting functions w_m , $m = 1, 2, \dots, N$, in the range. Taking the inner product of Eq. (40) with each w_m and obtain

$$\sum_{n=1}^N \alpha_n \langle W_m, L(f_n) \rangle = \langle W_m, g \rangle \tag{42}$$

where $m = 1, 2, \dots, N$; $\langle \cdot \rangle$ is the inner product, the product of the two functions integrated over the domain.

5. Express the set of algebraic equations given by Eq. (40) in the matrix form

$$[I_{mn}][\alpha_n] = [g_m] \tag{43a}$$

where the matrix is given by

$$[I_{mn}] = \begin{bmatrix} W_1, L(f_1) & W_1, L(f_2) & \dots & W_1, L(f_N) \\ W_2, L(f_1) & W_2, L(f_2) & \dots & W_2, L(f_N) \\ \dots & \dots & \dots & \dots \\ W_N, L(f_1) & W_N, L(f_2) & \dots & W_N, L(f_N) \end{bmatrix} \tag{43b}$$

where α_N and g_N are the column vectors given by

$$[\alpha_N] = \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_N \end{bmatrix} \tag{44a}$$

$$[g_N] = \begin{bmatrix} \langle W_1, g \rangle \\ \langle W_2, g \rangle \\ \dots \\ \dots \\ \langle W_N, g \rangle \end{bmatrix} \tag{44b}$$

4.1. Moment-Method Solution for Radiation from Thin Wire

Two types of volume integral equations are used for the linear antenna and wire scatterer problem. These are the integral equation of Hallen type and the integral equation of Pocklington type. Hallen's integral equation usually necessitates the postulation of a delta-gap voltage at the feedpoint and also requires the inversion of an $(N + 1)$ -order matrix. The advantages of Pocklington's integral equation is that it is possible to incorporate different source configurations and it requires inversion of a matrix of order N .

For a current-carrying perfectly conducting wire, the Hallen's integral equation obtained by solving the scalar wave equation is given by (1)

$$I_z(z') \frac{\exp(-jkR)}{4\pi R} dz' = -j\sqrt{\epsilon/\mu}[B_1 \cos(kz) + B_2 \sin(kz)] \tag{45}$$

where

$I_z(z')$ = current flowing through elementary length of wire

R = distance of the observation point from elementary length

I = total length of center-fed wire

$\epsilon, \mu, \sigma = 0$ = primary constants of medium in which the antenna is radiating k is the derived secondary constant, namely, the wavevector of the medium

B_1 and B_2 = are constants to be determined

The Pocklington's integral equation is given by

$$I_z(z') \left[\left(\frac{\partial^2}{\partial z^2} + k^2 \right) G(z, z') \right] dz' = -j\omega\epsilon E_z^i \text{ (at } \rho = a) \tag{46}$$

where for thin wire the radius $a \ll \lambda$, the free-space Green function $G(z, z')$ is given by

$$G(z, z') = G(R) = \frac{\exp(-jkR)}{4\pi R} \text{ with } R = \sqrt{a^2 + (z - z')^2} \tag{47}$$

E_z^i = the incident field (this is the source field for antennas and scattered field for scatterers)

The availability of high-speed computers, graphics, and software packages, along with the enormous development of microcomputers, has made electromagnetic numerical computation extremely viable. An attractive feature of numerical methods is their ability to handle arbitrarily shaped and electrically large bodies and bodies with non-uniformity and anisotropy where exact solutions can only at best provide some physical insight. For large problems, it is possible to get a linear system with a minimum set of equations to achieve a certain accuracy.

An account of the area of numerical computation of thin wire problem is well-documented in the literature [1,3,6–13]. As described in Ref. 8, there are many important computational issues involved in thin wire problems. These are (1) segmentation of the structure and the correct number of segments, (2) choice of right current expansion functions, (3) the thin-wire approximation (radius $a \ll \lambda$), (4) roundoff error due to matrix factorization, (5) near-field numerical anomaly, (6) treatment of the junctions of the segments, (7) wire-grid modeling, and (8) computer time required. Also, the errors [7] involved are of concern. There are two types of errors encountered: (1) the physical modeling error, because in the absence of an exact solution for a variety of semicomplex and complex structures, it is the natural departure of the assumed structural details from the actual structure; and (2) the numerical modeling error, since all numerical methods are approximate but sufficiently accurate for the application.

4.2. Formulation

Before we discuss the formulation of the thin-wire integral equation, comments on the expansion functions used in this study are in order. There are broadly two types of expansion functions:

1. *Entire-Domain Functions.* As the name suggests, these functions are defined over the entire integration path C , and the subdomain is defined over pieces on the integration path C . Some of these are Fourier, MacLaurin, Chebyshev, Hermite, Legendre, and so on. Tables available in Richmond’s work [17] and also in Ref. 8 are reproduced in Table 1.

2. *Subdomain Expansion Functions.* Subdomain expansions are attractive, convenient, and less expensive in terms of computer time. This stems from the fact that the current is matched on part of the integration path, whereas for the entire domain the integration is performed over the whole path and for all N terms of the expansions and coefficients determined.

Miller and Deadrick [8] provide a table containing the many basis and weighting functions that have been tested in computer runs. This table also compares the suitability of the use of different functions in different problems. The table is too big to reproduce here, and it is left to the reader to look up. It tabulates the method, integral equation type, basis function, current conditions for interior and end segments, the basis function in terms of unknown for unknown and end segments, weighting function for interior and end segments, number of unknowns, and specific comments on the applicability of the expansion functions.

4.3. The Electric Field Integral Equation and Its Matrix Representation

Figure 5 gives the geometry of the arbitrarily oriented straight wire. The wire is broken into segments, or subsections. The mininumerical electromagnetic code (MININEC) relates the current distribution on the wire due to the incident field E^i , magnetic vector potential \mathbf{A} , and electric scalar potential ϕ are given by

$$-E^i \cdot \hat{t} = -j\omega\mathbf{A} \cdot \hat{t} - \hat{t} \cdot \nabla\phi \tag{48a}$$

where

$$\mathbf{A} = \frac{\mu_0}{4\pi} \int \mathbf{I}(s)\mathbf{S}(s)k(r) ds \tag{48b}$$

$$\phi = \frac{1}{4\omega\epsilon} \int q(s)k(r) ds \tag{48c}$$

Table 1. Entire-Domain Current Expansions Using Different Polynomials

<i>A. The Polynomials</i>					
Fourier: $I(z) = I_1 \cos(\pi x/2) + I_2 \cos(3\pi x/2) + I_3 \cos(5\pi x/2) + \dots$					
MacLaurin: $I(z) = I_1 + I_2 x^2 + I_3 x^4 + \dots$					
Chebyshev: $I(z) = I_1 T_0(x) + I_2 T_2(x) + I_3 T_4(x) + \dots$					
Hermite: $I(z) = I_1 H_0(x) + I_2 H_2(x) + I_3 H_4(x) + \dots$					
Legendre: $I(z) = I_1 P_0(x) + I_2 P_2(x) + I_3 P_3(x) + \dots$					
where $-1/2 \leq x = 2z/L \leq 1/2$

5	0.040	1.871	0.0146	0.0073	0.0322

Figure 5. Wire segmentation with pulses for current and charges: (a) unweighted current pulses; (b) unweighted charge representation. The whole length is broken into several segments. Each segment is assigned a pulse, and the pulses represent the assumed current distribution.

t is a unit vector tangential to the wire at any distance along the path of integration which is the length of the wire and $k(R)$ is given by

$$k(R) = \frac{1}{2\pi} \int_{\phi=0}^{2\pi} \frac{\exp(-jkR)}{R} d\phi \quad (49)$$

The continuity equation given below determines the relationship between the charge $q(s)$ and the rate of change of current with distance:

$$q(s) = -\frac{1}{j\omega} \frac{dl}{ds} \quad (50)$$

The MININEC solves the integral equation using the following steps:

1. The wires are divided into small equal segments such that the length of the segment is still large compared to the radius of the wire ($a \ll \lambda$, typically $\frac{1}{100}$ th of a wavelength). The radius vectors $m, n = 0, 1, 2, \dots$ are defined with reference to a global origin.
2. The unit vectors are defined as

$$s_{n+1/2} = \frac{\mathbf{r}_{n+1} - \mathbf{r}_n}{|\mathbf{r}_{n+1} - \mathbf{r}_n|} \quad (51)$$

The testing and expansion functions are pulse functions that are defined by

$$P_n(s) = \begin{cases} 1 & \text{for } s_{n-1/2} < s < s_{n+1/2} \\ 0 & \text{otherwise} \end{cases} \quad (52)$$

where the points $s_{n+1/2}$ and $s_{n+1/2}$ are the segment mid-points and are given by

$$s_{n+1/2} = \frac{s_{n+1} + s_n}{2}, \quad s_{n-1/2} = \frac{s_n - s_{n-1}}{2} \quad (53)$$

In terms of global coordinates, we obtain

$$r_{n+1/2} = \frac{r_{n+1} + r_n}{2}, \quad r_{n-1/2} = \frac{r_n + r_{n-1}}{2} \quad (54)$$

When the pulse functions of Eq. (52) are inserted in parentheses, we obtain

$$\begin{aligned} E^i(s_m) \cdot & \left[\left(\frac{s_m - s_{m-1}}{2} \right) S_{m-1/2} + \left(\frac{s_{m+1} - s_m}{2} \right) S_{m+1/2} \right] \\ = j\omega A(s_m) \cdot & \left[\left(\frac{s_m - s_{m-1}}{2} \right) S_{m-1/2} \right. \\ & \left. + \left(\frac{s_{m+1} - s_m}{2} \right) S_{m+1/2} \right] \end{aligned} \quad (55)$$

The exact kernel treatment developed above is for observation points on source segments. For observation points near but not on the source, a segment has been developed by Wilton, and MININEC has incorporated it (16).

4.4. Expansion of Currents

The currents are expanded in terms of pulse functions as shown in Fig. 5, excluding the endpoints where the currents are chosen as zeros to satisfy boundary conditions at the ends. The current expansion is given by

$$I(s) = \sum_{n=1}^N I_n P_n(s) \quad (56)$$

Using this current expansion in Eq. (48b) and after mathematical manipulations which are available in Ref. 1 and are not detailed here, we get the linear system matrix equation in N unknowns

$$[V_m] = [Z_{mn}] [I_n] \quad (57)$$

where $m, n = 1, 2, \dots, N$, $[Z_{mn}]$ is the square impedance matrix, and $[V_m]$ and $[I_n]$ are applied voltage and current column vectors:

$$\begin{aligned} Z_m = & -\frac{1}{4\pi j\omega\epsilon} \left[k^2 (r_{m+1/2} - r_{m-1/2}) \cdot (s_{n+1/2} \psi_{m,n,n+1/2} \right. \\ & + s_{n-1/2} \psi_{m,n-1/2,n}) - \frac{\psi_{m+1/2,n,n+1}}{s_{n+1} - s_n} + \frac{\psi_{m+1/2,n-1,n}}{s_n - s_{n-1}} \\ & \left. + \frac{\psi_{m-1/2,n,n-1}}{s_{n+1} - s_n} - \frac{\psi_{m-1/2,n-1,n}}{s_n - s_{n-1}} \right] \end{aligned} \quad (58)$$

This matrix has elliptical integrals involved in it. These elliptical integrals can be evaluated numerically.

These equations are valid for any radius other than small, for which the expression for ψ breaks down, and Harrington [19] provided an approximate formula for ψ .

This is given by

$$\psi = \frac{1}{2\pi\Delta s} \ln \left[\Delta \frac{s}{\alpha} \right] - j \frac{k_0}{4\pi} \quad \text{for } m = n \quad (59a)$$

$$= \frac{\exp(-jkr_m)}{4\pi r_m} \quad \text{for } m \neq n \quad (59b)$$

The integral is given by

$$\psi_{m,u,v} = \int k_0(s_m - s') ds' \quad (60)$$

4.5. Inclusion of Nonradiating Structures

4.5.1. The Ground Plane. When the wire structure near the ground plane is assumed to be perfectly conducting, an image is created. The structure and the ground plane is equivalent to the structure and the image.

The voltage and current relationship is given by

$$[V_m] = [Z'_{mn}] [I_n] \quad (61)$$

where

$$Z'_{mn} = Z_{mn} + Z_{m,2N-n+1}$$

4.5.2. Wire Attached to Ground. When a wire is attached to the ground on one or both sides, there will be a residual component of current at one or both ends. In this case, a current pulse is automatically added to the end point in the formulation.

4.5.3. Lumped-Parameter Loading. If an additional complex load is added to the perfectly conducting wire (Fig. 6), there will be an additional voltage drop created at that point if the location of the load ($Z_l = R_l + jX_l$) is at a point of nonzero pulse function. The impedance matrix is modified to

$$[V_m] = [Z'_{mn}] [I_n]$$

where Z'_{mn} is the modified impedance matrix and is given by

$$Z'_{mn} = \begin{cases} Z_{mn} + Z_{load} & \text{for } m = n \\ Z_{mn} & \text{for } m \neq n \end{cases}$$

4.6. Validation of the MININEC code

Extensive work has been reported on the validation of the MININEC. Numerous validation runs have been carried out to meet the following requirements: (1) the segmentation density, (2) thin-wire criteria, (3) small radius calculation, (4) step changes in wire radius, (5) spacing of wires, (6) loop antenna, and (7) monopoles and antennas above ground.

Figure 6. Overlap scheme used at a multiple junction of wires: (a) wire 1 with no end connections; (b) wire 2 overlaps onto wire 1; (c) wire 3 overlaps onto wire 1.

4.7. Operation of Currents—LU Decomposition

The operation is oriented around the menu shown below. Here we describe the DOS version [19,20], but the Windows version is also available [21–23]:

```

Figure 7. Geometry of the “tee” antenna. Typical dimensions are shown.

impedance calculations of the tee antenna using different computer programs, including CURLU in MININEC and have been compared with measurements [25].

4.8.2. Near and Far Fields. The near- and far-field programs (FIELDS) calculate near and far fields using the current distribution on the structure obtained by integral equation formulations. The current distribution can be computed using three programs: CURLU, CURTE, and CURRO. The current distribution can be computed using perfect and imperfect ground, although the real ground corrections are applied to the far field only. The real ground correction is included in the form of reflection coefficients for parallel and perpendicular polarizations. For details, the reader is referred to Chap. 8 of Ref. 7. The menu is given below. User input(UI) means the user is expected to respond at that point.

5. THE THICK LINEAR ANTENNA

The thin linear antenna is frequency-sensitive. In practical communication scenarios, the transponders use

Figure 10. Monopole near fields: H_ϕ versus radial distance.

Figure 11. Percentage difference in electric fields E_z and E_r versus radial distance.

wideband signals to increase the channel capacity and therefore needs antennas that can handle a large band of frequencies. One way of increasing the bandwidth is to use electrically thick wires.

A thick cylindrical dipole (Fig. 16) is the inexpensive way to increase the bandwidth of linear antennas. The increase in thickness leads to circumferential component I_ϕ of the otherwise linear current. This can be handled with the integral equation formulation. Figures 17a and 17b, respectively, show the variation of input resistance and reactance of the dipole with $l/2a$ ratios 25 (thick), 50, and 10,000 (thin), where $2a$ is the diameter of the wire.

6. THE SLEEVE DIPOLE

The structure that closely resembles an asymmetric dipole is the sleeve dipole (Fig. 18), which is a base-fed monopole

Figure 12. Monopole near fields: percentage difference in H_ϕ versus radial distance.

Figure 13. Monopole near fields: vertical electric field versus vertical distance.

Figure 15. Monopole magnetic field H_ϕ at surface versus vertical distance.

on a ground plane. The outer conductor of the coax line is extended to give wideband characteristics apart from impedance control and mechanical strength. Another way of increasing the bandwidth will be to coat the metal wire

Figure 16. The center-fed thick dipole. A thick dipole has a frequency characteristic over a much wider band than a thin antenna. The diagram shows how such a dipole will receive power from the feeder network.

with a low-loss dielectric or just push the metal wire into a sleeve (a thin dielectric pipe). It can be fed symmetrically, but the problem of impedance matching and using a proper matching network will increase the complexity and cost of the device. For further discussion on sleeve dipoles, the reader is referred to Ref. 1.

7. COMPUTER CODES

7.1. A Summary of Different Available Codes

The following subsections summarize the scope of the codes currently used for linear antenna analysis.

7.1.1. The Electromagnetic Surface Patch Code. The electromagnetic surface patch (ESP) code version IV [26], which uses the method of moments (MoM), is written for the analysis of radiation and scattering from three-dimensional geometries. These geometries include the interconnection of thin wires and perfectly conducting and thin dielectric polygonal plates. This code works for open as well as closed surfaces since the formulation is based on electric field integral equation. It uses polygonal plates modeling, which can generate an object as complex as an aircraft with only 12 polygonal plates. The ESP code is capable of doing the following:

1. It can model an arbitrary thin wire by using a number of piecewise straight segments.
2. It can be model an arbitrary perfectly conducting surface by a combination of polygonal plates. The plates can be of thin dielectric sheets, which have been modeled using impedance approximation.
3. The code incorporates the wire-junction with the restriction that the junction must be at least one-tenth wavelength away from the nearest edge; it can take care of several plates generated from a common edge.

In order to use this code, the user specifies the (x,y,z) coordinates of the corners of each plate by entering the (x,y,z) coordinates of the corners of each plate and the maximum segment size in wavelengths for calculating the MoM modes. The code automatically takes care of the frequency independence of the models.

In summary, the ESP code can treat a variety of geometries: (1) thin wires with finite conductivity and lumped loads, (2) perfectly conducting or thin dielectric polygonal plates (30 wire-plate junctions) at least 0.1λ from the edge of a plate, (3) plate-plate junctions, including several plates of different sizes that intersect along a common edge, and (4) excitation by either a voltage generator or an incident plane wave.

ESP can compute the key characteristics of engineering interest of an antenna, namely, current distributions, antenna input impedance, radiation efficiency, mutual coupling, near- or far-zone radiation patterns for all polarizations, and near- or far-zone back, bistatic, and forward scattering patterns (full scattering matrix). These are still bugs in the ESP code, and new features are being

Figure 17. The input impedance of wire dipoles with dipole length in wavelengths: (a) input resistance in ohms; (b) input reactance in ohms. Every antenna presents an input complex impedance at its feed terminals. It is very important to know how the real and imaginary parts of the impedance vary with parameters so that antenna can be matched to the feeder.

added to the codes. Nevertheless, it should be possible to customize the code for a specific application.

7.1.2. The Mininumerical Electromagnetic Code (MININEC). The MININEC [20,21] is a computer program prepared in BASIC language using the method of moments for the analysis of linear antennas. It uses a Galerkin procedure [19] to solve for wire currents using an integral equation formulation that relates the vector and scalar potentials to the electric field. This formulation can easily be programmed for use in microcomputers. The code can solve for impedance and currents on arbitrarily wires including configurations with multiple wire junctions. The code incorporates lumped impedance loading and near-zone electric and magnetic fields when the wire is in free space as well as over a perfectly conducting ground. MININEC is written in a IBM PC-DOS-compatible BASIC language.

8. FEED FOR LINEAR ANTENNAS

In all practical antennas, there exists a mechanism of feeding the antenna to launch the desired current distribution. This requires a finite gap with a nonzero current and alters the normally assumed current distribution. Hence, a correction factor should be introduced to accurately model the feedpoint current. Several methods of feeding half-wave antennas are shown in Figs. 19a–19d. Normally, since the complex input impedance of the dipole is quite different from the real input resistance (under high frequency approximation), there is a need to use a matching network to match the input impedance to the feeder and keeping the voltage standing-wave ratio (VSWR) close to unity in the frequency range of operation. Figure 19a shows the balanced line-type center feed. Figure 19b shows a “delta match” or “shunt feed” feeder that provides a good impedance mismatch and low VSWR

Figure 18. The sleeve dipole. Apart from making the wire thick, another way of increasing the bandwidth of a thin wire is to put it in a sleeve, which is basically a dielectric coating, and terminate by a ground plane on one side.

on the feeder line. The simplest feeding arrangement is the “end feed” (Fig. 19c), where the vertical transmission line radiates energy. The configuration in Fig. 19d can be made efficient by tapping the vertical line at an appropriate location.

To account for the nonzero current at the finite gap feed terminals and consequent distortion in the current distribution.

Figure 19. Methods of exciting linear antennas: (a) center feed; (b) delta match or shunt feed; (c) end feed; (d) impedance-matched tapping. Excitation mechanisms are very important in order to launch maximum power. Not shown are matching transformers to ensure maximum power transfer.

Figure 20. Comparison of measured and calculated admittance values for a coated dipole length $L=8$ in.; $2a=0.025$ in.; $2b=0.146$ in.; $\epsilon_2=2.3\epsilon_0$. The figures show the bandwidth of antennas: (a) conductance; (b) susceptance of an insulated dipole versus length in wavelengths.

The modified current is given by [28]

$$I_z(x', y', z') = \begin{cases} a_z \{ I_0 \sin[k(l/2 - z')] + j\alpha I_0 [\cos(kz') - \cos(kl/2)] \} & \text{for } 0 \leq z' \leq l/2 \\ a_z \{ I_0 \sin[k(l/2 + z')] + j\alpha I_0 [\cos(kz') - \cos(kl/2)] \} & \text{for } -l/2 \leq z' \leq 0 \end{cases} \quad (62)$$

where α = the coefficient dependent on the length of the gap and the antenna. If the radius of the wire and the gap are small the value of this coefficient is small.

For a half-wave dipole, we obtain

$$I_0(x', y', z') = a_z I_0(1 + j\alpha) \cos(kz') \quad \text{for } 0 \leq |z'| \leq \lambda/4$$

The shape of the current does not change for a half-wave dipole, but it does for other lengths, such as a wavelength.

9. BANDWIDTH OF LINEAR ANTENNAS

The bandwidth of an antenna is the frequency range over which the performance of the antennas meets a specific requirement, such as that the gain does not fall below 3 dB of the maximum, or the midfrequency value. There is no unique characterization of bandwidth since the different properties such as input impedance, radiation pattern, polarization, and gain of an antenna vary in entirely different ways in a frequency range. The definition meets the requirement of specific application. Nevertheless, the bandwidth is defined in three different ways: (1) half-power bandwidth is the frequency range within which the gain does not fall by more than 3 dB, (2) the percentage bandwidth normally defined for a narrowband antenna is defined as the bandwidth (the difference between upper and lower frequencies of operation) divided by the center frequency and then multiplied by 100, and (3) for wideband- or frequency-independent antennas it is the ratio of higher and lower frequencies of operation.

The thin linear antenna that we have dealt with in this article is based on the assumption that the radius is small compared with the wavelength of operation. This necessarily means that the current on the wire is linear and has no tangential component. In a practical situation an antenna has to operate in a frequency band. This assumption is no longer valid and the thin linear antenna becomes frequency-sensitive. Therefore, something needs to be done to the thin antenna so that it develops the capability of handling a wide frequency band.

The way of achieving wider bandwidth will be to use electrically thick dipoles or to coat thin metallic wires with lossy dielectrics. A thick dipole and a dielectric coated dipole with their centrally located feeding source are shown in Figs. 20a and 20b, respectively. The effect of coating the thin linear antenna with a layer of electrically and magnetically lossless and lossy material is discussed in two papers in (28) and (29) and summarized in (1). The analytical techniques used is a moment method solution. Two parameters, P and Q [28,29], involving the electrical and magnetic parameters, inner and outer radii, are found to be of interest in moment method solutions and help in designing antenna characteristics using coating of electrically and magnetically lossless and lossy material. They are given by

$$P = \left(\frac{\epsilon_r - 1}{\epsilon_r} \right) \ln \left(\frac{b}{a} \right) \quad (63a)$$

$$Q = (\mu_r - 1) \ln \left(\frac{b}{a} \right) \quad (63b)$$

where a = radius of the thin wire, $b - a$ = thickness of the coating, ϵ_r = the relative permittivity of the coating or the medium in which the thin wire is embedded, and μ_r = relative permeability of the coating or the medium in which the thin wire is embedded.

It turns out that the effects of increasing the real part of both P and Q are to increase the peak value of input impedance, to increase the electric length which lowers the resonant frequency and to reduce the bandwidth of operation. The effects of increasing the imaginary part of P and Q are to decrease the peak value of input impedance, to decrease the electrical length which increases the resonant frequency, and to increase the bandwidth. This means a proper choice of a lossy dielectric with maximum imaginary parts of P and Q and minimum real parts of P and Q can achieve an optimum bandwidth. But this will be at the cost of antenna efficiency because of the lossy coating.

LOCAL-AREA NETWORKS (LANs)

JOSEPH B. EVANS
University of Kansas
Lawrence, Kansas

Local-area networks (LANs) are data communications networks that are restricted in extent to an office, home,

building, or in some cases, areas as large as a college or university campus. Because of the spectacular growth in networking, LANs can be found deployed in almost every organization. Various established and evolving technologies are used in LANs, based on physical facilities ranging from copper and optical fiber to radio. The characteristics of commonly used LAN technologies will be discussed below.

1. LAN TOPOLOGIES

LANs can be logically organized in several topologies, the most popular of which are the bus, star, and ring.

In the bus structure, illustrated in Fig. 1, nodes (computers, printers, or similar devices) are interconnected to a common, shared physical resource, typically a wire or cable. This topology is inexpensive, since wiring expenses are shared among the nodes. Unfortunately, this scheme involves sharing the limited bandwidth resources of the bus, and can also be somewhat unreliable, as bus failures in the vicinity of one node can affect the others on the same bus. IEEE 802.3 10base5 and 10base5 Ethernet are examples of networking standards based on a bus topology at the physical layer. Despite its shortcomings, this remains a common topology because of the simplicity of deployment. Because of the nature of the wireless medium, it is the topology used by wireless LANs such as those based on IEEE 802.11.

An alternative is the star topology, shown in Fig. 2, in which each node has dedicated resources to some central switching site. This has the advantage of dedicated bandwidth to the interconnection point, but the attendant cabling costs are often higher than those for the bus topologies. Switched Ethernet and asynchronous transfer mode (ATM) are examples of networking standards based on a star topology. There is increasing dependence on star topologies because the limited bandwidth on a cable is not shared and traffic is not subject to internode arbitration delays for access to the medium.

Another option is the ring topology, shown in Fig. 3, in which each node is interconnected to its neighbor. The IEEE 802.5 Token Ring and the Fiber Distributed Data Interface (FDDI) are examples of networking standards based on a ring topology. This topology shares many of the advantages and disadvantages of the bus topology—inexpensive wiring, but with reliability problems if the ring should be broken. Ring-based LANs have been designed to overcome the reliability issues by using counterrotating rings (e.g., FDDI). Depending on the protocols in use, bandwidth in a ring-based network can be reused (since the ring is not physically contiguous), and hence such a

Figure 1. Bus topology.

Figure 2. Star topology.

topology can have a capacity greater than the equivalent bus.

2. IEEE 802 LAN STANDARDS

Much of the growth in deployment of LAN technology can be attributed to the standardization of selected technology options, which has enabled multivendor interoperability and has spawned a highly competitive market. The IEEE 802 LAN standards are among the most widely used data protocols yet developed.

The IEEE 802.2 standard specifies the logical link control (LLC) protocols used by the other IEEE LAN standards. IEEE 802.2 allows the lower-level protocols to interface with higher-level protocols in a consistent manner. Using this approach, for example, the Internet Protocol (IP) need not know the type of underlying hardware being used on a particular host, which implies that software can be simplified and made more reliable. Note that

certain other protocol suites (e.g., IP over ATM) use the IEEE LLC SAP (service access point) codes for protocol multiplexing and demultiplexing, so that similar benefits can be obtained. IEEE 802.2 provides several services; which services are used and the extent to which they are used depends on the needs of the other protocols involved.

The IEEE 802.3 standard has been one of the most successful in the IEEE LAN suite. This standard describes the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) protocol that forms the basis for the Ethernet family (note that the 802.3 standard and Ethernet differ slightly, but can be made to interoperate). The IEEE 802.3 standard consists of several related protocols, for different physical media. Included are the original 10base5 standard for CSMA/CD on 50- Ω -thick coaxial cable, the 10base2 standard for lighter 50- Ω coaxial cable, and the 10baseT standard for unshielded twisted-pair cables. No longer commonly used are the 1base5 StarLAN standard and the 10broad36 standard for more widely dispersed networks. Fiber extension options are available for distributed site interconnection (within protocol distance limits). Ethernets can be found in almost all corporate data networks. Although networks based on the 10-Mbps (megabits per second) data rate are still deployed, higher-rate Ethernet protocols are becoming increasingly popular, particularly 100-Mbps Fast Ethernet, Gigabit Ethernet, and most recently 10-Gbps Ethernet. The 100-Mbps and 1-Gbps Ethernet varieties utilize both fiber and copper; the latter are restricted to server rooms and other facilities with small distances between nodes.

The IEEE 802.4 standard specifies the token bus protocol. This protocol has been the basis for several networking technologies, including the MAP/TOP suite. Multiple physical layers are defined for token bus on 75- Ω coaxial cable, including systems at 1, 5, and 10 Mbps. These are all broadband systems. The original 1-Mbps system was quite popular because of its low cost and relative simplicity.

The IEEE 802.5 standard specifies the token ring protocol. This standard was extensively deployed in PC-based networks and became second only to Ethernet in ubiquity, although it is no longer widely used. It uses unshielded

Figure 3. Ring topology.

twisted-pair cabling, with data rates at 4 and 16 Mbps. It has several very desirable features, including robust behavior in the presence of high traffic loads and bounded delay (to transmit) times.

3. PROTOCOL LAYERING

For standardization purposes, networking protocols are most often conceptually partitioned into several layers. In the case of LAN technologies, the physical layer (PHY), media access layer (MAC), and logical link layer (LLC) are commonly specified. The latter two are often grouped together to form the data link layer in standard layering schemes.

3.1. PHY Layer

The PHY, or physical layer, is the lowest layer of a protocol stack. The standards for this layer typically describe the medium to be used (e.g., cable, fiber, wireless), modulation schemes, and encoding schemes used to transmit information across the medium.

The PHY layers of LAN protocols generally fall into two categories: baseband and broadband. A *baseband* PHY layer is one in which the information bearing signals are digital signals, typically encoded using simple level-based keying, Manchester encoding, or differential Manchester encoding. This is the most common type of PHY layer in current LANs, as it is relatively inexpensive and sufficiently robust for most local environments. The disadvantages are distance limitations, typically 100 m to at most 1000 m on copper, and bandwidth no more than about 1 Gbps over copper using current technologies. Baseband techniques may be used over optical fiber at much greater distances and rates, but with the attendant installation and network equipment costs. For typical LAN installations, however, baseband systems on copper are sufficient.

Encoding schemes are another key element of the PHY layer. A variety of encodings, tailored to the physical medium for a given protocol, have been developed. Some typical encodings are depicted in Fig. 4. These can be broadly classed as non-return-to-zero (NRZ) techniques and biphasic techniques.

The conceptually simplest encodings are the NRZ methods. In the NRZ-level approach, for example, zeros (0s) are encoded as low voltage level, and ones (1s) are encoded as a high voltage level. In optical fiber systems, the corresponding encodings may be that ones are the presence of optical power; zeros, the lack of light. In the NRZI (NRZ with invert on ones) approach, a transition (either falling or rising edge) denotes a one, and the lack of a transition signifies a zero.

While simple, the NRZ schemes have several shortcomings. Most significantly, recovery of bit timing at the receiver can be difficult—the moment in time at which to sample a bit to determine whether it is a zero or one is seldom apparent in the presence of noise and other such impairments. A technique that provides an unambiguous timing reference is highly desirable. Furthermore, the occurrence of a long string of zeros or ones can result in an undesirable DC voltage bias on the transmission medium,

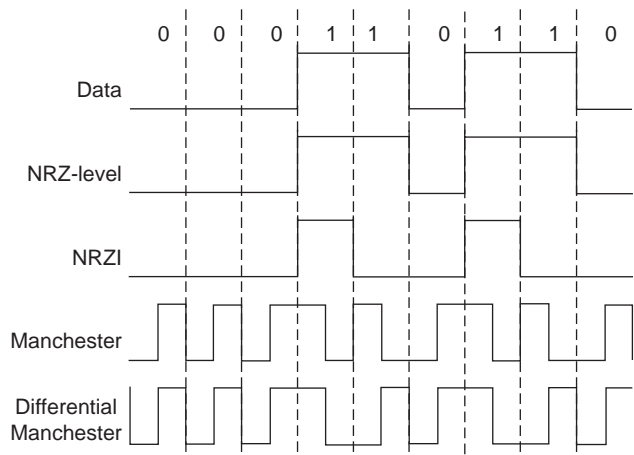

Figure 4. Baseband PHY encoding schemes.

which may cause threshold-related errors and problems with the use of transformers. There are several approaches to resolving these related problems, which center around the need for signal transitions.

The 4B/5B (4-byte/5-byte) and related techniques (4B/6B and 8B/10B are also common) involves guaranteeing sufficient transitions by inserting extra bits into the signal stream. Data symbols, 4 bits in this case, are mapped into a 5-bit code, which is then transmitted using NRZI, for example. This is illustrated in Table 1. An inspection of this table will prove that strings with a maximum of three consecutive zeros are possible, even when codewords are concatenated. Multiple ones are not an issue if NRZI is used for transmission, as ones force a transition to occur. The cost of a 4B/5B mapping, of course, is that only 80% efficiency is possible.

The biphasic encodings are beneficial with respect to signal balance maintenance, and bit timing recovery is particularly easy to implement in this scheme. These are based on signal transitions at a rate double that of the bit rate. A transition (rising edge or falling edge) is guaranteed to occur at the center of the bit period. The absence

Table 1. 4B/5B Encoding

Data Symbol	Codeword
0000	11110
0001	01001
0010	10100
0011	10101
0100	01010
0101	01011
0110	01110
0111	01111
1000	10010
1001	10011
1010	10110
1011	10111
1100	11010
1101	11011
1110	11100
1111	11101

of such a transition can be used as an error detection method.

In Manchester encoding, a zero is encoded as a rising edge at the center of the bit period, and a one as a falling edge at such a time. The encoding mechanism can be implemented as an exclusive-OR operation between the data and the clock. This is the encoding used for most of the original IEEE 802.3 protocols (10base5, 10base2, 10baseT). Differential Manchester encoding uses the mid-period transition for a clocking reference only, and uses the presence (denoting a zero) or absence (denoting a one) of a transition at the beginning of the bit period to encode the information. This is the method used for the IEEE 802.5 token ring standard.

The primary disadvantage of biphase signaling is that transitions happen at twice the data rate, which means that the bandwidth required is greater than that of the equivalent NRZ system, and the hardware need operate twice as quickly. The former is particularly critical in wireless systems.

A broadband PHY layer is one in which the information is coupled into the medium by analog signals, which are modulated by some carrier, and encoded using frequency shift keying (FSK), amplitude shift keying (ASK), phase shift keying (PSK), or some similar scheme. This type of PHY layer is most often used in situations where longer distances need be served or additional bandwidth is required. Much greater bandwidths may be supported on one cable using broadband schemes, as multiple frequencies can be used. The primary disadvantage of the broadband approach is the cost of modulators, demodulators, and the associated analog hardware.

3.2. MAC Layer

The MAC, or media access layer, is used to arbitrate access to the PHY layer. For example, in the case of Ethernet, there is a shared medium (cable) that must be used by several nodes, and only one of the nodes can be permitted to access the cable at a particular time.

The MAC layer influences the effective throughput over a given physical layer and should be efficient in its use of the available bandwidth. This includes minimizing the overhead due to factors such as protocol headers and deadtime between transmissions, while at the same time maximizing the successful transmissions on a busy shared medium network. In addition, the MAC layer is often designed to ensure that errors are not propagated to the higher-layer protocols.

Various MAC schemes have been developed for the LAN protocols. The two most common are the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) protocol used in Ethernet, the token ring protocols, and the token bus protocol.

The CSMA/CD MAC protocol involves detecting the use of the medium by another station by checking the state of the carrier. If a station has data to transmit, it first attempts to verify whether the medium is unused. If it is available, the station transmits. If the medium is not available, the station waits until it becomes idle and

then immediately begins to transmit (note that this is the IEEE 802.3 solution, but other options are possible in the general case of CSMA). The success or failure of transmissions is monitored on the shared medium, and if a transmission is unsuccessful, that is, a collision is detected, the station waits a prescribed random amount of time (binary exponential backoff) and attempts to transmit again. This procedure is repeated until the transmission is successful, or the limit to the number of transmission attempts (16 in IEEE 802.3) is reached. CSMA/CD is simple, inexpensive, and performs well under light loads. Unfortunately, it can perform poorly under heavy loads, and be sensitive to physical layer errors. The CSMA/CD protocol, however, need not be invoked in a full-duplex switched Ethernet network. In a full-duplex switched network, each segment from switch to station or from switch to switch is its own isolated domain, and no collisions that require CSMA/CD can occur.

Token ring protocols use a “token” to arbitrate access to the transmission medium. A token is a small frame that is exchanged between stations in order to gain the right to transmit. If a station has data to transmit, it waits until a token is seen on the medium. This station then modifies the token and appends the necessary fields as well as its data. When this frame returns around the ring to the originating station, it is purged from the medium. When data transmission is complete, the station inserts a new token onto the ring. Token rings support fair, controlled access to the medium, and perform well under heavy load conditions. A disadvantage is the need for careful token maintenance, particular in the presence of errors. Several varieties of token ring exist; some of these will be discussed in subsequent sections.

The token bus protocol is closely related to the token ring, but with an underlying physical bus topology. The token exchange mechanism, however, does in fact use a logical ring for token passing. This logical ring is simply an ordering of stations on the bus. Once the logical ring is in place, token passing can proceed as in a ring-based system. This system provides controlled access to the bus, and is robust under heavy loads. One of the disadvantages of this approach is that ring initialization and maintenance is more complex than in a physical ring—the ordering of stations must be determined through some algorithm, and stations additions and deletions must be managed.

3.3. Logical Link Control (LLC) Layer

The LLC, or logical link control layer, can be viewed as the upper part of the data link layer. It is used to provide data services to the higher layers. In particular, two types of services, connectionless and connection-oriented, are defined. In LANs supporting complex higher layer protocols, such as TCP/IP, only the simplest LLC services are commonly used.

An example of an LLC protocol is the IEEE 802.2 layer. This provides both connectionless and connection-oriented services. The unacknowledged connectionless service provides simple datagram support for the multiplexing and demultiplexing of higher layer protocols. In addition,

Figure 5. IEEE 802.2 LLC frame format.

a connectionless service with acknowledgments (for monitoring systems, for example) is supported, as well as a connection-oriented service that furnishes flow control and error recovery capabilities based on the lower-layer CRC (cyclic redundancy check) and a “go-back-N” strategy. The IEEE 802.2 LLC frame format is depicted in Fig. 5. The SAP and SSAP (direction and source service access point) fields are used to indicate the service type [e.g., IP or IPX (Internet protocol and internetwork packet exchange)] to higher layers. The control field is used for the LLC service support, including indication of the type of service.

4. ETHERNET (IEEE 802.3)

The Ethernet, and the closely related IEEE 802.3 standard, has been one of the most successful LAN protocols developed to date. This technology is based on CSMA/CD, and takes a variety of forms at the PHY layer. A typical Ethernet installation is depicted in Fig. 6.

The Ethernet frame format is illustrated in Fig. 7. The preamble is used for frame delineation. The destination and source address fields (48 bits each) are globally unique identifiers for each Ethernet adapter, and are used for station-to-station communication, as well as broadcast (all ones) and multicast (the first bit is one). It should be noted that the 48-bit addresses used in Ethernet have become a common feature in IEEE 802-based LANs. The type field (Ethernet) can be used for higher-layer demultiplexing, as in an LLC protocol. The length field (IEEE 802.3) is used to aid in end-of-frame detection. A 32-bit CRC is used for error detection, and is followed by a postamble for end-of-frame detection.

Figure 7. Ethernet frame format.

5. TOKEN-PASSING BUS (IEEE 802.4)

The IEEE 802.4 token bus standard has been widely used in manufacturing systems and early office automation products. Because it is based on a broadband physical medium, it is somewhat more resistant to the low-frequency EM noise that might arise on a factory floor.

A token-passing bus is a LAN with a bus topology that operates on the principle that a token will be received prior to the transmission of data by a station. The token bus frame format includes a preamble, frame control byte for denoting whether a particular frame is a token or data, the destination and source addresses (48 bits, as in 802.3), the data (an LLC frame), a error detection field (CRC-32, as in 802.3), and the postamble.

The token bus operates by first establishing a logical ring that overlays the physical bus topology. Station additions and deletions require reconfiguration of the logical ring. When a token is received, a station is permitted to transmit multiple packets, until its token holding time has expired. The token bus offers optional support for multiple classes of service through the use of complex timer specifications that enable per-class bandwidth guarantees. Support for simpler nontoken stations is included to allow low cost devices to respond to polling requests using this medium.

6. MAP/TOP

MAP is the Manufacturing Automation Protocol developed by General Motors Corporation for communication among automated manufacturing devices, including robotic equipment and the associated controllers. It was primarily designed to support communication between very different sorts of devices, in real time with low, predictable

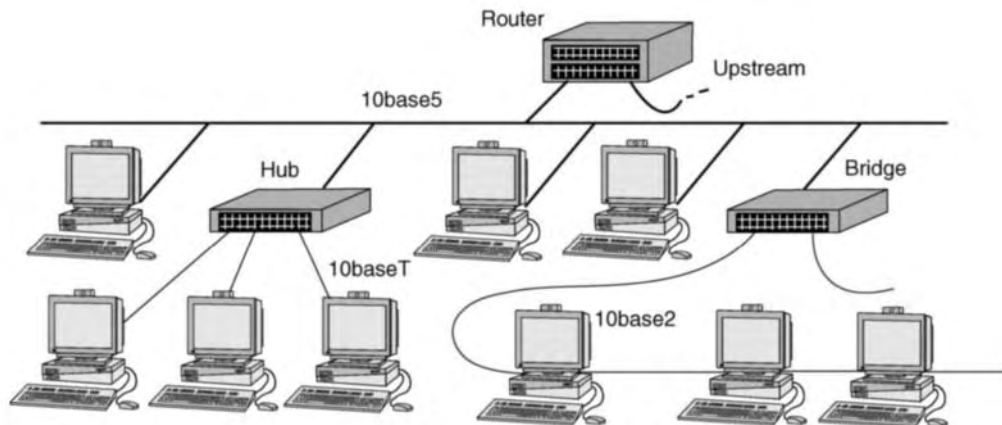

Figure 6. Typical Ethernet installation.

delays. It supports applications as varied as word processing and equipment telemetry (temperature measurement, for example).

TOP is the Technical and Office Protocol developed by Boeing Corporation for communication between office automation devices such as word processing systems and printers. Interoperability between devices from a variety of manufacturers was a key design goal of this protocol.

The MAP/TOP protocol suite is based on the IEEE 802.4 token bus protocols. As such, MAP/TOP networks are often interconnected with some variety of token passing network for ease of interface design.

7. TOKEN RING (IEEE 802.5)

The token ring protocol was widely deployed in networks based on PCs before Ethernet became the dominant LAN technology. Token ring operates on the principle of the exchange of a “token” to a station before it is permitted to transmit. Only one token is allowed on the ring at one time.

The IEEE 802.5 token ring frame formats are illustrated in Fig. 8. The first format is used for token frames, and only includes start and end delimiters, and the access control field with priorities and reservation information. The second format includes start and end delimiters, a frame control word for optional LC support, source and destination addresses (in 802.3 format), the LLC (data) frame, a CRC-32, and a frame status word used by transmitting stations to verify reception.

8. OTHER TOKEN RINGS

Another example of token ring technology in wide use today is the Fiber Distributed Data Interface (FDDI) standard. This technology supports multiple packets on the ring at one time, with rates of 100 Mbps. Provisions are made for multiple service classes (synchronous and asynchronous) with differing throughput and delay requirements. Further, reliability support is provided through the capability for optional redundant counter-rotating rings, which can mask a station or fiber failure.

8.1. Slotted Ring

Slotted-ring technology uses multiple “slots” that rotate around the ring to arbitrate access. Each slot is a small frame that can be marked empty or full. When an empty slot arrives at a station with data to transmit, the slot is marked full and data is injected. The slot is marked empty

when it returns around the ring to its source. A given station cannot transmit again when it has an outstanding slot. The provision for multiple packets from different sources on the ring at one time assists in fair utilization and quality of service support.

The Cambridge ring is an early example of such technology (some claim that it is also the ancestor of the ATM protocols, also based on small fixed frame sizes). A slot contains one octet each for the source and destination addresses, five control bits, and two, four, six, or eight data octets, and thus slot sizes are extremely small. This implies that higher-layer packet data are almost always segmented into small units prior to transmission. Stations could choose not to receive packets from particular sources; some of the control bits support this through response codes. The Cambridge ring was simple to implement, but somewhat wasteful of bandwidth due to the header overhead in such small datagrams.

8.2. Register Insertion Ring

Register insertion rings are a common LAN technology, and can be used to provide high performance through their support for multiple packets on the ring at one time. The register insertion ring uses a small shift register at each station to control forwarding and insertion onto the ring. The shift register is at least as large as the maximum frame size. This allows a station to store a frame as it passes. If the station has no data to send, a passing frame is buffered long enough to determine whether it is destined for the local station. If it is destined locally, a typical implementation will both copy the frame into adapter memory and forward the frame back around the ring in order to support acknowledgments. Transmission when the medium is available is handled by simply copying the data onto the ring. If a frame arrives during this time, it is buffered in the insertion register. The register insertion method provides excellent ring utilization due to the multiple simultaneous packets on the ring without the overhead penalty of the slotted ring. The disadvantage of this technology is that the purge mechanism, that is, the technique used to remove problematic packets from the ring, is generally more complex than in other systems.

9. HYPER CHANNEL, HIPPI, AND FIBRE CHANNEL

A number of LAN protocols are designed for very-high-speed interconnection of computers and their peripherals.

Figure 8. Token ring frame format.

HYPERchannel, developed by Network Systems Corporation, is one of these. This protocol was developed in the mid-1980s for the interconnection of supercomputers and high-performance peripherals, and has been used with Cray and Amdahl systems, among others. It supports data rates of up to 275 Mbps over a variety of physical layers.

HIPPI (high-performance parallel interface) is another of the protocols developed primarily for interconnection of supercomputers. This protocol supports 800-Mbps or 1.6-Gbps links over a large parallel cable, which is either 32 or 64 lines wide and runs at 25 MHz. The distances over which HIPPI can be used is quite limited, but large enough for a typical supercomputer center equipment floor. Interconnection of sites can be accomplished using fiber extension options. Simple flow control features are provided to lessen problems with computers and peripherals of widely different I/O (input/output) bandwidth. Although simple and effective, this flow control scheme does contribute to the problems of extending HIPPI networks over larger distances while maintaining high throughput. In order to build HIPPI networks of nontrivial size, simple switches are used to interconnect devices. These switches are typically not designed to switch between sources and destinations at high rates, as with routers and packet switches, but rather act as interconnection panels that may be reconfigured at reasonable rates for the sharing peripherals.

Fibre Channel is a LAN protocol suite designed for high-speed communication between nodes using optical fiber. Rates of up to 4 Gbps are supported. Fibre Channel is designed to combine the features of channel protocols (such as HIPPI) and switched LAN protocols in order to provide a scalable and reliable interconnection with the high speeds and low latency required for servers and their peripherals in storage-area networks (SANs).

10. OTHER LAN PROTOCOLS

A number of new, flexible, and high-performance LAN protocols have been developed. These developments include FireWire (IEEE 1394) and USB (universal serial bus), high-speed protocol suites based on serial interconnection technology. There are several varieties of FireWire, for example, with support for bandwidths of up to 800 Mbps with up to 63 devices (with no more than 16 cable hops) per bus in the more commonly deployed versions. More recent FireWire standards offer bandwidths up to 1.2 Gbps with continued increases expected. FireWire is most commonly used for interconnection of digital media (video and audio) devices. USB 1.1, a 12-Mbps serial protocol with chaining support, was originally designed primarily as an improvement over traditional serial port technologies. Peripherals such as keyboards and mice now most often use USB, and more exotic USB peripherals such as storage media devices are increasingly commonplace. With the introduction of USB 2.0, which supports speeds of up to 480 Mbps, it is expected that USB video and audio devices will also be widespread.

Asynchronous transfer mode (ATM) technology was also deployed in LANs. ATM is a switch-based technology that uses small packets (53 bytes) called *cells*. Interconnection of nodes is through virtual circuits, which are analogous to circuits in voice telephony. Multiple physical layers are supported, including both copper and fiber infrastructure options. Although ATM is often viewed as a wide-area networking (WAN) technology, it does provide support for features that are not available in other technologies. For example, ATM allows the definition of virtual LANs that provide network administrators with options that are not available in less sophisticated technologies. Virtual or emulated LANs are interconnections of LANs, perhaps widely separated, which are configured to emulate a single local-area network. Furthermore, multiple logical local area networks can be supported over a single physical infrastructure using this capability. Because of its complex administration, ATM LAN deployments have largely been restricted to networks with applications needing its unique capabilities.

11. WIRELESS LANs

Wireless LANs use radio or infrared as the transmission medium, as opposed to the traditional wire or fiber. This has significant advantages, particularly for deployment in older buildings where wiring costs are high, as well as environments in which workers may be moving frequently.

Many of the initial wireless LANs in the United States have used radiofrequencies in one of the ISM (instrumentation, scientific, medical) bands, which generally may be used without individual site licensing subject to restrictions on power output. The data rates on these systems range from tens of kilobits per second to tens of megabits per second, with typical ranges of a few hundreds of meters. Wireless LANs are still evolving, but instances of several standards are now the basis for extremely popular products.

The most significant developments in this area are based on the IEEE 802.11 standard. It is based on a CSMA/CA (CSMA with Collision Avoidance) MAC layer with multiple physical layers, including direct sequence spread spectrum, orthogonal frequency-division multiplexing, frequency-hopping spread spectrum, and infrared. The widely deployed IEEE 802.11b standard provides data rates of 11 Mbps over a range of approximately 100 m in typical radio configurations using the 2.4-GHz ISM band. This has been supplemented by the IEEE 802.11g standard that provides data rates up to 22 Mbps at these same frequencies in a backward compatible manner. The IEEE 802.11a standard provides 54 Mbps rates using radios in the 5-GHz unlicensed bands.

Another wireless local area networking technology that is increasingly popular is Bluetooth. This is intended to be a very-local-area-network, often referred to as a personal-area network, with ranges typically up to only 10 m and data rates below 1 Mbps. This standard also uses the 2.4-GHz ISM frequency band, with frequency hopping spread spectrum. Although Bluetooth is often called a

“cable replacement” technology, it also offers computer-to-computer connectivity within its local region.

Wireless LANs will offer the opportunity to connect all manners of devices such as sensors and instruments to the increasingly pervasive network.

LOOP ANTENNAS

KAZIMIERZ SIWIAK
TimeDerivative, Inc.
Coral Springs, Florida

The *IEEE Standard Definitions of Terms for Antennas* [1] defines the loop as “an antenna whose configuration is that of a loop,” further noting that “if the current in the loop, or in the multiple parallel turns of the loop, is essentially uniform and the loop circumference is small compared with the wavelength, the radiation pattern approximates that of a magnetic dipole.” That definition and the further note imply the two basic realms of loop antennas: electrically small, and electrically large structures.

There are hundreds of millions of loop antennas currently in use [2] by subscribers of personal communication devices, primarily pagers. Furthermore, loops have appeared as transmitting arrays, like the massive multielement loop array at shortwave station HCJB in Quito, Ecuador, and as fractional wavelength-size tunable HF transmitting antennas. The loop is indeed an important and pervasive communication antenna.

The following analysis of loop antennas reveals that the loop, when small compared with a wavelength, exhibits a radiation resistance proportional to the square of the enclosed area. Extremely low values of radiation resistance are encountered for such loops, and extreme care must be taken to effect efficient antenna designs. Furthermore, when the small loop is implemented as a transmitting resonant circuit, surprisingly high voltages can exist across the resonating capacitor even for modest applied transmitter power levels. The wave impedance in the immediate vicinity of the loop is low, but at close distances

(0.1–2 wavelengths) exceeds the intrinsic free-space impedance before approaching that value.

A loop analysis that applies to loops of arbitrary circular diameter and of arbitrary wire thickness is summarized here. The analysis leads to some detail regarding the current density in the cross section of the wire. Loops of shapes other than circular are less easily analyzed, and are best handled by numerical methods such as moment method described in Ref. 3.

Loops are the antennas of choice in pager receivers, and appear as both ferrite loaded loops and as single-turn rectangular shaped structure within the radio housing. Body-worn loops benefit from a field enhancement due to the resonant behavior of human body with respect to vertically polarized waves. In the high-frequency bands, the loop is used as a series resonant circuit fed by a secondary loop. The structure can be tuned over a very large frequency band while maintaining a relatively constant feedpoint impedance. Large loop arrays consisting of one-wavelength-perimeter square loops have been successfully implemented as high-gain transmitting structures at high-power shortwave stations.

1. ANALYSIS OF LOOP ANTENNAS

Loop antennas, particularly circular loops, were among the first radiating structures analyzed beginning as early as 1897 with Pocklington’s analysis [4] of the thin wire loop excited by a plane wave. Later, Hallén [5] and Storer [6] studied driven loops. All these authors used a Fourier expansion of the loop current, and the latter two authors discovered numerical difficulties with the approach. The difficulties could be avoided, as pointed out by Wu [7], by integrating the Green function over the toroidal surface of the surface of the wire. The present author coauthored an improved theory [8,9] that specifically takes into account the finite dimension of the loop wire and extends the validity of the solution to wires thicker than previously considered. Additionally, the work revealed some detail of the loop current around the loop cross section. Arbitrarily shaped loops, such as triangular loops and square loops, as well as loop arrays, can be conveniently analyzed using numerical methods.

1.1. The Infinitesimal Loop Antenna

The infinitesimal current loop consists of a circulating current I enclosing an infinitesimal surface area S , and is solved by analogy to the infinitesimal dipole. The fields of an elementary loop element of radius b can be written in terms of the loop enclosed area $S = \pi b^2$ and a constant excitation current I (when I is RMS, then the fields are also RMS quantities). The fields are “near” in the sense that the distance parameter r is far smaller than the wavelength, but far larger than the loop dimension $2b$. Hence, this is *not* the *close* near-field region. The term kIS is often called the *loop moment* and is analogous to the similar term Ih associated with the *dipole moment*. The infinitesimally small loop is pictured in Fig. 1a next to its elementary dipole analog (Fig. 1b). The dipole uniform current I flowing over an elemental length h is the dual of a

Figure 1. Small-antenna geometry showing (a) the parameters of the infinitesimal loop moment, (b) its elementary dipole dual. Source: After Siwiak [2].

“magnetic current” $M_z S = Ih$ and the surface area is $S = h/k$. The fields due to the infinitesimal loop are then found from the vector and scalar potentials.

1.1.1. Vector and Scalar Potentials. The wave equation, in the form of the inhomogeneous Helmholtz equation, is used here with most of the underlying vector arithmetic omitted (see Refs. 10–12 for more details). For a magnetic current element source, the electric displacement \mathbf{D} is always solenoidal (the field lines do not originate or terminate on sources); that is, in the absence of source charges the divergence is zero

$$\nabla \cdot \mathbf{D} = 0 \quad (1)$$

and the electric displacement field can be represented by the curl of an arbitrary vector \mathbf{F}

$$\mathbf{D} = \varepsilon_0 \mathbf{E} = \nabla \times \mathbf{F} \quad (2)$$

where \mathbf{F} is the vector potential and obeys the vector identity $\nabla \cdot \nabla \times \mathbf{F} = 0$. Using Ampere’s law in the absence of electric sources

$$\nabla \times \mathbf{H} = j\omega \varepsilon_0 \mathbf{E} \quad (3)$$

and with the vector identity $\nabla \times (-\nabla\Phi) = 0$, where Φ represents an arbitrary scalar function of position, it follows that

$$\mathbf{H} = -\nabla\Phi - j\omega \mathbf{F} \quad (4)$$

and for a homogeneous medium, after some manipulation, we get

$$\nabla^2 \mathbf{F} + k^2 \mathbf{F} = -\varepsilon_0 \mathbf{M} + \nabla(\nabla \cdot \mathbf{F} + j\omega \mu_0 \varepsilon_0 \Phi) \quad (5)$$

where k is the wavenumber and $k^2 = \omega^2 \mu_0 \varepsilon_0$. Although Eq. (2) defines the curl of \mathbf{F} , the divergence of \mathbf{F} can be independently defined and the *Lorentz condition* is chosen

$$j\omega \mu_0 \varepsilon_0 \Phi = -\nabla \cdot \mathbf{F} \quad (6)$$

where ∇^2 is the Laplacian operator given by

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad (7)$$

Substituting the simplification of Eq. (6) into (5) leads to the inhomogeneous Helmholtz equation

$$\nabla^2 \mathbf{F} + k^2 \mathbf{F} = -\varepsilon_0 \mathbf{M} \quad (8)$$

Similarly, using Eqs. (6) and (4), it is seen that

$$\nabla^2 \Phi + k^2 \Phi = 0 \quad (9)$$

Using Eq. (4) and the Lorentz condition of Eq. (6), we can find the electric field solely in terms of the vector potential \mathbf{F} . The utility of that definition becomes apparent when we consider a magnetic current source aligned along a single vector direction, for example, $\mathbf{M} = \mathbf{z}M_z$, for which the vector potential is $\mathbf{F} = \mathbf{z}F_z$, where \mathbf{z} is the unit vector aligned with the z -axis, and Eq. (8) becomes a scalar equation.

1.1.2. Radiation from a Magnetic Current Element. The solution to the wave equation [Eq. (8)] presented here, with the details suppressed, is a spherical wave. The results are used to derive the radiation properties of the infinitesimal current loop as the dual of the infinitesimal current element. The infinitesimal magnetic current element $\mathbf{M} = \mathbf{z}M_z$ located at the origin satisfies a one-dimensional, hence scalar, form of Eq. (8). At points excluding the origin where the infinitesimal current element is located, Eq. (8) is source-free and is written as a function of radial distance r

$$\nabla^2 F_z(r) + k^2 F_z(r) = \frac{1}{r^2} \frac{\partial}{\partial r} \left[r^2 \frac{\partial F_z(r)}{\partial r} \right] + k^2 F_z(r) = 0 \quad (10)$$

which can be reduced to

$$\frac{d^2 F_z(r)}{dr^2} + \frac{2}{r} \frac{dF_z(r)}{dr} + k^2 F_z(r) = 0 \quad (11)$$

Since F_z is a function of only the radial coordinate, the partial derivative in Eq. (10) was replaced with the ordinary derivative. Equation (11) has a solution

$$F_z = C_1 \frac{e^{-jkr}}{r} \quad (12)$$

There is a second solution where the exponent of the phasor quantity is positive; however, we are interested here in outward traveling waves so we discard that solution. In the static case the phasor quantity is unity. The constant C_1 is related to the strength of the source current, and is found by integrating Eq. (8) over the volume including the source, giving

$$C_1 = \frac{\varepsilon_0}{4\pi} kIS \quad (13)$$

and the solution for the vector potential is in the \mathbf{z} unit vector direction

$$\mathbf{F} = \frac{\varepsilon_0}{4\pi} kIS \frac{e^{-jkr}}{r} \mathbf{z} \quad (14)$$

which is an outward propagating spherical wave with increasing phase delay (increasingly negative phase) and with amplitude decreasing as the inverse of distance. We may now solve for the magnetic fields of an infinitesimal current element by inserting Eq. (14) into Eq. (4) with Eq. (6) and then for the electric field by using Eq. (2). The fields, after sufficient manipulation, and for $r \gg kS$, are

$$H_r = \frac{kIS}{2\pi} e^{-jkr} k^2 \left[\frac{j}{(kr)^2} + \frac{1}{(kr)^3} \right] \cos(\theta) \quad (15)$$

$$H_\theta = \frac{kIS}{4\pi} e^{-jkr} k^2 \left[-\frac{1}{kr} + \frac{j}{(kr)^2} + \frac{1}{(kr)^3} \right] \sin(\theta) \quad (16)$$

$$E_\phi = \eta_0 \frac{kIS}{4\pi} e^{-jkr} k^2 \left[\frac{1}{kr} - \frac{j}{(kr)^2} \right] \sin(\theta) \quad (17)$$

where $\eta_0 = c\mu_0 = 376.730313$ is the intrinsic free-space impedance, c is the velocity of propagation (see Ref. 13 for definitions of constants), and I is the loop current.

The equations for the *magnetic* fields H_r and H_θ of the infinitesimal [Eqs. (15) and (16)] loop have exactly the same form as the *electric* fields E_r and E_θ for the infinitesimal dipole, while Eq. (17) for the *electric* field of the loop E_ϕ has exactly the same form as the *magnetic* field H_ϕ of the dipole when the term kIS of the loop expressions is replaced with Ih for the infinitesimal ideal (uniform current element) dipole. In the case where the loop moment kIS is superimposed on, and equals the dipole moment Ih , the fields in all space will be circularly polarized.

Equations (15)–(17) describe a particularly complex field behavior for what is a very idealized selection of sources: a simple linear magnetic current M representing a current loop I encompassing an infinitesimal surface $S = \pi b^2$. Expressions (15)–(17) are valid only in the region sufficiently far ($r \gg kS$) from the region of the magnetic current source M .

1.1.3. The Wave Impedance of Loop Radiation. The *wave impedance* can be defined as ratio of the total energy in the electric field divided by the total energy in the magnetic field. We can study the wave impedance of the loop fields by using Eqs. (15)–(17) for the infinitesimal loop fields, along with their dual quantities for the ideal electric dipole. Figure 2 shows the loop field wave impedance as a function of distance kr from the loop along the direction of maximum far-field radiation. The wave impedance for the elementary dipole is shown for comparison. At distances near $kr = 1$ the wave impedance of loop radiation exceeds $\eta_0 = 376.73\Omega$, the intrinsic free space impedance, while that of the infinitesimal loop is below 376.73Ω . In this region, the electric fields of the loop dominate.

1.1.4. The Radiation Regions of Loops. Inspection of Eqs. (15)–(17) for the loop reveal a very complex field structure. There are components of the fields that vary as the inverse third power of distance r , the inverse square of r , and the inverse of r . In the near field or induction region of the idealized infinitesimal loop, that is, for $kr \ll 1$ (however,

Figure 2. Small loop antenna and dipole antenna wave impedances compared. *Source:* After Siwiak [2].

$r \gg kS$ for the loop and $r \gg h$ for the dipole), the magnetic fields vary as the inverse third power of distance.

The region where kr is nearly unity is part of the radiating near field of the Fresnel zone. The inner boundary of that zone is taken by Jordan [12] to be $r^2 > 0.38D^3/\lambda$ and the outer boundary is $r < 2D^2/\lambda$ where D is the largest dimension of the antenna, here equal to $2b$. The outer boundary criterion is based on a maximum phase error of $\pi/8$. There is a significant radial component of the field in the Fresnel zone.

The far field or Fraunhofer zone is region of the field for which the angular radiation pattern is essentially independent of distance. That region is usually defined as extending from $r < 2D^2/\lambda$ to infinity, and the field amplitudes there are essentially proportional to the inverse of distance from the source. The far-zone behavior is identified with the basic free-space propagation law.

1.1.5. The Induction Zone of Loops. We can study the “induction zone” in comparison to the “far field” by considering “induction zone” coupling which was investigated by Hazeltine [14], and which was applied to low-frequency radio receiver designs of his time. Today the problem might be applied to the design of a miniature radio module where inductors must be oriented for minimum coupling. The problem Hazeltine solved was one of finding the geometric orientation for which two loops in parallel planes have minimum coupling in the induction zone of their near fields and serves to illustrate that the near-field behavior differs fundamentally and significantly from far-field behavior. To study the problem, we invoke the principle of reciprocity which states

$$\int_V [\mathbf{E}_b \cdot \mathbf{J}_a - \mathbf{H}_b \cdot \mathbf{M}_a] dV = \int_V [\mathbf{E}_a \cdot \mathbf{J}_b - \mathbf{H}_a \cdot \mathbf{M}_b] dV \quad (18)$$

Figure 3. Two small loops in parallel planes and with $\theta = 54.736$ degrees will not couple in their near fields. *Source:* After Siwiak [2].

That is, the reaction on antenna *a* of sources *b* equals the reaction on antenna *b* of sources *a*. For two loops with loop moments parallel to the *z* axis, we want to find the angle θ for which the coupling between the loops vanishes, that is, both sides of Eq. (18) are zero. The reference geometry is shown in Fig. 3. In the case of the loop, there are no electric sources in Eq. (18), so $\mathbf{J}_a = \mathbf{J}_b = 0$, and both \mathbf{M}_a and \mathbf{M}_b are aligned with \mathbf{z} , the unit vector parallel to the *z* axis. Retaining only the inductive field, components and clearing common constants in Eqs. (15) and (17) are placed into (18). We require that $(H_r \mathbf{r} + H_\theta \theta) \mathbf{z} = 0$. Since $\mathbf{r} \cdot \mathbf{z} = -\sin(\theta)$ and $\mathbf{r} \cdot \mathbf{z} = \cos(\theta)$, we are left with $2 \cos^2(\theta) - \sin^2(\theta) = 0$, for which $\theta = 54.736^\circ$. When oriented as shown in Fig. 3, two loops parallel to the *x-y* plane whose centers are displaced by an angle of 54.736° with respect to the *z* axis will not couple in their near fields. To be sure, the angle determined above is “exactly” correct for infinitesimally small loops; however, that angle will be nominally the same for larger loops. Hazeltine [14] used this principle, placing the axes of the inductors in a common plane each at an angle of 54.7° with respect to the normal form the radio chassis, to minimize the coupling between the inductors.

The same principle can be exploited in the design of a metal detector, as depicted in Fig. 4. The loop *a* is driven with an audiofrequency oscillator. Loop *b*, in a parallel plane and displaced so that nominally $\theta = 54.7^\circ$, is connected to a detector that might comprise an audio amplifier that feeds a set of headphones. Any conductive object near loop *a* will disrupt the balance of the system and result in an increased coupling between the two loops, thus indicating the presence of a conducting object near *a*.

Figure 4. A metal detector employs two loops initially oriented to minimize coupling in their near fields.

1.1.6. The Intermediate and Far-Field Zones of Loops. The loop coupling problem provides us with a way to investigate the intermediate and far-field coupling by applying Eq. (18) with Eqs. (15) and (16) for various loop separations kr . In the far-field region only the H_θ term of the magnetic field survives, and by inspection of Eq. (16), the minimum coupling occurs for $\theta = 0$ or 180° . Figure 5 compares the coupling (normalized to their peak values) for loops in parallel planes whose fields are given by Eqs. (15)–(17). Figure 5 shows the coupling as a function of angle θ for an intermediate region ($kr = 2$) and for the far-field case ($kr = 1000$) in comparison with the induction-zone case ($kr = 0.001$). The patterns are fundamentally and significantly different. The coupling null at $\theta = 54.7^\circ$ is clearly evident for the induction-zone case $kr = 0.001$ and for which the $(1/kr)^3$ terms dominate. Equally evident is the far-field coupling null for parallel loops on a common axis when the $1/kr$ terms dominate. The intermediate zone coupling shows a transitional behavior where all the terms in kr are comparable.

1.1.7. The Directivity and Impedance of Small Loops. The *directive gain* of the small loop can be found from the far-field radially directed Poynting vector in a ratio to the average Poynting vector over the radian sphere:

$$D(\theta, \phi) = \frac{|\mathbf{E} \times \mathbf{H} \cdot \mathbf{r}|}{\frac{1}{4\pi} \int_0^{2\pi} \int_0^\pi |\mathbf{E} \times \mathbf{H} \cdot \mathbf{r}| \sin(\theta) d\theta d\phi} \quad (19)$$

Only the θ component of *H* and the ϕ component of *E* survive into the far-field. Using Eq. (16) for H_θ and (17) for E_ϕ and retaining only the $1/kr$ terms, Eq. (19) yields $D = 1.5 \sin^2(\theta)$ by noting that the functional form of the product of *E* and *H* is simply $\sin^2(\theta)$ and by carrying out the simple integration in the denominator of Eq. (19).

Figure 5. Normalized induction zone, intermediate zone, and far zone coupling between loops in parallel planes. *Source:* After Siwiak [2].

Taking into account the directive gain, the far-field power density P_d in the peak of the pattern is

$$P_d = \frac{1.5 I^2 R_{\text{radiation}}}{4\pi r^2} = H_0^2 \eta_0 = \left[\frac{kS}{4\pi} \frac{k}{r} I \right]^2 \eta_0 \quad (20)$$

for radiated power $I^2 R_{\text{rad}}$; hence, we can solve for the radiation resistance

$$R_{\text{rad}} = \frac{(kS)^2}{6\pi} \eta_0 = \eta_0 \frac{\pi}{6} (kb)^4 \quad (21)$$

for the infinitesimal loop of loop radius b .

When fed by a gap, there is a dipole moment that adds terms not only to the impedance of the loop but also to the close near fields. For the geometry shown in Fig. 6, and using the analysis of King [15], the electrically small loop, having a diameter $2b$ and wire diameter $2a$, exhibits a feedpoint impedance given by

$$\begin{aligned} Z_{\text{loop}} = \eta_0 \frac{\pi}{6} (kb)^4 [1 + 8(kb)^2] \left[1 - \frac{a^2}{b^2} \right] \cdots \\ + j\eta kb \left[\ln \left[\frac{8b}{a} \right] - 2 + \frac{2}{3} (kb)^2 \right] [1 + 2(kb)^2] \end{aligned} \quad (22)$$

including dipole-mode terms valid for $kb \ll 0.1$. The leading term of Eq. (22) is the same as derived in Eq. (21) for the infinitesimal loop. Expression (22) adds the detail of terms considering the dipole moment of the gap-fed loop as well as refinements for loop wire radius a . The small loop antenna is characterized by a radiation resistance that is proportional to the fourth power of the loop radius b . The reactance is inductive and hence is proportional to the antenna radius. It follows that the Q is inversely proportional to the third power of the loop radius, a result that is consistent with the fundamental limit behavior for small antennas.

Using Eq. (22), and ignoring the dipole mode terms and second-order terms in a/b , the unloaded Q of the loop antenna, is

$$Q_{\text{loop}} = \frac{6}{\pi} \frac{\left[\ln \left[\frac{8b}{a} \right] - 2 \right]}{(kb)^3} \quad (23)$$

which for $b/a = 6$ becomes

$$Q_{\text{loop}} = \frac{3.6}{(kb)^3} \quad (24)$$

Figure 6. Parameters of the fat wire loop. *Source:* After Siwiak [2].

which has the proper limiting behavior for the small loop radius. The Q of the small loop given by Eq. (23) is indeed larger than the minimum possible $Q_{\text{min}} = (kb)^{-3}$ predicted in Siwiak [2] for a structure of its size. It must be emphasized that the actual Q of such an antenna will be smaller than given by Eq. (24) because of unavoidable dissipative losses not represented in Eq. (22)–(24). We can approach the minimum Q but never be smaller, except by introducing dissipative losses.

1.2. The Gap-Fed Loop

The analysis of arbitrarily fat wire loops follows the method in Ref. 8, shown in simplified form in Ref. 9 and summarized here. The toroid geometry of the loop is expressed in cylindrical coordinates ρ , ϕ , and z with the toroid located symmetrically in the $z = 0$ plane. The relevant geometry is shown in Fig. 6.

1.2.1. Loop Surface Current Density. The current density on the surface of the toroidal surface of the loop is given by

$$J_\phi = \sum_{n=-\infty}^{\infty} \sum_{p=-\infty}^{\infty} A_{n,p} e^{jn\phi} F_p \quad (25)$$

where the functions F_p are symmetric about the z axis and are simple functions of $\cos(n\psi)$, where ψ is in the cross section of the wire as shown in Fig. 6 and is related to the cylindrical coordinate by $z = a \sin(\psi)$. These functions are orthonormalized over the conductor surface using the Gram–Schmidt method described in Ref. 16, yielding

$$F_0 = \frac{1}{2\pi\sqrt{ab}} \quad (26)$$

and

$$F_1 = F_0 \sqrt{\frac{2}{1 - (a/2b)^2}} \left[\cos(\psi) - \frac{a}{2b} \right] \quad (27)$$

The higher-order functions are lengthy but simple functions of $\sin(p\psi)$ and $\cos(p\psi)$.

1.2.2. Scalar and Vector Potentials. The electric field is obtained from the following vector and scalar potentials:

$$\mathbf{E} = -\nabla\Phi - j\omega\mathbf{A} \quad (28)$$

The boundary conditions require that E_ϕ , E_ψ , and E_ρ be zero on the surface of the loop everywhere except at the feed gap $|\phi| \leq \epsilon$. Because this analysis will be limited to wire diameters significantly smaller than a wavelength, the boundary conditions on E_ψ and E_ρ will not be enforced. In the gap $E_\phi = V_0/2\epsilon\rho$, where V_0 is the gap excitation voltage.

The components of the vector potential are simply

$$A_\phi = \frac{1}{4\pi} \int_S \int J_\phi \cos(\phi - \phi') dS \quad (29)$$

and

$$A_\rho = \frac{1}{4\pi} \int_S \int J_\phi \sin(\phi - \phi') dS \quad (30)$$

and the vector potential is

$$\Phi = \frac{j\eta_0}{4\pi k} \int_S \int \frac{1}{\rho} \frac{\partial J_\phi}{\partial \phi} G dS \quad (31)$$

where the value of $dS = [b + a \sin(\psi)]a d\psi$. Green's function G is expressed in terms of cylindrical waves to match the rotational symmetry of the loop

$$G = \frac{1}{2j} \sum_{m=-\infty}^{\infty} e^{-jm(\phi-\phi')} \int_{-\infty}^{\infty} J_m(\rho_1 - v) H_m^{(2)}(\rho_2 - v) e^{-j\zeta(z-z')} d\zeta \quad (32)$$

where

$$\begin{aligned} v &= \sqrt{k^2 + \zeta^2} \\ \rho_1 &= \rho - a \cos(\psi) \\ \rho_2 &= \rho + a \cos(\psi) \end{aligned}$$

and where $J_m(v\rho)$ and $H_m^{(2)}(v\rho)$ are the Bessel and Hankel functions, respectively.

1.2.3. Matching the Boundary Conditions. Expression (8) is now inserted into Eqs. (5)–(8), and the electric field is then found from Eq. (2) and the boundary condition is enforced. For constant ρ on the wire

$$\int_{-\pi}^{\pi} E_\phi e^{jm\phi} d\phi = -\frac{V_0}{\rho} \frac{\sin(m\varepsilon)}{m\varepsilon} \quad (33)$$

This condition is enforced on the wire as many times as there are harmonics in ψ . Truncating the index p as described in Ref. 9 to a small finite number P , we force $E_\phi = 0$ except in the feeding gap along the lines of constant ρ on the surface of the toroid. If we truncate to P , the number of harmonics F_p in ψ , and to M the number of harmonics in ϕ , we find the radiation current by solving M systems of $P \times P$ algebraic equations in $A_{m,p}$. In Ref. 9, $P = 2$ and M in the several hundreds was found to be a reasonable computational task that led to useful solutions.

1.2.4. Loop Fields and Impedance. With the harmonic amplitudes $A_{m,p}$ known, the current density is found from Eq. (1). The electric field is found next from Eq. (2) and the

magnetic field is given by

$$H_\rho = -\frac{\partial A_\phi}{\partial z} \quad (34)$$

$$H_\phi = -\frac{\partial A_\rho}{\partial z} \quad (35)$$

$$H_z = -\frac{\partial A_\phi}{\partial \rho} + \frac{A_\phi}{\rho} - \frac{1}{\rho} \frac{\partial A_\rho}{\partial \rho} \quad (36)$$

The loop current across a section of the wire is found by integrating the function J_ϕ in Eq. (25) around the wire cross section. The loop radiation impedance is then the applied voltage V_0 in the gap divided by the current in the gap. Figure 7 shows the loop feed radiation resistance, and Fig. 8 shows the corresponding loop reactance, as a function of loop radius kr for a thin-wire ($\Omega = 15$) loop and a fat wire ($\Omega = 10$) loop where $\Omega = 2 \ln(2\pi b/a)$. The thin-wire loop has very sharp resonant behavior compared with the fat-wire loop, especially for a half-wavelength-diameter ($kb = 0.5$) structure. The higher resonances are less pronounced for both loops. Fat-wire loops exhibit an interesting behavior in that at a diameter of about a half-wavelength, the reactance is essentially always capacitive and the total impedance remains well behaved.

1.2.5. Small Gap-Fed Loops. The detailed analysis of the fat, gap-fed wire loop, as shown in Refs. 8 and 9, reveals that the current density around the circumference of the wire, angle ψ in Fig. 6, is not constant. An approximation to the current density along the wire circumference for a small diameter loop is

$$J_\phi = \frac{I_\phi}{2\pi a} [1 - 2 \cos(\phi)(kb)^2][1 + Y \cos(\psi)] \quad (37)$$

where I_ϕ is the loop current, which has cosine variation along the loop circumference, and where the variation

Figure 7. Loop radiation resistance.

Figure 8. Loop reactance.

around the *wire circumference* is shown as a function of the angle ψ . Y is the ratio of the first-order to the zero-order modes in ϕ , and is not a simple function of loop dimensions a and b , but can be found numerically [2] and from the analysis of the previous section. For the small loop Y is negative and of order a/b , so Eq. (37) predicts that there is current bunching along the inner contour ($\psi = 180^\circ$) of the wire loop. Table 1 gives representative values for Y as a function of a/b .

This increased current density results in a corresponding increase in dissipative losses in the small loop. We can infer that the cross-sectional shape of the conductor formed into a loop antenna will impact the loss performance in a small loop.

The small loop fed with a voltage gap has a charge accumulation at the gap and will exhibit a close near electric field. For a small loop of radius b and centered in the x - y plane, the fields at $(x,y)=(0,0)$ are derived in Ref. 9 and given here as

$$E_\phi = -j \frac{\eta_0 k I}{2} \quad (38)$$

where I is the loop current and

$$H_z = \frac{I}{2b} \quad (39)$$

Table 1. Parameter Y for Various Loop Thickness and $b = 0.01$ Wavelengths

Ω	a/λ	Y
19.899	0.000003	-0.0039
17.491	0.00001	-0.0090
15.294	0.00003	-0.020
12.886	0.0001	-0.048
10.689	0.0003	-0.098
8.2809	0.001	-0.179

Expression (39) is recognized as the classic expression for the static magnetic field within a single-turn solenoid. Note that the electric field given by Eq. (38) does not depend on any loop dimensions, but was derived for an electrically small loop. The wave impedance Z_w at the origin is the ratio of E_ϕ to H_z and from Eqs. (38) and (39) is

$$Z_w = -j\eta_0 kb \quad (40)$$

In addition to providing insight into the behavior of loop probes, Eqs. (38)–(40) are useful in testing the results of numerical codes like the Numerical Electromagnetic Code (NEC) described in Ref. 3, and are often used in the numerical analysis of wire antenna structures.

When the small loop is used as an untuned and unshielded field probe, the current induced in the loop will have a component due to the magnetic field normal to the loop plane as well as a component due to the electric field in the plane of the loop. A measure of sensitivity of the E field to the H field is apparent from expression (40). The electric field to magnetic field sensitivity of a simple small loop probe is proportional to the loop diameter. The small gap-fed loop, then, has a dipole moment, which complicates its use as a purely magnetic field probe.

2. LOOP APPLICATIONS

Loop antennas appear in pager receivers as both ferrite-loaded loops and as single-turn rectangular structures within the radio housing. When worn on the belt, the loop benefits from coupling to the vertically resonant human body. In the high-frequency bands, the loop has been implemented as a series resonant circuit fed by a secondary loop. The structure can be tuned over a very large frequency band while maintaining a relatively constant feedpoint impedance. One-wavelength-perimeter square loops have been successfully implemented as high-gain transmitting structures.

2.1. The Ferrite-Loaded Loop Antenna: A Magnetic Dipole

Let us examine a small ferrite-loaded loop antenna with dimensions, $2h = 2.4$ cm and $2a = 0.4$ cm, and at a wavelength of about $\lambda = 8.6$ m as depicted in Fig. 9. When the permeability of the ferrite is sufficiently high, this antenna behaves like a magnetic dipole. The magnetic fields are strongly confined to the magnetic medium, especially near the midsection of the ferrite rod, and behave as the dual of the electric dipole excited by a triangular current distribution. We can therefore analyze its behavior using a small dipole analysis as shown by Siwiak [2].

The impedance at the midpoint of a short dipole having a current uniformly decreasing from the feed point across its length $2h$ is

$$Z_{\text{dipole}} = \frac{\eta_0}{6\pi} (kh)^2 - j \frac{\eta_0}{2\pi} \left[\ln \left[\frac{2h}{a} \right] - 1 \right] \quad (41)$$

Figure 9. A Ferrite loaded loop antenna. *Source:* After Siwiak [2].

The corresponding unloaded Q of the dipole antenna is

$$Q_{\text{dipole}} = \frac{3 \left[\ln \left[\frac{2h}{a} \right] - 1 \right]}{(kh)^3} \tag{42}$$

Equation (42) has the expected inverse third power with size behavior for small antennas, and for $h/a = 6$

$$Q_{\text{dipole}} = \frac{4.5}{(kh)^3} \tag{43}$$

Comparing the Q for a small dipole given by Eq. (43) with the Q of a small loop of Eq. (24), we see that the loop Q is small even though the same ratio of antenna dimension to wire radius was used. We conclude that the small loop utilizes the smallest sphere that encloses it more efficiently than does the small dipole. Indeed, the thin dipole is essentially a one-dimensional structure, while the small loop is essentially a two-dimensional structure.

We can use Eqs. (41) and (42) for the elementary dipole to examine the ferrite-loaded loop antenna since it resembles a magnetic dipole. The minimum ideal Q of this antenna is given by Eq. (42), 1.0×10^6 . The corresponding bandwidth of such an antenna having no dissipative losses would be $2 \times 35f/Q = 70 \text{ MHz}/1.3 \times 10^6 = 69 \text{ Hz}$. A practical ferrite antenna at this frequency has an actual unloaded Q_A of nearer to 100, as can be inferred from the performance of belt-mounted radios shown in Table 2. Hence, an

Table 2. Paging Receiver Performance Using Loops

Frequency Band (MHz)	Paging Receiver, at Belt Average Gain (dBi)	Field Strength Sensitivity (dB · μV/m)
30–50	–32 to –37	12–17
85	–26	13
160	–19 to –23	10–14
280–300	–16	10
460	–12	12
800–960	–9	18–28

estimate of the actual antenna efficiency is

$$10 \log \frac{Q_A}{Q} = -40 \text{ dB} \tag{44}$$

and the actual resultant 3 dB bandwidth is about 700 kHz. Such an antenna is typical of the type that would be used in a body-mounted paging receiver application. As detailed in Siwiak [2], the body exhibits an average magnetic field enhancement of about 6 dB at this frequency, so the average belt-mounted antenna gain is –34 dBi. This is typical of a front-position body-mounted paging or personal communication receiver performance in this frequency range.

2.2. Body Enhancement in Body-Worn Loops

Loops are often implemented as internal antennas in pager receiver applications spanning the frequency bands from 30 to 960 MHz. Pagers are often worn at belt level, and benefit from the “body enhancement” effect. The standing adult human body resembles a lossy wire antenna that resonates in the range of 40–80 MHz. The frequency response, as seen in Fig. 10, is broad, and for belt-mounted loop antennas polarized in the body axis direction, enhances the loop antenna azimuth-averaged gain at frequencies below ~500 MHz.

The far-field radiation pattern of a body-worn receiver is nearly omnidirectional at very low frequency. As frequency is increased, the pattern behind the body develops a shadow that is manifest as a deepening null with increasing frequency. In the high-frequency limit, there is only a forward lobe with the back half-space essentially completely blocked by the body. For horizontal incident polarization there is no longitudinal body resonance and there is only slight enhancement above 100 MHz.

2.3. The Small Resonated High-Frequency Loop

The simple loop may be resonated with a series capacitor having a magnitude of reactance equal to the loop

Figure 10. Gain-averaged body-enhanced loop response. *Source:* After Siwiak [2].

reactance, and indeed, is effectively implemented that way for use in the HF bands as discovered by Dunlavy [17]. When fed by a second untuned loop, this antenna will exhibit a nearly constant feedpoint impedance over a 3:1 or 4:1 bandwidth by simply adjusting the capacitor to the desired resonant frequency. The reactive part of the loop impedance is inductive, where the inductance is given by $\text{Im}\{Z_L\} = \omega L$, so ignoring the higher-order terms

$$L = \frac{\eta_0 k b \left[\ln \left[\frac{8b}{a} \right] - 2 \right]}{\omega} \quad (45)$$

which, with the substitution $\eta_0 k / \omega = \mu_0$, becomes

$$L = \mu_0 b \left[\ln \left[\frac{8b}{a} \right] - 2 \right] \quad (46)$$

The capacitance required to resonate this small loop at frequency f is

$$C = \frac{1}{(2\pi f)^2 L} \quad (47)$$

The loop may be coupled to a radio circuit in many different ways, including methods given in Refs. 17 and 18. When used in transmitter applications, the small loop antenna is capable of impressing a substantial voltage across the resonating capacitor. For a power P delivered to a small loop with unloaded Q of Eq. (23) and with resonating the reactance X_C given by the reactive part of Eq. (22), it is easy to show that the peak voltage across the resonating capacitor is

$$V_p = \sqrt{X_C Q P} \quad (48)$$

by recognizing that

$$V_p = \sqrt{2} I_{\text{RMS}} X_C \quad (49)$$

where I_{RMS} is the total RMS loop current

$$I_{\text{RMS}} = \sqrt{\frac{P}{\text{Re}\{Z_{\text{loop}}\}}} \quad (50)$$

along with Q at the resonant frequency in Eq. (23).

Transmitter power levels as low as one watt delivered to a moderately efficient small-diameter ($\lambda/100$) loop can result in peak values of several hundred volts across the resonating capacitor. This is not intuitively expected; the small loop is often viewed as a high-current circuit that is often described as a short-circuited ring. However, because it is usually implemented as a *resonant circuit* with a resonating capacitor, it can also be an extremely high-voltage circuit, as will be shown below. Care must be exercised in selecting the voltage rating of the resonating capacitor even for modest transmitting power levels, just

as care must be taken to keep resistive losses low in the loop structure.

As an example, consider the Q and bandwidth of a small loop antenna, $2b = 10$ cm in diameter, resonated by a series capacitor and operating at 30 MHz. The example loop is constructed of $2a = 1$ -cm-diameter copper tubing with conductivity $\sigma = 5.7 \times 10^7$ S/m. The resistance per unit length of round wire of diameter $2a$ with conductivity σ is

$$R_s = \frac{1}{2\pi a \delta_s \sigma} = \frac{1}{2\pi a} \sqrt{\frac{\omega \mu_0}{2\sigma}} \quad (51)$$

where δ_s is the skin depth for good conductors, ω is the radian frequency, and $\mu_0 = 4\pi \times 10^{-7}$ H/m is the permeability of free space, so $R_s = 0.046 \Omega$. From Eq. (22) the loop impedance is $Z = 0.00792 + j71.41$. Hence the loop efficiency can be found by comparing the loop radiation resistance with loss resistance. The loop efficiency is $R_s / (R_s + \text{Re}\{Z\}) = 0.147$ or 14.7%. From Eqs. (46) and (47) we find the resonating capacitance $C = 74.3 \mu\text{F}$. From Eqs. (48)–(50), we see that if 1 W is supplied to the loop, the peak voltage across the resonating capacitor will be 308 V, and the loop current will be 4.3 A. The *resonated* loop is by no means the “low-impedance structure” that we normally imagine it to be.

2.4. The Rectangular Loop

Pager and other miniature receiver antennas used in the 30–940 MHz frequency range are usually implemented as electrically small rectangular loops. For a rectangle dimensioned $b_1 \times b_2$ of comparable length, and constructed with $2a$ -diameter round wire, the loop impedance is given in Ref. 19 as

$$Z_{\text{rect}} = \frac{\eta_0}{6\pi} (k^2 A)^2 + j \frac{\eta_0}{\pi} \left[b_1 \ln \left[\frac{2A}{a(b_1 + b_c)} \right] + \left[b_2 \ln \left[\frac{2A}{a(b_2 + b_c)} \right] + 2(a + b_c - b_1 - b_2) \right] \right] \quad (52)$$

where $A = b_1 b_2$ and $b_c = (b_1^2 + b_2^2)^{1/2}$. The loss resistance is found by multiplying R_s in Eq. (51) by perimeter length of the loop, $2(b_1 + b_2)$. For a given antenna size the lowest loss occurs for the circular loop.

2.5. The Quad Loop Antenna

The quad loop antenna, sometimes called the “cubical quad,” was developed by Clarence C. Moore in the 1940s as a replacement for a four element parasitic dipole array (Yagi–Uda array). The dipole array exhibited corona arcing at the element tips severe enough to damage the antenna when operated at high power levels (10 kW) in a high-altitude (10,000-f) shortwave broadcasting application in the 25-m band. Moore sought an antenna design with “no tips” that would support extremely high electric field strengths, in order to avoid destructive arcing. His solution was a 1λ -perimeter square loop, later with a loop

Figure 11. Two element loop array.

director element as shown in Fig. 11. The configuration exhibited no arcing tendencies, and a new shortwave antenna configuration was born.

As pictured in Fig. 11, the driven element is approximately one-quarter wavelength on an edge. Actually, resonance occurs when the antenna perimeter is about 3% greater than a wavelength. The reflector element perimeter is approximately 6% larger than a wavelength, and may be implemented with a stub tuning arrangement. Typical element spacing is 0.14–0.25 wavelength. The directivity of a quad loop is approximately 2 dB greater than that of a Yagi antenna with the same element spacing.

LOW NOISE AMPLIFIERS

VIJAY NAIR
Intel Corporation
Hillsboro, Oregon

1. INTRODUCTION

Low-noise amplifiers (LNAs) are one of the most critical components of the today's communication receivers. In wireless systems, the input signal from the antenna first passes through an LNA that provides sufficient gain and noise reduction for the subsequent stages for the RF receiver at the frequency band of interest. This LNA should operate at low voltage, consume very low power, have wide dynamic range, and exhibit excellent low-noise properties. It should also have sufficient linearity for application in systems that employ digital modulation schemes. Very-low-power-consumption low-noise amplifiers are necessary for increasing talk time of wireless communication products. Semiconductor devices having high linearity and better noise figure–gain performance are needed for digital wireless systems. Front-end circuits with good performance have been fabricated using silicon CMOS, BJT, BiCMOS, GaAs MESFET, HFET, HBT, and SiGe technologies [1]. In this article we will discuss the low-noise amplifier design fundamentals, with special emphasis on low-power communication circuits.

2. DEVICE MODELING

A low-noise amplifier consists of transistors to provide the gain and matching circuits to tune the performance at the frequency range of interest. The gain and noise

characteristics of a transistor can be completely specified by the transistor's S -parameters and noise parameters. When an active device, such as a transistor, is employed in a two-port system, the amount of noise that it generates has to be considered carefully. This is often characterized by the ratio of the output signal power to output noise power. A term called *noise factor* is used to express this noise deterioration of the systems. The noise factor F is defined as

$$F = \frac{S/N \text{ power ratio at input}}{S/N \text{ power ratio at output}} \quad (1)$$

where N is noise and S is signal.

If G is the gain of the device, then the signal at the output is given by

$$S_{\text{output}} = GS_{\text{input}} \text{ and the noise at the output is given by } N_{\text{output}} = GN_{\text{input}} + \text{noise generated by the device.}$$

Hence, (1) can be rewritten as

$$F = \frac{N_{\text{output}}}{GN_{\text{input}}} \quad (2)$$

The noise figure in decibels is given by

$$F(\text{dB}) = 10 \log(F) \quad (3)$$

The major sources of noise in active device are thermal noise generated by the resistance and the shot noise generated by the current flowing through the active-device junctions. Noise properties of bipolar transistors can be described by an equivalent circuit as shown in Fig. 1a. Three noise generators are introduced into this common-emitter equivalent circuit to analyze the bipolar transistor noise properties. These noise generators are due to the fluctuations in the DC base current, collector current and thermal noise of the base resistance.

A simple noise equivalent circuit of a common-source FET, as shown in Fig 1b, considers the noise contributions of the gate resistance R_g , source resistance R_s , gate-to-source capacitance C_{gs} , and associated charging resistance R_i . Noise contributions due to other reactive parasitic elements such as the gate and source lead inductance are ignored, since they are negligible.

The noise figure in the presence of the source admittance Y_s can be written as

$$F = F_{\min} + \frac{R_n}{G_s} |Y_s - Y_{\text{opt}}|^2 \quad (4)$$

where $Y_s = G_s + jB_s$, connected at the input port. F_{\min} , R_n , and Y_{opt} characterize the device and are independent of its output terminations [2]. The optimum source admittance, $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$, is that particular value of source admittance Y_s for which the optimum noise factor F_{\min} is realized. Thus the noise performance of the device can be characterized by a set of four noise parameters: the minimum noise figure F_{\min} , the noise resistance R_n , and the optimum source admittance $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$, where G_{opt} and B_{opt} individually affect the noise figure.

Thus (4) can be rewritten as follows:

$$F = F_{\min} + \left(\frac{R_n}{G_s} \right) [(G_s - G_{\text{opt}})^2 + (B_s - B_{\text{opt}})^2] \quad (5)$$

Equation (5) can be converted to arbitrary impedance form as

$$F = F_{\min} + \frac{R_n [(R_{ss} - R_{\text{opt}})^2 + (X_{ss} - X_{\text{opt}})^2]}{R_{ss} (R_{\text{opt}}^2 + X_{\text{opt}}^2)} \quad (6)$$

where

$$Y_s = G_s + jB_s = \frac{1}{Z_s} = \frac{1}{(R_{ss} + jX_{ss})} \quad (7)$$

$$Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}} = \frac{1}{Z_{\text{opt}}} = \frac{1}{R_{\text{opt}} + jX_{\text{opt}}} \quad (8)$$

Thus, knowing the noise parameters F_{\min} , R_n , R_{opt} , and X_{opt} , the noise figure of the device can be calculated using (4) when the device is matched to Z_s instead of Z_{opt} .

3. LOW-NOISE BEHAVIOR OF BJTs AND FETs

The noise behavior of a bipolar device can be analyzed by introducing noise generators due to the fluctuations in the DC base current, collector current, and thermal noise of the base resistance into the common-emitter equivalent circuit shown in Fig. 1a. The mean-square values of these generators are given by [3]

$$i_b^2 = 2qI_b \Delta f \quad (9)$$

$$i_c^2 = 2qI_c \Delta f \quad (10)$$

$$e_b^2 = 4kTr_b \Delta f \quad (11)$$

where i_b is the base current noise generator, i_c is the collector current noise generator, e_b is the thermal noise voltage of the base resistor, I_b is the DC base current, I_c is the dc collector current, Δf is the narrow frequency interval, r_b is the base resistance, q is the electronic charge, k is the Boltzmann constant, and T is the absolute temperature.

Theoretical and experimental study of noise characteristics of a GaAs MESFET were performed by several researchers [4,5]. Fukui [6,7] developed a set of simple analytical expressions for the noise parameters of a MESFET. The Fukui equations shown below are used

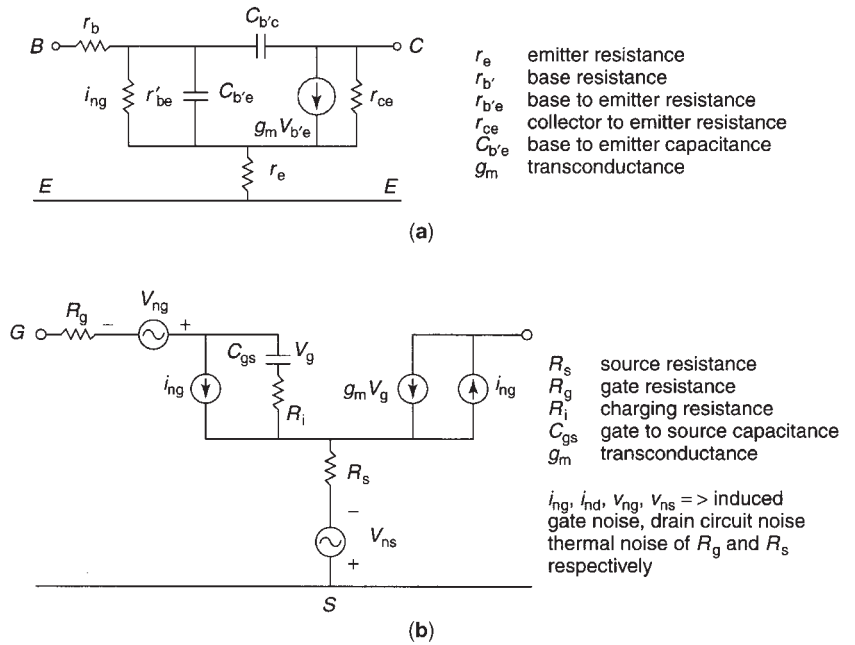

Figure 1. (a) Small-signal equivalent circuit of common-emitter BJT; (b) noise-equivalent circuit of a common-source FET.

extensively to estimate the noise parameters of a device

$$\begin{aligned}
 F_{\min} &= 1 + k_1 f C_{gs} \left(\sqrt{\frac{R_s + R_g}{g_m}} \right) \\
 R_n &= \frac{k_2}{g_m} \\
 R_{\text{opt}} &= k_3 \left[\frac{1}{4g_m} + R_s + R_g \right] \\
 X_{\text{opt}} &= \frac{k_4}{f C_{gs}}
 \end{aligned}
 \tag{12}$$

where k_1 , k_2 , k_3 , and k_4 are fitting factors and f is the operating frequency.

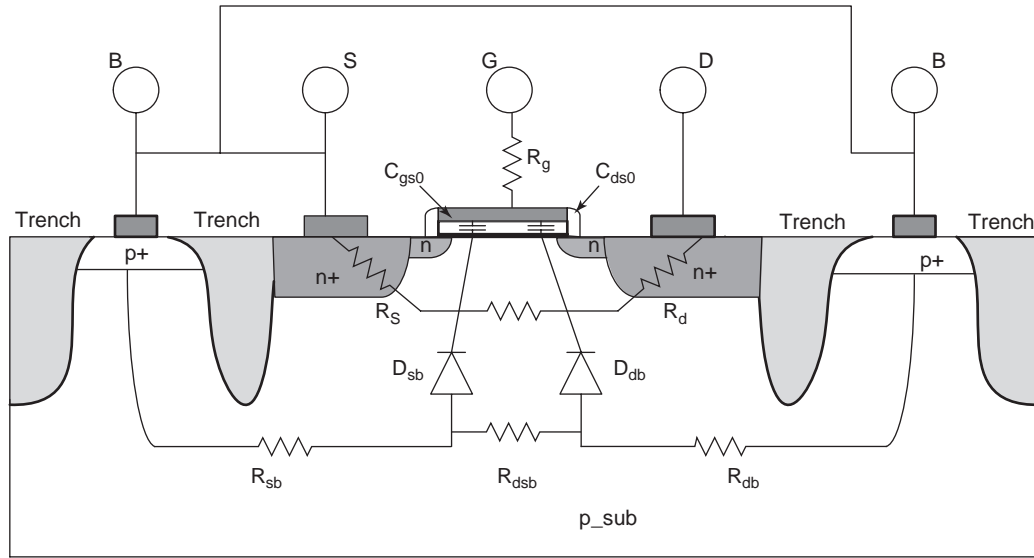

These fitting factors, estimated on the basis of the measured data on microwave transistors, are $k_1 = 0.016$, $k_2 = 0.8$, $k_3 = 2.2$, and $k_4 = 160$, provided the resistance is measured in ohms; transconductance g_m , in siemens; gate-to-source capacitance C_{gs} , in picofarads; and frequency f , in gigahertz. These empirical constants depend on the device manufacturing process and give a good estimate of the capabilities of different types of semiconductor device technologies. These constants have to be determined by measuring the S parameters and noise parameters of the devices.

The noise parameters and the S parameters should be taken into account while choosing a device for a low-noise amplifier design. A method for experimentally determining the noise parameters of a FET is described in Ref. 8. The noise characteristics of heterostructure devices such as HEMT and P-HEMT have been studied by Cappy et al. [9].

Advances in CMOS technology enabled the fabrication of MOSFETs having gate lengths below 100 nm. These devices have realized very high transit frequencies and very low noise figures. CMOS amplifiers with very good low-noise performance have been demonstrated for wireless system applications [10,11]. Figure 2a shows a schematic cross section of a MOSFET that depicts the origin properties of several parasitic elements. Although MOSFETs and MESFETs are very different in their operation and large-signal properties, the small-signal operations are very similar. Therefore theoretical and experimental studies of MESFET behavior can be used to analyze the MOSFET small-signal and high-frequency noise properties. A simplified equivalent circuit of a MOSFET suitable for noise analysis is shown in Fig. 3. Just as in the MESFET, the most important parasitic parameters are the gate resistance R_g , source resistance R_s , channel conductance g_0 , and gate capacitance C_{gs} . The dominant noise sources are the thermal noise associated with the gate noise, source resistance, and channel conductance. A noisy two-port network analysis can be used to study the MOSFET noise properties. Following an analysis similar to MESFET noise analysis, one can show that [12]

$$F_{\min} = 1 + 2\gamma g_{d0} \frac{f}{f_T} \left[\sqrt{\frac{R_g + R_s}{\gamma g_{d0}}} + \frac{f}{f_T} (R_g + R_s) \right]
 \tag{13}$$

where F_{\min} is the minimum noise figure, g_{d0} is the equivalent noise conductance of the channel, γ is a bias-dependent parameter, and R_s and R_g are the source and gate resistances, respectively. Since the second term inside the brackets is typically much smaller than the first, we can

| S - Source | D _{db} - Drain-to-bulk junction diode |
| D - Drain | R _{ds} - Drain-to-source resistance |
| G - Gate | R _{db} - Drain-to-substrate resistance |
| R _s - Source resistance | R _{sb} - Source-to-substrate resistance |
| R _d - Drain resistance | R _{dsb} - Drain-source to substrate resistance |
| R _g - Gate resistance | C _{gs0} - Gate-source overlap capacitance |
| | C _{ds0} - Gate-drain overlap capacitance |

Figure 2. Small-signal equivalent circuit of a CMOS device showing the origins of the parasitic components. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

approximate (13) as

$$F_{\min} \approx 1 + 2 \frac{f}{f_T} \sqrt{\gamma g_{d0} (R_g + R_s)} \quad (14)$$

and the optimum reactance is

$$X_{\text{opt}} = \frac{1}{\omega(C_{gs} + C_{gd})} \quad (19)$$

The cutoff frequency f_T is given by

$$f_T = \frac{g_m}{2\pi(C_{gs} + C_{gd})} \quad (15)$$

where g_m is the transconductance of the device and C_{gs} and C_{gd} are the gate-to-source and gate-to-drain capacitances, respectively.

The noise conductance G_n can be written as

$$G_n = \left(\frac{f}{f_T}\right)^2 \gamma g_{d0} \quad (16)$$

The optimum impedance is given by

$$Z_{\text{opt}} = R_{\text{opt}} + X_{\text{opt}} \quad (17)$$

where the optimum resistance is

$$R_{\text{opt}} \approx \frac{f_T}{f} \sqrt{\frac{R_g + R_s}{\gamma g_{d0}}} \quad (18)$$

For low-noise amplifier design, the device should be biased at the minimum noise figure point and the device width should be chosen so that optimum resistance is close to the driving resistance, which is typically 50 Ω. Also note that the minimum noise figure is independent of the gate width. In order to achieve a minimum noise figure, the

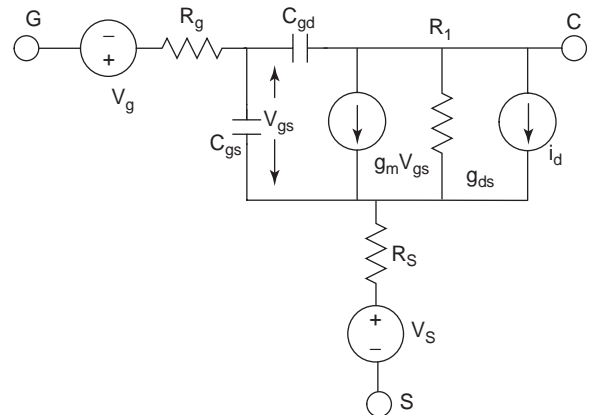

Figure 3. Noise-equivalent circuit of a common-source CMOS.

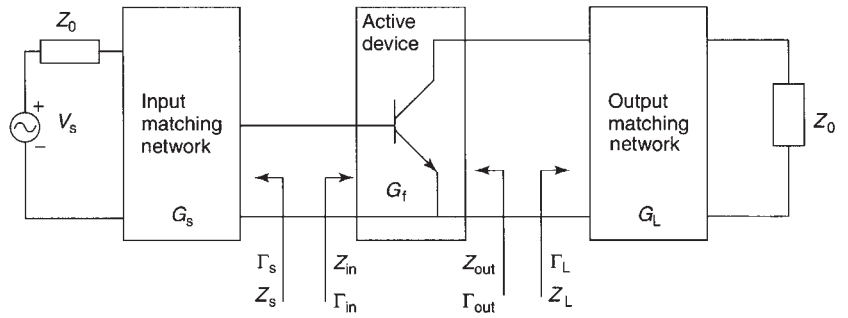

Figure 4. RF amplifier circuit block diagram depicting different power gains and reflection coefficients.

cutoff frequency of the device should be much higher than the operating frequency.

4. AMPLIFIER POWER GAIN EQUATIONS

Many power gain equations are derived from the two-port S parameters of the amplifier. Let us consider the power flow from the source to the load. Figure 4 shows a RF amplifier circuit block diagram depicting the different power gains and reflection coefficients.

The transducer power gain G_T of an amplifier is defined as the ratio of the output power P_L delivered to the load Z_L and the input power P_{avs} available from the source to the network.

$$G_T = G_T(\Gamma_G, \Gamma_L, S) = \frac{P_L}{P_{avs}} \quad (20)$$

This can be expressed in terms of two-port S parameters by

$$G_T = \frac{(1 - |\Gamma_s|^2)|S_{21}|^2(1 - |\Gamma_L|^2)}{|1 - S_{11}\Gamma_s|^2|1 - \Gamma_{out}\Gamma_L|^2} \quad (21)$$

or

$$G_T = \frac{(1 - |\Gamma_s|^2)|S_{21}|^2(1 - |\Gamma_L|^2)}{|1 - \Gamma_{in}\Gamma_s|^2|1 - S_{22}\Gamma_L|^2} \quad (22)$$

where

$$\Gamma_{in} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \quad (23)$$

$$\Gamma_{out} = S_{22} + \frac{S_{12}S_{21}\Gamma_s}{1 - S_{11}\Gamma_s} \quad (24)$$

When both the input and output networks are perfectly matched to the source impedance and the load impedance, respectively, the transducer power gain is given by

$$G_{Tm} = |S_{21}|^2 \quad (25)$$

The unilateral transducer power gain (i.e., $|S_{12}| = 0$) G_{Tu} is given by

$$G_{tu} = \frac{(1 - |\Gamma_s|^2)}{|1 - S_{11}\Gamma_s|^2} |S_{21}|^2 \frac{(1 - |\Gamma_L|^2)}{|1 - S_{22}\Gamma_L|^2} \quad (26)$$

We can rewrite this in the form

$$G_{tu} = G_s G_0 G_L \quad (27)$$

Term G_s , which depends only on the S_{11} parameter of the transistor and the source reflection coefficient, represents the gain or loss of the input matching circuits. Similarly G_L depends on the S_{22} parameter of the transistor and the load reflection coefficient. This represents the gain or loss of the output matching circuits. A block diagram of maximum unilateral gain amplifier is shown in Fig. 5. The middle term depends only on the S_{21} parameter of the transistor.

Maximum unilateral gain $G_{Tu,max}$ is achieved when

$$\Gamma_s = S_{11}^* \quad \text{and} \quad \Gamma_L = S_{22}^* \quad (28)$$

Figure 5. A block diagram of the maximum unilateral gain configuration of an RF amplifier.

and is given by

$$G_{\text{TU max}} = \frac{|S_{21}|^2}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (29)$$

5. AMPLIFIER STABILITY

Stability of RF amplifiers is one of the most important criteria in the circuit design. The amplifier stability can be determined from the S parameters, input and output matching networks, and circuit terminations. The amplifier can be conditionally or unconditionally stable. A two-port network as shown in Fig. 4 is unconditionally stable at a given frequency if the input and output resistances (the real part of Z_{in} and Z_{out}) of the device are positive for all passive source and load terminations. This also means that $|\Gamma_s| \leq 1$ and $|\Gamma_L| \leq 1$ in this case. An amplifier is conditionally stable if the real part of input impedance and output impedance of the amplifier are greater than zero for some positive part of real source and load impedances at a specific frequency.

5.1. Stability Circles

The conditions for unconditional stability can be written in terms of reflection coefficients as follows:

$$|\Gamma_s| \leq 1; \quad |\Gamma_L| \leq 1 \quad (30)$$

$$|\Gamma_{\text{in}}| = \left| S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \right| < 1 \quad (31)$$

$$|\Gamma_{\text{out}}| = \left| S_{22} + \frac{S_{12}S_{21}\Gamma_s}{1 - S_{11}\Gamma_s} \right| < 1 \quad (32)$$

Solutions to these equations give the required conditions for an amplifier to be unconditionally stable. When a two-port network is potentially unstable (or conditionally stable), there may be values of Γ_s and Γ_L for which the real parts of Z_{in} and Z_{out} are positive.

If we set $|\Gamma_{\text{in}}|$ and $|\Gamma_{\text{out}}|$ to unity, a boundary is established beyond which the amplifier becomes unstable. The boundary condition is given by

$$\left| S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \right| = 1 \quad (33)$$

$$\left| S_{22} + \frac{S_{12}S_{21}\Gamma_s}{1 - S_{11}\Gamma_s} \right| = 1 \quad (34)$$

Solutions to these two equations provide the values of Γ_s and Γ_L . It can be shown that the solutions for Γ_L and Γ_s lie on circles [13]. These circles are known as the *stability*

circles. The equations for these are given by

$$\left| \Gamma_L - \frac{(S_{22} - \Delta S_{11}^*)^*}{|S_{22}|^2 - |\Delta|^2} \right| = \frac{S_{12}S_{21}}{|S_{22}|^2 - |\Delta|^2} \quad (35)$$

$$\left| \Gamma_s - \frac{(S_{11} - \Delta S_{22}^*)^*}{|S_{11}|^2 - |\Delta|^2} \right| = \frac{S_{12}S_{21}}{|S_{11}|^2 - |\Delta|^2} \quad (36)$$

where

$$\Delta = S_{11}S_{22} - S_{12}S_{21} \quad (37)$$

The circles in the Γ_L plane where $|\Gamma_{\text{in}}| = 1$ are called *output stability circles* and the circles in the Γ_s plane where $|\Gamma_{\text{out}}| = 1$, the *input stability circles*. The radii and centers of input stability circles are given by

$$r_s \text{ (radius of } \Gamma_s \text{ circles)} = \left| \frac{S_{12}S_{21}}{|S_{11}|^2 - |\Delta|^2} \right| \quad (38)$$

$$C_s \text{ (center of } \Gamma_s \text{ circles)} = \frac{(S_{11} - \Delta S_{22}^*)^*}{|S_{11}|^2 - |\Delta|^2} \quad (39)$$

The radii and centers of output stability circles are given by

$$R_L \text{ (radius of } \Gamma_L \text{ circles)} = \left| \frac{S_{12}S_{21}}{|S_{22}|^2 - |\Delta|^2} \right| \quad (40)$$

$$C_L \text{ (center of } \Gamma_L \text{ circles)} = \frac{(S_{22} - \Delta S_{11}^*)^*}{|S_{22}|^2 - |\Delta|^2} \quad (41)$$

These equations can be plotted on a Smith chart provided the S parameters of the two-port network are known. Figure 6 illustrates the graphical construction of the stability circles where $|\Gamma_{\text{in}}| = 1$ and $|\Gamma_{\text{out}}| = 1$ in the Γ_L and Γ_s planes, respectively. On one side of the stability circle boundary in the Γ_L plane $|\Gamma_{\text{in}}| < 1$, and on the other side $|\Gamma_{\text{in}}| > 1$.

Similarly, on one side of the stability circle boundary in the Γ_s plane $|\Gamma_{\text{out}}| < 1$, and on the other side $|\Gamma_{\text{out}}| > 1$.

Figure 6. Graphical illustration of construction of stability circles where $|\Gamma_{\text{in}}| = 1$ and $|\Gamma_{\text{out}}| = 1$: (a) Γ_L plane; (b) Γ_s plane.

Stability circles can be plotted on the Smith chart directly. These circles separate the output or input planes into stable or unstable regions. A stability circle plotted on the input plane indicates the values of all the loads that provide negative real part of output impedances. Similarly stability circle plotted on the output plane indicates the values of all the loads that provide negative real parts of input impedances. A *negative real part* of impedance is defined as a reflection coefficient that has a magnitude that is greater than unity. The presence of the negative part of impedances at amplifier input or output causes the amplifier to oscillate. The next step is to determine which area in the Smith chart region is stable:

If $Z_L = Z_0$, then $\Gamma_L = 0$, and $\Gamma_{in} = |S_{11}|$ [from (30)].

If $|S_{11}| < 1$, then $|\Gamma_{in}| < 1$ when $\Gamma_L = 0$.

This means that the center of the Smith chart represents a stable operating point in the Γ_L plane:

If $|S_{11}| > 1$ when $Z_L = Z_0$, then $|\Gamma_{in}| > 1$ when $\Gamma_L = 0$.

This means that the center of the Smith chart represents an unstable operating point. These two cases are shown in Figs. 7a and 7b. The shaded area represents values of Γ_L that produce a stable region. Similarly, Figs. 8a and 8b show stable and unstable regions in the Γ_s plane.

For unconditional stability, any passive source or load impedances in a two-port network must produce stability circles completely outside the Smith chart as shown in Figs. 9a and 9b. The conditions for unconditional stability for all passive loads and sources can be expressed in the form:

$$||C_L| - r_L| > 1 \text{ for } |S_{11}| \tag{42}$$

$$||C_s| - r_s| > 1 \text{ for } |S_{22}| \tag{43}$$

The necessary and sufficient stability conditions can be summarized as follows. A stability factor K for an amplifier can be expressed as

$$K = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |\Delta|^2}{2|S_{12}S_{21}|} > 1 \tag{44}$$

$$1 - |S_{11}|^2 > |S_{12}S_{21}| \tag{45}$$

$$1 - |S_{22}|^2 > |S_{12}S_{21}| \tag{46}$$

Figure 7. Smith chart showing stable and unstable regions in the Γ_L plane: (a) $|S_{11}| < 1$; (b) $|S_{22}| > 1$. The shaded area represents the stable region.

Figure 8. Smith chart showing stable and unstable regions in the Γ_s plane: (a) $|S_{22}| < 1$; (b) $|S_{22}| > 1$. The shaded area represents the stable region.

For unconditional stability

$$K > 1 \tag{47}$$

$$|\Delta| < 1 \tag{48}$$

5.2. Constant-Gain Circles

These are contours mapped on a Smith chart showing the impedance values that produce a constant gain for a given operating condition of an amplifier.

5.2.1. Unilateral Case ($S_{12} = 0$). In the unilateral case, for $\Gamma_s = S_{11}^*$ or $\Gamma_L = S_{22}^*$, the power gain G_s or G_L are at maximum value, and for $|\Gamma_s| = 1$ or $|\Gamma_L| = 1$, the power gain G_s or G_L is zero. A general expression for the G_s and G_L can be written in the following form:

$$G_s = \frac{(1 - |\Gamma_s|^2)}{|1 - S_{11}\Gamma_s|^2} \tag{49}$$

$$G_L = \frac{(1 - |\Gamma_L|^2)}{|1 - S_{22}\Gamma_L|^2} \tag{50}$$

Figure 9. Smith chart showing stability circles for an unconditionally stable amplifier.

A normalized gain factor g_i can be defined as

$$g_i = \frac{G_i}{G_{i\max}} = \frac{(1 - |\Gamma_i|^2)1}{(1 - S_{ii}\Gamma_i^*)} (1 - |S_{ii}|^2) \quad (51)$$

where $i=s$, ($ii=11$), and $i=L$ ($ii=22$). These equations can be rearranged to prove that they represent a family of circles [14]. It is quite often convenient to draw these circles on a Smith chart. The centers of these circles are located on the vector drawn from the center of the Smith chart to the point S_{11}^* or S_{22}^* . The distance from the center of the Smith chart to the center of the constant-gain circles along the vector S_{11}^* for the source side is given by

$$d_s = \frac{g_s |S_{11}|}{1 - |S_{11}|^2 (1 - g_s)} \quad (52)$$

The radius of the constant-gain circles is expressed as

$$r_s = \frac{(1 - |S_{11}|^2) \sqrt{(1 - g_s)}}{1 - |S_{11}|^2 (1 - g_s)} \quad (53)$$

Similar expressions for load-side constant-gain circles can be derived by replacing the S parameters of the signal side with that of the load side.

5.2.2. Simultaneous Conjugate Match: Bilateral Case ($S_{12} \neq 0$). This case occurs when S_{12} cannot be neglected. The transducer power gain is given by Eq. (22). Conditions required for maximum transducer gain are given by

$$\Gamma_{\text{in}} = \Gamma_s^*, \quad \Gamma_{\text{out}} = \Gamma_L^* \quad (54)$$

The simultaneous conjugate match condition thus obtained is shown in Fig. 10.

The gain values Γ_s^* and Γ_L^* can be written as follows:

$$\Gamma_s^* = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{11}\Gamma_L} \quad (55)$$

$$\Gamma_L^* = S_{22} + \frac{S_{12}S_{21}\Gamma_s}{1 - S_{22}\Gamma_s} \quad (56)$$

By solving these last two equations simultaneously, we can get

$$\Gamma_{\text{Ms}} = \frac{B_1 \pm \sqrt{B_1^2 - 4|C_1|^2}}{2C_1} \quad (57)$$

$$\Gamma_{\text{ML}} = \frac{B_2 \pm \sqrt{B_2^2 - 4|C_2|^2}}{2C_2} \quad (58)$$

$$B_1 = 1 + |S_{11}|^2 - |S_{22}|^2 - |\Delta|^2 \quad (59)$$

$$B_2 = 1 + |S_{22}|^2 - |S_{11}|^2 - |\Delta|^2 \quad (60)$$

$$C_1 = S_{11} - \Delta S_{22}^* \quad (61)$$

$$C_2 = S_{22} - \Delta S_{11}^* \quad (62)$$

where Γ_{Ms} and Γ_{ML} are the values of input and output reflection coefficients when the amplifier is conjugate-matched simultaneously.

The maximum transducer power gain, under simultaneous conjugate-matched conditions, is achieved when $\Gamma_s = \Gamma_{\text{Ms}}$ and $\Gamma_L = \Gamma_{\text{ML}}$. Applying these conditions to equation (22), we get

$$G_{\text{t,max}} = \frac{(1 - |\Gamma_{\text{Ms}}|^2)|S_{21}|^2(1 - |\Gamma_{\text{ML}}|^2)}{|(1 - S_{11}\Gamma_{\text{Ms}})(1 - S_{22}\Gamma_{\text{ML}}) - S_{21}S_{12}\Gamma_{\text{Ms}}\Gamma_{\text{ML}}|^2} \quad (63)$$

This can be simplified to

$$G_{\text{t,max}} = \left(\frac{|S_{21}|}{|S_{12}|} \right) (K - \sqrt{K^2 - 1}) \quad (64)$$

where the stability factor K is as defined in (44).

The maximum stable gain G_{msg} , defined as the value of $G_{\text{T,max}}$ when $K=1$, is given by

$$G_{\text{msg}} = \frac{|S_{21}|}{|S_{12}|} \quad (65)$$

This G_{msg} is a figure of merit that represents the maximum value of $G_{\text{T,max}}$.

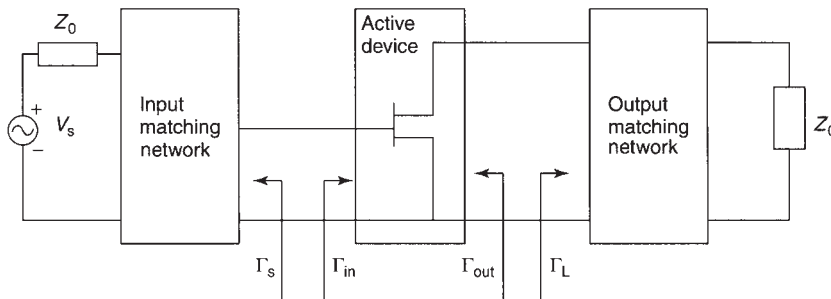

Figure 10. A block diagram of the conjugately matched RF amplifier. (Simultaneous conjugate match is achieved when $\Gamma_{\text{in}} = \Gamma_s^*$ and $\Gamma_{\text{out}} = \Gamma_L^*$.)

5.3. Constant-Noise-Figure Circles

In some applications the major design objective is to obtain the lowest possible noise figure for the circuit. Since minimum noise figure and maximum power gain cannot be obtained simultaneously, constant-noise-figure circles should be plotted on the same Smith chart along with the constant-power-gain circles. The reflection coefficient can then be selected that give the optimum performance in terms of the noise figure and power gain.

The noise figure equation (4) discussed in Section 2 can be rewritten as

$$F = F_{\min} + \frac{r_n}{g_s} (|\bar{Y}_s - \bar{Y}_{\text{opt}}|^2) \quad (66)$$

where r_n is the normalized noise resistance of the two-port network, $\bar{Y}_s = g_s + jb_s$ is the normalized source admittance, and $\bar{Y}_{\text{opt}} = g_{\text{opt}} + jb_{\text{opt}}$ is the normalized source admittance, which results in the minimum noise figure. Usually the normalizing impedance is 50 Ω .

We can express the normalized source admittances \bar{Y}_s and \bar{Y}_{opt} in terms of the source reflection coefficients as

$$\bar{Y}_s = \frac{1 - \Gamma_s}{1 + \Gamma_s} \quad (67)$$

and

$$\bar{Y}_{\text{opt}} = \frac{1 - \Gamma_{\text{opt}}}{1 + \Gamma_{\text{opt}}} \quad (68)$$

Substitution of these quantities into (66) gives the noise figure equations as

$$F = F_{\min} + \frac{4r_n |\Gamma_s - \Gamma_{\text{opt}}|^2}{(1 - |\Gamma_s|^2)(1 + |\Gamma_{\text{opt}}|^2)} \quad (69)$$

The resistance r_n can be found by measuring noise figure for $\Gamma_s = 0$, when a 50 Ω resistance is used. Then

$$r_n = (F_{50} - F_{\min}) \frac{(1 + |\Gamma_{\text{opt}}|^2)}{4|\Gamma_{\text{opt}}|^2} \quad (70)$$

To determine the noise figure circle for a given noise figure F_i , we define a noise figure parameter N_i as

$$N_i = \frac{|\Gamma_s - \Gamma_{\text{opt}}|^2}{1 - |\Gamma_s|^2} = \left(\frac{F_i - F_{\min}}{4r_n} \right) |1 + \Gamma_{\text{opt}}|^2 \quad (71)$$

which can be rewritten in the following form [18]:

$$\left| \Gamma_s - \frac{\Gamma_{\text{opt}}}{1 + N_i} \right|^2 = \frac{N_i^2 + N_i(1 - |\Gamma_{\text{opt}}|^2)}{(1 + N_i)^2} \quad (72)$$

These equations represent a family of circles in terms of N_i . The center of the circle is given by

$$C_F = \frac{\Gamma_{\text{opt}}}{1 + N_i} \quad (73)$$

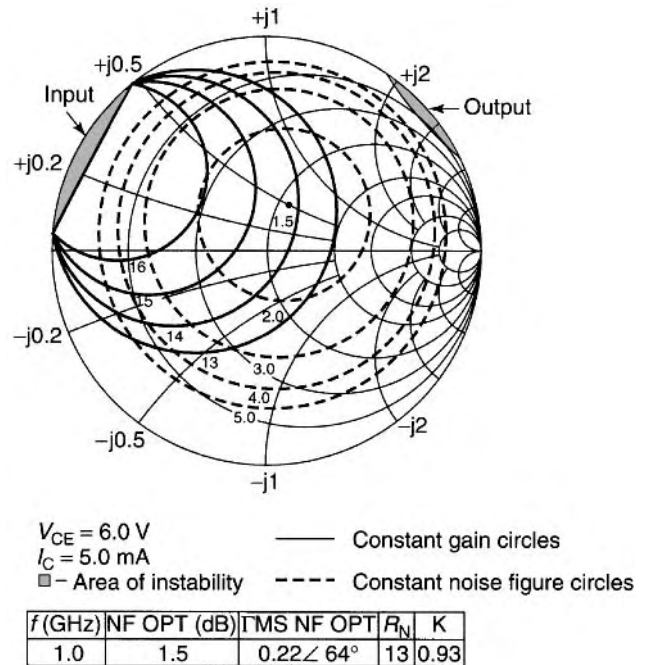

Figure 11. Smith chart showing the constant-gain circles and constant-noise-figure circles for optimum impedance determination. (With permission from Wiley [1].)

and the radius is given by

$$r = \frac{1}{(1 + N_i)} \sqrt{[N_i^2 + N_i(1 - |\Gamma_{\text{opt}}|)]} \quad (74)$$

A set of constant-gain circles and constant-noise-figure circles, as shown in Fig. 11, are drawn on the same Smith chart for the amplifier design. This plot shows the tradeoff between the noise figure and the gain of a device.

6. NARROWBAND AMPLIFIERS

Typical narrowband amplifiers have bandwidth less than 10% of the center frequency. Most of the amplifiers designed for portable communication amplifiers fall into this category. These types of amplifiers can be further divided into maximum power gain amplifiers and low-noise amplifiers. A different design procedure has to be followed for each case.

6.1. Maximum Power Gain Design

From the discussions in Section 5.2.2, the reflection coefficient of the source and load impedance required to conjugately match the amplifier are given by Eqs. (57)–(62). Knowing the values of Γ_{Ms} and Γ_{ML} provided by the device manufacturers, the input-output matching network for the amplifier can be designed.

The source equivalent circuit for maximum power transfer can be written as

$$Z_{\text{in}} = \frac{1 + \Gamma_{Ms}}{1 - \Gamma_{Ms}} \quad (75)$$

where

$$\Gamma_{Ms} = |\Gamma_{Ms}| \cos(\text{ang}(\Gamma_{Ms})) + j|\Gamma_{Ms}| \sin(\text{ang}(\Gamma_{Ms})) \quad (76)$$

The input impedance for minimum noise figure can be written as follows:

$$Z_{in(\text{opt})} = Z_0 \frac{1 - |\Gamma_{Ms}|^2 + j2|\Gamma_{Ms}| \sin(\text{ang}(\Gamma_{Ms}))}{1 + |\Gamma_{Ms}|^2 - 2|\Gamma_{Ms}| \cos(\text{ang}(\Gamma_{Ms}))} \quad (77)$$

The load impedance for maximum power transfer can be written as

$$Z_{out} = Z_0 \frac{1 - |\Gamma_{ML}|^2 + j2|\Gamma_{ML}| \sin(\text{ang}(\Gamma_{ML}))}{1 + |\Gamma_{ML}|^2 - 2|\Gamma_{ML}| \cos(\text{ang}(\Gamma_{ML}))} \quad (78)$$

Once these impedances are determined, CAD tools may be used to compute matching elements of the amplifier.

6.2. Low-Noise Amplifier Design

In this case the minimum noise figure is more important than determining the maximum gain. The noise parameters of the devices are included in the data sheets provided by the vendor or foundry. Figure 12 shows a block diagram of a low-noise narrowband amplifier. The impedances at various points along the circuits are illustrated in this figure. The design procedure is similar to the maximum power gain design, except that we start with the input reflection coefficients for the minimum noise figure. This reflection coefficient is then converted to the equivalent input impedance or admittance. The matching elements are then designed to transform these impedances to $50\ \Omega$.

Let Γ_0 be the optimum reflection coefficient for the minimum noise figure. From Eq. (77), we obtain

$$Z_{opt} = Z_0 \frac{1 - |\Gamma_0|^2 + j2|\Gamma_0| \sin(\text{ang}(\Gamma_0))}{1 + |\Gamma_0|^2 - 2|\Gamma_0| \cos(\text{ang}(\Gamma_0))} \quad (79)$$

We may compute the output impedance computed similarly if we know the load reflection coefficient for the minimum noise figure using Eq. (78).

7. WIDEBAND AMPLIFIER DESIGN

Wideband LNAs have many applications in instrumentation, high-speed microwave, and wireless communication systems. The design methodology for wideband

LNA is more complex than the narrowband amplifiers because of the power gain rolloff characteristics of the device. The matching circuit of the amplifier has to be carefully designed to achieve a constant gain over a broad frequency of interest. The variation in the device S parameters has to be carefully considered. As the frequency increases, the forward gain S_{21} of the device decreases at the rate of 6 dB/octave and the reverse gain S_{12} increases at about the same rate. The input and output impedances S_{11} and S_{22} also vary significantly with frequency.

Several circuit design approaches are employed to achieve the desired broadband characteristics of the amplifier. Broadband amplifier design techniques using negative feedback, compensated impedance matching, and balanced amplifications are discussed in the next section.

7.1. Negative-Feedback Amplifier Design

In this configuration a feedback network is used to compensate for the gain rolloff of the device. Figures 13a and 13b show the shunt feedback amplifier configuration for a bipolar device and a FET, respectively. Similarly, Figs. 14a and 14b show the series feedback configuration for a bipolar device and a FET, respectively. The series feedback enhances the input match of the amplifier, while the shunt feedback flattens the forward gain S_{21} of the amplifier over the frequency range of interest. Typically a resistor is used as the primary feedback element. A capacitor is often added to the shunt feedback circuit to decouple the DC bias of the transistor.

An equivalent circuit of a bipolar transistor can be represented as shown in Fig. 15a and that of a FET, as in Fig. 15b. Other parasitic elements are neglected for simplicity and because their contributions to the amplifier performance are relatively insignificant. The admittance matrix of the network can be written as

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} \frac{1}{R_1} & -\frac{1}{R_1} \\ \frac{g_m}{1 + g_m R_2} - \frac{1}{R_1} & \frac{1}{R_1} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \quad (80)$$

Figure 12. A block diagram of the minimum noise figure narrowband RF amplifier.

Figure 13. Shunt feedback amplifier: (a) bipolar transistor; (b) FET.

By converting this *Y* parameter equation to *S* parameters, we can get

$$S_{11} = S_{22} = \frac{1}{D} \left[1 - \frac{g_m Z_0^2}{R_1(1 + g_m R_2)} \right] \quad (81)$$

$$S_{21} = \frac{1}{D} \left[\frac{-2g_m Z_0}{(1 + g_m R_2)} + \frac{2Z_0}{R_1} \right] \quad (82)$$

$$S_{12} = \frac{2Z_0}{DR_1} \quad (83)$$

where

$$D = 1 + \frac{2Z_0}{R_1} + \frac{g_m Z_0^2}{R_1(1 + g_m R_2)} \quad (84)$$

For the ideal case of $VSWR = 1$, $S_{11} = S_{22} = 0$

$$1 + g_m R_2 = \frac{g_m Z_0^2}{R_1} \quad (85)$$

or

$$R_2 = \frac{Z_0^2}{R_1} - \frac{1}{g_m} \quad (86)$$

$$S_{21} = \frac{Z_0 - R_1}{Z_0} \quad (87)$$

$$S_{12} = \frac{Z_0}{Z_0 + R_1} \quad (88)$$

Also note that when the transconductance $g_m \gg 1$, we obtain

$$Z_0 = \sqrt{R_2 R_1} \quad (89)$$

Figure 14. Series feedback amplifier: (a) bipolar transistor; (b) FET.

Figure 15. Equivalent circuit of feedback amplifier: (a) bipolar transistor; (b) FET.

Equation (87) shows that S_{21} depends on R_1 only. This shows that gain flattening can be achieved for an amplifier by using parallel feedback.

It can also be seen from Eq. (87) that the minimum transconductance is realized when R_2 is zero:

$$g_m(\min) = \frac{R_1}{Z_0^2} \quad (90)$$

From Eq. (82), it can also be shown that

$$g_m(\min) = \frac{1 - S_{21}}{Z_0^2} \quad (91)$$

$$R_1 = Z_0(1 + |S_{21}|) \quad (92)$$

The phase of S_{21} is an important consideration in negative-feedback amplifier design. At lower frequencies, the phase of S_{21} is close to 180° , but as the operating frequency increases, the phase increases rapidly. The phase difference between the input and output voltages could become zero at some frequency, creating positive feedback. This problem can be avoided by adding a reactive element to the feedback circuit.

7.2. Compensated Matching Technique

In this technique the input and output matching impedances are mismatched to compensate for the variation in the magnitude of S_{21} with frequency. Since the amplifier has to operate over a wide bandwidth, VSWR optimization must cover a wide frequency range. Even though the analytical technique using Smith chart can be used to determine a matching circuit, a more accurate design can be achieved by using computer-aided design procedures.

7.3. Balanced Amplifier Design

It is difficult to achieve good VSWR for broadband amplifiers that employ a compensated matching technique. The mismatching of the input and output impedances causes the VSWR to degrade significantly. Balanced amplifier design can be used to achieve good gain flatness and excellent VSWR. Figure 16 shows the schematic of the balanced amplifier. The input coupler circuit divides input power equally between the amplifier A and B input ports. The output coupler circuit combines the amplified signal from each amplifier. The unused ports of the couplers are terminated at 50Ω impedance to eliminate reflections. In this approach the input and output matching of each amplifier

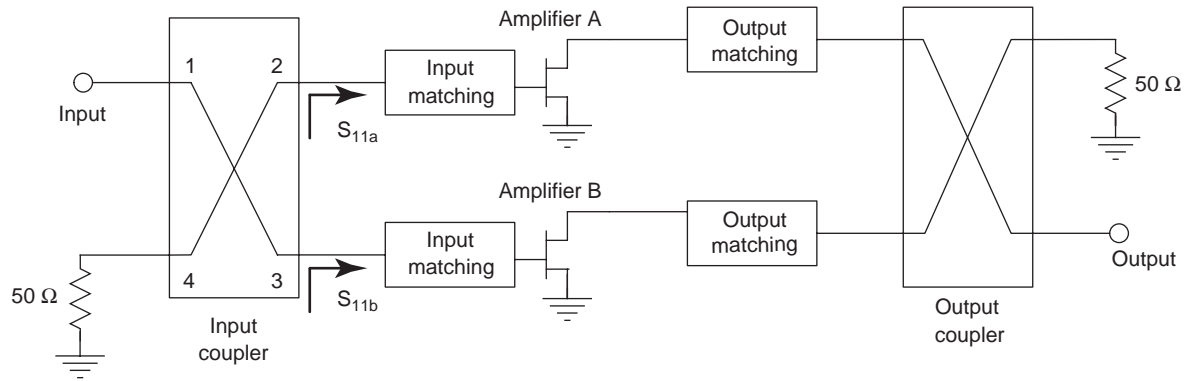

Figure 16. Balanced FET amplifier configuration.

can be mismatched to determine the gain flatness. The combined amplifier will be matched when parallel amplifiers A and B are combined. This will provide excellent VSWR at the input and output of the circuit. The coupler can be realized in many different ways and is discussed elsewhere in this book and in Ref. 1.

For the balanced amplifier that uses a 3-dB coupler, we obtain

$$S_{11} = 0.5[S_{11a} - S_{11b}] \quad (93)$$

$$S_{22} = 0.5[S_{22a} - S_{22b}] \quad (94)$$

The forward power gain is

$$|S_{21}|^2 = 0.25|S_{21a} + S_{21b}|^2 \quad (95)$$

The reverse power loss is

$$|S_{12}|^2 = 0.25|S_{12a} + S_{12b}|^2 \quad (96)$$

The input standing-wave ratio is

$$\text{VSWR}_{\text{in}} = \frac{1 + |S_{11}|}{1 - |S_{11}|} \quad (97)$$

The input standing-wave ratio is

$$\text{VSWR}_{\text{out}} = \frac{1 + |S_{22}|}{1 - |S_{22}|} \quad (98)$$

These types of amplifiers achieve high-gain flatness over a wide range and a high degree of stability and are easy to cascade. However, to achieve this performance, two amplifier chains are required. Hence this amplifier has high power consumption and a larger chip size.

LOW NOISE AMPLIFIERS: DEVICE NOISE CHARACTERIZATION AND DESIGN

SUNGJAE LEE
 KEVIN J. WEBB
 Purdue University
 West Lafayette, Indiana

1. INTRODUCTION

Receiver sensitivity is limited by noise associated with the elements of the receiver. The most critical element is the

one that first processes the detected signal, usually an amplifier. Therefore, achieving low noise amplifier (LNA) designs is critical in many receiver systems.

Given the input signal-to-noise ratio, the receiver noise, which is the noise added by the receiver component, degrades the signal-to-noise ratio. It is common to use noise figure (F) as a system parameter that characterizes the ability of the component (e.g., the amplifier) to process low-level signals [1]. The noise figure is the ratio of the input to output signal-to-noise ratios, resulting in $F \geq 1$. Assuming that dissipative circuit losses are small, the active device (e.g., the transistor) dominates the receiver noise. An effective receiver amplifier thus requires a suitable low-noise device. It is also important to present an appropriate impedance through matching networks.

The device can be characterized using two-port noise and scattering (S)-parameter measurements. The measurement of the noise figure for various source admittances yields three noise parameters, the minimum noise figure (F_{\min}), the noise resistance (R_n , or conductance G_n), and the optimum source admittance for minimum noise ($Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$) [2]. The S -parameter measurements can be used to extract the values for an equivalent-circuit representation for the transistor. The measured noise parameters can then be used to construct a noise equivalent network that, coupled with the device equivalent circuit, can be used to predict the noise performance of this device in, for example, an amplifier configuration, and hence for the design of LNAs.

An empirical relation between the noise figure and the circuit parameters that employs fitting parameters was proposed for GaAs FETs. Fukui describes the dependence of F_{\min} on the operating frequency and the model elements in the equivalent circuit [3]. More quantitative equivalent circuit modeling has been pursued in several works [4–7], where Nyquist noise sources were represented equivalently as temperature or resistance/conductance [8].

Within the active device, there are parasitic noise contributions due to contact metal and contact resistance, along with intrinsic noise mechanisms. Low-noise silicon device technology (e.g., CMOS) has made great strides, showing fairly good performance [9]. However, the lowest-noise-figure device is the high-electron-mobility transistor (HEMT), based on compound semiconductor materials. To first order, a higher-speed device will have lower noise.

2. NOISE FIGURE OF A MULTISTAGE SYSTEM

The analysis of the noise figure in a multistage system demonstrates the importance of good LNA design in receivers. Knowing the noise figure and gain of the individual stages, one can determine the noise figure of the multistage system as [1]

$$F_{\text{tot}} = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \dots \quad (1)$$

where the first three stages have gains G_1, G_2, G_3 , and noise figures F_1, F_2, F_3 . Equation (1) clearly shows that the

Table 1. Microwave and Millimeter-Wave Noise Performance (Measured) of GaAs, InP, and GaN-based HEMTs

HEMT (Substrate)	Frequency (GHz)	F_{\min} (dB)	Gate Length (μm)
AlInAs/GaInAs (GaAs) [10]	18	0.48	0.1
AlInAs/GaInAs (InP) [11]	63	0.8	0.2
AlGaN/GaN (SiC) [12]	18	0.75	0.25

noise performance of a multistage system is dominated by the noise figure and the gain of the first stage, since the noise of the later stages is reduced by the gain of the previous stages. Thus, high gain in the first stage (the LNA) reduces the influence of the noise of later stages, making the noise of the first stage critical.

3. NOISE MECHANISMS IN HEMTS

High-gain and low-noise characteristics have made HEMTs the device of choice for building low-noise transistor amplifiers. GaAs-based HEMTs have long been used in microwave low-noise amplifiers [10]. When grown on an InP substrate, GaAs-based HEMTs have demonstrated low noise figure at millimeter-wave frequencies [11]. More recently demonstrated AlGaN/GaN HEMTs on SiC offer promising microwave noise performance [12]. Table 1 summarizes the noise performance achieved with these devices.

One can consider three uncorrelated noise mechanisms in the intrinsic HEMT, associated with velocity fluctuation, gate leakage, and traps, as shown in the schematic of Fig. 1. The velocity fluctuation or diffusion noise is due to electron scatter from the heterojunction, the lattice (phonon), and impurities. This diffusion noise contracts to thermal or Johnson noise if the Einstein relation holds [13]. The bandwidth of this process is proportional to the

HEMT (Substrate)	Frequency	F_{\min}	Gate length
AlInAs/GaInAs (GaAs) [10]	18 GHz	0.48 dB	0.1 μm
AlInAs/GaInAs (InP) [11]	63 GHz	0.8 dB	0.2 μm
AlGaN/GaN (SiC) [12]	18 GHz	0.75 dB	0.25 μm

Figure 1. Fundamental noise mechanisms in AlGaN/GaN HEMTs.

inverse of the scattering time, making it frequency-independent (i.e., white noise) in the microwave regime where the device is typically operated. This fundamental noise process results in a drain current noise variance ($\langle |i_d|^2 \rangle$) that will be ideally white and dominated by the channel conduction process. The associated gate voltage variance ($\langle |v_g|^2 \rangle$) is coupled to the channel random process by the gate capacitance (C_{gs}). Physically, one could view this as a random variation in the electric field lines that terminate on the local random variation in channel charge, due to velocity or charge density fluctuation, and the induced gate charge. The line integral of this field gives the gate voltage. A frequency independent $\langle |i_d|^2 \rangle$ will therefore result in $\langle |v_g|^2 \rangle$ being frequency-independent. This model suggests that the correlation between the gate (v_g) and drain (i_d) noise sources will be a function of the degree of electron scatter in the channel, and that it would tend to reduce with increasing channel length.

The gate leakage noise process is associated with electron injection into the channel over the gate Schottky barrier. The randomness of this emission process leads to classical shot noise ($\langle |i|^2 \rangle = 2eI_g A^2/\text{Hz}$, with $e = 1.6 \times 10^{-19} \text{ C}$ and I_g the gate DC current) [13]. This gate leakage noise is also ideally independent of frequency.

Finally, a $1/f^\alpha$ noise process (where $\alpha = 0.5\text{--}2$) occurs as a result of the trapping of electrons in surface states (near the gate) or AlGaIn/GaN interface states (near the channel). This lower frequency noise is particularly important when the device operation is nonlinear, and leads to the noise sidebands on an oscillator signal.

All three of these noise processes will contribute to both the gate and drain noise variances. In addition to the intrinsic noise sources, there is thermal noise associated with various resistances, including source and drain contact resistance and gate finger resistance. All of these parasitic noise sources are uncorrelated with each other and with the intrinsic noise.

4. TWO-PORT NOISE FIGURE

As suggested by Rothe and Dahlke [2], all noise within a linear two-port device can be represented as two equivalent and partially correlated noise sources, and two forms are shown in Fig. 2, with the same two-port device now considered noiseless. In the circuit of Fig. 2(a), the random current i_A and random voltage v_A can be related by

$$i_A = Y_c v_A + i_u \quad (2)$$

Figure 3. Equivalent noise circuit with two independent noise sources and a correlation admittance ($i_A = Y_c v_A + i_u$).

where v_A and i_u are uncorrelated and $Y_c (= G_c + jB_c)$ is a correlation admittance. In this way, two independent noise sources (v_A, i_u) can be used, as in Fig. 3. This allows the convenient expression of the two-port noise figure and other noise parameters using superposition.

A zero-mean Gaussian noise model is assumed. Also, white noise is assumed over the frequency range of interest. The variance of the noise sources in Fig. 3 can be written using Nyquist's theorem [8] as

$$\langle |v_A|^2 \rangle = 4kT_0 B R_n \quad (3)$$

$$\langle |i_u|^2 \rangle = 4kT_0 B G_n \quad (4)$$

where $\langle \rangle$ denotes the statistical average, k is Boltzmann's constant, T_0 is room temperature (e.g., 290 K), B is the noise bandwidth, and the values of R_n and G_n determine the variances. The two-port noise figure, $F [= 1 + (\langle |i|^2 \rangle_{G'} / \langle |i|^2 \rangle_G)$ in Fig. 3], with source admittance $Y_s (= G_s + jB_s)$, becomes [2]

$$F = 1 + \frac{1}{G_s} [G_n + R_n |Y_s + Y_c|^2] \quad (5)$$

Partial derivatives of (5) with respect to G_s and B_s [$(\partial F / \partial G_s) = 0$, $(\partial F / \partial B_s) = 0$] give the optimum value of Y_s for the minimum F . This optimum input admittance, $Y_{\text{opt}} (= G_{\text{opt}} + jB_{\text{opt}})$, is given by

$$Y_{\text{opt}} = \sqrt{\frac{G_n}{R_n} + G_c^2} + j(-B_c) \quad (6)$$

Substituting $Y_s = Y_{\text{opt}}$ into (5) gives

$$F_{\text{min}} = 1 + 2R_n G_c + 2R_n \sqrt{\frac{G_n}{R_n} + G_c^2} \quad (7)$$

Figure 2. (a) Equivalent noise circuit with noise sources (v_A and i_A) at the input (ABCD representation); (b) equivalent noise circuit with current noise sources (i_1, i_2) at input and output (Y representation).

Rather than expressing F as a function of G_n and Y_c , as in (5), it can be expressed in terms of F_{\min} [using (7)] and Y_{opt} as

$$F = F_{\min} + \frac{R_n}{G_s} |Y_s - Y_{\text{opt}}|^2 \quad (8)$$

A noise-figure meter is commonly used for noise measurements [14–16]. Measurement of the noise figure for various Y_s allows the determination of F_{\min} , R_n , and Y_{opt} in (8) by means of a least-mean-square error fit to $F(Y_s)$ [17]. Then, the parameters G_c , B_c , and G_n can be evaluated from (6) and (7). Measurements of this type are common, and work has been done, for example, to relate the data to noise sources within GaAs, GaN, and CMOS devices [7,18,19].

5. GATE–DRAIN NOISE CORRELATION EFFECT

In the simple FET circuit model of Fig. 4, one can generally anticipate correlation between the gate and drain noise current by capacitive coupling [7]. For example, i_d induces the gate voltage v_g through the transconductance g_m . Then, $v_g = i_d/g_m$ if perfect correlation can be assumed, and $i_g = j\omega C_{gs}v_g = j\omega C_{gs}i_d/g_m$. Finally, $\langle |i_g|^2 \rangle = \omega^2 C_{gs}^2 \langle |i_d|^2 \rangle / g_m^2$. It has been demonstrated experimentally [7] that, in the case of velocity fluctuation, $\langle |i_d|^2 \rangle$ is independent of frequency in the microwave operating range of the transistor (white noise), and $\langle |i_g|^2 \rangle \propto \omega^2$, thus establishing the concept of capacitive coupling between the gate and drain noise. In order to assess the effect of the correlation between i_g and i_d , the correlation coefficient C is defined in normalized form as [4]

$$C = \frac{\langle i_g i_d^* \rangle}{\sqrt{\langle |i_g|^2 \rangle \langle |i_d|^2 \rangle}} \quad (9)$$

With perfect correlation assumed in the ideal noise model of Fig. 4, $C = j1$.

To investigate the influence of C on the total noise, the ideal FET noise model in Fig. 4 is considered with velocity fluctuation noise only, to calculate the minimum noise figure, F_{\min} , in terms of $\langle |i_g|^2 \rangle$, $\langle |i_d|^2 \rangle$, and the correlation coefficient C , by setting $\langle i_g i_d^* \rangle = j|C| \sqrt{\langle |i_g|^2 \rangle \langle |i_d|^2 \rangle}$ (imaginary correlation only). Then, F_{\min} can be expressed

Figure 4. Ideal FET model with white-noise random processes i_d and v_g (i_g).

as [4,7]

$$F_{\min} = 1 + \frac{\sqrt{\langle |i_g|^2 \rangle \langle |i_d|^2 \rangle}}{2kT_0 B g_m} \sqrt{1 - |C|^2} \quad (10)$$

Equation (10) indicates that, with no parasitics, perfect correlation ($|C| = 1$) cancels the noise contribution from $\langle |i_g|^2 \rangle$ and $\langle |i_d|^2 \rangle$ completely, giving $F_{\min} = 1$. Therefore, high correlation ($j1$ is the theoretical maximum) would be desirable for a low-noise device, since correlation is a cancellation term in calculating the total noise of the FET.

6. LOW-NOISE AMPLIFIER DESIGN

There are design tradeoffs between noise figure, gain, and bandwidth. Tradeoffs exist between noise figure and gain because the desired source reflection coefficients for low-noise figure, the optimum being F_{\min} , and maximum available gain values are different. The stability of the LNA circuit is also important. If the transistor used is conditionally unstable, source and load impedances presented by the input and the output matching networks should stabilize the circuit first over all frequencies [20]. Additionally, the linearity performance (third-order intercept point, i.e., IP3) must be adequate to ensure sufficient dynamic range of the receiver system.

Low-noise amplifier design techniques have been investigated by many authors, resulting from various technologies (especially GaAs-based transistors) and circuit architectures. Examples of low-noise amplifiers, including design techniques, can be found in a series of reprint articles edited by Fukui [21]. Computer-aided design synthesis tools provide a convenient platform.

In general, in order to achieve the lowest possible noise figure, the input matching network is designed to provide the source admittance for low-noise figure, and the output matching network is optimized for high gain. The noise parameters F_{\min} , R_n , and Y_{opt} should be determined first for the particular device being used (either from the measurement or given by the manufacturer). Then, these parameters can be used in low-noise transistor amplifier design and simulation with the S parameters.

Figure 1. Lowpass filter requirements.

A first-order lowpass filter is shown in Fig. 2. The transfer function is

$$\frac{V_{out}(s)}{V_{in}(s)} = \frac{1}{s + \frac{1}{RC}}$$

The pole-zero diagram is shown in Fig. 3.

An active second-order lowpass filter is shown in Fig. 4. The circuit is known as the *Sallen-Key lowpass circuit*. The transfer function is

$$\frac{V_{out}(s)}{V_{in}(s)} = \frac{\alpha}{s^2 + \left(\frac{1}{R_1C_1} + \frac{1}{R_2C_1} + \frac{1-\alpha}{R_2C_2} \right) s + \frac{1}{R_1R_2C_1C_2}} \quad (1)$$

where $\alpha = 1 + r_2/r_1$. The pole-zero diagram is shown in Fig. 5.

An approach to design a circuit (a lowpass filter) whose frequency response satisfies the lowpass requirements shown in Fig. 1 consists of two steps: approximation of the requirements by a transfer function and synthesis of the transfer function.

There are several approximation methods, for instance, Butterworth, Chebyshev, inverse Chebyshev, and Cauer approximations. A transfer function obtained by one method is different from those obtained by the others, and has different properties. However, the frequency response of each of the transfer functions satisfies the lowpass requirements. The Butterworth approximation method is described below.

Compute the scaling factor k given by the equation below:

$$k = \sqrt{10^{0.1A_p} - 1}$$

Figure 2. First-order lowpass filter.

LOW-PASS FILTERS

CHIU H. CHOI
University of North Florida
Jacksonville, Florida

A lowpass filter suppresses the high-frequency components of a signal, leaving intact the low-frequency ones. A lowpass filter specification can be expressed as shown in Fig. 1. In the stopband (above f_2 Hz), the attenuation is at least A_s dB. In the passband (below f_1 Hz), the attenuation is at most A_p dB. The band from f_1 to f_2 is called the *transition band*.

Figure 3. Pole-zero diagram of the first-order lowpass filter.

Next, compute the quantity

$$\frac{\log_{10}\left(\frac{10^{0.1A_s} - 1}{k^2}\right)}{2 \log_{10}\left(\frac{f_2}{f_1}\right)}$$

Choose the order n of the filter to be the smallest integer not smaller than the quantity given above. Solve for all the left-half-plane roots Z_i s of the equation

$$(-1)^n S^{2n} + 1 = 0$$

The Butterworth lowpass transfer function is formed as follows:

$$T_{LP}(s) = \frac{1}{\prod_{i=1}^n (S - Z_i)} \Big|_{s = k^{1/n} s / 2\pi f_1}$$

Example 1. Find the Butterworth transfer function for a lowpass filter with $A_s = 15$ dB, $A_p = 0.5$ dB, $f_1 = 1$ kHz, and $f_2 = 5$ kHz:

$$k = \sqrt{10^{0.1(0.5)} - 1} = 0.35$$

$$\frac{\log_{10}\left(\frac{10^{0.1(15)} - 1}{0.35^2}\right)}{2 \log_{10}\left(\frac{5\text{k}}{1\text{k}}\right)} = 1.72$$

Choose $n = 2$. The left-half-plane roots of the equation

$$(-1)^2 s^{2(2)} + 1 = 0$$

Figure 4. Sallen-Key lowpass circuit.

Figure 5. Pole-zero diagram of the Sallen-Key lowpass filter.

are $1/\sqrt{2}(-1 \pm j)$. Therefore, the Butterworth transfer function is

$$T_{LP}(s) = \left. \frac{1}{s^2 + \sqrt{2}s + 1} \right|_{s = \sqrt{0.35} s / 2\pi(1000)}$$

which simplifies to

$$T_{LP}(s) = \frac{1.128 \times 10^8}{s^2 + 1.502 \times 10^4 s + 1.128 \times 10^8}$$

These calculations have all been performed before, and the results and available in tabular and computer program forms.

The Sallen-Key lowpass circuit can be used to realize a second-order lowpass transfer function of the form

$$T(s) = \frac{K}{s^2 + as + b}$$

Compare $T(s)$ with Eq. (1):

$$K = \frac{\alpha}{R_1 R_2 C_1 C_2} \quad a = \frac{1}{R_1 C_1} + \frac{1}{R_2 C_1} + \frac{1 - \alpha}{R_2 C_2}$$

$$b = \frac{1}{R_1 R_2 C_1 C_2}$$

Since there are more unknowns than equations, one can assign values to certain unknowns and then solve for the remaining unknowns. As an example, choose $C_1 = 1$, $C_2 = 1$, $\alpha = 2$. Then

$$K = 2b \quad R_1 = \frac{1}{a} \quad R_2 = \frac{a}{b}$$

The impedance-scaling method can be used to scale the values of R s and C s into the practical ranges.

In general, a higher-order lowpass transfer function obtained by Butterworth and Chebyshev approximations can be factorized into a product of biquadratic functions and possibly one first-order expression. Each of the biquadratic functions can be synthesized by using the Sallen and Key or other lowpass circuits. The first-order transfer function can be realized by an active or passive circuit. By cascading all the biquad and first-order circuits together, the lowpass filter is realized.

LOW-POWER BROADCASTING

CHIP MORGAN
 CMBE, Inc.
 Bridport, Vermont

Low-power broadcasting systems are very interesting from a technical perspective for several reasons. Although they appear to be simple to build and easy to design, they can actually be more critical than higher-powered stations. In fact, since the signal is local and likely to receive or cause interference, design and optimization methods for low-power systems can make the difference between a successful operation and a failure.

It is a mistake to think that a low-powered facility cannot perform as well (within its intended coverage area) as a full-powered station. Around the world, there are many facilities operating at low power that provide excellent full-time service to communities every day.

Modern techniques allow some very interesting project work, such as synchronized systems, directional systems to fill in specific areas, and local systems (such as in tunnels, buildings, or temporary high-density populated areas such as stadiums). These techniques also have application for fill-in service for satellite-delivered services as well as terrestrial digital broadcasting.

1. DEFINITIONS

A low-power station is typically a facility with a transmitter power of 1 kW output or less. Although antenna gain plays a large role in the effective radiated power (ERP) of a given facility, it is easier to define the power of a station in general terms by transmitter power. However, when regulating the location and coverage of a given facility, ERP and height above average terrain (HAAT) are often specified.

1.1. Translator

A translator is a radiofrequency (RF) device that retransmits a television or FM signal within a specific broadcast band. The translator alters none of the signal characteristics except frequency and amplitude with a main purpose to extend or fill in the coverage of a transmitted signal. It typically receives a signal, changes its carrier frequency, and then rebroadcasts the changed carrier at

substantially higher levels of radiated energy. A translator is essentially a repeater.

As an example, a broadcast station might have a zone within its trade area that receives a poor signal from its main transmitter. The technical consultant of the station prepares a study to identify the existence of frequencies for a translator. The consultant recommends a site and a specific design.

Listeners and/or viewers within the coverage area of the translator receive primary station programming on a different frequency from the primary station. Thus, the station signal is translated in that area.

1.2. Booster

A booster is an RF device that retransmits a TV or FM signal within a specific broadcast band. It alters none of its characteristics, including frequency or amplitude, with a main purpose to extend or fill in the coverage of a transmitted signal. A booster operates on the same frequency as the primary signal and rebroadcasts it at substantially higher levels of radiated energy. The signal of a booster is the same as the primary station. Boosters are complicated, and a poorly designed or built booster can cause much more harm than good. A booster is an isofrequency transmitter.

As an example, a station might have a location within its trade area that receives a poor signal from its main transmitter. The consultant of the station prepares a study to identify a site with appropriate terrain shielding or to allow the operation of a booster without substantial interference to or from the main signal. Listeners and/or viewers receive the programming from the primary station on the same frequency as the primary station. Thus, the station signal is boosted in that area.

1.3. LPTV

An LPTV (low-power television) station can be defined as one that may operate as a translator or originate programming and operate as a subscription service low-powered TV system intended to serve a local area. It functions as a full-powered TV station, but with reduced output power.

1.4. ITFS, MDS, and MMDS

ITFS (instructional television fixed service), MDS (multi-point distribution service), and MMDS (multichannel MDS) are television transmission systems authorized to provide specific programming to subscribers. Technically, ITFS and MDS are quite similar to each other as well as to broadcast television transmission.

2. GENERAL GUIDELINES

Following are some tips and points to consider when designing a low-power system. Some of these items are simple common sense; others require high-powered computer system analysis to compare options and identify predicted results. These guidelines also apply to high-powered systems. In most cases, low-powered systems have very

stringent requirements due to specific signal challenges. Before designing a system, a complete understanding of all the technical issues will minimize problems. The field is quite complex. For example, propagation and signal analysis is a career unto itself, but understanding the basics will help you identify potential problems in the initial design of a system. Use the services of a professional who designs systems regularly for the best results.

2.1. Location of Antenna in Relation to Population

Locate the transmitting antenna site as close to the target population as possible. Building penetration and received signal strength decreases rapidly as distance between transmitter and receiver increases. RF energy diminishes with the square of the distance. If the transmitter site is distant from the target population, system design is much more critical and difficult.

2.2. Height of Antenna above Population

More antenna height usually means better coverage. However, one should specify an antenna height as high as is needed for the specific requirements, but not any higher. Excessive antenna height leads to unnecessary interference, increased cost of construction and operation, and decreased reliability. The antenna should be just high enough for adequate Fresnel ellipsoid clearance to the target area but not much above that height.

2.3. Fresnel Ellipsoid Clearance of Signal into Target Market

The antenna signal is not a narrow ray of energy like a laser beam. The signal is a noncoherent three-dimensional beam that gets wider as it leaves the transmitting antenna, just like the beam from a flashlight. For maximum received signal strength, all the energy in the Fresnel ellipsoid must pass from the transmitter to the receiver with no obstacles affecting the path of transmission. The receiving antenna works exactly opposite from the transmitting antenna. It gathers energy from a three-dimensional area and narrows it down to the location of the receiver, just as a telescope gathers light from a wide area and focuses it at on small area. At the midpoint of the transmission/reception path, the signal beam is its widest. Therefore, even if you can see the population you want to serve from the transmitter site, the broadcast signal may not be able to reach it due to obstructions below the line-of-sight path.

2.4. Tuning and Installing an Antenna

A transmitting antenna is just as sensitive to its immediate environment as a receiving antenna. If you have ever adjusted a “rabbit ear” antenna on a TV set or the rod antenna on a “boombox,” you understand the concept. A very small change in the antenna orientation or environment has a drastic effect on its performance. Install the antenna and tune it properly from the beginning and the facility will perform as predicted. The supporting structure, the antenna design, and the way the antenna is mounted all affect the quality of the signal.

2.5. Elevation Pattern of an Antenna

There is often population below the height of a transmitting antenna—especially if it is on a tall tower or hill. The elevation pattern of the antenna identifies the amount of signal radiated toward the horizon as well as the amount radiated below the horizon, into low-lying population. The elevation pattern is critical in systems design because control of energy in specific areas can be an important factor in system performance. Conversely, a receiving antenna often receives from a location above its horizontal plane, and the elevation pattern above the horizon is important. The number, spacing, and type of elements in the antenna array typically control the elevation pattern of a wire-type antenna.

2.6. Interference from Adjacent-Channel and Cochannel Stations

Unless the station is located in an area with very few signals, certain portions of the service area will receive interference from other nearby or more powerful transmitters. This can come from stations as far as three channels above or below the carrier frequency. Consider the potential of interference in the design of a facility. Most complaints of poor performance are a result of interference, due to poor signal from the intended transmitter in an area or excessive signal from an interferer or “jammer.”

2.7. Receiver-Induced Third-Order Harmonic Interference

When a receiver is near other transmitters, even if the desired station has a strong local signal, the receiver will overload or “be blanketed” by the relatively higher signal levels of the jamming transmitter. The selectivity (ability to reject strong local interference) of the receiver determines its susceptibility to this kind of interference. In other cases, harmonic mixes occur within the receiver itself, causing the desired signal to be jammed. This situation is receiver-induced third-order harmonic interference.

2.8. Condition of Antenna System

Most transmitters have a test meter that indicates if the antenna has failed to the point that it can harm the transmitter. However, there is typically no accurate test equipment available at a transmission facility to show qualitatively how well the transmitter or antenna is performing. Most antenna complaints are very subjective; you just cannot “get” the station as you used to—it does not sound right or look right any more, and so on. The only way to tell if an antenna is working correctly is to test it with appropriate test equipment used by antenna manufacturers and consultants.

2.9. Quality of Modulation

A commonly overlooked cause of signal problems is poor source material. In this case, no amount of improvement to the antenna or transmission system will correct the problem.

3. LOW-POWER SYSTEM DESIGN

Site selection is the first step in designing a system. The details of the site determine many other design criteria, so an overall review of the impact of any potential site must be exhaustive. Choice of the best site for a transmission system is often a series of compromises. Strike a balance between economical issues, environmental issues, and performance issues of the particular site under review.

In addition to these restrictions, the site must be available; must satisfy all regulatory, practical, and engineering requirements; and must be accessible during the time construction is planned to take place.

The primary technical consideration of site selection is the performance of a transmission system that is located there. Computer analysis should be performed to predict the performance at all intended receiving locations, to predict the interference generated to other operators from the proposed site, and to demonstrate the relative quality of any particular site with others being considered. In addition to the performance of the transmitter(s) located at the proposed site, receiving capability of the primary signal must be possible. This may mean satellite reception, microwave link reception, or off-air reception of the modulating signal.

When using off-air rebroadcast, the site selection is critical. For example, if a booster receives its primary signal from a receiver tuned to the primary FM transmitter, the booster's transmitted signal generally ranges from 90 to 110 dB stronger than the intended input signal. If feedback contamination is to be limited to less than 30 dB, the transmitting antennas and receiving antennas have to have between 120 and 140 dB isolation.

A high degree of shielding between the antennas is required. Sometimes this can be accomplished by terrain or even by a building. Depending on system power levels, a physical separation between highly directional antennas may be enough.

It is good engineering practice to choose a site that is accessible in varying weather conditions. That is, it cannot be subject to factors such as excessive winds, erosion, snow, heat, or water.

3.1. Antennas

Some system designers mistakenly believe that running all the power the license permits and using the largest antenna they get is the best course of action. The problem with higher-gain antennas is that they have small vertical beamwidths that can cause deadspots in the minor lobes due to the nulls in the radiation pattern. Since the major lobe provides the most gain to the detriment of areas near the antenna, signals in the remote areas will likely be excellent, at the cost of local signals. Sometimes, however, this is an intended effect when areas near the antenna are lightly populated.

Beamtilt will not solve a problem caused by insufficient Fresnel ellipsoid clearance ("shadowing"). Antenna tuning will also not solve this kind of problem. If a site has poor performance due to radio shadowing, no amount of manipulation of the antenna system will make a substantial

improvement over a properly operating antenna system. Some operators are willing to pay for minor improvements, but a better use of finances is to analyze carefully a potential site before building it. Examine every proposed system with care to analyze accurately the magnitude of the potential problem areas. Antenna pattern control equals better system performance, less co-channel and adjacent channel interference, and better spectrum utilization.

3.1.1. Transmitting Antennas. There are a number of factors to consider when it comes to designing the antenna system for a low-power operation. Careful attention to materials selected is key. A poor-quality antenna will adversely affect the best system. For omnidirectional usage, use low-power versions of the standard higher-powered transmitting antennas. (They are available in horizontal, vertical, and elliptically polarized models.) Virtually all transmitting and receiving antennas are available in 50- or 75- Ω models. The relationship between the tower and the radiating elements is essential. The best designs are custom tuned for the specific situation.

When designing an antenna system, make sure that antenna and tower manufacturers or owners are kept abreast of any possible problem areas, such as wind resistance, the antenna's postinstallation directivity patterns, and mounting procedures.

Calculate ERP by multiplying the antenna's power gain by the transmitter output in watts less losses (hybrid, coax, duplexer, circulators, etc.). Be aware of the antenna's vertical plane pattern as well as the probable signal levels at various points in the service area, because the measuring gain on VHF antennas is usually set at zero degrees. (The gain at other elevation angles may be considerably less.)

Antenna beamwidth equals the number of degrees between the major lobe half-power points. If it is necessary to have coverage in local *and* distant areas, choose the highest possible antenna location and the antenna configuration that will be the best compromise. A high antenna with no obstructions between the transmission site and the receiving sites is required for consistent service to the intended audience.

If local coverage is of paramount importance, utilize a high-gain antenna with a moderate degree of beamtilt, or lower power and an omnidirectional antenna. This will make the best use of radiated power and reduce interference.

3.1.2. Receiving Antennas for Retransmission. The input signal's delivery to the transmitter is an essential factor in overall system design when retransmitting a signal. A poor-quality input signal makes all the difference in the entire operation of the system.

A simple antenna on a nearby tower is sometimes sufficient for off-air reception. More often, measures that are more intricate are necessary. Sometimes, increasing antenna gain or narrowing the pattern of the arrangement is an option. A 30° horizontal pattern width from a single receiving antenna has been known to allow for reception of an interfering signal. A number of methods can resolve

retransmission reception difficulties, including signal filtering to minimize out-of-band products, antenna-mounted preamplification to increase signal levels, and horizontal and vertical antenna stacking techniques to increase antenna gain and directivity.

The majority of difficulties related to the input signal have to do with weak input signal strength, measured in microvolts on the receiver front panel. Depending on the manufacturer, equipment specifications usually specify that 2–10 μV will result in a good output signal, but those numbers are reflective of equipment capabilities only.

Practical limits at a site tend to be much higher for several reasons. Depending on local conditions, weak signals can result in fades. Upward of 100–300 μV is usual, but even this level of signal can have problems during a fade. Carefully monitoring proposed sites helps avoid the problem from the start. The level of RF noise near a receiving antenna can influence input. Noise levels can be higher than the signal strength of the desired signal. Subsequent filtering or antenna location can help resolve the issue.

In many cases, one must take special measures to ensure that reception and retransmission signals stay clean. A weak signal with poor signal-to-noise ratio is generally the problem. The system's receiving section must contain a superior signal conditioning system, preamp, and receiving antenna to maximize clarity.

4. ANTENNA STACKING

Antenna stacking increases the gain of an antenna array. Stacking can be either horizontal or vertical. Stacking applies in transmission and reception and can be helpful in solving certain reception difficulties.

Vertical antenna stacking influences vertical beamwidth. It is effective in amplifying the gain of the array. Horizontal stacking narrows the array's beamwidth from side to side. If the antennas are in phase, this method adds 3 dB to antenna gain for every doubling of the stack. (A single Yagi antenna has a horizontal acceptance angle of approximately 30° between the 3 dB down points off its front.) Note that horizontal beamwidth decreases considerably and vertical beamwidth remains unaffected.

A variation in stacking resolves certain interference and reception difficulties. There are myriad ways to make use of this technique, including offset antenna arrangements, which allow phase reinforcement off the front of the array and phase cancellation off its rear. The process involves vertical stacking of the antennas (i.e., one antenna forward of another by precisely $\frac{1}{4}\lambda$ at the center frequency of the rejected channel). Use this formula to calculate stacking:

$$D (\text{in.}) = 2951 \text{ divided by frequency of} \\ \text{undesired signal (MHz)}$$

RF signals travel faster in free space than in cable, so connect the rear antenna to the common junction with a short feedline. Then connect the front antenna to the com-

mon junction with a feedline whose length results from the formula multiplied by the velocity of propagation of the cable used, plus the amount of cable that is used for the rearmost antenna.

As another example, set the space from one antenna boom to another so that it will cancel an unwanted signal from a specific forward direction. Install the antennas with the center of each spaced so the unwanted signal is out of phase at the connection between the two antennas, and the interfering signals will negate each other at the combined output.

4.1. Transmitters

Transmitters provide the RF power for the antenna. Proper design of a low-power facility includes selection of the appropriate transmitter for the job. A primary consideration is adequate power in order to achieve desired effective radiated power. The gain of the antenna(s) and the length of the transmission line(s) affect this power level requirement. The available electrical power and the cooling system available at the transmission site also affect the RF power level design. Generally, low-power facilities do not need more complex electrical power systems, such as three-phase power or high-voltage power systems. As in any design, the transmitter should be well designed and easy to maintain and provide diagnostic information about its status and condition.

4.1.1. ITFS and MDS Transmitters. Usually, transmitters for MDS and ITFS rate at 10–100 W visual power and 10% aural capability; 10-W transmitters are typically solid state. Higher-powered transmitters typically operate with vacuum tubes.

Internally and externally diplexed transmitters are widely used. Low-level internal systems work well in uncongested areas due to their ease of use and cost efficiency. Externally diplexed systems reduce cross modulation of video synchronization components onto the aural carrier. They also offer better rejection of products caused by the intermodulation of aural and visual carriers. Aural carrier signal integrity is a considerable element in system performance with multichannel sound and pay television encoding and decoding. Amplitude, phase precorrection methods, and contemporary linear amplifier design ensure good signal performance.

4.1.2. LPTV Transmitters. When choosing an LPTV transmitter, there are a few terms to remember. Linear waveform distortion, called the "2T K factor," measures the distortion of a picture's fine detail. The 2T sine-squared pulse and the 2T bar define the K factor, or actual distortion. The K factor must be less than 3% to meet LPTV standards.

Envelope delay is the delay within the system of the modulation envelope. It is usually a frequency function, with higher frequencies equaling shorter delays. For transmitters, the standard is built on a baseline of the delay within the equipment between 0.05 and 0.2 MHz. For up to 3 MHz, that delay is to be maintained. Past that,

the delay should linearly decrease up to 4.18, so the delay is -170 ns with respect to the baseline at 3.58 MHz.

Differential gain is the difference in gain of the LPTV system's translator for a small, high-frequency signal (chrominance) at two specific levels of a low-frequency signal (luminance) on which the high-frequency signal is superimposed. Differential gain cannot exceed 10% at an average picture level ranging from 10% to 90%.

Differential phase is the difference in the output phase of a signal such as that used in differential gain measurements. It should never exceed 7° past the range of blanking to white.

4.1.3. FM Transmitters. Low-power FM transmitters are usually either a standard FM exciter with lowpass filter or an exciter with a low-power amplifier. Many of the low-power systems are solid state; others operate with vacuum tubes. In a translator or rebroadcast application, several systems are available as complete solutions, with built-in receivers and audio processors. In most cases, the transmitter is simple to install and operate.

4.2. Transmission Lines

Transmission lines play a major role in the design of a low-power system. They provide the connection between the antennas and the equipment—whether transmitters or receivers. It is common for designers to pay little attention to this important part of the design process. In fact, often, low-power systems designers completely forget about the existence of feedline losses. Since these installations operate at low power and are usually on a tight budget, they generally use inexpensive small-diameter coaxial cables. The savings in transmission line costs tend to result in a compromised signal level.

Detailed engineering data are available to allow the user to calculate accurately and compensate for feedline losses. Use the best cable in low-power applications to maximize the power delivered from the transmitter to the antenna or from the antenna to the receiver. The antenna can radiate only the power it receives.

Avoid using a foam-type dielectric cable unless it has a rigid outer connector. Foam dielectric is flexible and has no need for pressurization, but extended exposure to high temperatures can result in migration of center conductors and impedance variations. In some cases, rigid outer conductor foam dielectric cable may be more cost efficient than air dielectric lines if it is installed carefully without sharp bends or kinks. Keep in mind that air dielectric cable, or some alternate means of delivering nitrogen gas, must be provided if the antenna requires pressurization.

An air dielectric transmission-line has a spiral-wound spacer that runs along its length to hold the center conductor in place. It is harder to handle and install than foam because it is so stiff, but it is much sturdier. Air dielectric lines have diameters ranging from $\frac{1}{2}$ in. to 5 in., but the most common sizes for low-power operations are $\frac{7}{8}$ in. and $1\frac{5}{8}$ in.

Here are some important points to remember about coaxial cabling:

The coaxial cable and connector quality is just as important as that of the quality of the system components. All it takes is one bad connector to make a system worthless.

Use a semirigid line for optimum performance. Never use braided cables. If there is any cross-coupling between receiver cables and transmitter cables, all the isolation available will be unusable. Since shield movement can cause noise in systems, secure all flexible cables to keep them safe from strain and unnecessary motion.

Become familiar with the dielectric material, as connectors are the weakest link in every coaxial cable system. Avoid nylon connectors—they can soak up moisture as well as high-frequency RF energy. Polystyrene and Teflon are excellent choices. Only buy superior-quality connectors from a company with a respected name.

Avoid permanently installed adapters. Adapter construction is a compromise providing greater loss and inferior stability than using the correct cable terminations. It can introduce high VSWR into the system, thereby deteriorating overall performance and decreasing isolation.

Above all, pay attention to manufacturer instructions. Just about any good-quality connector works well if protected from cable motion and properly installed.

4.3. Towers

The supporting structure for a low-power antenna may be very short, or it can be 500 m tall. Tower design details are beyond the scope of this article, but it is important for the designer of a low-power system to be aware of various aspects of tower use.

Towers are expensive and dangerous and have a tremendous impact on the surrounding environment. Delays in construction can last for years if proper planning and coordination does not occur. In the initial design phase, use of only the best-quality tower can help avoid many devastating problems in the end.

The loss of a tower can cause more time off the air than the loss of any other major component and can cause severe damage as well. It is essential to give proper attention to the tower supporting any broadcast antenna. While purchasing the best tower money can buy sounds like an expensive proposition, it is nothing compared to the cost of two towers plus any damage resulting from failure.

4.4. Frequency Separation

The strategy of frequency or channel selection for low-power systems, particularly translators, is an art form of itself. According to a common theory, the output frequency of a translator should be as close to the input as possible and ideally an adjacent channel. The reality is that practical and technical issues may preclude this possibility. The majority of quality equipment should be able to operate well on adjacent channels, but there are other more complex issues. For example, operation of a translator on an adjacent frequency always causes interference to the

main station. If the translator is located in the center of a large population, it could actually cause more harm than good.

On the other side of the coin, there is no limit to the frequency separation. Somewhere between the two extremes lies the solution. If maximum quality is the design goal, use at least 2 MHz separation for an FM translator and 60 MHz for a TV translator so that filters and traditional engineering solutions can be used in case of installation difficulties.

4.5. Signal Treatments

If every installation were perfect, there would be no need for signal treatment. The only time when it is unlikely that special treatment for reception or transmission of a signal will be needed is when the facility is located away from all other transmission and reception systems and is not near a populated area. In most of the real world, planning for signal treatment is necessary and important in system design.

4.5.1. Receiving Preamplifiers. Many manufacturers produce tower-mounted preamps with gains ranging from 10 dB to more than 60 dB. Since the received signal may experience increased noise and loss as it travels from the cable to the translator, mount the preamp as close to the antenna as possible. A high-quality amplifier should have no effect on signal reception except to increase amplitude to conquer cable and/or system losses as well as render the signal useful. A preamp with greater gain does not necessarily mean better performance than one with a smaller gain. The reason is that high-gain preamps become more subject to overload as signal input increases. Select a preamp so that installation and input signal requirements are compatible. Overloading during input will result in distortion that can never be “cleaned up” afterward. Moreover, if a preamp experiences a poor signal-to-noise ratio at the input, an equal or slightly worse signal-to-noise ratio will be on the output.

4.5.2. Receiver Filtering. There are many ways to implement filtering. When a low-power receiver is tuned to a frequency near its output, increased out-of-band products result. In early gain stages of receiving equipment, tuning is broader, and a strong first or adjacent second signal may overload the input or mix in the receiver. Increased sharpness of input tuning can result in an increase in system noise.

Traps or bandpass filters at the input or at the tower may help in certain situations. Usually, a bandpass filter attenuates everything but the desired signal and a trap may attenuate a specific signal, causing interference.

4.5.3. Transmitter Filtering. Bandpass cavities are commonly used to reduce a transmitter’s sideband noise. They pass the desired signal with a minimum of loss while sharply attenuating those frequencies that lie above and below the passband.

Notch cavities have a response curve that is the reverse of a bandpass filter—it possesses the same general

configuration. Some people call a notch cavity a “trap filter” or a “reject” because of its ability to pass the desired frequency while it suppresses the rest.

Pass reject (sometimes called “pass notch”) cavities are a combination of the two other cavities. When the interfering frequency is extremely close to the undesired frequency, a pass reject is used.

4.5.4. Combiners. Wireless communications usage increases every day, and tower or system space is becoming more difficult to arrange due to environmental pressures, lack of real estate, and costs. Transmission sites are becoming crowded, and these trends are resulting in a greater need to mix two or more transmitters into one antenna. Combiners do a number of good things at the same time. They filter potential interference and intermodulation, they provide isolation between transmitters, and they allow two or more transmitters to be mixed into one coax run and antenna. Although combiners themselves are relatively expensive, the cost savings to operators of tower sites are high.

Cavity combiners are generally manufactured from inter-cabled bandpass cavities. The isolation is the result of the cavity’s resonant response curve. Sometimes pass reject cavities provide for closer frequency spacing or better isolation.

Advantages of cavity combiners include flexible configuration, cost efficiency, and low insertion loss. Negative features include large size, reduced channel capacity, and possible redesign of a combiner when frequencies are changed or added.

Use a combiner when the frequency spacing between channels is extremely wide. The minimum spacing for the FM band is usually about 1 MHz.

5. INSTALLATION AND TROUBLESHOOTING

Every transmitter site has a potential for problems. While it is impossible to anticipate every conceivable difficulty, proper foresight and planning can help avoid the likelihood of many disasters.

5.1. Boosters

Boosters may experience two kinds of major problems. The first problem is when the booster’s output corrupts the input with the booster’s signal. The second example occurs at a location that receives signals from the booster and the original station.

When isolation between receive and transmit antennas is less than the booster’s overall gain, the result is a power oscillator rather than a power amplifier. Logperiodic antennas rather than omnidirectional antennas are highly recommended. Self-oscillation takes place when the booster is transmitting an unmodulated signal and the booster’s power meter indicates normal operation. Try turning the RF gain control down. If the transmitted signal sounds clean, advance the gain control until the system breaks into oscillation and find a compromise gain setting.

If that does not solve the problem, then the installation is to blame. Disconnect the receive antenna from the down

converter. If the oscillation persists after the antenna is disconnected, there are a few things to do:

The transmission line is carrying energy to the down converter. Burying the interconnecting transmission line underground often resolves the situation.

If there is no energy present at the downconverter end of the transmission line, relocate the transmitting or receiving antennas or both. Or shield the receiving antenna by locating it over the edge of a hill or behind an obstruction such as a water tower. One more solution is to increase the separation between the transmit and receive antennas until the system is stable.

5.2. Translators

If an installed translator fails to operate correctly from the beginning, the cause is nearly always site related. Problems can generally be traced to at least one of the following:

Receive and Transmit Antennas Are Too Close. Translator output power is usually in the millions of microvolts while the input signal is just a few microvolts. Poor translator performance is the result of spacing the antennas a few meters apart because the relatively high-powered output puts too much strain on the receive section. A distance of at least 15 vertical meters is recommended. To ascertain whether antenna separation is the problem, replace the transmit antenna with a dummy load.

Incoming Signal Is Poor-Quality. Translators cannot improve the quality of signal they receive. Some translators are operational with signals from primary stations as much as 160 km away, usually when the elevation is high at the transmit and receive points and low at the transmission path. It is important to monitor the received signal for a good length of time using recording equipment in such cases, since signal quality can come and go.

An Adjacent Channel Is Present. This can be exasperating, because the adjacent channel can sound weak and yet be powerful enough to create distortion in the desired signal. When modulation components overlap on adjacent channels, mixing occurs, resulting in deceptive product generation. The problem can be fixed through special intermediate filters or external filters on the receive antenna.

A High-Powered Station Is Nearby. Serious performance issues can arise when the FM station's output energy mixes with that of the translator. This is a common problem. Tubes and output transistors are not totally linear and thus tend to operate as mixers, producing false signal generation that interferes with sensitive receiving equipment. Because the problem goes away when the translator is shut off, inexperienced technicians tend to blame the translator. The truth is that all translators react this way under the same conditions. The goal is to keep external signals from the final RF stage of the translator. Installing an

isolator in the output transmission line is a cost-efficient way to solve the problem. A second option is to employ a high Q cavity in the output, which bypasses the translator output and rejects the offending signal.

Input and Output Channels Are Too Close in Frequency.

The majority of transmitting equipment (including FM translators) produces spurious emissions extending several megahertz from the principal carrier. These signals possess an infinite amount of signals with the same frequencies as the desired signal so they infiltrate the translator and are amplified. Solve the problem with good antenna and frequency separation, usually with at least 1 MHz between input and output.

Harmonic Problems Cause Interference. The translator's main carrier is almost always the cause. It overburdens the front of the translator or the preamp associated with it. Although the translator suppresses harmonics by at least 60 dB, the seemingly obvious addition of an extra external harmonic filter will not do a bit of good. By placing a bandpass filter into the translator in front of any preamplification, the interfering signal will be too feeble to cause difficulties. Alternatively, try moving the translator installation far enough away that its carrier will not be powerful enough to do harm.

5.3. ITFS and MDS

There are a number of potential RF system difficulties with ITFS and MDS. Both services use 100 W or less per channel, so field intensities are fairly low in contrast to full-service broadcast. The ITFS and MDS services rely heavily on radio line-of-sight coverage, so the use of frequencies greater than 2000 MHz creates a need for better consideration of signal path clearances. The receive system needs a low-noise-figure downconverter (which generally changes a block of the ITFS/MDS band frequency to VHF) and a relatively high-gain antenna. Other problem areas include adjacent-channel and cochannel interference. As the spectrum becomes more crowded, the probability of interference grows in relation. In response, many cities are planning adjacent channel systems. A number of MDS systems, in particular, are already experiencing cochannel interference problems. As the ITFS band grows, so does the likelihood that it, too, will develop problems.

Luckily, a good number of the common engineering principles that solve UHF and VHF broadcast difficulties are proving helpful. Suppressing out-of-band products is essential, as older transmit systems frequently display high levels of lower sideband reinsertion and out-of-band product formation. Externally diplexed linear transmitters and waveguide filters can bring these products to more workable levels. Offset frequency operation can be utilized with relatively high levels of cochannel interference.

The area of best signal coverage is within the areas receiving the entire Fresnel ellipsoid. These areas can extend beyond visible line of sight due to the refraction of electromagnetic waves in the atmosphere. Use a path clearance of at least 0.6 Fresnel zone to avoid excessive diffraction loss due to path obstructions. The formula is as

follows:

$$R = ((\text{wavelength} \times d_1 \times d_2) / (d_1 + d_2))^{1/2}$$

d_1 = the distance from the transmitter to the obstruction

d_2 = the distance from the obstruction to the receiver

Path clearances above 1.3 Fresnel zones can yield multipath propagation, nulls in received levels, and/or picture ghosts in the received pictures. Moving the antenna slightly can help alleviate the problem.

5.4. Spurious Emissions

Looking at the data that come with the translator is a good way to ensure that the system is clean and clear of unwanted emissions, except for harmonic products, which are undetectable by the test data measuring output performance. Low levels of distortion and high signal-to-noise ratios generally indicate clean transmission. The problem with unwanted emissions is that the undesirable products they generate fall inside *and* outside the assigned output channel.

When there are several stations located at one transmitter site where you are receiving interference, there may be harmonic mixes between the other stations that fall on or near your frequency. Sometimes these harmonics originate within the transmitters involved in the mix—and if the spurious harmonic signals are above a certain threshold, they may be in violation of governmental rules. The existence of this type of interference is verified by using a spectrum analyzer at the towers of the offending stations. The source of this kind of interference can be verified only by connecting test equipment to the various transmitters involved.

Most complaints are about interference to nearby television translators. Usually the harmonic stems from the television translator, not the FM translator. Any overloaded amplifier is subject to harmonic generation. Installing a highpass filter at the output of the receive antenna might help. The advantage to going this route is that low loss of the filter does not compromise the integrity of the TV translator. This method could fail if the FM and TV translator antennas are just a few meters apart. If a filter does not work and the antennas are properly spaced, cabinet radiation or power line feedthrough is the culprit.

5.5. Spectrum Analyzers

Spurious emissions are not necessarily transmitter related. Spectrum analyzers can be unreliable when it comes to harmonic measurements if not used properly. Towers and other metallic objects can reradiate signals and cause nonlinear distortion, resulting in spurious emission.

Use a spectrum analyzer to examine the output channel. If the translator datasheet reveals that solid data yet unwanted emissions are present, the cause is usually an adjacent channel. There are several courses of actions to resolve the issue. Use narrowband filters in the IF section of the translator, reduce the signal level of the interfering adjacent channel, or increase the level of the desired channel.

5.6. Desensing

Desensing is the result of brute-power RF transmissions in the surrounding area. It is entirely possible to have a translator operating on 10 μ V, for example, and a 100-kW station 1 km away. Intermodulation occurs when the translator tries in vain to accommodate the lower-level input signal while being hit by the much stronger signal, which runs into the first translator it sees. Filtering on the input line is the best way to solve the problem before the signals mix in the first place. If the site lacks a strong enough input signal to overcome the insertion loss of a selective filter, consider using special preamps designed just for that purpose. Relocating or redesigning the input antenna structure is another viable option. Other methods include raising the receive antenna, adding a preamp to overcome line loss, adding or stacking receive antennas, and relocating receive antennas (or perhaps the entire site).

After translator installation is complete and the power is turned on, there is nothing but hash and noise. But once the translator is off and the receiver is hooked up to the receive antenna, there is no problem. This is because any translator conveys undesirable products as well as the desired modulation. These products possess a wide bandwidth, which is usually several megahertz from the main carrier frequency. Generated products are composed of the energy caused by the random motion of electrons (Johnson noise) and sideband components from the desired modulation. Generally, the undesirable products are quite weak, so they cannot be observed on a spectrum analyzer without suppressing the main carrier. Regardless of whether the undesirable products are modulation components or noise, some of these undesirable products will be in phase between the input and the output of the translator.

5.7. Problem Solving

Providing a filter at the translator's output can solve many problems. The purpose of the filter is to subdue those undesirable products that fall on the translator's input channel, but execution is more difficult than it sounds. Note that the quality factor, known simply as Q , ascertains how lossy the filter will be in operation.

If a translator operates at 100.1 MHz, it would need a filter to prevent undesirable products from falling on the input channel at 102.1 MHz. Two megahertz is the separation factor, so to make sure that no products from output fall on the input, the bandwidth cannot be more than 1 MHz. So $Q = 100.1/1 = 100.1$ is the minimum value. To have a filter with a low insertion loss and a minimum of energy loss, the Q for every element inside the filter has to be 100 times the minimum, or 10,000 times. But the realization of such a Q factor necessitates the use of costly cavity-type filters.

It is much more cost-efficient to use Q factors of around 800 for the filter elements. The filter uses a combination of two techniques: bandstop and bandpass. The bandstop section is a slot about 300 kHz wide, adjusted to the input channel frequency.

The bandpass section passes carrier frequency and useful modulation data. This low-loss device adds more selectivity that optimizes the system's performance. It can also decrease the radiation of out-of-band signals. A good illustration would be between an antenna and transmitter combiner, where the filter's job is to overpower any harmonics originating in the ferrite isolators and downgrade any broadband transmitter noise so that receive sensitivity remains intact. Energy from the translator output that falls on the input frequency is attenuated by approximately 50 dB. Using an example of $5 \mu\text{V}$ worth of undesirable products falling on the input after passing through the filter, the magnitude is reduced by 50 dB ($0.0158 \mu\text{V}$ the $\text{SNR} = 10/0.0158 = 632 = 56 \text{ dB}$). Now performance is excellent.

LOW-TEMPERATURE COFIRE CERAMIC (LTCC) TECHNOLOGY IN RF AND MICROWAVE ENGINEERING

KE-LI WU
The Chinese University of
Hong Kong
Shatin, NT, Hong Kong

1. INTRODUCTION

LTCC is a rapidly developing passive integration and package technology that offers an attractive solution to RF and microwave products in three aspects: (1) embedded passives, (2) packaging and system integration,

and (3) low manufacturing cost for high-volume production, featuring excellent electrical performance at RF and microwave frequencies.

LTCC has distinct advantages in embedded passives and packaging in that it provides a harmonic carrier for ICs (digital and analog) with embedded passives, control and power lines, and functional accessories. As far as interconnect is concerned, LTCC offers the capability of fine pitch on each layer. Since each layer is processed individually, LTCC is more cost-effective than any other sequentially processed technologies.

As shown in Table 1, another advantage of LTCC is its stability and relative insensitivity to environmental stress. The dense structure of a fired ceramic body has very low permeability to moisture, which allows LTCC parts to perform in high humidity without special packaging or protection [1].

The three key areas for LTCC technology are the development of LTCC tape and conductive paste materials; the manufacturing process that leads to high-precision, high-reliability, and low-cost products; and the design technology that needs to take all the necessary electromagnetic couplings and parasitics into account.

In developing dielectric material for an LTCC system, the electrical and thermomechanical aspects must be investigated for enabling the production and usage of reliable components. In the case of RF applications, the dielectric properties such as low-loss tangent [$\tan(\delta)$], permittivity (ϵ_r), and coefficient of thermal expansion (CTE) are important. The typical properties of three major commercial LTCC tape systems are listed in Table 2. After a tape system is developed, matched conductive paste must be developed for different usages such as solderable and wirebondable paste for surface-mounted components and IC dies, solderable paste for BGA (ball grid array) attachment, and conducting paste for inner layer and via filling.

LTCC tapes need to withstand handling and via punching and produce, after lamination and low temperature cofiring, a solid material with the desired properties. A good surface smoothness and compatibility with embedded conductive lines are also essential properties [2].

The current LTCC products can be divided into two major categories: functional components and modules. Chip LC filters, baluns, couplers, and chip antennas are good examples of functional components. On the other hand, modules usually integrate active devices such as IC dies with other required passive components to form a subsystem. In designing LTCC modules or components, electromagnetic phenomena must be taken into account as

Table 1. Performance Characteristics of Dielectric Materials

Materials	Process Temperature (°C)	Expansion Coefficient (ppm/°C)	Moisture Permeability
Polymers	< 200	25-100	Medium to high
Metals	> 600	20-25	Low
Ceramics	800-1700	4-10	Low to medium

accurately as possible. This demands the design tools to incorporate electromagnetic (EM) simulation, in conjunction with the standard circuit-level simulation function for system-level design. Since the LTCC circuit is a multilayer configuration with vias connecting the circuitry on different layers, the EM simulation tools have to be able to handle the current flowing in both horizontal and vertical directions. Additionally, if the thickness of printed conductors is noticeable as compared to the thickness of the dielectric layer, the conductor thickness must be accounted for in an accurate design. The research for effective EM design of LTCC module and design methodologies has attracted a great deal of attention in the field.

2. HISTORY OF LTCC [3]

Like other good invention, LTCC was born of necessity. In 1982, Hughes Aircraft was concerned with developing a process for a group of high complexity multilayer substrates. The solution to this was a dielectric layer that was tape-cast. The tape could be via-punched, filled, and printed with conductor and then fired in place. This process became known as *Ttran* and formed the basis for the three generations of LTCC that we have gone through to date.

The firsthand cast formulations of LTCC tape were based on existing multilayer dielectric pastes from DuPont, ESL, Ferro, and other manufacturers. While made with the most primitive methods to demonstrate the technology and with the aid of some sewing needles for via formation the first real LTCC parts were made in the lab. This grew into the DuPont 851 Green Tape. The dielectric loss of this material at microwave frequencies prompted the development and commercialization of the Ferro A6M system. There were a great deal of refinements and development of additional inks (both metallic and

resistive), and this completed the development of LTCC generation 1.

The environmental movement was key in spurring DuPont to develop the 951 formulation. This eliminated the “made with chlorinated solvents” stigma and allowed continued marketing in Europe and Asia. Improvements in the organic portion of the formulation were made as part of this transition greatly improving produceability and reducing costs. At about the same time Ferro sought to broaden their offering by creating lower cost-versions of their flagship A6M product, including A6C, A6B, and the still available (as of Sept. 2003) A6S.

Nearly concurrent with this effort, Heraeus developed the CT600 and CT800 materials that are nearly equivalent to the Ttran and 951 products. Additionally Heraeus worked toward constrained sintering for “zero shrink” production process. The market for LTCC was growing rapidly during this time with many commercial adoptions in areas such as automotive applications and modules for wireless communication system. The bursting of the Internet and wireless bubbles slowed down the worldwide economy enough to end the development phase of LTCC generation 2 by mid-2001.

Generation 3 of LTCC technology marks the maturing of the LTCC industry. New compositions targeted not at increasing technical merit but lowering system cost. In one instance, Motorola introduced T2000 material, which was designed with its physical properties balanced to have a “zero” T_f . This material has been commercialized by Heraeus as CT2000. Heraeus has also developed this material in a self-constrained version as HL2000 under their HeraLock patent as a way to increase array precision, thus allowing larger arrays for lower assembly cost. Another aspect of LTCC generation 3 is the emergence of low-cost LTCC foundries in the Far East, Taiwan, and mainland China. This further enables low-cost manufacturing but at the same time requires the designer to have the expertise to do the full design and engineering of the product.

3. BASICS OF LTCC DIELECTRIC MATERIALS AND PROCESS

Dielectric materials used for LTCC components must have proper firing, dielectric, and thermomechanical properties so that mechanically reliable multilayer structures with the desired electrical performance can be produced.

Proper firing properties means that the dielectric material has to achieve a dense, nonporous microstructure below 950°C so that it can be cofired with low resistive conductor materials such as silver or copper. As revealed by Table 3, unlike traditional cofired ceramics with firing temperature in excess of 1400°C and only those low conductive with high melting point metals such as tungsten can be embedded, by keeping the firing temperature below 950°C, all the metals with high conductivity can be used.

For commercial LTCC materials, the firing profile is specified accurately in the information given by the manufacturers, and for new dielectric materials, this is an essential part of their development. Figure 1 shows a typical firing profile for LTCCs. Steps 1, 3, and 5 are heating and cooling periods, step 2 is for burning out the organic additives, and step 4 is the actual sintering period. For Heraeus' CT2000, for instance, the recommended firing profile is 3.0°C/min to 100°C, 3.0°C/min to 450°C, 5.5°C/min to 865–875°C, held for 20–30 min. The cooling rate is approximately 6–10°C/min (furnace cooling rate). Firing must be done on flat setter material since the tape will conform to the setter material.

The permittivity of LTCC dielectric is particularly important because the length of a resonator is roughly inversely proportional to the square root of the permittivity. The LTCC materials available commercially have permittivities of 5–10, but higher values (≤ 85) are also available for noncommercial materials.

The number of possible different materials and compositions to decrease the firing temperature of crystalline ceramic is countless. The most common method is to use SiO₂-based glass compositions.

The tape-casting process consists of a slurry preparation and its casting as shown in Fig. 2. The basic formula for the tape casting slurry includes the ceramic powder, solvents, and organic additives. In the fired product the ceramic material is all that remains, and thus the solvents and additives have to be removed in earlier process steps. These ingredients are added only to facilitate the fabrication of the tape with an appropriate thickness and density and to make the tape strong enough for subsequent processing [4].

Table 3. Conductivity and Melting Points for Some Commonly Used Conductors

Conductor	Conductivity σ (S/m)	Melting Point (°C)
Silver (Ag)	6.17×10^7	961
Copper (Cu)	5.8×10^7	1083
Gold (Au)	4.10×10^7	1063
Tungsten (W)	1.815×10^7	3370

Figure 1. Typical firing profile for LTCC components.

After drying the tape in air, it is further processed to form multilayer components as shown in Fig. 3. The tape is first blanked to size and the required vias are formed using mechanical or laser punching. After via filling and screen printing of the conductive patterns on each separate layer, they are stacked together, laminated, and cofired.

4. LTCC EMBEDDED PASSIVE COMPONENTS

The ability to embed passive elements is one of the most attractive features of LTCC technology. Simple passive elements include inductors, resistors, capacitors, *LC* shunt elements, *LC* series elements, and various functional circuits such as filters. Some common configurations of embedded passive components are listed in Table 4. The main parasitic capacitors in each circuit layout are marked as C_p in the circuit models.

The circular series inductor on a single layer shown in (a) may provide about 10–15% higher *Q* value than its rectangular shaped counterpart shown in (b). The inductors in (c) and (d) are the implementation of the inductors with multilayer windings to increase the inductance value. Usually, the inductor winding layers should be kept as far away from the ground as possible to minimize the loss [5]. To trade off the occupied area and the *Q* value, the ovum-shaped inductor shown in (e) would be a good choice. Capacitors are usually in rectangular shape as shown in (f) and (g). Multilayered interdigital capacitors in (h) are commonly used for high-value capacitance. By combining the basic elements of inductors and capacitors, we can construct various simple functional *LC* networks such as capacitor π network (i), *LC* series network (j), and *LC* resonator tank (k). In constructing the *LC* resonator tank it is wise to lay the inductors above the shunt capacitor to minimize the loss caused by the ground and the parasitic capacitance on the inductor. This guideline is also applicable to the design of the lowpass network (l) and the highpass network (m). In the bandpass filter with one transmission zero (n) [6], the mutual coupling *M* is realized by two side-by-side inductor strips. The mutual coupling *M* in the bandpass filter (o), which has one transmission zero at the lower stopband and a transmission zero at the upper stopband, can be created by a overlapped two inductor strips [7]. It is worth mentioning

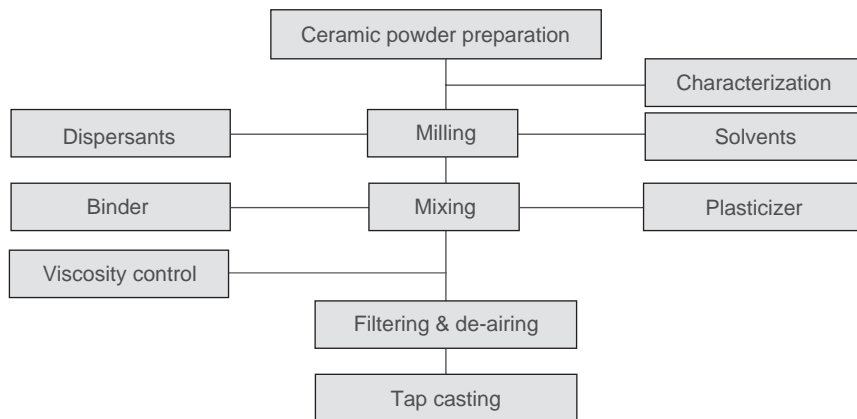

Figure 2. General production process of ceramic tape casting. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

that in designing high-performance filters, the parasitic coupling between the input and the output must be carefully taken into account [8].

5. LTCC RF MODULES

In most radiofrequency (RF) applications, in order to meet size requirements, a large part of the circuit is usually integrated in a semiconductor die. However, the required functional passive circuits in the system such as filters and baluns form an exception due to the power handling and the requirement for low signal losses. The losses in transmit and receive channels directly influence the power consumption and receiver sensitivity. With this regard, LTCC provides an option to integrate those required high-*Q* passive circuits while providing a packaging substrate to the Si or GaAs IC dies. LTCC enables low-loss stripline designs and geometries realizable with standard screen-printing techniques. In addition, the use of thick-film silver metallization in LTCC substrate ensures lower conductor loss than building circuits on Si or GaAs.

A good example of LTCC modules is the antenna switch diplexer front-end module for GSM/DCS/PCS applica-

tions, in which the diplexer is realized using lowpass and highpass filters. In addition to a lowpass filter at the switch end of DCS band, some elaborately designed resonant circuits are built in the diplexer circuit to trap the second, third, and fourth harmonics. Figure 4a shows the lumped-element model for an LTCC antenna switch diplexer. The 3D layout of a realization of the lumped-element model is illustrated in Fig. 4b with its response shown in Fig. 4c. Due to the strong EM couplings in the embedded passives, an accurate EM modeling and efficient optimization scheme must be used in the design [9].

6. LTCC LAMINATED WAVEGUIDE AT MICROWAVE FREQUENCY

At microwave frequencies, the dielectric loss becomes more significant as compared to the cases in RF frequencies. A part of the loss is contributed by the surface wave. On the other hand, due to the filling effect of a high-dielectric-constant material, some low-loss transmission lines whose dimension is considered as bulky in conventional applications become suitable in LTCC applications. A good example of this type of transmission line is the laminated waveguide [10], a derivation of rectangular

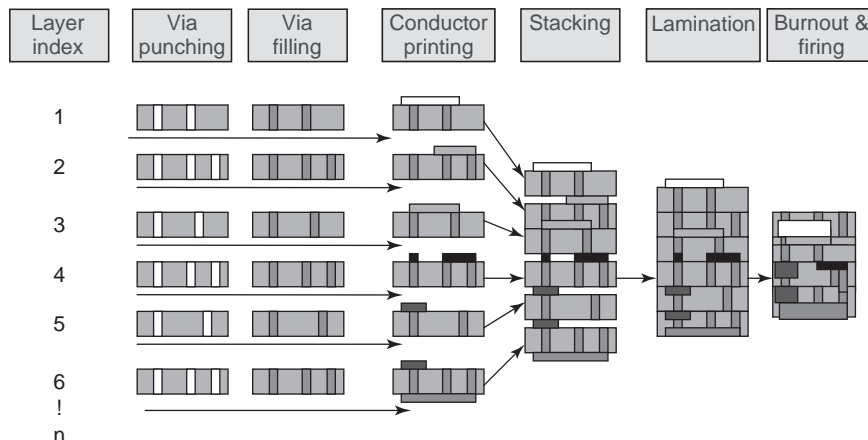

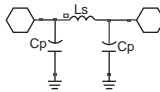

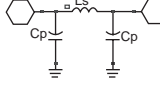

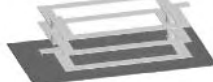

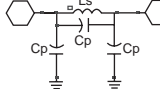

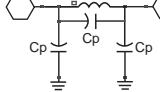

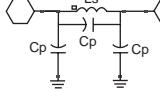

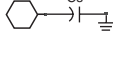

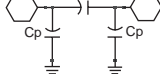

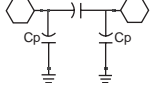

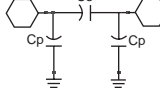

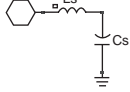

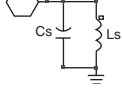

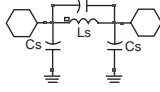

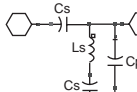

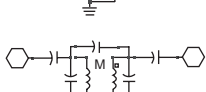

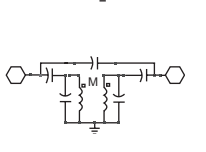

Figure 3. General production process of LTCC multilayer components. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

waveguide. As shown in Fig. 5, a laminated waveguide is composed of an LTCC substrate, a pair of main conductive layers on the upper and lower surfaces of the substrate, and a pair of conducting walls formed by a plurality of via holes extending in a thickness direction. The inner conductive layers connecting the via holes play a very important rule in reducing the leakage of electromagnetic waves. The laminated waveguide has also been used in ridge waveguide bandpass filters [11] and surface-mounted bandpass chip filters [12].

In developing an LTCC integrated module at microwave frequencies, people always need to use various transition and packaging structures to connect one type of transmission line to another. For example, some common transitions between laminated waveguide to striplines were proposed in a U.S. patent [13]. A waveguide-

microstrip line transition was proposed in another U.S. patent [14]. A broadband transition between a waveguide and an LTCC laminated waveguide was developed by Huang and Wu [15].

7. CONCLUDING REMARKS

It has been suggested that LTCC as a high-density packaging and passive integration technology offers many benefits over other competing technologies. However, three major limitations need to be mentioned: shrinkage control, strength, and thermal conductivity. These concerns have been addressed by the industry by introducing “zero shrinkage” materials, improving materials, fabrication process, and thermal via/heatsink technology. For high-power applications, LTCC-on-metal (LTCC-M) technology is a good candidate. Another cost-effective way to dissipate heat is the use of cavities in the LTCC structure, allowing access to the underlying heat spreader.

While continuing reduction of material cost, development of a large format process will be another direction toward cutting manufacturing cost.

Today, LTCC products can be found in radar, space, medical, and wireless communication systems; computer hardware; biotechnology; satellite communication; and automobile manufacturing. It is expected that with steady improvement of LTCC materials and process technologies, an increasing number of new applications will appear in our lives.

1. RELEVANCE OF ELECTROMAGNETIC FIELD MEASUREMENTS

The measurement of electromagnetic (EM) fields is relevant for various purposes: for scientific and technical applications, for radio propagation, for electromagnetic compatibility (EMC) tests (i.e., testing of the immunity of electronic equipment to electromagnetic emissions aiming at the protection of radio reception from radio interference), and for safety reasons (i.e., the protection of persons from excessive field strengths). For radio propagation and EMC measurements, below about 30 MHz a distinction is made between electric and magnetic components of the EM field to be measured. In the area of human safety, this distinction is continued to even higher frequencies.

2. QUANTITIES AND UNITS OF MAGNETIC FIELDS

Especially in the measurement of radio propagation and of radio interference, magnetic field measurements with loop antennas have traditionally been used to determine the received field intensity, which was quantified in units of the electric field strength, namely, in $\mu\text{V/m}$, respectively, in $\text{dB}(\mu\text{V/m})$. For radio propagation this can be justified for far-field conditions where electric field strength E and magnetic field strength H are related via the impedance Z_0 of the free space; $E = HZ_0$ (see also antenna factor definition). Commercial EMC standards in Refs. 1 and 2 specify radiated disturbance measurements below 30 MHz with a loop antenna; however, until 1990 measurement results and limits were expressed in $\text{dB}(\mu\text{V/m})$. Since this measurement is done at less than the far-field distance from the equipment under test (EUT) over a wide frequency range, the use of units of the electric field strength was difficult to justify. Therefore, the CISPR (the International Special Committee on Radio Interference) decided in 1990 to use units of the magnetic field strength $\mu\text{A/m}$, respectively, $\text{dB}(\mu\text{A/m})$.

Guidelines and standards for human exposure to EM fields specify the limits of electric and magnetic fields. In the low-frequency range (i.e., below 1 MHz [3]), limits of the electric field strength are not proportional to limits of the magnetic field strength. Magnetic field limits in frequency ranges below 10 kHz are frequently expressed in units (T and G, for tesla and gauss) of the magnetic flux density B despite the absence of magnetic material in human tissue. Some standards specify magnetic field limits in A/m instead of T (see Ref. 4 in contrast to Ref. 5). For

easier comparison with other applications we therefore convert limits of the magnetic flux density to limits of the magnetic field strength using $H = B/\mu_0$ or $1\text{ T} = 10^7/4\pi\text{ A/m} \approx 0.796 \cdot 10^6\text{ A/m}$ and $1\text{ G} = 79.6\text{ A/m}$. At higher frequency ranges all standards specify limits of the magnetic field strength in A/m. Above 1 MHz the limits of the magnetic field strength are related to limits of the electric field strength via the impedance of the free space. Nevertheless both quantities, electric and magnetic fields, have to be measured, since in the near field the exposition to either magnetic or electric field may be dangerous.

3. RANGE OF MAGNETIC FIELD LEVELS TO BE CONSIDERED FOR MEASUREMENT

In order to show the extremely wide range of magnetic field levels to be measured, we give limits of some national or regional standards. In different frequency ranges and applications magnetic field strength limits vary from as much as 10 MA/m down to less than 1 nA/m (i.e., over 16 decades). This wide range of field strength levels will normally not be covered by one magnetic field meter. Different applications require either broadband or narrowband equipment.

On the high level end there are safety levels and limits of the magnetic field strength for the protection of persons that vary from as much as 4 MA/m (i.e., $4 \times 10^6\text{ A/m}$ corresponding to the specified magnetic flux density of 5 T in nonferrous material) at frequencies below 0.1 Hz, to less than 0.1 A/m at frequencies above 10 MHz (see Fig. 1) [3–6]. These limits of the magnetic field strength are derived from basic limits of the induced body current density (up to 10 MHz), respectively, basic limits of the specific absorption rate (SAR, above 10 MHz). There are also

Figure 1. Safety limits of the magnetic field strength derived from the European Prestandard ENV 50166 Parts 1 and 2: 120 dB(A/m) are equivalent to 1 MA/m corresponding to 1.25 T, 0 dB(A/m) are equivalent to 1 A/m.

Figure 2. Magnetic field strength limits derived from U.S. MIL-STD-461D RE101 (Navy only) [7]. These limits are originally given in dB(pT) (decibels above 1 pT). The measurement procedure requires a 36-turn shielded loop antenna with a diameter of 13.3 cm. Measurement distance is 7 cm for the upper limit and 50 cm for the lower limit.

derived limits of the electric field strength which are however not of concern here.

By using an approach different from the one of the safety standards, the Swedish standard MPR II, which has become an international de-facto standard for video-display units (VDUs) without scientific proof, specifies limits of the magnetic flux density in two frequency ranges, which are bounded by filters: a limit of 40 nT (≈ 0.032 A/m) in the range from 5 Hz to 2 kHz and a limit of 5 nT (≈ 0.004 A/m) in the range from 2 kHz to 400 kHz.

On the low-level end there are limits for the protection of radio reception and electromagnetic compatibility in some military standards (see Figs. 2 and 3).

Figure 3. Narrowband emission limits of the magnetic field strength derived from the German military standard VG 95343 Part 22 [8]. This standard gives the limits of $H \cdot Z_0$ in dB(μV/m) of four equipment classes, the emissions have to be measured with a loop antenna calibrated in dB(μV/m) in the near field of the equipment under test (EUT). Therefore, the limits have been converted into dB(μA/m). The lower limits is Class 1, the upper is Class 4.

Figure 4. Radiated emission limits for navigational receivers according to draft revision IEC 945 (IEC 80/124/FDIS), originally given in dB(μV/m), for the purpose of this article converted into dB(μA/m).

International and national monitoring of radio signals and the measurement of propagation characteristics require the measurement of low-level magnetic fields down to the order of -30 dB(μA/m): see also subsequent discussions and Refs. 7–9. For the protection of radio reception, international, regional (e.g., European) and national radiated emission limits and measurement procedures have been standardized for industrial, scientific, medical (ISM) and other equipment [1,2,10–12]. An example is given in Fig. 4.

Radiated emission limits of fluorescent lamps and luminaires are specified in a dB(μA) using a large-loop-antenna system (LAS) [10]. For further information, see the text below.

4. EQUIPMENT FOR MAGNETIC FIELD MEASUREMENTS

4.1. Magnetic Field Sensors Others than Loop Antennas

An excellent overview of magnetic field sensors other than loop antennas is given in Ref. 13. Table 1 lists the different types of field sensors that are exploiting different physical principles of operation.

4.2. Magnetic Field Strength Meters with Loop Antennas

Especially for the measurement of radiowave propagation and radiated electromagnetic disturbance pickup devices, the antennas become larger and therefore are used separately from the indicating instrument (see Fig. 5). The instrument is a selective voltmeter, a measuring receiver, or a spectrum analyzer. The sensitivity pattern of a loop antenna can be represented by the surface of two spheres (see Figs. 6 and 7). In order to determine the maximum field strength, the loop antenna has to be turned into the direction of maximum sensitivity.

To obtain an isotropic field sensor, three loops have to be combined in such a way that the three orthogonal components of the magnetic field H_x , H_y , and H_z are combined to fulfill the equation

Table 1. Overview of Different Magnetic Field Sensors, their Underlying Physical Effects, their Applicable Level, and Frequency Ranges from Ref. 13^a

Type	Principles of Operation	Level of Operation	Frequency Range
Search coil magnetometer	Faraday's law of induction	10^{-6} – 10^9 A/m	1 Hz–1 MHz
Flux gate magnetometer	Induction law with hysteresis of magnetic material	10^{-4} – 10^4 A/m	DC–10 kHz
Optically pumped magnetometer	Zeeman effect: splitting of spectral lines of atoms	10^{-6} – 10^2 A/m	DC
Nuclear precession magnetometer	Response of nuclei of atoms to a magnetic field	10^{-5} – 10^2 A/m	DC (upper frequency limited by gating frequency of hydrocarbon fluid)
SQUID magnetometer	Superconducting quantum interference device	10^{-8} – 10^{-2} A/m; speciality: differential field measurements	DC
Hall effect sensor	Hall effect	10^{-1} – 10^5 A/m	DC–1 MHz
Magnetoresistive magnetometer	Magnetoresistive effect	10^{-4} – 10^4 A/m	DC–1 GHz
Magnetodiode	Semiconductor diode with undoped silicon	10^{-2} – 10^3 A/m	DC–1 MHz
Magnetotransistor	Hall and Suhl effects	10^{-3} – 10^3 A/m	DC–1 MHz
Fiberoptic magnetometer	Mach-Zehnder interferometer	10^{-7} – 10^3 A/m	DC–60 kHz
Magneto-optical sensor	Faraday polarization effect	10^2 – 10^9 A/m	DC–1 GHz

^aTo facilitate comparison with values given in text, the values from Ref. 13 have been converted from gauss to A/m.

Figure 5. Magnetic field strength measuring loop. The network may consist of a passive or active circuit.

$$H = \sqrt{H_x^2 + H_y^2 + H_z^2}$$

Isotropic performance is, however, only a reality in broadband magnetic field sensors, where each component is detected with a square-law detector and combined subsequently. For the measurement and detection of radio signals isotropic antennas are not available. Hybrids may be used for limited frequency ranges to achieve an omnidirectional azimuthal (not isotropic) pickup.

4.2.1. Antenna Factor Definition. The output voltage V of a loop antenna is proportional to the average magnetic field strength H perpendicular to the loop area. If the antenna output is connected to a measuring receiver or a spectrum analyzer, the set consisting of antenna and receiver forms a selective magnetometer.

The proportionality constant is the antenna factor K_H for the average magnetic field strength H :

$$K_H = \frac{H}{V} \text{ in } \frac{\text{A}}{\text{m}} \frac{1}{\text{V}} = \frac{1}{\Omega \cdot \text{m}} \quad (1a)$$

Figure 6. Cross section of a loop antenna sensitivity pattern. The arrow length H_x shows the indicated field strength at an angle α which is a fraction of the original field strength H , with $H_x = H \cos \alpha$.

Figure 7. Direction of the field vectors (H , E and P) under far-field conditions.

For the average magnetic flux density B the corresponding proportionality constant is

$$K_B = \frac{B}{V} = \frac{\mu_0 H}{V} = \mu_0 K_H \quad \text{in} \quad \frac{V \cdot s}{A \cdot m} \frac{A}{m} \frac{1}{V} = \frac{V \cdot s}{m^2} \frac{1}{V} = \frac{T}{V} \quad (1b)$$

In the far field, where electric field and magnetic fields are related via the free-space wave impedance Z_0 , the loop antenna can be used to determine the electric field strength E . For this case the proportionality constant is

$$K_E = \frac{E}{V} = \frac{Z_0 H}{V} = Z_0 K_H \quad \text{in} \quad \frac{V}{A} \frac{A}{m} \frac{1}{V} = \frac{1}{m} \quad (1c)$$

In the area of radiowave propagation and radio disturbance measurement, quantities are expressed in logarithmic units. Therefore, the proportionality constants are converted into logarithmic values, too:

$$k_H = 20 \log(K_H) \quad \text{in dB} \left(\frac{1}{\Omega m} \right) \quad (2a)$$

$$k_B = 20 \log(K_B) \quad \text{in dB} \left(\frac{T}{V} \right) \quad (2b)$$

$$k_E = 20 \log(K_E) \quad \text{in dB} \left(\frac{1}{m} \right) \quad (2c)$$

By using logarithmic antenna factors, a field strength level $20 \log(H)$ is obtained in $\text{dB}(\mu\text{A}/\text{m})$ from the measured output voltage level $20 \log(V)$ in $\text{dB}(\mu\text{V})$ by applying the equation: $20 \log(H) = 20 \log(V) + k_H$. The final section of this article describes a method calibrate the antenna factors of circular loop antennas.

4.2.2. Concepts of Magnetic Field Strength Meters. The loop antenna of a magnetic field strength meter may be mounted on the measuring receiver (or used as a separate unit, connected to the measuring receiver) with a coaxial cable. CISPR 16-1, the basic standard for emission measurement instrumentation to commercial (i.e., nonmilitary) standards, requires a loop antenna in the frequency range from 9 kHz to 30 MHz which is completely enclosed by a square having sides 0.6 m in length. For protection against stray pickup of electric fields, loop antennas employ a coaxial shielding structure. For optimum performance, the shielding structure may be arranged symmetrically in two half-circles around a circular loop with a slit between the two halves in order to avoid electric contact between the two shields.

For narrowband magnetic field measurements of radio disturbance, measuring receivers employ standardized bandwidths and weighting detectors in order to produce standardized measurement results for all types of perturbations including impulsive signals. For comparison with the emission limit, usually the quasipeak (QP) detector is to be used.

Figure 8. Detector response of a test receiver for impulsive interference as specified in Ref. 1.

To understand the function of a weighting curve in measuring receivers, the following interpretation is given. The test receiver has certain elements that determine a weighting curve (e.g., for the QP detector): the measurement bandwidth, the charge and discharge times of the detector circuit, and the time constant of the meter. When measured with a QP detector, for the frequency range given in Fig. 8, an impulsive signal with a constant impulse strength and a pulse repetition frequency of 100 Hz will cause a meter indication 10 dB above that of the indication when the pulse repetition frequency is 10 Hz. Or, to produce the same indication on the meter as a signal with 100 Hz repetition frequency, the level of the 10-Hz impulsive signal will have to be increased by an amount of 10 dB.

Earlier manually operated field-strength meters achieved high sensitivity by operating the loop at resonance [14]. The sensitivity was raised by the amount of the Q factor of the resonating circuit. One of the latest models that was used up to the 1980s reached a sensitivity of $-60 \text{ dB}(\mu\text{A}/\text{m})$ with a measurement bandwidth of 200 Hz in the frequency range from 100 kHz to 30 MHz [15].

For automated field strength measurement systems, tuning of the loop circuit could no longer be afforded. A broadband active loop employs an output voltage proportional to the short-circuited loop current, thus achieving a flat response of the antenna factor versus frequency [16].

A flat response of the system is also achieved using a current probe that measures the short-circuit current in the large-loop antenna system [LAS] described by Bergervoet and van Veen [9]. It is essentially a magnetic-field-induced current measurement (see subsequent explanations). The highest sensitivity described in the literature for a wideband system was achieved with a specially designed active loop. With additional frequency-dependent switching of elements [17], sensitivity is even better than that of manually operated field strength meters with tuning of the loop circuit. Figure 9 shows the amplitude density of the minimum detectable magnetic field strength H_{Neq} in $\text{dB}(\mu\text{A}/\text{m}\sqrt{\text{Hz}})$ equivalent to the internal electronic noise of the system consisting of antenna and measuring receiver.

Figure 9. Sensitivity per hertz bandwidth of the active loop [16].

5. MAGNETIC FIELD STRENGTH MEASUREMENT METHODS

5.1. Measurement of Magnetic Fields with Regard to Human Exposure to High EM Fields

Usually, to measure magnetic fields with regard to human exposure to high fields, magnetic field strength meters are using broadband detectors and apply an isotropic response. Modern concepts of low-frequency electric and magnetic field strength meters apply fast Fourier transform (FFT) for proper weighting of the total field with regard to frequency-dependent limits [18,19].

5.2. Use of Loop Antennas for Radiowave Field Strength Measurements up to 30 MHz

ITU-R Recommendation PI.845-1 Annex 1 gives guidance to accurate measurement of radio wave field strengths. Rod antennas are the preferred receiving antennas since they provide omnidirectional azimuthal pickup. The positioning of vertical rod antennas is important, however, since the result is very sensitive to field distortions by obstacles and sensitive to the effects of ground conductivity. It is a well-known fact that measurements with loop antennas are less sensitive to these effects and their calibration is not affected by ground conductivity apart from the fact that the polarization may deviate from horizontal if ground conductivity is poor. Therefore, many organizations use vertical monopoles for signal measurements but standardize results by means of calibration data involving comparisons for selected signals indicated by field strength meters incorporating loop-receiving antennas. Accuracy requirements are given in Ref. 20, general information on equipment and methods of radio monitoring are given in Ref. 21.

5.2.1. Solutions to Problem with Ambients in Commercial EMI Standards. CISPR Class B radiated emission limits in the frequency range from 9 kHz to 30 MHz have been at 34 dB(μV/m) at a distance of 30 m from the EUT for a long time. Moreover, the test setup with EUT and vertical loop antenna required turning of both EUT and the loop antenna to find the maximum emission. On most of the

Figure 10. Conversion factors ΔH for the limit of the magnetic field strength from measurement distance 30 m to measurement distances 10 and 3 m above a conducting ground plane according to Ref. 23. The upper curve is for 30–3 m; the lower curve is for 30–10 m distance.

open-area test sites the ambient noise level makes compliance testing almost impossible. This is due to the fact that ambient noise itself is near or above the emission limit. Two different approaches were proposed as a solution to that problem:

1. To reduce the measurement distance from 30 to 10 m or even 3 m. A German group proposed frequency-dependent conversion factors, justified by calculations and an extensive amount of measurements. The conversion factors are given in Fig. 10. In Fig. 10 the slopes between 1.8 and 16 MHz show the transition region from near field, where H is inversely proportional with r^3 or $r^{2.6}$, to far field, where H is inversely proportional with r .
2. To reduce the measurement distance to zero. A Dutch group proposed the large-loop antenna system mentioned previously [9]. With this method the EUT is placed in the center of a loop antenna system, which consists of three mutually perpendicular large-loop antennas (Fig. 11). The magnetic field emitted by the EUT induces currents in the large-loop antennas. Since there are three orthogonal loops, there is no need to rotate either the EUT or the loop antenna system. The current induced in each loop is measured by means of a current probe, which is connected to a CISPR measuring receiver. Since the current is measured, emission limits are given in dB(μA) instead of dB(μA/m). Each loop antenna is constructed of a coaxial cable that contains two slits, positioned symmetrically with respect to the position of the current probe. Each slit is loaded by resistors in order to achieve a frequency response flat to within ± 2 dB in the frequency range from 9 kHz to 30 MHz [9,10]. In order to verify and validate the function of each large loop, a specially designed folded dipole has been developed [9,10]. It

Figure 11. Simplified drawing of a large-loop antenna system with position of the EUT.

produces both a magnetic dipole moment m_H and an electric dipole moment m_E , when a signal is connected to the folded dipole. The folded dipole serves to test large loop antenna for its sensitivity in eight positions.

5.2.2. Problems in the Near-Field–Far-Field Transition Zone. Problems with magnetic field strength measurements in the transition region between near field and far field are discussed in detail in Ref. 22. When a small magnetic dipole is located in the free space, the electromagnetic field in a point $P(r, \theta, \varphi)$ is described by the following three relations (see Fig. 12):

$$H_r = \frac{jk}{2\pi} \frac{m_H \cos \theta}{r^2} \left(1 + \frac{1}{jkr}\right) e^{-jkr} \quad (3a)$$

$$H_\theta = \frac{-k^2}{4\pi} \frac{m_H \sin \theta}{r} \left(1 + \frac{1}{jkr} - \frac{1}{(kr)^2}\right) e^{-jkr} \quad (3b)$$

$$E_\varphi = \frac{Z_0 k^2}{4\pi} \frac{m_H \sin \theta}{r} \left(1 + \frac{1}{jkr}\right) e^{-jkr} \quad (3c)$$

where $k = 2\pi/\lambda$ and $m_H = \pi R_0^2 I_0$ is the magnetic dipole moment, a vector perpendicular to the plane of the dipole. Equations (3a)–(3c) completely describe the electromagnetic field of the magnetic dipole.

Two situations are discussed further: (1) the near field, where r is much smaller than λ but larger than the maximum dimension of the source (i.e., $kr \ll 1$); and (2) the far field, where r is much larger than λ and much larger than the maximum dimension of the source (i.e., $kr \gg 1$).

For the near-field case, where $kr \ll 1$ and using $e^{-jkr} = \cos(kr) - j \sin(kr)$, Eqs. (3a)–(3c) are simplified to

$$H_r = \frac{2m_H \cos \theta}{4\pi r^3} \quad (4a)$$

$$H_\theta = \frac{m_H \sin \theta}{4\pi r^3} \quad (4b)$$

Figure 12. Field components H_r , H_θ , and E_φ in \mathbf{P} at a distance r from the center of the magnetic dipole in the xy plane.

$$E_\varphi = \frac{kZ_0 m_H \sin \theta}{4\pi r^2} \quad (4c)$$

From Eqs. (4a)–(4c) we can see that H_r and H_θ are inversely proportional to r^3 , whereas E_φ is inversely proportional to r^2 .

For the far-field case where $kr \gg 1$, Eqs. (3a)–(3c) are reduced to

$$H_r = \frac{jk m_H \cos \theta}{2\pi r^2} e^{-jkr} \Rightarrow 0 \quad (5a)$$

$$H_\theta = \frac{-k^2 m_H \sin \theta}{4\pi r} e^{-jkr} \quad (5b)$$

$$E_\varphi = \frac{k^2 Z_0 m_H \sin \theta}{4\pi r} e^{-jkr} \quad (5c)$$

From Eqs. (5a)–(5c) one can see that in the far field H_r vanishes in comparison to H_θ and that H_θ and E_φ are inversely proportional to r .

In the frequency range from 9 kHz to 30 MHz, where emission limits have been set, the corresponding wavelength is 33 km–10 m. Since for compliance testing, ambient emissions on an open-area test site require a reduction of the measurement distance to 10 m or even 3 m, measurements are carried out in the near-field zone over a wide frequency range. At the higher frequency range the transition zone and the beginning far field zone are reached. Goedbloed [22] investigated the transition zone and identified the critical condition where H_r and H_θ are equal in magnitude. It occurs where

$$\frac{2m_H}{4\pi r^3} \sqrt{1 + k^2 r^2} = \frac{m_H}{4\pi r^3} \sqrt{1 - k^2 r^2 + k^4 r^4} \quad (6)$$

or where

$$fr = 112.3 \text{ in MHz} \cdot \text{m} \quad (7)$$

For $r = 10$ m, $H_{\theta \max} > H_{r \max}$ at frequencies greater than 11 MHz.

Figure 13. Basic CISPR setup for magnetic field measurements. Both EUT and loop antennas have to be turned round until the maximum indication on the receiver has been found.

The CISPR magnetic field measurement method is illustrated in Fig. 13, with the test setup on a metallic ground plane and the receiving antenna in the vertical plane. In Figs. 14 and 15, two different cases of radiating electrically small magnetic dipoles are illustrated; the first one, with the dipole moment parallel to the ground plane and the second one, with the dipole moment perpendicular to the ground plane. Because of the reflecting ground plane two sources are responsible for the field at the location of the receiving antenna: the original source and the mirror source. The points and crosses drawn in both sources show the direction of the current. In Fig. 14, the currents are equally oriented. In this case the loop antenna detects the radial component $H_{d,r}$ and the direct tangential component $H_{d,\theta} = 0$ since $\theta_d = 0$. Therefore, direct radiation will only contribute if $fd \ll 112 \text{ MHz} \cdot \text{m}$ [see Eq. (7)]. In the case of $fd \gg 112 \text{ MHz} \cdot \text{m}$, the loop antenna will receive direct radiation if it is rotated by 90° . This may be observed frequently in practical measurements: at low frequencies the maximum radiation is found with loop antenna in parallel to the EUT and at high frequencies with the loop antenna oriented perpendicular to the EUT. In addition to these direct components, the indirect radial and tangential components $H_{i,r}$ and $H_{i,\theta}$ are superpositioned in the loop antenna. Assuming near-field conditions it follows from Eqs. (4), that the magnitude of the mag-

Figure 14. (a) Receiving conditions for a magnetic dipole with a horizontal dipole moment; (b) vectors of the directly and indirectly radiated H -field components.

netic field H_m is given by

$$H_m = H_{d,r} + H_{i,r} \cos \theta_i - H_{i,\theta} \sin \theta_i$$

$$= \frac{m_H}{4\pi d^3} \left(2 + \frac{d^3}{d_1^3} (2 \cos^2 \theta_i - \sin^2 \theta_i) \right) \quad (8)$$

where $d_1 = \sqrt{(2h)^2 + d^2}$ is the distance between the mirror dipole and the loop antenna.

Goedbloed gives a numerical example with $m_H = 4\pi 10^3 \mu\text{A} \cdot \text{m}^2$ (e.g., 100 mA through a circular loop with a diameter of 0.40 m). Using Eq. (8) with $d = 3 \text{ m}$ and $h = 1.3 \text{ m}$ will give $H_m = 38.6 \text{ dB}(\mu\text{A/m})$ with the mirror source and $37.4 \text{ dB}(\mu\text{A/m})$ without the mirror source, which shows that in this case the reflecting ground plane has little influence. The influence of the ground plane is quite different in the case of a vertical dipole moment, specifically, a dipole moment perpendicular to the ground plane as illustrated in Fig. 15. In the case of Fig. 15 the loop antenna does not receive direct radiation at all, as $H_{d,r}(\theta_d = \pi/2) = 0$ and $H_{d,\theta}$ is parallel to the loop antenna. Hence, the received signal is completely determined by the radiation coming from the mirror source, which also means that the result is determined by the quality of the reflecting ground plane. With the reflecting ground plane $H_m = H_{i,r} \sin \theta_i + H_{i,\theta} \cos \theta_i = 27.2 \text{ dB}(\mu\text{A/m})$, whereas without the reflecting ground plane no field strength will be measured. If the loop antenna were positioned horizontally above the ground plane at $h = 1.3 \text{ m}$, then $H_m = H_{d,\theta} + H_{i,r} \cos \theta_i - H_{i,\theta} \sin \theta_i = 32.4 \text{ dB}(\mu\text{A/m})$ and $H_m = 31.4 \text{ dB}(\mu\text{A/m})$ without the reflecting ground plane. Measurements in a shielded room would be even less predictable, since the result would be determined by mirror sources on each side, including the ceiling of the shielded room. Absorbers are not very helpful in the low frequency ranges. From the results, Goedbloed concludes that in order to judge the interference capability of an EUT, the method proposed by Bergervoet and van Veen [9], is an efficient method of magnetic field measurements.

Figure 15. (a) Receiving conditions for a magnetic dipole with a vertical dipole moment, and the receiving loop antenna in the vertical position as specified by the standard; (b) vectors of the indirectly radiated H -field components (no reception of direct radiation).

6. CALIBRATION OF A CIRCULAR LOOP ANTENNA

A time-varying magnetic field at a defined area S can be determined with a calibrated circular loop. For narrow-band magnetic field measurements, a measuring loop consists of an output interface (point \mathbf{X} on Fig. 5), which links the induced current to measuring receiver. It may have a passive or an active network between loop terminals and output. The measuring loop can also include a shielding over the loop circumference against any perturbation of strong and unwanted electric fields. The shielding should be interrupted at a point on the loop circumference.

Generally in the far field that streamlines of magnetic flux are uniform, but in the near field, that is, in the vicinity of the generator of a magnetic field, they depend on the source and its periphery. Figure 19 shows the streamlines of the electromagnetic vectors generated by the transmitting loop \mathbf{L}_1 . In the near field, the spatial distribution of the magnetic flux, $B = \mu_0 H$, over the measuring loop area is not known. Only the normal components of the magnetic flux, averaged over the closed-loop area, can induce a current through the loop conductor.

The measuring loop must have a calibration (conversion) factor or set of factors, that, at each frequency, expresses the relationship between the field strength impinging on the loop and the indication of the measuring receiver. The calibration of a measuring loop requires the generation of a well-defined standard magnetic field on its effective receiving surface. Such a magnetic field is generated by a circular transmitting loop when a defined root-mean-square (RMS) current is passed through its conductor. The unit of the generated or measured magnetic field H_{av} is A/m and therefore is also an RMS value. The subscript "av" strictly indicates the average value of the spatial distribution, not the average over a period of T of a periodic function. This statement is important for near-field calibration and measuring purposes. For far-field measurements the result indicates the RMS value of the magnitude of the uniform field. In the following we discuss the requirements for the near-zone calibration of a measuring loop.

7. CALCULATION OF STANDARD NEAR-ZONE MAGNETIC FIELDS

To generate a standard magnetic field, a transmitting loop \mathbf{L}_1 is positioned coaxial and plane-parallel at a separation distance d from the loop \mathbf{L}_2 , as in Fig. 16. The analytical formula for the calculation of the average magnetic field strength H_{av} in A/m generated by a circular filamentary loop at an axial distance d including the retardation due to the finite propagation time was obtained earlier. The average value of field strength H_{av} was derived from the retarded vector potential A_φ as tangential component on the point P of the periphery of loop \mathbf{L}_2 :

$$H_{av} = \frac{I r_1}{\pi r_2} \int_0^\pi \frac{e^{-j\beta R(\varphi)}}{R(\varphi)} \cos(\varphi) d\varphi \quad (9a)$$

$$R(\varphi) = \sqrt{d^2 + r_1^2 + r_2^2 - 2r_1 r_2 \cos(\varphi)} \quad (9b)$$

Figure 16. Configuration of two circular loops.

In these equations for the thin circular loop, I is transmitting loop RMS current in amperes, d is distance between the planes of the two coaxial loop antennas in meters, r_1 and r_2 are filamentary loop radii of transmitting and receiving loops in meters, respectively, β is wave-length constant, $\beta = 2\pi/\lambda$, and λ is wavelength in meters.

Equations (9a) and (9b) can be determined by numerical integration. To this end we separate the real and imaginary parts of the integrand using Euler's formula $e^{-j\varphi} = \cos(\varphi) - j \sin(\varphi)$ and rewrite Eq. (9a) as

$$H_{av} = \frac{I r_1}{\pi r_2} (F - jG) \quad (10a)$$

where

$$F = \int_0^\pi \frac{\cos[\beta R(\varphi)]}{R(\varphi)} \cos(\varphi) d\varphi \quad (10b)$$

$$G = \int_0^\pi \frac{\sin[\beta R(\varphi)]}{R(\varphi)} \cos(\varphi) d\varphi \quad (10c)$$

and the magnitude of H_{av} is then obtained as

$$|H_{av}| = \frac{I r_1}{\pi r_2} \sqrt{F^2 + G^2} \quad (10d)$$

It is possible to evaluate the integrals in Eqs. (10) by numerical integration with an appropriate mathematics software on a personal computer. Some mathematics software can directly calculate the complex integral of Eqs. (9).

8. ELECTRICAL PROPERTIES OF CIRCULAR LOOPS

8.1. Current Distribution around a Loop

The current distribution around the transmitting loop is not constant in amplitude and in phase. A standing wave of current exists on the circumference of the loop. We can

Figure 17. Current distribution on a circular loop.

determine this current distribution along the loop circumference by assuming that the loops circumference $2\pi r_1$ is electrically smaller than the wavelength λ and the loop current is constant in phase around the loop and that the loop is sufficiently loss-free. The single-turn thin loop was considered as a circular balanced transmission line fed at points **A** and **D** and short-circuited at points **E** and **F** (Fig. 17).

In an actual calibration setup the loop current I_1 is specified at the terminals **A** and **D**. The average current was given as a function of input current I_1 of the loop:

$$I_{av} = I_1 \frac{\tan(\beta\pi r_1)}{\beta\pi r_1} \tag{11}$$

The fraction of I_{av}/I_1 from Eq. (11) expressed in dB gives the conditions for determining of the highest frequency f and the radius of the loop r_1 . The deviation of this fraction is plotted in Fig. 18.

The current I in Eqs. (9) must be substituted with I_{av} from Eq. (11). Since Eq. (11) is an approximate expression, it is recommended to keep the radius of the transmitting loop small enough for the highest frequency of calibration to minimize the errors. For the dimensioning of the radius

Figure 18. Deviation of I_{av}/I_1 for a loop radius, 0.1 m as $20 \log(I_{av}/I_1)$ in dB versus frequency.

of the receiving loop these conditions are not very important, until the receiving loop is calibrated with an accurately defined standard magnetic field, but the resonance of the loop at higher frequencies must be taken into account.

8.2. Circular Loops with Finite Conductor Radii

A measuring loop can be constructed with one or more winding. The form of the loop is chosen as a circle, because of the simplicity of the theoretical calculation and calibration. The loop conductor has a finite radius. At high frequencies the loop current flows on the conductor surface and it shows the same proximity effect as two parallel, infinitely long cylindrical conductors. Figure 19 shows the cross section of two loops intentionally in exaggerated dimensions. The streamlines of the electric field are orthogonal to the conductor surface of the transmitting loop L_1 and they intersect at points **A** and **A'**. The total conductor current is assumed to flow through an equivalent thin filamentary loop with the radius $a_1 = \sqrt{r_1^2 - c_1^2}$, where $a_1 = \overline{OA} = \overline{OP} = \sqrt{\overline{OQ}^2 - \overline{QP}^2}$. The streamlines of the magnetic field are orthogonal to the streamlines of electric field. The receiving loop L_2 with the finite conductor radius c_2 can encircle a part of magnetic field with its effective circular radius $b_2 = r_2 - c_2$.

The sum of the normal component of vectors H acting on the effective receiving area $S_2 = \pi b_2^2$ induces a current in the conductor of the receiving loop L_2 . This current flows through the filamentary loop with the radius a_2 . The average magnetic field vector H_{av} is defined as the integral of vectors H_n over effective receiving area S_2 , divided by S_2 . The magnetic streamlines, which flow through the

Figure 19. Filamentary loops of two loops with finite conductor radii and orthogonal streamlines of the electromagnetic vectors, produced from transmitting loop L_1 .

conductor and outside of loop \mathbf{L}_2 , cannot induce a current through the conductor along the filamentary loop \mathbf{Ar} , \mathbf{Ar}' , of \mathbf{L}_2 . The equivalent filamentary loop radii a_1 , a_2 and effective circular surface radii b_1 , b_2 can directly be seen from Fig. 19.

The equivalent thin current filament radius a_1 of the transmitting loop \mathbf{L}_1 :

$$a_1 = \sqrt{r_1^2 - c_1^2} \quad (12a)$$

The equivalent thin current filament radius a_2 of the receiving loop \mathbf{L}_2 :

$$a_2 = \sqrt{r_2^2 - c_2^2} \quad (12b)$$

The radius b_1 of the effective receiving circular area of the loop transmitting \mathbf{L}_1 :

$$b_1 = r_1 - c_1 \quad (12c)$$

The radius b_2 of the effective receiving circular area of the receiving loop \mathbf{L}_2 :

$$b_2 = r_2 - c_2 \quad (12d)$$

8.3. Impedance of a Circular Loop

The impedance of a loop can be defined at chosen terminals \mathbf{Q} , \mathbf{D} , as $Z = V/I_1$ (Fig. 17). Using Maxwell's equation with the Faraday's law curl $\mathbf{E} = -j\omega\Phi_m$, we can write the line integrals of the electric intensity \mathbf{E} along the loop conductor through its cross section, along the path joining points \mathbf{D} , \mathbf{Q} , and the load impedance Z_L between the terminals \mathbf{Q} , \mathbf{A} :

$$\int_{(AEFD)} \mathbf{E}_s ds + \int_{(DQ)} \mathbf{E}_s ds + \int_{(QA)} \mathbf{E}_s ds = -j\omega\Phi_m \quad (13a)$$

Here, Φ_m is the magnetic flux. The impressed emf V acting along the path joining points \mathbf{D} and \mathbf{Q} is equal and opposite to the second term of Eq. (13a):

$$V = - \int_{(DQ)} \mathbf{E}_s ds \quad (13b)$$

The impedance of the loop at the terminals \mathbf{D} , \mathbf{Q} can be written from Eqs. (13) dividing with I_1 as

$$\begin{aligned} Z = \frac{V}{I_1} &= \frac{\int_{(AEFD)} \mathbf{E}_s ds}{I_1} + \frac{\int_{(QA)} \mathbf{E}_s ds}{I_1} + \frac{j\omega\Phi_m}{I_1} \\ &= Z_i + Z_L + Z_e \end{aligned} \quad (14)$$

Z_i indicates the internal impedance of the loop conductor. Because of the skin effect, the internal impedance at high frequencies is not resistive. Z_L is a known load or a source impedance on Fig. 17. Z_e is the external impedance of the

loop:

$$Z_e = j\omega \frac{\Phi_m}{I_1} = j\omega \frac{\mu_0 H_{av} S}{I_1} \quad (15a)$$

We can consider that the loop consists of two coaxial and coplanar filamentary loops (i.e., separation distance $d = 0$). The radii a_1 and b_1 are defined in Eqs. (12). The average current I_{av} flows through the filamentary loop with the radius a_1 and generates an average magnetic field strength H_{av} on the effective circular surface $S_1 = \pi b_1^2$ of the filamentary loop with the radius b_1 . From the Eqs. (9) and (11) we can rewrite Eq. (15a), for the loop \mathbf{L}_1 :

$$\begin{aligned} Z_e &= j \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \\ &\times \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi \end{aligned} \quad (15b)$$

$$R_0(\varphi) = \sqrt{a_1^2 + b_1^2 - 2a_1 b_1 \cos(\varphi)} \quad (15c)$$

The real and imaginary parts of Z_e are the radiation resistance and the external inductance of loops, respectively:

$$\begin{aligned} \text{Re}(Z_e) &= \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \\ &\times \int_0^\pi \frac{\sin(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \end{aligned} \quad (15d)$$

$$\begin{aligned} \text{Im}(Z_e) &= \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \\ &\times \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \end{aligned} \quad (15e)$$

From Eq. (15e) we obtain the external self-inductance:

$$\begin{aligned} L_e &= \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 a_1 b_1 \\ &\times \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \end{aligned} \quad (15f)$$

Equations (15) include the effect of current distribution on the loop with finite conductor radii.

8.4. Mutual Impedance between Two Circular Loops

The mutual impedance Z_{12} between two loops is defined as

$$Z_{12} = \frac{V_2}{I_1} = \frac{Z_2 I_2}{I_1} \quad (16)$$

The impedance of Z_2 in Eq. (16) can be defined in the same way as Eq. (14):

$$Z_2 = \frac{V_2}{I_2} = Z_{2i} + Z_L + Z_{2e} \quad (17)$$

here Z_{2i} is the internal impedance, Z_L is the load imped-

ance, and Z_{2e} is the external impedance of the second loop \mathbf{L}_2 .

The current ratio I_2 to I_1 in Eq. (16) can be calculated from Eqs. (9),(11), and (12). The current I_1 of the transmit loop with separation distance d :

$$I_1 = \frac{H_{av}\pi b_2}{\frac{\tan(\beta\pi a_1)}{\beta\pi a_1} a_1 \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi} \quad (18a)$$

$$R_d(\varphi) = \sqrt{d^2 + a_1^2 + b_2^2 - 2a_1 b_2 \cos(\varphi)} \quad (18b)$$

and the current I_2 of the receive loop for the same H_{av} (here $d = 0$) is

$$I_2 = \frac{H_{av}\pi b_2}{\frac{\tan(\beta\pi a_2)}{\beta\pi a_2} a_2 \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi} \quad (18c)$$

$$R_0(\varphi) = \sqrt{a_2^2 + b_2^2 - 2a_2 b_2 \cos(\varphi)} \quad (18d)$$

The general mutual impedance between two loops from Eqs. (16) and (17) is

$$Z_{12} = (Z_{2i} + Z_L + Z_{2e}) \frac{I_2}{I_1} = Z_{12i} + Z_{12L} + Z_{12e} \quad (19a)$$

here Z_{12i} is the mutual internal impedance, Z_{12L} denotes the mutual load impedance, and Z_{12e} is the external mutual impedance.

Arranging Eq. (15b) for Z_{2e} and the current ratio I_2/I_1 from Eqs. (18) external mutual impedance yield

$$Z_{12e} = j \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_2 \times \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (19b)$$

The real part of Z_{12e} may be described as mutual radiation resistance between two loops.

The imaginary part of Z_{12e} divided by ω gives the mutual inductance

$$M_{12e} = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 a_1 b_2 \times \int_0^\pi \frac{\cos(\beta R_d(\varphi))}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (19c)$$

Equations (19b) and (19c) include the effect of current distribution on the loop with finite conductor radii.

9. DETERMINATION OF THE ANTENNA FACTOR

The antenna factor K is defined as a proportionality constant with necessary conversion of units. K is the ratio of the average magnetic field strength bounded by the loop to

the measured output voltage V_L on the input impedance R_L of the measuring receiver. For evaluation of the antenna factor there are two methods. The first is by calculation of the loop impedances, and the second is with the well-defined standard magnetic field calibration, which will also be needed for the verification of calculated antenna factors [24].

9.1. Determination of the Antenna Factor by Computing from the Loop Impedances

If a measurement loop (e.g., \mathbf{L}_2) has a simple geometric shape and a simple connection to a voltage measuring device with a known load R_L , we can determine the antenna factor by calculation. In the case of unloaded loop from Fig. 17 the open-circuit voltage is

$$V_0 = j\omega\mu_0 H_{av} S_2 \quad (20a)$$

For the case of loaded loop the current is

$$I = \frac{V_0}{Z} = \frac{V_0}{R_L + Z_i + Z_e} \quad (20b)$$

The antenna factor from Eq. (9a) can be written with $V_L = Z_L I$ and Eqs. (20) as

$$K_H = \left| \frac{1}{j\omega\mu_0 S_2} \left(1 + \frac{Z_e}{R_L} + \frac{Z_i}{R_L} \right) \right| \text{ in } \frac{\text{A}}{\text{m}} \frac{1}{\text{V}} \quad (21)$$

The effective loop area is $S_2 = \pi b_2^2$. The external loop impedance Z_e can be calculated with Eqs. (15).

9.2. Standard Magnetic Field Method

In the calibration setup in Fig. 20 we measure the voltages with standard laboratory measuring instrumentation with the $50\ \Omega$ impedance. The device to be calibrated consists at least of a loop and a cable with an output connector. Such a measuring loop can also include a passive or active network between the terminals **C,D** and a coaxial shield on the circular loop conductor against unwanted electric fields, depending on its development and construction. The impedance Z_L at the terminals **C,D** is not accurately measurable. Such a complex loop must be calibrated with the standard magnetic field method. The antenna factor in Eqs. (1) can be defined by measuring of the voltage V_L and the uncertainties between loop terminals **C,D** and measuring receiver are fully calibrated. The attenuation ratio α of the voltages V_2 and V_L can be measured for each frequency:

$$\alpha = \frac{V_2}{V_L} \quad (22)$$

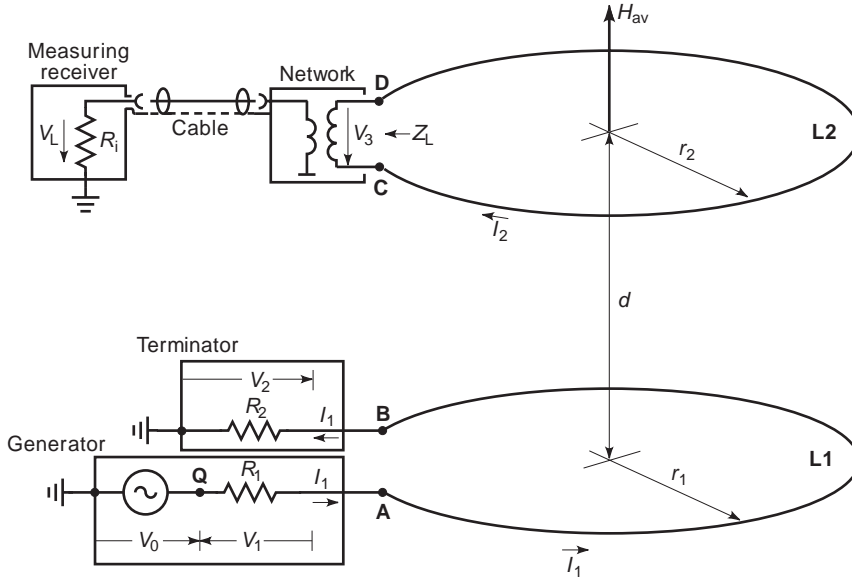

Figure 20. Calibration setup for circular loop antennas.

Using Eqs. (22),(1),(11), and (12), with $V_2 = -I_1 R_2$, and $V_0 = \text{constant}$, Eq. (9a) can be rewritten:

$$K_H = \left| \alpha \frac{1}{R_2} \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \frac{a_1}{\pi b_2} \times \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d(\varphi) \right| \quad (23)$$

R_d is defined by Eq. (18b)b. Equation (23) can also be expressed logarithmically

$$k_H = 20 \log(K_H) \text{ in dB} \left(\frac{\text{A}}{\text{m}} \frac{1}{\text{V}} \right)$$

Equation (23) reduces the calibration of the loop to an accurate measurement of attenuation α for each frequency. The other terms of Eq. (23) can be calculated depending on the geometric configuration of the calibration setup at the working frequency band of the measuring loop. The calibration uncertainties are also calculable with the given expressions. The uncertainty of the separation distance d between two loops must be taken into consideration as well. At a separation distance $d < r_1$ the change of the magnetic field is high.

For a calibration setup the separation distance d can be defined as small as possible. However, the effect of the mutual impedance must be taken into account in the calibration process, and a condition to define the separation distance d must be given (Fig. 20). If the second loop is open-circuited, that is the current $I_2 = 0$, the current I_1 is defined only from the impedances of the transmitting loop. In the case of a short-circuited second loop, I_2 is maximum and the value of I_1 will change depending on the supply circuit and loading of the transmitting loop. A current ratio q between these two cases can be defined as the condition of the separation distance d between the two loops.

It is assumed that the generator voltage V_0 is constant. The measuring loop L_2 is terminated by Z_L . For $Z_L = 0$ and $V_{CD} = 0$, one obtains the current I_1 in the transmitting loop as

$$I_{1(Z_L=0)} = \frac{V_0}{R_1 + R_2 + Z_{AB} - \frac{Z_{12}^2}{Z_{CD}}} \quad (24a)$$

and for $Z_L = \infty$, that is, $I_2 = 0$

$$I_{1(Z_L=\infty)} = \frac{V_0}{R_1 + R_2 + Z_{AB}} \quad (24b)$$

The ratio of Eq. (24a) to Eq. (24b) is

$$q \equiv \frac{I_{1(Z_L=0)}}{I_{1(Z_L=\infty)}} = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB} \left(1 - \frac{Z_{12}^2}{Z_{AB} Z_{CD}} \right)} \right| \quad (25a)$$

here with the coupling factor $k = Z_{12} / \sqrt{Z_{AB} Z_{CD}}$ between two loops:

$$q = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB}(1 - k^2)} \right| \quad (25b)$$

where $R_1 = R_2 = 50 \Omega$, Z_{AB} , Z_{CD} , and Z_{12} can be calculated from Eqs. (15) and (19). For greater accuracy one must try to keep the ratio q close to unity (e.g., $q = 1.001$).

The influence of the loading of the second loop on the transmitting loop can also be found experimentally. The change of the voltage V_2 at R_2 in Fig. 20 must be considerably small (e.g., < 0.05 dB), while putting a short-circuited measuring loop at the chosen separation distance.

With the determining of K_H or k_H the loop can completely be calibrated up to its 50Ω output. A network analyzer is usually used for the attenuation measurement

instead of a discrete measurement at each frequency with signal generator and measuring receiver. A network analyzer can normalize the frequency characteristic of the transmit loop and gives a quick overview on measured attenuation for the frequency band.

MAGNETIC MATERIALS

ROBERT B. VAN DOVER
Bell Labs, Lucent Technologies

1. HISTORICAL BACKGROUND

Magnetic materials have been known since ancient times—for example, in 380 B.C.E. Plato wrote [1] of the “stone which Euripides calls a magnet,” which we infer was Fe₃O₄, now known as *magnetite*. The scientific quality of magnetism studies abruptly and dramatically jumped with the publication in 1600 by Gilbert of the classic text *De Magnete* [2]. Quantitative measurements of magnetic materials were enabled by the 1820 discovery by Oersted that an electric current creates a magnetic field. In 1846 Faraday made systematic studies of the attraction and repulsion of materials in a gradient field and classified materials as *diamagnetic* if they are repelled by a region of increased flux density and *paramagnetic* if they are attracted. To this we add *ferromagnetic* (strongly magnetic, like iron) to form the set of three basic classes of magnetic response.

Since the early part of the twentieth century, magnetic materials have been the subject of deep and broad research and development because of their economic and scientific importance, and much of our knowledge is mature. Nevertheless, startling discoveries continue to be made, such as the discovery of Nd–Fe–B permanent magnets and the “giant magneto-resistance” effect in thin-film multilayers.

2. MAGNETIC FIELDS AND THE MAGNETIC RESPONSE OF MATERIALS

The magnetic properties of matter may be viewed as a response to an applied stimulus, namely, the magnetic field strength \mathbf{H} . The macroscopic response of a material is given by its magnetization \mathbf{M} , and the overall field is the sum of the two, called the magnetic induction \mathbf{B} . In a vacuum the magnetization is strictly zero. For this article we adopt SI units, so we have $\mathbf{B} = \mu_0 \mathbf{H}$ in a vacuum, where \mathbf{B} is measured in tesla (Wb/m²), \mathbf{H} is measured in amperes per meter, and by definition $\mu_0 = 4\pi \times 10^{-7}$ H/m². The magnetic response adds directly to the applied field, giving $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$.

The issue of units in magnetism is perennially vexing. In the past, cgs (Gaussian) units have been commonly used by scientists working with magnetic materials. In that system, \mathbf{B} is measured in gauss, \mathbf{H} in oersteds, and \mathbf{M} in emu/cm³, where emu is short for the uninformative term *electromagnetic unit*. The constitutive relation in Gaussian units is $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M}$. Important conversion factors to keep in mind are 10^4 Ga = 1 T and 12.5 Oe = 1 kA/m. A definitive discussion of units and dimensions is given in the Appendix of Jackson's *Classical Electrodynamics* [3].

3. TYPES OF MAGNETIC MATERIALS: TAXONOMY

3.1. Basic Families

Two of the basic families of magnetic materials involve a highly linear response (i.e., $\mathbf{M} = \chi\mathbf{H}$, where χ is defined as the magnetic susceptibility). The main magnetic response of all materials is due to the magnetic moment of individual electrons, a property directly connected to their spin. The moment of a single electron is 1 Bohr magneton, $\mu_B = 1.165 \times 10^{-29}$ Wbm. Due to the Pauli principle, in many cases the electrons in an atom are precisely paired with oppositely directed spins, leading to an overall cancellation. Nevertheless, a magnetic response can be discerned in all materials, as observed by Faraday.

3.2. Diamagnetism

Diamagnets have a negative value for χ , that is, the induced moment is opposite to the applied field. The susceptibility is temperature independent and typically small (see Fig. 1). Diamagnetism is due to the effect of a magnetic field on orbital motion of paired electrons about the nucleus (superficially comparable to Lenz' law). The diamagnetic susceptibility of most materials is very small—in the vicinity of -1×10^{-5} . A tabulation of diamagnetic susceptibilities of various atoms, ions, and molecules is given by Carlin [4].

A large negative magnetic susceptibility is characteristic of only one class of materials (namely, superconductors). A type I superconductor in the Meissner state exhibits complete exclusion of magnetic flux from the interior of the sample, $\mathbf{M} = -\mathbf{H}$, or $\mathbf{B} = 0$. Superconductors can also exhibit partial flux penetration, $0 < B < \mu_0 H$. In both cases the spectacular observation of stable levitation is possible, something that cannot be achieved using only

Figure 1. Schematic temperature dependence of the susceptibility of a diamagnet, paramagnet, ferromagnet, and antiferromagnet.

materials with $\chi > 0$ (as prove by Earnshaw's theorem). Note that stable levitation is possible even for bodies that are only weakly diamagnetic given a sufficiently large magnetic field gradient [5].

3.3. Paramagnetism

Paramagnets have a positive value for χ , that is, the induced moment is in the same direction as the applied field. Paramagnetism is due chiefly to the presence of unpaired electrons—either an overall odd number of electrons or an unfilled inner shell. Nuclei can also show paramagnetism, although typically of an extremely small magnitude. The electron gas of a metal is also usually slightly paramagnetic, though exchange coupling can sometimes lead to ordering (e.g., ferromagnetism). Independent unpaired electrons give each atom or molecule a small permanent dipole moment, which tends to be aligned by an external magnetic field. Langevin showed that thermal energy disrupts this alignment, leading to a susceptibility $\chi = Nm^2/3k_B T$, where N is the density of dipoles, m is the moment of each dipole, k_B is the Boltzmann constant, and T is the absolute temperature. Curie and Weiss found that the temperature in this formula should be replaced by $T \rightarrow (T - T_c)$ for materials with an ordering temperature T_c (the “Curie temperature”). The paramagnetic susceptibility of a material can give important insights into its chemistry and physics, but it is an effect of limited engineering significance at present.

3.4. Ferromagnetism

Ferromagnetism is the spontaneous magnetic ordering of the magnetic moments of a material in the absence of an applied magnetic field. Nearly all technologically important magnetic materials exhibit some form of ferromagnetism. In such materials, the magnetic moments of electrons couple together, so that they respond collectively. In this manner it is possible for all magnetic moments in an entire sample to point in the same direction, potentially giving a very strong effect. The details of how the

individual moments couple with each other can be understood in terms of quantum mechanics. There are three types of “exchange” interaction generally found:

- The first is direct exchange, in which an unpaired electron on one atom interacts with other unpaired electrons on atoms immediately adjacent via the Coulomb interaction. This is the strong mechanism that dominates in most metallic magnetic materials, such as Fe, Ni, Co, and their alloys. It results in a positive exchange energy, so the spins on adjacent atoms tend to align parallel.
- The second is indirect exchange, or superexchange, in which the moment of an unpaired electron on one atom polarizes the (paired) electron cloud of a second atom, which in turn interacts with the unpaired electron on a third atom. This is the mechanism that dominates in most oxide materials, such as ferrites. For example, in Fe_3O_4 the Fe ions (with unpaired electrons) interact through O ions (which have only paired electrons). Superexchange creates a negative exchange energy.
- Finally, there is the possibility of interaction between electrons that are not localized but can move freely as in a metal. This interaction, known as the RKKY interaction after its discoverers (Ruderman, Kittel, Kasuya, and Yoshida), is usually weaker than direct exchange. It plays an important role in the behavior known as “giant magnetoresistance” and can result in either a positive or negative exchange energy.

The main properties that characterize ferromagnetic materials are the Curie temperature T_c , the saturation magnetization M_s , the magnetic anisotropy energy K , and the coercive field H_c (see Fig. 2). The first two are intrinsic to a material. The third has both intrinsic and extrinsic factors. The last is extrinsic and depends on the form (microstructure, overall shape, etc.) of the material and will be discussed later.

- The exchange interaction that leads to ferromagnetism can be disrupted by thermal energy. At temperatures above T_c , the disruption is so great that the ferromagnetism ceases, and the material exhibits

Figure 2. Schematic temperature dependence of the saturation magnetization M_s for a ferromagnet.

only paramagnetism. Thus T_c measures the magnitude of the exchange coupling energy. For example, the T_c of Fe is 770°C while for Co, $T_c = 1115^\circ\text{C}$, and for Ni, $T_c = 354^\circ\text{C}$. The ferromagnetic transition is a second-order phase transition, which means that the order parameter (magnetization) increases continuously from zero as the temperature is lowered below T_c .

- The saturation magnetization is the macroscopic magnetic moment of all of the spins averaged over the volume of the sample. Thus, in a material with many unpaired electrons per atom, M_s will be large (e.g., Fe with $\mu_0 M_s = 2.16\text{ T}$ at room temperature). Conversely, M_s will be much smaller in materials that also contain nonmagnetic atoms or ions (e.g., Fe_3O_4 with $\mu_0 M_s = 0.60\text{ T}$ at room temperature).
- The electron spins couple weakly to their orbital motion in a process known as spin-orbit coupling, a relativistic effect. As a result, the energy of the system depends on the orientation of the spins (i.e., the magnetization) with respect to the orbitals of the atoms (i.e., the orientation of the sample). This results in an intrinsic coupling of the magnetization to the crystal lattice. It leads to magnetic anisotropy—that is, the energy of the system depends on the orientation of the magnetization with respect to the sample. The direction along which the magnetic moment tends to lie is known as the “easy axis.” The magnitude of the anisotropy may be large, as in SmCo_5 permanent magnets that strongly resist demagnetization with $K \sim 10^7\text{ J/m}^3$, or it may be quite small, as in the high-permeability materials $\text{Ni}_{0.8}\text{Fe}_{0.2}$ (Permalloy) or a $\text{Fe}_{0.80}\text{P}_{0.13}\text{C}_{0.07}$ (an amorphous alloy).
- Another source of anisotropy can arise from the shape of the specimen, or from the shape of individual grains within the specimen. This is a local magnetostatic effect, rather than an intrinsic effect, and is called *shape anisotropy* (see Fig. 3). It is an extremely

Figure 3. Shape anisotropy quantitatively describes the observation that needles and plates are most easily magnetized along a long dimension.

important factor in any real application. Two extremes are illustrative. A long thin needle (i.e., an acicular particle) can be readily magnetized along its long axis but will require a large field to force the magnetization to be across a short axis. The magnitude of field required is $H_a = M_s/2$ (i.e., $H_a = 8.5 \times 10^5$ A/m for the case of an Fe needle). A flat plate, on the other hand, will require twice that field, $H_a = M_s$, to magnetize it parallel to the normal.

- A third source of anisotropy is due to the magnetostriction of magnetic materials, coupled with stresses in the material. Magnetostriction is the change in dimensions of a sample when the magnetization is aligned along various crystallographic directions; it occurs as a response that minimizes the magneto-crystalline energy. Conversely, when a sample is strained along some crystallographic direction, this contributes to the magnetic anisotropy. This is called *stress anisotropy*. It can be an important effect in low-anisotropy materials that are highly strained, such as almost all thin films.
- The various magnetic anisotropies that may exist in a material all act simultaneously. The best way to analyze their cumulative effect is in terms of the anisotropy energy, which is the sum of all of the energies arising from individual anisotropies. The details of this analysis can be complex; see Bozorth or Brailsford, listed in the Further Reading list, for examples and guidance.

Useful magnetic materials almost inevitably consist mostly of Fe, Co, or Ni or a combination of these three elements, because these are the elements that are ferromagnetic at room temperature and above. A great variety of other elements may be added to form alloys or compounds with specific useful properties, but inevitably a large fraction of Fe, Co, or Ni will be present. When a nonmagnetic metal is alloyed with these elements, M_s and T_c generally decrease rapidly because of dilution. For example, Fig. 4a (Bozorth, pp. 308–309) shows the effect of alloying Ni with Cu (which together form a continuous solid solution), showing the monotonic decrease in M_s with increasing Cu content. Other effects may occur, such as bandstructure effects or the formation of compounds, which will alter the trends with alloying (e.g., formation of Fe_3Al , as shown schematically in Fig. 4b).

Alloying with rare-earth metals is often used in cases where a high intrinsic anisotropy is desired, such as in permanent magnets. The lanthanide rare-earth metals are all highly magnetic because of unpaired electrons in the 4f-shell (inner) orbitals. The T_c of these materials is below room temperature because the exchange interaction between inner orbitals of adjacent atoms is small, but the intrinsic anisotropy is generally large because the spin-orbit interaction is largest in atoms with high atomic number (and therefore highly relativistic orbitals). Adding a small amount of a rare earth can dramatically increase the magnetocrystalline anisotropy of an Fe-, Co-, or Ni-based compound, often with only a modest decrease in T_c and M_s . The modern “rare earth” permanent

Figure 4. (a) Saturation magnetization and T_c for Fe–Cu alloys, normalized to the values for pure Fe (the monotonic decrease is typical of systems that form a continuous solid solution); (b) saturation magnetization of Fe–Al compositions, normalized to the value for pure Fe. The anomalous behavior near the composition Fe_3Al (25% Al) is due to the formation of the Fe_3Al phase.

magnetic materials use this effect, as in SmCo_5 and $\text{Nd}_2\text{Fe}_{14}\text{B}$.

3.5. Domains and M–H Loops

While positive exchange coupling tends to align all of the spins in the same direction, real materials generally exhibit this uniformly oriented state only if they are very small (<100 nm). Larger samples “demagnetize” by breaking up into magnetic domains. In each domain the local magnetic moments are uniformly aligned, usually along an easy axis. The directions of magnetization of the various domains can balance such that the overall magnetization is zero and the magnetostatic energy is small. When an external field is applied along an easy axis, domains aligned with the field tend to grow, while those antialigned tend to shrink. At high enough field the sample will be forced into single-domain state, and the saturation magnetization will be observed. The formation of domains implies the presence of domain walls—boundaries between adjacent domains—that have increased exchange and anisotropy energies due to misalignment of neighboring spins. The density and orientation of domains in a sample is determined partly by energy balance between the domain wall and magnetostatic terms, but is also strongly affected by nonequilibrium considerations such as domain wall nucleation and pinning. In general, the growth and shrinking of domains (i.e., the motion of domain walls) dissipates energy, so the M – H curve is hysteretic, as shown schematically in Fig. 5.

Figure 5. Schematic M - H curve, showing saturation magnetization M_s , remanent magnetization M_r , coercive force H_c , and initial permeability $\mu(0)$ (defined for an initially demagnetized sample, i.e., with $H=0$ and $M=0$).

This hysteretic, sigmoidally shaped M - H curve is very typical of ferromagnetic materials. Four important parameters are immediately evident from examination of the M - H curve:

1. The limiting magnetization is just M_s , the single most important measure of a ferromagnetic material.
2. The slope of the M - H curve at $M=0$ is the small-signal permeability $\mu(0)$, which measures the responsiveness of the magnetic material to an external field when it is close to its demagnetized state. This parameter is particularly important for soft magnetic materials, which use the magnetic material to obtain a flux multiplication by the factor $\mu(0)$. This parameter is determined partly by the magnetic anisotropy that is characteristic of the material but is also affected by factors that impede domain-wall motion, such as physical grain structure, microscopic inclusions, dislocations, or magnitude of the magnetocrystalline anisotropy.
3. The magnetization observed at zero field (after the sample has been fully magnetized) is called the *remanence*, M_r . This is an important parameter for permanent magnets, as it measures the magnitude of M available when the material is isolated. Note that the “squareness ratio,” M_r/M_s , is dominated by extrinsic aspects of the material, such as grain structure and defect, along with underlying anisotropies including the shape of the specimen.
4. The field required to reduce the external magnetization to zero (again, defined only after the sample has first been fully magnetized) is called the “intrinsic coercivity” or coercive field H_c . At this field, the sample is in a multidomain state and the magnetizations from all of the various domains exactly cancel out. The coercive field is an important property for permanent magnets, as it measures the ability of a material to withstand the action of an external magnetic field, whether applied or self-generated. It

is also determined mainly by extrinsic aspects of the material such as grain structure.

The interpretation of M - H loops can often involve subtle aspects of the loop, including directional properties, the approach to saturation, possible nonsigmoidal curving, discrete jumps (known as “Barkhausen jumps”), and so on. These may reflect coherent rotation of spins in a domain when the external field is not aligned with an easy axis or may be due to subtleties of domain wall motion. Development of superior magnetic materials often involves intensive research into these issues, but usually the designers of devices need only focus on a few properties.

3.6. Negative Exchange Interaction

The exchange interaction, as mentioned previously, need not be positive, inducing alignment of adjacent spins. When it is negative, adjacent spins will tend to align antiparallel. This can lead to a variety of behaviors depending on the structure of the material.

3.7. Antiferromagnetism

The simplest configuration that can be obtained with a negative exchange energy is antiferromagnetism, in which the spins on adjacent sites in a unit cell cancel to give no net magnetic moment. A simple example is NiO, which forms in the rock salt (NaCl) structure (see Fig. 6). The ordering temperature for antiferromagnetic materials is called the “Néel temperature”, T_N , after the discoverer of antiferromagnetism, and is analogous to the Curie temperature of a ferromagnet. Above $T_N=250^\circ\text{C}$, NiO is of course, paramagnetic. In the antiferromagnetic state the susceptibility is not negative, as in the case of a diamagnet (which has no permanent dipoles) but is positive, small, and depends on the direction of the external field due to intrinsic magnetocrystalline anisotropy. The details of spin configurations and other properties of antiferromagnets

Figure 6. Antiferromagnetic structure of NiO, showing Ni atoms in the $(\bar{1}01)$ plane. The spins are aligned along $[11\bar{1}]$ directions as shown. The magnetic unit cell is twice the length of the crystallographic unit cell.

can be very complicated. Antiferromagnetism is difficult to detect by conventional magnetic measurements. Neutron scattering measurements are typically required to confirm the existence of antiferromagnetism.

Antiferromagnetic materials have been known and understood since the work of Néel beginning in 1932, but there are presently no important applications of bulk antiferromagnetic materials. Thin films ($\sim 1\text{--}100$ nm thick) of antiferromagnetic materials now play an important role in state-of-the-art magnetic recording, specifically in magnetoresistive read heads. The antiferromagnetic thin films are used to magnetically bias the magnetoresistive sensor using a phenomenon called exchange anisotropy: the surface interaction between a ferromagnetic and antiferromagnetic material in intimate contact (see Fig. 7.). Since this is an interfacial phenomenon, its magnitude is only significant when the surface/volume ratio is high, as in a very thin film.

3.8. Ferrimagnetism

In a compound with two magnetic sublattices and antiferromagnetic coupling, the magnetic moments of each sublattice will generally not cancel exactly. Then the material will exhibit an overall magnetization that in many regards will appear exactly like that of a ferromagnet, with a hysteretic $M\text{--}H$ loop, a coercivity, and a remanence. Such materials are called *ferrimagnets*, because the prototypical examples are ferrites. Some properties, such as the temperature dependence of the magnetization, can be radically different from those of ferromagnets. For example, the different temperature dependencies of the magnetization on two sublattices can sometimes lead to exact cancellation of the net magnetization at a particular temperature, called the *compensation temperature* T_{comp} (often denoted T_c , which leads to confusion with the Curie temperature). At that temperature the material behaves as if it were an antiferromagnet.

While ferrimagnets behave in many ways like ferromagnets, the highest saturation flux density in ferrimagnets is typically only about 0.6 T, and they cost significantly more than iron or silicon iron. Their crucial advantage is that they are usually good insulators and therefore are useful at high frequencies due to low eddy-current losses. Three classes of ferromagnetic materials are predominant in applications:

- Garnets have a generic formula of $R_3\text{Fe}_5\text{O}_{12}$, where R represents a lanthanoid (Sc, Y, or lanthanide rare earth). These compounds have a T_c around 275°C and a rather low saturation flux density at room temperature, $B_s = 0.18$ T. They have proven useful for bubble memories because high-quality single-crystal garnets can be prepared, and they continue to be used for UHF applications because they have particularly low losses in that frequency regime.
- Spinel ferrites are an especially large class of materials with a wide range of properties. The generic formula unit is AB_2O_4 , where A is a divalent ion and B is a trivalent ion, usually Fe^{3+} . Most of the useful spinel ferrites are magnetically soft (that is, they have a low anisotropy energy and a high permeability). The prototypical spinel ferrite is Fe_3O_4 , but Zn-substituted MnFe_2O_4 and NiFe_2O_4 are the soft ferrites used in most applications. Another extremely important ferrite is commonly used as a magnetic recording medium—namely, $\gamma\text{-Fe}_2\text{O}_3$, which is a modified spinel in which one in nine Fe sites is systematically vacant.
- Hexagonal ferrites are a much smaller class of materials, but this class includes the important ceramic permanent magnet materials. A typical formula unit for a hard hexagonal ferrite is $\text{BaFe}_9\text{O}_{12}$. These materials have a platelet-type growth habit with a very high uniaxial anisotropy and an easy axis normal to the platelet. This makes it difficult for the magnetization of a platelet to change, which accounts for the hard magnetic properties. The fact that these materials are insulating is often not an important issue since they are used to create a dc magnetic field.

When a magnetic dipole is aligned (e.g., by intrinsic anisotropy) along an axis and a radiofrequency (RF) field is applied perpendicular to that axis, the dipole does not respond simply by oscillating in the direction of the RF field, but it precesses around its axis in accordance with classical mechanics. The precession frequency is commonly expressed as $\omega = \gamma H_{\text{an}}$, where γ is the gyromagnetic constant [$\gamma = 35$ kHz/(A/m) for most materials] and H_{an} is the anisotropy field. If the RF field is at exactly this frequency, the dipole can readily absorb energy from the field (and convert it into heat via coupling to the lattice). This

Figure 7. Schematic illustration of exchange anisotropy arising from interface coupling between an antiferromagnetic and ferromagnetic material. The schematic $M\text{--}H$ loop indicates that the loop is offset in H and that with no external field there is only one stable state (namely, the saturated state). That is, at $H = 0$ there can be no domain structure.

phenomenon is known as *ferromagnetic resonance* (FMR), although it is most important in insulating ferrimagnets where eddy currents do not already dominate the losses. Above the FMR frequency the magnetic material has a nonmagnetic response.

At very high frequencies the response of ferrimagnets is not dominated by domain-wall motion, which is sluggish, but by coherent rotation of the spins in the sample. Then the permeability is given simply by $\mu_c = B_s/H_{an}$, so $\omega_{FMR} \mu_c = \gamma B_s$. This equation, known as “Snoek’s law,” says that for a given material, a higher FMR frequency can only be obtained at the cost of a correspondingly smaller permeability. It is a basic limitation to the use of ferromagnetic materials at frequencies above about 10 MHz. Other issues, such as domain-wall resonances, may reduce the maximum frequency even further.

3.9. Metamagnetism

If a large enough magnetic field is applied to an antiferromagnet along an easy axis, the spins that are anti-aligned with the field will suddenly flip their orientation to achieve a lower energy state; that is, for a sufficiently high magnetic field, \mathbf{H} , the magnetostatic energy $\mathbf{m} \cdot \mathbf{H}$ (where \mathbf{m} is the dipole moment of an individual atom) will inevitably outweigh the exchange energy. In some antiferromagnetic materials this flipping can be observed with achievable magnetic fields; it is then called metamagnetism. Note that in principle all antiferromagnets will exhibit this behavior at a high enough field—the distinction is only in whether the required field can be produced in the laboratory.

Antiferromagnets with a relatively low anisotropy energy can exhibit an intermediate state between the antiferromagnetic and metamagnetic states as the field is increased. In this case, application of the field along the easy axis will cause the spins to reorient perpendicular to the magnetic field, and still in an approximately antiferromagnetic configuration, as shown schematically in Fig. 8. This transition is called “spin flopping.”

Neither metamagnetism nor the spin-flop transition are of practical significance in bulk applications of magnetism. However, the metamagnetic transition is an

Figure 8. The spin-flop transition and metamagnetic transition in antiferromagnetic materials. The spin-flop transition occurs only in materials with relatively low magnetic anisotropy energy K , binding the spins to the easy axis (in the case, the horizontal axis).

essential feature of the phenomenon of giant magnetoresistance (GMR), which is observed in metallic thin-film ferromagnet/paramagnet multilayers (vide infra).

3.10. Spin Glass State

When a magnetic material has structural disorder, it is sometimes not possible for the exchange interaction among various neighbors to be satisfied, and no long-range orientational order (either ferromagnetic or antiferromagnetic) can be achieved. At low enough temperature such a “frustrated” material will achieve a quasiordered configuration in which the spins are static but aligned in random directions. This is the “spin glass” state. In a given sample, the magnetic properties are found to be history dependent: For example, the saturation magnetization depends on whether the sample was cooled in a magnetic field or in zero field. So-called spin glass materials should not be confused with the metallic glasses discussed later. The nature of the spin glass state has been a productive area of study for physicists for many years, but the phenomenon has no current engineering significance [6].

A related concept is that of “geometric frustration,” which occurs in materials that have triangular site coordination and that therefore are frustrated even in a perfectly ordered material. These materials are presently being explored intensively by physicists, but also have no current engineering significance [7].

3.11. Double-Exchange Materials

Along with the exchange mechanisms listed previously, there is a fourth mechanism, double exchange, that is relevant only to a small class of materials. The prototype material is $(\text{La,Ca})\text{MnO}_3$, a perovskite oxide, in which the Ca substituted for La acts as an electron donor. Electrons hopping from one Mn atom to another do not change their spin orientation during the hop, so the Mn atoms orient ferromagnetically. The most interesting property of these materials is observed in the paramagnetic state—in zero field the Mn spins are randomly oriented, inhabiting electron hopping and yielding a high resistivity. When the Mn spins are partially aligned by applying a large magnetic field, the hopping probability is enhanced, and the resistivity decreases dramatically. At an optimum temperature (near T_c), a resistivity decrease by a factor of 10^5 to 10^6 has been observed at a field of 4 MA/m, a result that has led the effect to be known as colossal magnetoresistance (CMR). The effect is colossal at low temperatures and for only a small temperature range, and it requires very large fields to be applied, so it has not proven useful for engineering applications at present.

3.12. Superparamagnetism

In small single-domain particles of ferromagnetic material, the magnetization tends to align along the easy axis, and the energy barrier required to move the magnetization is on the order of KV , where K is the anisotropy energy density and V is the volume of the particle. For the simple case of uniaxial anisotropy, $\Delta E = KV$. If the thermal energy $k_B T$ is greater than this energy, then fluctuations in the

orientation of the magnetization will lead to zero spontaneous magnetization and a response to an applied field that is analogous to the local moments of a normal paramagnetic material. The effect is seen, for example, in Co particles smaller than about 7.5 nm. The moment of a Co sphere of diameter 7.5 nm is roughly 20,000 times larger than the moment of single Co atom, so the effect is called *superparamagnetism*. While superparamagnetism is not technologically useful itself, it does represent an important limitation to the particle size of future magnetic recording media, and is therefore being intensively investigated.

3.13. Thin Films

Thin films of magnetic materials behave exactly like bulk magnetic materials in most respects, albeit in profoundly different regimes for some parameters. For example, thin films have a demagnetization factor normal to the film and essentially zero demagnetization factor in the plane of the film. Thus it is generally very hard to magnetize a thin film normal to the plane but fairly easy to move the magnetization in the plane. A simple consideration such as this can have wide-ranging implications, from an increased FMR frequency to gross effects on the structure of domain walls (i.e., the transition from conventional Bloch walls to Néel walls as the film thickness is decreased below about 100 nm). Thin films also tend to have stresses that are extremely high compared to stresses in bulk materials—500 MPa values are not uncommon. These stresses couple to the magnetostriction of the material to create a stress anisotropy that can strongly influence the magnetic behavior.

Thin films are used in a wide variety of applications, the most important of which are as media in hard disks and magneto-optic disks, miniature electromagnets in hard-disk write heads, and magnetoresistive sensors in hard-disk read heads.

Thin films inherently possess a unique direction, the growth direction. This is usually the normal, although it can be oblique if the incident atomic flux used to grow the film arrives from an oblique angle. For some materials the growth direction directly leads to a large intrinsic uniaxial anisotropy. For example, in amorphous Tb–Fe one might expect that there would be no anisotropy at all. Instead, films grown with the incident Tb and Fe atoms arriving essentially perpendicular to the substrate exhibit a large intrinsic uniaxial anisotropy oriented along the normal, and with a sense that leads to a perpendicular easy axis. The anisotropy is sufficient to overcome demagnetization, so domains form in which the magnetization is oriented perpendicular to the film. Such materials are used in magneto-optic recording (vide infra) [8].

Some behaviors seen in thin films are either absent or not commonly observed in bulk magnetic materials. An important example is the phenomenon of so-called giant magnetoresistance in thin-film multilayers. These multilayers are typically formed by sequentially depositing metallic ferromagnetic and paramagnetic layers, each ~1–3 nm thick, using sputtering or evaporation in a high-vacuum chamber. Between two and a hundred

layers might be built up in this way. The ferromagnetic layers couple with each other by the RKKY interaction through the paramagnetic metal, so, depending on the thickness of the paramagnetic layer, the interlayer coupling may be antiferromagnetic or ferromagnetic. For example, a film consisting of 100 repeats of 1.0-nm-thick Co adjacent to 0.6-nm-thick Cu exhibits an antiferromagnetic state at zero field; even though each Co layer is individually ferromagnetic, alternate layers have oppositely directed magnetizations. When a moderate field H is applied, the magnetizations of all of the layers align with the external field, producing a metamagnetic transition.

Baibich et al. [9] discovered the most interesting aspect of the metamagnetic transition in metallic multilayers: the effect it has on the resistivity of the sample. The aligned state has a greatly reduced resistivity compared to the antialigned state. The magnetoresistance ratio $[R(H=0) - R(H=H_s)]/R(H=H_s)$ can be as high as ~100% depending on the choice of materials. This is far greater than the highest normal magnetoresistance observed in any material at room temperature; hence the name giant magnetoresistance. It is attributed to spin-dependent scattering of electrons, which is enhanced when magnetizations of adjacent layers are antialigned. This effect is crucial for the highest-performance magnetic disk read heads being currently designed (vide infra) [10].

4. MAGNETIC MATERIALS USED IN APPLICATIONS

Useful magnetic materials are often divided into three categories:

- Soft magnets, in which the magnetization is readily changed with an external field, thereby providing a flux-multiplying effect
- Hard magnets (permanent magnets), which have high coercive fields and therefore resist demagnetization by stray fields including their own
- Magnet recording media, which combine aspects of softness and hardness

4.1. Soft Magnetic Materials

Soft magnetic materials are used in applications such as transformers and inductors. An obvious example would be the iron, known as “electrical steel,” used in transformers for inexpensive power supplies. At frequencies above about 10 kHz, eddy currents limit the use of metallic magnetic materials, so high-resistivity ferrites such as (Mn, Zn)Fe₂O₄ are used.

4.1.1. Permeability. An important property of soft magnetic materials is their relative permeability, nominally defined by $\mu_r = B/\mu_0 H$. Actually, since the $B(H)$ curve is neither linear nor single-valued, a large number of useful permeability parameters can be defined, such as the initial permeability, the maximum permeability, and the anhysteretic permeability. For simplicity, we will consider only the initial small-signal permeability, defined as $\mu(0) \equiv \partial B / \partial H|_{H=0}$. Values from $\mu(0) = 10$ (high-frequency

ferrites) to $\mu(0) = 10,000$ (low-frequency inductors) are typically encountered in applications.

4.1.2. Power Devices. Probably the main use of magnetic materials at present, on a weight basis, is in power transformers. These can range from huge transformers used in substations, to miniature transformers used to convert line voltage to a level suitable for small consumer devices, to small ferrite transformers used in switching power supplies.

Low-frequency power applications almost inevitably employ low Si percentage Fe–Si alloys known as “silicon iron” or “electrical steel.” This is because Fe is by far the cheapest magnetic material available. The coercive field of pure Fe is typically about 80 A/m. The addition of a small amount of Si to Fe lowers the anisotropy, resulting in lower losses and a coercive force of about 40 A/m. It also substantially increases the resistivity, which decreases eddy currents. Eddy currents in transformers are usually further reduced by lamination (i.e., using a stack of Fe–Si plates, each electrically insulated by a coating layer, rather than a single thick piece). The laminations are arranged so that eddy currents are interrupted by the presence of the insulator and forced to circulate only within each lamination (i.e., so that any AC magnetic flux is perpendicular to the normal). Properly designed, the thickness of each plate should be smaller than a skin depth δ , given by $\delta = (2\rho/\omega\mu)^{1/2}$, where ρ is resistivity, ω is the angular frequency of the AC magnetic field, and μ is the permeability. Note that the permeability can also be frequency-dependent.

Improved varieties of silicon iron are prepared using specific sequences of forging (rolling) and annealing to obtain a grain-oriented microstructure. In such materials the crystallographic orientation of individual grains is forced to be aligned over the entire piece. The advantage is that materials with lower losses are obtained, although the material is also somewhat more expensive. At present, most power transformers utilize grain-oriented silicon iron.

The highest-performance materials for low-frequency transformer applications are the metallic glasses, amorphous alloys of Fe and Co with one or more metalloid additions (usually B, C, Si, and P). These materials can have losses that are 10 times smaller than silicon iron and coercive fields below 0.5 A/m. But the saturation flux density is generally ~ 1.5 T, and the materials are substantially more expensive than silicon iron. These negative aspects of metallic glasses have precluded their widespread use.

Power supplies with low weight and volume are highly desirable for some electronic applications, and this can be achieved with the design called “switching” power supplies. An additional benefit is circuit versatility and flexibility, while the main tradeoffs are increased cost and design complexity. A switching power supply uses power electronics [typically metal oxide semiconductor field-effect transistors (MOSFETs)] to chop and rectify power at high frequency, a power transformer or inductor to change the voltage, and control electronics to synchronize and control the system. The frequencies used range from about 50 kHz to a present upper limit of 1 MHz.

At these frequencies, metallic ferromagnets cannot be used as the desirable lamination thickness would be prohibitively small. Fortunately at such high frequencies, the energy that must be stored in the transformer or inductor is correspondingly small for a given power capacity ($E \sim P/\omega$, where E is the maximum stored energy, P is the maximum power, and ω is the angular frequency). Therefore, the cost of the magnetic part need not dominate, especially considering the cost of the electronics involved, so the use of relatively expensive but very high resistivity ferrites is feasible. In most cases an (Mn,Zn)Fe₂O₄ spinel ferrite is chosen as a compromise between saturation flux density, losses, resistivity, and cost. At the highest frequencies, (Ni,Zn)Fe₂O₄ may prove useful, as it has a higher resistivity and therefore is less susceptible to eddy-current losses.

Motors and generators inevitably employ iron or silicon iron to act as a flux concentrator. The armature and stator are commonly constructed of grain-oriented silicon iron, although small motors often employ nonoriented silicon iron or metallic glass materials. As in transformers, the ferromagnetic parts must be laminated to reduce eddy-current losses.

4.1.3. Inductors. Small-signal transformers and inductors are used in a variety of circuit applications, as in impedance-matching and isolation transformers, antennas, and chokes. Signal-level devices do not have to carry substantial power, so they can be small and the cost of materials can easily be outweighed by performance considerations. Thus a wider variety of magnetic materials is used in these devices.

At audiofrequencies and below, transformers and inductors were once commonly used for signal applications. For example, long-distance analog telephone circuits were balanced by the periodic addition of loading coils—inductors designed to match the large distributed capacitance of phonelines. A common choice for the magnetic core in those coils was Permalloy (Ni₈₀Fe₂₀) or a related alloy, and the cores were formed by rolling a long tape into a toroidal core. However, in modern telecommunication systems the analog signals are quickly converted to digital signals at the central exchange and then transmitted by the fiberoptic, satellite, or microwave relay. The need for loading coils is minimal. Similarly, the function of audiofrequency impedance-matching transformers and other inductive electronic components has largely been displaced by more elaborate but much cheaper integrated circuit designs. Low-frequency magnetics are used in modem isolation transformers to provide DC electrical isolation with audio coupling; these are made with either laminated metallic or solid ferrite cores.

At RF frequencies (50 kHz–50 MHz) magnetic cores are widely used; for example, in antennas, RF transformers, chokes, and resonant circuits. The usual choices for magnetic cores are the spinels (Mn,Zn)Fe₂O₄ (up to about 1 MHz) and (Ni,Zn)Fe₂O₄ (up to about 10–50 MHz). The manganese zinc ferrites are cheaper but have a resistivity typically less than 1000 $\Omega \cdot \text{cm}$. Eddy current losses limit their usefulness at high frequencies. The initial permeability is roughly 1000–3000. Nickel zinc ferrites can have

resistivities as high as $10^5 \Omega \cdot \text{cm}$ and initial permeabilities on the order of 1000. Their upper frequency limit is dictated by the need to avoid FMR losses. Material designed for operation above about 10 MHz typically is prepared with moderate porosity to inhibit domain-wall motion and losses associated with domain-wall resonance. The permeability mechanism then is limited to that of coherent rotation of the spins, which implies a much smaller value ($\mu_c \sim M_s/H_k \sim 10\text{--}100$).

Above about 50 MHz, magnetic materials are not commonly used in transformers and inductors, as Snoek's law demands that the permeability be uselessly small in order for the FMR frequency to be sufficiently greater than the frequency of operation. Snoek's law can be circumvented by the use of materials with a large biaxial anisotropy (e.g., the hexagonal magnetoplumbite-type ferrites) or by using thin films with a high saturation magnetization. At present, however, those approaches are not commercially important.

4.1.4. Write Heads. An important application of soft magnetic materials is in the recording heads used in tape and disk systems. Write heads essentially consist of an electromagnet with a toroidal magnetic core and a very small airgap (~ 100 nm to 300 nm). The flux that extends from the airgap, called the "fringing field," is used to magnetize the magnetic medium passing nearby (see Fig. 9). In tape and floppy-disk systems the magnetic medium is in actual contact with the head, while in hard-disk systems the head flies aerodynamically over the spinning medium at a height of 25–75 nm. The maximum magnetic field available for magnetizing the medium is proportional to the saturation magnetization of the head material.

Originally the magnetic recording heads were made from laminated metal alloys, such as Permalloy or Sendust (an alloy of Fe, Si, and Al notable for being magnetically soft and physically very hard), but as recording

Figure 9. Schematic of a magnetic recording head. Recording is accomplished using the magnetic fringing field (i.e., the field that leaks from the gap).

densities and frequencies increased, an inevitable move was made to ferrite materials. Ferrite heads are made from cast pieces that are carefully polished to form a precise airgap and then are assembled with the driving coil. As recording densities have increased, media with higher coercivities are necessary, so head materials with high saturation magnetization are needed. Unfortunately this is where the ferrites are most deficient, with maximum $B_s \sim 0.6$ T. One approach to obtain improved performance is to add a thin film of relatively high B_s material (such as Permalloy, $B_s = 0.9\text{--}1.1$ T) on the inside edge of the gap of each piece. The thin film acts as a flux concentrator and increases the fringing field significantly. This approach is called the metal-in-gap (MIG) design.

The highest-performance recording heads are constructed using thin films and photolithography. They have the advantage of great precision in layout, leading to extremely narrow pole tips, precise gap widths, and precise placement of the driving coils. Permalloy and related alloys are most commonly used at present, but soft amorphous alloys such as $\text{Co}_{0.85}\text{Nb}_{0.08}\text{Zr}_{0.7}$ offer significant improvements with $B_s \sim 50\%$ greater than Permalloy. The resistivity of the amorphous alloys is in the range $\rho \sim 100 \mu\Omega \cdot \text{cm}$, about fivefold higher than Permalloy, which reduces eddy-current losses, allowing recording at higher frequencies. Further advantage can be obtained by using the recently developed nanocrystalline (grain size $\sim 1\text{--}5$ nm) alloys such as $\text{Fe}_{0.92}\text{Ta}_{0.05}\text{N}_{0.03}$, which have extremely high $B_s \sim 2.0$ T and also have resistivities in the range of $100\text{--}150 \mu\Omega \cdot \text{cm}$. These materials are being vigorously developed for future generations of high-performance recording, especially hard-disk drives.

4.1.5. Read Heads. The same magnetic structure that is used for magnetic recording can also be used for reading the recorded signal. The passage of recorded domains across the gap of the recording head will induce a small voltage on the driving coil, which is amplified and processed. Indeed, this inductive read head is the simplest and cheapest approach to magnetic recording. However, the signal level is very low and limits the performance of hard-disk drives. The present generation of hard disk drives uses a separate magnetic structure (incorporated in a single read/write head) for reading the recorded magnetic signal. The sensor in this device is a magnetoresistive thin film made of Permalloy and biased with a DC current. External flux from the recording medium couples to the Permalloy film, rotating the magnetization with respect to the fixed direction of the DC current. This changes the resistance of the Permalloy [the so-called conventional or anisotropic magnetoresistance effect (AMR)] and therefore the voltage developed across the device. The AMR effect is relatively small, about 5%, but is sufficient to deliver signal superior to that of an inductive head.

Superior performance can be obtained by incorporating materials that exhibit giant magnetoresistance. These can have responses that are about 10-fold higher than AMR materials. So-called spin valves employ the same physical principle as GMR (namely, spin-dependent scattering) in a more highly controlled and responsive magnetic structure. The higher signal output of spin valve read heads, in

conjunction with careful redesign of the entire magnetic recording system (including media, head structure, electronics, signal processing, etc.), can lead to substantial increase in recording density.

4.1.6. Shields. Soft magnetic materials are also used to make magnetic shields, typically used to protect electronic components from magnetic interference or to contain the external field around a component that generates magnetic flux. An example of the former are shields for cathode-ray tubes, such as computer monitors, while an example of the latter are shields for speakers, such as “multimedia” speakers intended for placement close to a (unshielded) monitor. These shields are usually formed from Permalloy and related alloys. Often “Mumetal” is specified for these applications—this originally designated a particular Fe–Ni–Cu alloy but it is now used generically to refer to many high-permeability alloys. Note that RF shields (unlike DC magnetic shields) rely on eddy current screening and use high-conductivity paramagnetic metals such as Cu.

A related application is the use of materials that absorb RF energy. These are typically lossy ferrites and are used in the form of beads threaded on wires, where it is desired to suppress high-frequency signals. Manganese–zinc ferrites are generally used for this purpose, although nickel–zinc is used to obtain the highest cutoff frequencies. Lossy ferrites can also be used as an antiradar coating on military aircraft.

4.2. Hard (Permanent) Magnets

Permanent magnets are used in a wide variety of applications where a static magnetic field is desired. The dominant uses are in speakers and DC motors and as holding magnets. The field available from a given permanent magnet depends on the physical configuration but is limited to B_s , the saturation flux density in the optimum case. Specifically, for a toroidal part with a small airgap (see Fig. 10), the flux density in the gap will be B_s . For Fe this is $B_s = 2.15$ T, while for $\text{Fe}_{0.6}\text{Co}_{0.4}$ it is $B_s = 2.43$ T [11, p. 190], the highest value for any known bulk material. In

Figure 10. Airgap in magnetic circuits. The gray regions represent permanent magnet material, with the direction of magnetization shown. The hatched region represents soft magnetic material, which is used to complete the magnetic circuit.

less optimum geometries, the available flux density can be greatly reduced, as determined by magnetostatics. For arbitrary-shaped parts, the usual approach is to employ finite-element numerical calculations to infer the flux distribution.

In general, where the design figure of merit is the flux available per unit volume of magnetic material, the corresponding figure of merit for the magnetic material is the energy product $(BH)_{\max}$ [i.e., the largest value measured at any point in the second quadrant (positive B , negative H) of the B – H curve]. This is only a crude way to evaluate the usefulness of a material; nevertheless it is indicative and is commonly quoted by permanent magnet manufacturers. Four main types of permanent magnet materials are commonly used:

- Alnico, a class of Fe–Al–Ni–Co–Cu alloys. The properties of this material are entirely dependent on complex metallurgical processing and microstructural control. Commonly used Alnico materials have $(BH)_{\max} = 50 \times 10^3 \text{ J/m}^3$.
- Barium ferrite, typically $\text{BaO} \cdot (\text{Fe}_2\text{O}_3)_6$, is the standard “ceramic” magnetic material. The typical value $(BH)_{\max} = 25 \times 10^3 \text{ J/m}^3$ is smaller than that of Alnico, but the material is both lower density and cheaper to produce than Alnico and has almost entirely replaced Alnico in highly cost-sensitive applications. The high value of $(BH)_{\max}$ in this and the following materials is due to the very high intrinsic anisotropy.
- Sm–Co is the standard high-performance “rare earth” permanent magnet, with $(BH)_{\max} = 160 \times 10^3 \text{ J/m}^3$. The major disadvantage of this material is its cost.
- Nd–Fe–B, a more recent material, has an even higher value for $(BH)_{\max} = 320 \times 10^3 \text{ J/m}^3$ than Sm–Co, and its value is less expensive. The major disadvantage of this material in some applications is that the T_c is somewhat low, $T_c \sim 150^\circ\text{C}$.

Loudspeakers have long been a dominant application for permanent magnetic materials. The permanent magnet is used to establish a magnetic field in an annular region in which the voice coil is mounted. When a current is driven through the voice coil, an axial force is produced, in accordance with the Lorentz relation, $\mathbf{F} = e\mathbf{v} \times \mathbf{B}$, where \mathbf{F} is the force on an electron, e is the charge on an electron, and \mathbf{v} is the velocity of the electron. Motion of the voice coil is coupled to a speaker cone to move the air efficiently and thereby produce sound waves.

The energy product of a magnetic material is a good figure of merit for speaker applications, since for a given design, a higher-energy product will result in a higher flux density in the annular gap. Most loudspeakers are low-priced components, so the cost of the magnetic material is the other key factor. For this reason, barium ferrite is the dominant material used. In some applications, such as high-performance earphones, the amount of magnetic material is small so materials cost is less critical. In the past, Sm–Co magnets have been used for these applications, though Nd–Fe–B magnets are now clearly the best overall choice.

The materials used for permanent magnets inevitably cost more than silicon iron, so large motors and generators always use soft magnetic materials wound with coils to create the required magnetic field. In small motors, the economics are dominated by the cost of fabrication; the small coils and fine tolerances needed for electromagnet motors outweigh the added cost of permanent magnetic materials. A vast number of small DC motors are produced for a very wide range of applications, from clock motors to the dozens of motors in modern automobiles used to drive windows, locks, seats, windshield wipers, and so on.

An economically important use of permanent magnets is in the low-tech application of holding magnets. These range from decorative magnets for holding notes to a refrigerator door to functional magnets for holding and sealing the refrigerator door shut to strong magnetic chucks for holding ferrous materials for machine-forming operations. In almost all cases cost is paramount, and barium ferrite is used. For some applications the ferrite powder is mixed with a polymer precursor, formed into a tape, and polymerized to form a flexible magnet, albeit with reduced net flux density and therefore reduced holding power.

4.3. Magnetic Recording Media—Intermediate between Soft and Hard

Magnetic recording is a huge business, dominated by the hard disks and floppy disks pervasive in personal computers and by tape recording—audio, video, instrumentation, digital data storage, and so on. The media used in recording are magnetic materials that must have a relatively high coercive force so that they do not spontaneously demagnetize and lose information. But the coercive force cannot be much greater than about 100 kA/m because the leakage flux from the recording head is limited and must nevertheless be sufficient to saturate the medium.

The standard material used in tape and floppy-disk media is gamma iron oxide, $\gamma\text{-Fe}_2\text{O}_3$. It is moderately expensive to prepare (compared to conventional ferrites) because extremely reproducible and controllable properties are required. Acicular (needle-shaped) particles ~ 50 nm in diameter are prepared in order to obtain good recording characteristics. The coercivity of most tapes is about 20–30 kA/m. More recent high-performance formulations use cobalt-modified $\gamma\text{-Fe}_2\text{O}_3$, which has a thin cobalt-rich region on the surface of the particles. This material has an increased coercivity of about 50 kA/m and is routinely used for videotape. In the past, CrO_2 was used as a high-performance medium because it has a higher M_s than $\gamma\text{-Fe}_2\text{O}_3$ and can be prepared with a coercivity as high as 80 kA/m. However, it has a low T_c (only 130°C) and is relatively expensive, so it has been displaced by cobalt-modified $\gamma\text{-Fe}_2\text{O}_3$.

Hard disks used in digital recording are aluminum platters coated with paramagnetic Ni-P or Cr and then a recording medium such as Co-Cr. An extremely thin layer of C is usually then deposited along with an even smaller amount of lubricating fluid, in order to avoid catastrophic head contact with the medium (“head crashes”). The coercivity of hard-disk media is in the range

60–100 kA/m, and the saturation magnetization is about 1000 kA/m.

For many years it was expected that magnetic bubble memory might find a role for data storage in computers. However, bubble memory is slow and expensive compared to hard disks and semiconductor random-access memory (RAM). Its only advantages are that it is mechanically more robust than a hard-disk system, and it is more radiation resistant than semiconductor RAM. Therefore, the only present use for bubble memory is in certain military applications.

Bubble memories store data in cylindrical domains, perpendicular to the surface, that are generated in liquid-phase epitaxy (LPE) grown garnet films. The films are designed to have a large uniaxial anisotropy perpendicular to the film plane and are chosen to meet a number of other criteria. The bubbles are moved around using a rotating external magnetic field created by a miniature electromagnet, and they are detected using a magnetoresistance bridge.

Finally, there is magneto-optic recording. In this scheme data are stored on a plastic disk coated with an amorphous metallic thin film such as $\text{Tb}_{0.2}\text{Fe}_{0.8}$ or similar compositions doped with Dy and Co. They have a large uniaxial anisotropy, with an easy axis perpendicular to the plane of the film, so as with the garnet films designed for magnetic bubble applications, cylindrical domains are stable. Data are written by focusing a laser on the desired spot, which heats the films above its T_c , $\sim 100\text{--}150^\circ\text{C}$. If the film is exposed to a moderate magnetic field while it cools, the heated region will magnetize in the direction of the applied field. Thus alternating regions of, say, north-up and south-up can be written. The data are read with the same laser at lower power to avoid heating, using a polarizer to detect Faraday rotation (i.e., rotation of the polarization of light when it interacts with a magnetic material). This effect is known as *Kerr rotation* when it occurs on reflection from a metallic magnetic surface. The Kerr rotation in a magnetic material is in the opposite sense for regions magnetized north-up versus south-up. The maximum Kerr rotation in Tb-Fe films is rather small, $\sim 0.2^\circ$, which gives a low signal/noise ratio and correspondingly low data rate.

The data density in magneto-optic recording is comparable to that of a conventional CD-ROM but has the great advantage of being endlessly rewriteable. Magneto-optic drives are slower for writing data and more expensive than conventional hard drives, but they confer the advantage of cheap removable media and good archiveability and have found a small but significant market niche.

4.4. Miscellaneous

Along with the three conventional classes of applications for magnetic materials, there are a wide variety of specialized applications, too numerous to list exhaustively.

4.4.1. Nonreciprocal Materials. Some of the most interesting magnetic devices are based on the nonreciprocal propagation of UHF signals in insulating magnetic

materials. The behavior is formally identical to the small optical Faraday rotation observed in some nonferromagnetic materials, but the effect in ferrites can be very large and is commonly used in microwave applications (e.g., in isolators and circulators).

The nonreciprocal phenomena are due to interaction of the incident radiation with the precessing electron spin (see Magnetic resonance). A particularly straightforward case arises when the incident microwaves are circularly polarized with a propagation vector parallel to the easy axis of the magnetic material and at a frequency equal to the natural precession frequency of the electron spins. Then, if the sense of the circular polarization is the same as that of the electron spin precession, energy is readily transferred to the spins and dissipated as loss. If the sense is opposite (corresponding to propagation in the opposite direction), then there is little interaction and the loss is minimized. It is easy to imagine an isolator based on the directionality of this phenomenon, although the practical design of this and other nonreciprocal microwave devices can be very complex. In general, a moderately large external biasing magnet is required to set the FMR frequency equal to the operating frequency (a larger field is required for a higher operating frequency).

Three classes of materials dominate the magnetic materials used for microwave applications—the figure of merit for microwave devices is usually proportional to $1/\Delta H$, where ΔH is the FMR linewidth:

1. The garnet structure ferrites exhibit the highest performance available because they have the lowest FMR linewidths. A typical value for polycrystalline ceramic yttrium iron garnet (YIG) is $\Delta H = 4000$ A/m. Single crystals with linewidths as low as 40 A/m have been reported. Single crystals are relatively expensive but are usually the best choice at low frequencies.
2. The spinel ferrites are useful in a number of cases. Nickel zinc ferrite is particularly useful at high powers because it has a higher T_c than garnets, and it is often used in the range above 10 GHz. Manganese-magnesium ferrites are used in the range of 5–10 GHz because their lower saturation magnetization allows biasing at lower field.
3. The Z-type hexagonal ferrites have a hard axis normal to the basal plane, so the need for external biasing is reduced. They require expensive processing to produce oriented, high-quality ceramics. They are most useful for mm-wave applications.

In general, the key issues in developing materials for microwave applications are related to processing and micro-structure control rather than exploring new compositions. Small grain size is important to minimize losses from domain-wall resonance, to maximize the resistivity, and to make stronger materials that resist the thermal stresses caused by high-power operation. Obtaining a high density is always important, but densification usually is accompanied by grain growth. The art of designing or

choosing a microwave magnetic material is in balancing these conflicting requirements.

4.4.2. Ferrofluids. Ferrofluids are liquid suspensions of magnetic particles coated to avoid agglomeration. Typically the liquid is a hydrocarbon or silicon, and the magnetic particles are ferrites, but a wide range of combinations is possible. The behavior of ferrofluids is unique and scientifically interesting, and ferrofluids are commercially used for such diverse applications as gas-tight seals for rotary shafts, heat transfer agents for loud-speaker voice coils, and damping systems.

MAGNETIC MICROWAVE DEVICES

HOTON HOW
Hotech, Inc.
Belmont, Massachusetts

In this article we discuss the following topics on magnetic microwave devices: ferrite junction devices, lumped-element circulators, nonreciprocal resonators, YIG film devices, MSW devices, magneto-optic devices, absorbing/antireflection layers, and nonlinear responses. The article is organized as follows: Section 1 presents a general theoretical background underlying the physics for the operation of ferrite components in microwave devices. Discussions include derivation of the Polder permeability tensor, the effective fields associated with electron spin motion, the general dispersion spectrum and plane-wave solutions for electromagnetic waves propagating in a bulk magnetic medium, magnetostatic waves (MSWs) admitted by the geometry of a yttrium iron garnet (YIG) film, and the nonlinear instabilities for spin waves occurring at high power, including their routes leading to chaos. Section 2 introduces ferrite junction devices, including circulators and isolators. Broadband operation, size reduction, power-handling issues, and other novel applications are discussed in this section. Section 3 delineates the operation of lumped-element circulators in which interport impedances are portrayed. Section 4 defines the effective field associated with a magnetic easy plane from an operation perspective. Section 5 gives an example that ferrite nonreciprocal resonator can be used as a phase shifter whose operation is independent of the derived phase shift angles. Section 6 describes YIG film devices incorporating magnetostatic waves (MSWs), including delay lines, filters, directional couplers, and resonators. Section 7 depicts nonlinear magnetic devices of frequency-selective power limiters, signal-to-noise enhancers, amplitude correctors, and ferrimagnetic echoing devices. Section 8 introduces magnetic solitons, including Bloch domain wall solitons and Microwave magnetic envelope solitons. Section 9 discusses magneto-optic Kerr and Faraday effects, and the operation of magneto-optic Bragg diffraction devices. Finally, design of microwave absorbing layers and antireflection layers is briefly mentioned in Section 10.

1. THEORETICAL BACKGROUND

This section provides a theoretical background underlying the physics that allows for the operation of a magnetic microwave device. A magnetic microwave device generally requires the use of an insulating magnetic ferrite material so that magnetization or spin motion is coupled to Maxwell equations without inducing much eddy-current loss at high frequencies. Also, in order to eliminate domain wall motion, single-domain operation is demanded at RF frequencies, and the ferrite material needs to be magnetized to saturation using an external DC magnetic field. Alternatively, effective fields arising from either the crystalline or shape anisotropy of the ferrite material may be used to fulfill the bias requirement of the magnetic device.

Thus, under small-signal approximations the electromagnetic property of the ferrite is described by a tensor permeability whose nonzero off-diagonal elements permit noble applications of nonreciprocal devices, for example. Most importantly, the permeability tensor can be varied by adjusting the bias field strength, resulting in tunability of the microwave device over frequencies.

A magnetic microwave device is normally operational in the frequency range from 0.1 to 40 GHz or higher, and its performance can be interpreted in terms of the spin/magnetization motion of the ferrite material where coupling to optical/photon modes, elastic/phonon modes, or exchange/magnon modes may be utilized. Depending on the regime of applications, a microwave magnetic device may be distinguished either as a retarded-wave device or a magnetostatic-wave device. The first class of devices includes circulators, isolators, filters, phase shifters, patch antennas, and so on, whose operation requires the magnetization vector to be coupled with the full set of Maxwell equations. The second class consists of mainly high-quality single-crystal YIG film devices where the propagation of magnetization waves involves a wavelength comparable to the film thickness. As such, the displacement currents can be omitted in Maxwell equations. This renders the so-called magnetostatic approximation, which implies that the resultant RF magnetic field can be derived from a scalar potential. Important magnetostatic devices include delay lines, filters, resonators, echo lines, and other nonlinear devices, whose operation complements their low-frequency counterparts below 2 GHz involving surface acoustic wave (SAW) devices.

In the following subsections we first derive the coupling between the magnetization field and the other electromagnetic fields, giving rise to a Polder permeability tensor for the ferrite material under small-signal approximations. Effective fields are then introduced in the equation of motion allowing for coupling of the magnetization field with the other physical fields required for transducer applications. On the basis of the frequency-wavenumber dispersion diagram, the propagation of magnetization waves can be divided into three zones into which magnetic microwave devices are conventionally defined at several regimes. Plane-wave solutions are given describing the propagation of electromagnetic waves in ferrites in the retarded zone. Magnetostatic waves are then discussed, whose dispersion diagrams are described in terms of the bias field configuration relative to the YIG film device geometry. Finally, spin-wave instability is briefly mentioned, delineating the high power threshold that a ferrite device can operate before a cascading energy transfer occurs between the input RF power and the parametric excitation of spin waves.

1.1. Polder Permeability Tensor

In a source-free medium Maxwell equations take the form

$$\begin{aligned}\nabla \times \mathbf{h} &= j\omega\epsilon\mathbf{e}, & \nabla \times \mathbf{e} &= -j\omega\mathbf{b} \\ \nabla \cdot \mathbf{b} &= 0, & \nabla \cdot \mathbf{e} &= 0\end{aligned}\quad (1)$$

where \mathbf{e} and \mathbf{h} are the RF electric and magnetic fields and \mathbf{b} is the RF magnetic induction field. In Eq. (1) ε denotes the permittivity and the time dependence of the RF quantities is assumed to be $\exp(j\omega t)$. For a linear isotropic medium, one may define a constant μ , the permeability, so that \mathbf{b} and \mathbf{h} are linearly proportional to each other:

$$\mathbf{b} = \mu \mathbf{h} \quad (2)$$

This equation holds true if the medium is diamagnetic ($\mu < \mu_0$) or paramagnetic ($\mu > \mu_0$). Here μ_0 denotes the permeability of vacuum. For a ferromagnetic or a ferrimagnetic medium the relationship between \mathbf{b} and \mathbf{h} is neither linear nor isotropic. However, under small-signal approximations the linear relationship between \mathbf{b} and \mathbf{h} may be assumed, provided the scalar permeability needs to be replaced by a tensor. Thus, Eq. (2) becomes

$$\mathbf{b} = \underline{\underline{\mu}} \mathbf{h} = \mathbf{m} + \mathbf{h} \quad (3)$$

where \mathbf{m} denotes the RF magnetization field and $\underline{\underline{\mu}}$ is called the *Polder permeability tensor* [1].

In a magnetic substance the net magnetic dipole moment per volume, or the magnetization vector, denoted as \mathbf{M} , is nonzero as a result of spontaneous magnetization of the material. Denote the angular momentum per volume of the medium to be \mathbf{J} . The time rate change of angular momentum can be equated with the applied torque, and this implies

$$\frac{\partial \mathbf{J}}{\partial t} = \mu_0 \mathbf{M} \times \mathbf{H} \quad (4)$$

where \mathbf{H} denotes the internal magnetic field within the volume. From both classical mechanics and quantum mechanics, the relationship between \mathbf{J} and \mathbf{M} is linear, which can be expressed as

$$\mathbf{M} = \gamma \mathbf{J} \quad (5)$$

where γ is the gyromagnetic ratio, which can be written as

$$\gamma = -\frac{g|e|}{2m_e} \quad (6)$$

where g is the Lande g factor and e and m_e are charge and mass of an electron, respectively. Classically, $g = 1$ for orbital angular momentum, and $g = 2$ for spin angular momentum. Quantum-mechanically, g can take a noninteger value between 1 and 2 due to the interaction between the spin and the orbital motion of the electron [2]. However, for magnetic transition metal ions, Fe, Co, and Ni, the orbital motion of $3d$ electrons is normally quenched and hence $g \approx 2$. This implies $\gamma = -1.76 \times 10^7 \text{ rad (s} \cdot \text{Oe)}^{-1}$ (reciprocal seconds-oersteds). Combining Eqs. (4) and (5), we derive, therefore, the following constitution equation for a magnetic medium:

$$\frac{\partial \mathbf{M}}{\partial t} = \gamma \mu_0 \mathbf{M} \times \mathbf{H} \quad (7)$$

We now assume that the magnetic medium is magnetized to saturation either by an externally applied magnetic field, an internal anisotropy field, or both. Let the saturation magnetization be denoted as M_S . We separate the DC and the RF components of \mathbf{M} and \mathbf{H} as follows:

$$\mathbf{M} = \mathbf{M}_0 + \mathbf{m}, \quad \mathbf{H} = \mathbf{H}_0 + \mathbf{h} \quad (8)$$

Here, capital letters denote DC quantities, and small letters denote RF quantities. Under small-signal assumptions, $|\mathbf{m}| \ll |\mathbf{M}_0| \approx M_S$, $|\mathbf{h}| \ll |\mathbf{H}_0|$, Eq. (7) can be linearized to yield

$$\frac{\partial \mathbf{m}}{\partial t} = \gamma \mu_0 M_S \mathbf{e}_z \times \left(\mathbf{h} - \frac{H_0}{M_S} \mathbf{m} \right) \quad (9)$$

where we have assumed \mathbf{H}_0 , and hence \mathbf{M}_0 , to be along the z axis whose unit vector is denoted as \mathbf{e}_z . From Eqs. (3) and (9), we derive, assuming again the $\exp(j\omega t)$ time dependence

$$\underline{\underline{\mu}} = \mu_0 \begin{pmatrix} \mu & -j\kappa & 0 \\ j\kappa & \mu & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (10)$$

The Polder tensor elements μ and κ are given as

$$\mu = 1 + \frac{\omega_z \omega_m}{\omega_z^2 - \omega^2} \quad (11)$$

$$\kappa = \frac{\omega \omega_m}{\omega_z^2 - \omega^2} \quad (12)$$

and ω_z and ω_m are defined as

$$\omega_z = |\gamma| H_0 \quad (13)$$

$$\omega_m = |\gamma| \mu_0 M_S \quad (14)$$

Equations (1), (3), and (10) sufficiently describe the general behavior of a linear magnetic microwave device.

1.2. Effective Fields

In Eq. (7) the magnetic field \mathbf{H} is the internal field effectively experienced by electron spins in the magnetic medium. In other words, an effective field is defined if there exist a coupling between the magnetization motion of the medium and the other physical field quantities. The coupling energy density is denoted as $w(\mathbf{M}, \partial \mathbf{M} / \partial x_i)$, which may show dependence on the magnetization \mathbf{M} , the magnetic strains $\partial \mathbf{M} / \partial x_j$, or both. For example, the externally applied magnetic field \mathbf{H}_a can be associated with the Zeeman energy density $w = -\mathbf{H}_a \cdot \mathbf{M}$. For other couplings the resultant effective fields can be derived from the following Lagrangian equations [3,4]:

$$(\mathbf{H}_{\text{eff}})_i = -\frac{\partial w}{\partial M_i} + \sum_{j=1}^3 \frac{\partial}{\partial x_j} \frac{\partial w}{\partial (\partial M_i / \partial x_j)}, \quad i = 1, 2, 3 \quad (15)$$

The associated energy flux is

$$s_i = \sum_{j=1}^3 \frac{-\partial w}{\partial(\partial M_j / \partial x_i)} \frac{\partial M_j}{\partial t}, \quad i = 1, 2, 3 \quad (16)$$

so that

$$\frac{\partial \mathbf{w}}{\partial t} + \nabla \cdot \mathbf{s} = 0 \quad (17)$$

In general, \mathbf{H} in Eq. (7) consists of the following components

$$\mathbf{H} = \mathbf{H}_a + \mathbf{H}_D + \mathbf{H}_A + \mathbf{H}_E + \mathbf{H}_S + \mathbf{h}_{RF} + \mathbf{h}_d + \mathbf{h}_G \quad (18)$$

where

- \mathbf{H}_a = externally applied magnetic field (parallel to the z -axis)
- \mathbf{H}_D = DC demagnetizing field
- $\mathbf{H}_A = (2K/M_S) \mathbf{e}_z$ = uniaxial anisotropy field (along the z -axis)
- $\mathbf{H}_E = (2A/M_S^2) \nabla^2 \mathbf{M}$ = magnetic exchange field
- \mathbf{H}_S = magnetoelastic field
- \mathbf{h}_{rf} = externally applied RF driving field
- \mathbf{h}_d = RF dipolar field
- $\mathbf{h}_G = (-\lambda/\gamma M_S) \partial \mathbf{M} / \partial t$ = Gilbert damping field

where K , A , and λ are, respectively, (uniaxial) anisotropy constant, exchange stiffness, and Gilbert damping constant. We note that although \mathbf{H}_A , \mathbf{H}_E , and \mathbf{H}_S are written in capital letters, they may contain both DC and RF components. In this article we have used \mathbf{H}_0 as \mathbf{H}_a interchangeably in the following discussions. However, it is understood \mathbf{H}_0 can be the externally applied bias magnetic field, or the internal DC magnetic field experienced by electron spins, whichever is applicable.

The DC demagnetizing field \mathbf{H}_D , which results from the shape anisotropy, can be solved analytically only for an ellipsoidally shaped body. In this case a demagnetizing factor tensor $\underline{\underline{N}}_D$ can be calculated so that [1]

$$\mathbf{H}_D = -\underline{\underline{N}}_D \mathbf{M}_0 \quad (19)$$

where \mathbf{M}_0 denotes the DC component of the magnetization vector expressed in Eq. (8). For the limiting case of a thin flat ferrite slab lying on the x - y plane, Eq. (19) becomes

$$\mathbf{H}_D = -\mathbf{M} \cdot \mathbf{e}_z \mathbf{e}_z \quad (20)$$

The definition for \mathbf{H}_A in the list immediately following Eq. (18) denotes the effective field associated with a uniaxial anisotropy. For other anisotropy fields \mathbf{H}_A can be derived from Eq. (15) using the appropriate energy density of the anisotropy. For example, the corresponding energy density for a cubic anisotropy is

$$w_A = K_1(\alpha_1^2 \alpha_2^2 + \alpha_2^2 \alpha_3^2 + \alpha_3^2 \alpha_1^2) + K_2 \alpha_1^2 \alpha_1^2 \alpha_1^2 + \dots \quad (21)$$

where α_i , $i = 1, 2, 3$, is the directional cosine of the magnetization vector \mathbf{M} with respect to the i th cubic axis and K_1 and K_2 are the associated anisotropy constants [5].

Using Eq. (15), the magnetoelastic field can be derived from the following magnetoelastic energy density

$$w_S = b_1(\alpha_1^2 \epsilon_{11} + \alpha_2^2 \epsilon_{22} + \alpha_3^2 \epsilon_{33}) + 2b_2(\alpha_1 \alpha_2 \epsilon_{12} + \alpha_2 \alpha_3 \epsilon_{23} + \alpha_3 \alpha_1 \epsilon_{31}) \quad (22)$$

where the α_i terms, $i = 1, 2, 3$, are the directional cosines of the magnetization vector \mathbf{M} ; the ϵ_{ij} terms, $i, j = 1, 2, 3$, are the strain fields; and b_1 and b_2 are the magnetoelastic coupling constants [3]. The magnetoelastic coupling measures the response with which a strain signal or an acoustic signal interacts with a magnetic signal in a magnetoelastic transducer device, or vice versa.

The dipolar field \mathbf{h}_d denotes the RF field associated with the RF magnetization field \mathbf{m} in Eq. (8), which needs to be solved from Maxwell equations [Eq. (1)] and \mathbf{h}_d relates to \mathbf{m} as follows

$$\mathbf{h}_d = \frac{1}{\gamma} \left(\frac{\underline{\underline{I}}}{\underline{\underline{\mu}}/\underline{\underline{\mu}}_0 - \underline{\underline{I}}} \right) \mathbf{m} \quad (23)$$

where $\underline{\underline{\mu}}$ is the Polder tensor derived in Eq. (10) and earlier in this section and $\underline{\underline{I}}$ denotes the identity tensor. Under magnetostatic approximation, \mathbf{h}_d satisfies the following magnetostatic equations

$$\nabla \cdot \mathbf{h}_d = -\nabla \cdot \mathbf{m} \quad (24)$$

$$\nabla \times \mathbf{h}_d = 0 \quad (25)$$

subject to suitable boundary conditions. Thus, \mathbf{h}_d is solved from \mathbf{m} in almost the same way that the DC demagnetizing field \mathbf{H}_D is solved from \mathbf{M}_0 . In the literature \mathbf{h}_d is sometimes called the RF *demagnetizing field*.

The Gilbert damping field can be effectively accounted for if one replaces H_0 in Eq. (8) by $H_0 + (j\lambda/\gamma\mu_0)\omega$, or, equivalently [1]

$$H_0 \rightarrow H_0 + \frac{j\Delta H}{2} \quad (26)$$

where ΔH denotes the ferromagnetic resonance (FMR) linewidth. The Gilbert damping term is identical to the Landau-Lifshitz form in first order, and is introduced into the equation of motion, Eq. (7), phenomenologically to account for the damping torque experienced by electron spins undergoing precessional motion. Equation (26) describes very well the measured magnetic loss of a magnetic microwave device, provided that the applied RF frequency is not too far away from the frequency at which ΔH was measured. However, the physical meaning of the Gilbert damping, as related to the relaxation processes in the medium, is lacking, as in contrast to the other damping forms, such as the Bloch-Bloembergen damping [1].

Finally, we have to specify the boundary conditions on \mathbf{m} in the presence of an exchange field of \mathbf{H}_E appearing in

Eq. (18). The (direct) exchange coupling is associated with the overlapping integral that relates the spin–spin interaction for two electron spins at neighboring atomic sites. The exchange constant A is larger than 0 for ferromagnetic coupling, and A is smaller than 0 for ferrimagnetic and for antiferromagnetic couplings. The spatial boundary conditions on \mathbf{m} can be derived from the equation of motion, Eq. (7), which requires that the quantity

$$\mu_0 \mathbf{A} \mathbf{M} \times \frac{\partial \mathbf{M}}{\partial \mathbf{n}} \quad (27)$$

needs to be continuous across the ferrite boundaries. Here \mathbf{n} denotes the outward direction normal to the surface of the boundary. The time boundary condition is derived from the energy conservation law. Thus, from Eq. (16) we require the outward energy flux

$$-\mu_0 A \frac{\partial \mathbf{M}}{\partial \mathbf{n}} \cdot \frac{\partial \mathbf{M}}{\partial \mathbf{t}} \quad (28)$$

to be continuous across the material boundaries. However, instead of Eq. (28), it is popular in the literature to use the following spin-pinning condition at the material boundaries:

$$\frac{\partial \mathbf{M}}{\partial \mathbf{t}} = 0 \quad (29)$$

Since A is a microscopic quantity and at the boundary layers the environment there is quite different from that of the bulk, the spin-pinning condition, Eq. (29), might be more realistic than the one representing the macroscopic average, Eq. (28).

1.3. Dispersion Curves for Bulk Modes

Equations (1), (3), and (10) can now be solved for a bulk ferrite medium for plane-wave solutions. The resultant dispersion relation, ω versus k ($= 2\pi/\lambda$), is shown in Fig. 1. Here, k is the wavenumber and λ is the wavelength. In Fig. 1 the k space is conventionally divided into three zones. For the small- k region, $k < k_1$ ($\approx 0.1 \text{ cm}^{-1}$), electron spin motion is strongly coupled with the RF electromagnetic fields so that the full set of Maxwell equations is required to solve the dispersion relations. This region is called the “retarded zone,” and most magnetic microwave devices other than single-crystal YIG films making use of bulk ferrite materials are operational in this region, for example, circulators, isolators, phase shifters, and resonators. The next region consists of intermediate k values, k_1 ($\approx 0.1 \text{ cm}^{-1}$) $< k < k_2$ ($\approx 10^6 \text{ cm}^{-1}$), known as the *magnetostatic-wave zone*. In this region $\omega \ll k(\epsilon\mu_0)^{-1/2}$ and hence the displacement current, $\omega\epsilon\mathbf{e}$, can be ignored in Maxwell equations:

$$\nabla \times \mathbf{h} \approx 0 \quad (30)$$

This equation is called the *magnetostatic approximation*. A magnetostatic wave device usually require the use of a high-quality single-crystal magnetic film such as YIG

Figure 1. Dispersion curves of the coupled photon–magnon modes. The k space has been divided in three zones for retarded, magnetostatic, and spin-wave modes. Phonon dispersion curves are also shown in the figure.

whose thickness determines the spectrum of the resultant magnetostatic waves prevailing in the device structure. The last region is for $k > k_2$ ($\approx 10^6 \text{ cm}^{-1}$), which is called the *spin-wave zone*. In this region the dispersion curves grow proportional to k^2 , as dictated by the effective exchange field, \mathbf{H}_E , defined following Eq. (18). Although not many practical microwave devices are designed in this region, the spectrum of spin waves is important in the sense that the normal spin precessional motion will break up into spin waves at the onset of instability when a magnetic microwave device is driven beyond a high power threshold. The quadratic dependence of the spin-wave dispersion gives rise to an effective mass for magnons, $m^* = \hbar \delta(2A\omega_m)^{-1}$, where \hbar denotes Planck’s constant.

For a given wave propagation direction \mathbf{k} , Eqs. (1), (3), and (10) imply two plane-wave solutions. Similar to the plane-wave solutions in an isotropic medium, the three vectors, \mathbf{e} , \mathbf{b} , and \mathbf{k} for each mode in an anisotropic magnetic medium, are still mutually perpendicular to each other. However, unlike the isotropic case, the two modes in the magnetic medium are nondegenerate, possessing different effective permeabilities and polarizations. Because of the wrong sense in polarization, one mode is weakly coupled to the photon waves, and hence its dispersion curve represents little departure from that of the (uncoupled) photon modes. This dispersion curve is shown in Fig. 1 as a straight (short) dashed line in the retarded zone. The other mode couples strongly to the photon waves, giving rise to distortion of the dispersion curves in the retarded zone.

For the strongly coupled mode two branches show up, depending on whether the bias magnetic field is applied

above or below FMR. These two branches are shown in Fig. 1 as bottom and top curves, respectively (bias *above* FMR is referred to in the literature as the condition that the bias field is larger than that required by FMR; bias *below* FMR means the reverse. According to this convention, in Fig. 1 the bias-below FMR condition corresponds to the top curve, curve 3, and the bias-above FMR condition corresponds to the bottom curves, curves 1 and 2). The top branch, curve 3 in Fig. 1, lies entirely in the retarded zone and shows very little variation with respect to the wave propagation directions; that is, the propagation of strongly coupled electromagnetic waves biased below FMR is nearly isotropic in the magnetic medium. However, the bottom branch, curves 1 and 2, depends strongly on the wave propagation directions. When \mathbf{k} is parallel to the z axis, the dispersion curve is shown as curve 1 in Fig. 1, and when \mathbf{k} is perpendicular to the z axis, the dispersion curve is shown as curve 2. For other propagation directions, the dispersion curves are distributed between these two curves, and for this reason, the region bounded by curves 1 and 2 in Fig. 1 is usually referred to as the *spin-wave manifold*. In the literature curve 1 is known as the *Kittel mode* and curve 2, the *Voigt mode*. A Kittel mode possess a right-hand circular polarization, whereas a Voigt mode is associated with an elliptic polarization. In Fig. 1 θ_k denotes the angle between \mathbf{k} and the z axis, which is designated as the applied field direction, and ω_1 , ω_2 , and ω_3 are given as

$$\omega_1 = \omega_z \quad (31)$$

$$\omega_2 = [\omega_z(\omega_z + \omega_m)]^{1/2} \quad (32)$$

$$\omega_3 = \omega_z + \omega_m \quad (33)$$

and ω_1 and ω_2 are the limiting values of the magnetostatic modes in the retarded zone (see Fig. 2).

The elastic modes are also shown in Fig. 1 as straight (long) dashed lines. There are two kinds of phonon modes: longitudinal phonons and transverse phonons [6]. In the presence of magnetoelastic coupling, b_1 and b_2 are nonzero in Eq. (22), and the phonon, or acoustic, modes will couple to the spin-wave, or magnon, modes. For the coupled case the dispersion curves of the phonons and the magnons will avoid running across each other in the same fashion that the photon modes and the magnon modes detour each other in the retarded-zone region as shown in Fig. 1 [7]. (If one views the uncoupled dispersion lines of two modes as two intersecting straight lines, the coupled dispersion lines resemble the two branches of a hyperbola using the two intersecting lines as asymptotes.) In Fig. 1 the (uncoupled) magnon modes in the retarded zone are shown as dotted lines, extending curves 1 and 2 smoothly from the magnetostatic-wave zone, intersecting the photon line, and ending at ω_1 and ω_2 of the ω axis (see Fig. 2).

1.4. Plane-Wave Solutions

Plane-wave solutions are needed when performing numerical spectral-domain calculations where a stratified

Figure 2. Dispersion curves of magnetostatic waves in a magnetic layer. The MSFVW is shown as a heavy dotted line, rising from ω_1 to ω_2 as k increases from 0 to ∞ . The MSBVW and MSSW are shown hatched depending on the propagation direction of the magnetostatic waves. θ_k denotes the angle between the wave propagation direction and the applied field direction.

structure is considered consisting of dielectric/magnetic layers supporting electromagnetic wave propagation in the retarded zone [8]. We give in this subsection the plane-wave solutions following Maxwell equations, Eq. (1), assuming a Polder permeability tensor, Eqs. (3) and (10)–(14). We consider a bulk ferrite of infinite content (so as not to be bothered by the boundary conditions at infinity) that is biased by an external magnetic field H_0 along an arbitrary direction. Without loss of generality we assume that H_0 is along the z axis [see definition for H_a immediately below Eq. (18)]. Other effective fields can be readily added to H_0 according to Eq. (18). For a given direction of wave propagation, which is specified by a directional cosine vector $(\alpha_1, \alpha_2, \alpha_3)^T$, we have the following dispersion relationship

$$k^2 = \varepsilon_f \mu_0 \mu_{\text{eff}} \omega^2 \quad (34)$$

where ε_f is the permittivity of the ferrite bulk, and the effective (scalar) permeability μ_{eff} can be calculated from

$$\mu_{\text{eff}} =$$

$$1 + \frac{2\alpha_3^2 \omega_m}{(1 + \alpha_3^2)\omega_z + (1 - \alpha_3^2)\omega_m \mp [(1 - \alpha_3^2)^2(\omega_z + \omega_m)^2 + 4\alpha_3^2 \omega^2]^{1/2}} \quad (35)$$

where ω_z and ω_m are as given by Eqs. (13) and (14), respectively. The corresponding RF magnetic field is, within

a multiplication constant

$$h_x = \frac{1}{\gamma} \left[\alpha_1 \alpha_2 \mu_{\text{eff}} \omega j + (1 - \alpha_1^2 \mu_{\text{eff}}^2) \omega_z + \left(1 + \frac{\alpha_3^2 \mu_{\text{eff}}}{1 - \mu_{\text{eff}}} \right) \omega_m \right] \quad (36a)$$

$$h_y = \frac{1}{\gamma} [-(1 - \alpha_2^2 \mu_{\text{eff}}^2) \omega j - \alpha_1 \alpha_2 \mu_{\text{eff}} \omega_z] \quad (36b)$$

$$h_z = \frac{\alpha_3 \mu_{\text{eff}}}{\gamma} \left[\alpha_2 \omega j - \alpha_1 \left(\omega_z + \frac{\omega_m}{1 - \mu_{\text{eff}}} \right) \right] \quad (36c)$$

the RF electric field is

$$e_x = \frac{-\zeta \alpha_3}{\gamma} \left(\omega j - \frac{\alpha_1 \alpha_2 \omega_m \mu_{\text{eff}}}{1 - \mu_{\text{eff}}} \right) \quad (37a)$$

$$e_y = \frac{-\zeta \alpha_3}{\gamma} \left(\omega_z + \frac{(1 - \alpha_2^2 \mu_{\text{eff}}^2) \omega_m}{1 - \mu_{\text{eff}}} \right) \quad (37b)$$

$$e_z = \frac{\zeta}{\gamma} \left[\alpha_2 \omega_z + \alpha_1 \omega j + \alpha_2 \omega_m \left(1 + \frac{\alpha_3^2 \mu_{\text{eff}}}{1 - \mu_{\text{eff}}} \right) \right] \quad (37c)$$

the RF magnetization field is

$$m_x = \frac{\mu_0}{\gamma} [-(1 - \mu_{\text{eff}}) \omega_z - (1 - \alpha_2^2 \mu_{\text{eff}}^2) \omega_m] \quad (38a)$$

$$m_y = \frac{\mu_0}{\gamma} [(1 - \mu_{\text{eff}}) \omega j - \alpha_1 \alpha_2 \mu_{\text{eff}} \omega_m] \quad (38b)$$

$$m_z = 0 \quad (38c)$$

and the RF magnetic induction field is

$$b_x = \frac{\mu_0 \mu_{\text{eff}}}{\gamma} \left[\alpha_1 \alpha_2 \omega j + (1 - \alpha_1^2) \omega_z + \left(\frac{\alpha_3^2}{1 - \mu_{\text{eff}}} + \alpha_2^2 \right) \omega_m \right] \quad (39a)$$

$$b_y = \frac{-\mu_0 \mu_{\text{eff}}}{\gamma} [(1 - \alpha_2^2) \omega j + \alpha_1 \alpha_2 (\omega_z + \omega_m)] \quad (39b)$$

$$b_z = \mu_0 h_z \quad (39c)$$

where

$$\zeta = \left(\frac{\mu_0}{\epsilon_f} \right)^{1/2} \quad (40)$$

Thus, wave propagation in a magnetized ferrite is nondegenerate, assuming different effective permeability values for different modes, resulting in different propagation speeds and polarizations. Similar to the isotropic case, the directions of electric field \mathbf{e} , magnetic induction \mathbf{b} , and wave propagation \mathbf{k} for each mode are mutually perpendicular to each other, as dictated by Maxwell equations; magnetic field \mathbf{h} is no longer aligned with magnetic induction \mathbf{b} , although \mathbf{h} is still required to be perpendicular to the direction of electric field \mathbf{e} . These properties can be readily checked by the above field expressions, Eqs. (36)–(39).

1.5. Magnetostatic Waves in a Magnetic Layer

Wave propagation and dispersion in a magnetic layer can be derived in a manner similar to that shown in Fig. 1 except that boundary conditions need to be explicitly

considered at the layer–air interfaces. For MSW device applications the excited waves have wavelengths in an order comparable to that for the layer thickness. As such, the magnetostatic approximation, Eq. (30), applies, which implies that the RF magnetic field can be derived from a scalar potential, and hence the dispersion calculations are largely simplified. Figure 2 shows such a dispersion diagram. When compared with Fig. 1, we see that in Fig. 2 the retarded zone has been pushed away into the $k=0$ region and the exchange coupling showing k^2 dependence in the large- k region has been neglected. However, the magnetostatic dispersion does not imply horizontal lines, as depicted in the magnetostatic-wave zone of Fig. 1. The finite curvatures of the dispersion curves shown in Fig. 2 are due to the finite thickness of the magnetic layer d , which are restricted roughly to the region bounded by two vertical lines $k=0$ and $k=2\pi/d$ (the vertical line $k=2\pi/d$ is not shown in Fig. 2, although it is understood from the k -axis label).

Magnetostatic waves can be volume waves and surface waves. For a volume wave the RF magnetization varies sinusoidally along the thickness direction, whereas for a surface wave it varies exponentially in this direction. Thus, a volume wave penetrates the whole thickness of the magnetic layer, whereas a surface wave is concentrated near the surface and the film–substrate interface. For a forward wave the dispersion increases monotonically with k so that the group velocity $d\omega/dk$ is positive. This is in contrast with a backward wave where $d\omega/dk$ is negative. Thus, for a forward wave the transmitted power is along the same direction as wave propagation, whereas the power transmitted by a backward wave is opposite to the wave propagation direction.

When the external field is applied normal to the layer plane, magnetostatic waves are generated isotropically with respect to the wave propagation directions lying on the layer plane. This branch of waves is called *magnetostatic forward volume waves* (MSFVWs), whose dispersion is shown in Fig. 2 as a heavy dotted line. The MSFVW mode undergoes uniform precessional motion at the Kittel frequency ω_1 for $k=0$, and the frequency increases thereafter, approaching the bulk limit of the Voigt frequency ω_2 as k goes to infinity. Dispersion of this kind can be readily understood by determining the spin motion occurring in the layer.

However, when the external bias field is applied in the layer, plane anisotropy results in general except at $k=0$, where the uniform precessional motion occurs at the Voigt frequency ω_2 . When k increases further, two kinds of modes are possible: magnetostatic backward volume waves (MSBVWs) and magnetostatic surface waves (MSSWs). Depending on the propagation angle θ_k , MSBVW dispersion will decrease as k increases, approaching the respective bulk-mode limit as k goes to infinity. Therefore, unlike MSFVW, MSBVW occupies a finite area in the dispersion diagram, which is shown hatched between ω_1 and ω_2 in Fig. 2. For device applications, MSBVW is usually launched at $\theta_k=0$; that is, the excited MSBVW is collinear with the applied field direction, since it provides the widest frequency bandwidth among all the MSBVW propagation directions.

For MSSW the dispersion falls within the forbidden area of the bulk modes extending from ω_2 to ω_3 (see Figs. 1 and 2). MSSW dispersions increase as k increases, reaching limiting values at large k . The propagation of MSSW is anisotropic, and the largest dispersion occurs at $\theta_k = \pi/2$, which gives rise to a limiting frequency $\omega_s = \omega_z + 0.5 \omega_m$, known as the *Damon–Eshbach frequency*. The most popularly used MSSW is for $\theta_k = \pi/2$, which requires the MSSW to propagate transverse to the applied field direction and results in the widest frequency band for MSSW device applications.

In Fig. 2 MSFVW and MSBVW are shown only for the lowest-order volume modes. Higher-order volume waves are also possible. A high-order volume wave, which assumes additional nodal points along the thickness of the magnetic layer, will converge to the same frequency as the lower-order waves at large k , except that the curvature of the dispersion curve is reduced. In general magnetostatic waves are generated in single-crystal YIG films epitaxially grown on gadolinium gallium garnet (GGG) substrates. Very often, a dielectric superstrate, for example, alumina, is covered on top of the YIG film to facilitate the excitation of magnetostatic waves. For these situations the dispersion diagram of Fig. 2 remains unchanged. However, when a metal ground plane is placed on top of the superstrate shown in Fig. 3, the dispersion of MSSW, but not MSFVW and MSBVW, will change. The influence of a metal plane is that the MSSW dispersion curve will grow in a convex manner, increasing initially from ω_2 at $k=0$ to a maximum value less than ω_3 followed by decreasing to ω_s as k goes to infinity. When a second metal ground plane is added to the bottom side of the GGG substrate shown in Fig. 3, the propagation of MSSW becomes even nonreciprocal; that is, the dispersion curve is different depending on whether the wave propagation is along the $+k$ or the $-k$ direction. In Fig. 3 magnetostatic waves may be excited by using a microstrip line, consisting of only the top ground plane; or a stripline, consisting of both the top and the bottom ground planes. For a multilayered system containing alternating magnetic and dielectric layers, the bulk and the surface modes form a band structure in almost the same way that atomic energy levels crowded into energy

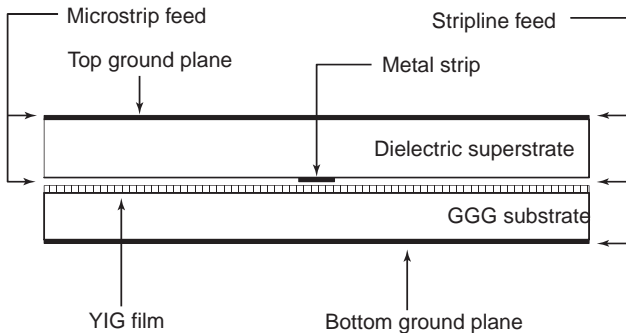

Figure 3. Magnetostatic wave excitation configuration. The YIG film is deposited on top of the GGG substrate. A superstrate can be used to provide microstrip excitation configuration. A bottom ground plane can also be deposited on the GGG substrate to provide stripline excitation configuration.

bands when atoms are brought together to form a periodic lattice [9,10].

Finally, let us discuss the propagation loss of a delay line. When an observer is traveling with the wave down the delay line for a delay time $t = \tau_d$, the electric field is

$$\mathbf{e} = \mathbf{e}_0 \exp[2\pi j(f + j\Delta f)\tau_d] \quad (41)$$

where \mathbf{e}_0 denotes the initial amplitude at $t=0$. This implies that the propagation loss in dB is

$$\alpha = 40\pi(\log_{10} e)\Delta f\tau_d \quad (42)$$

In Eq. (41) f and Δf respectively denote the real and the imaginary parts of frequency. Δf can be related to the linewidth measured with a resonator consisting of the delay line of a finite length but weakly coupled to by an external feeder line circuit. Thus, we have

$$\Delta f = \Delta f_m + \Delta f_d + \Delta f_c \quad (43)$$

where Δf_m , Δf_d , and Δf_c denote, respectively, contributions from magnetic loss, dielectric loss, and conductor loss. As discussed in deriving Eq. (26), Δf_m may be identified as half the FMR linewidth multiplied by a volume filling factor F_m denoting the volume ratio of the ferrite material relative to the total volume enclosing the resonating cavity:

$$\Delta f_m = \frac{F_m |\gamma| \mu_0 \Delta H}{2} \quad (44)$$

The other two linewidths (Δf_d and Δf_c) can be estimated in a similar manner dealing with a dielectric lossy cavity, for example, [11]. If we assume that magnetic loss dominates and approximate $F_m \approx 1$, Eqs. (42) and (44) imply

$$\alpha \approx 76.4\tau_d \Delta H \quad (45)$$

where τ_d is in microseconds and ΔH is in oersteds. Equation (45) was originally derived by Vittoria and Wilsey [12] for an MSW delay line. However, since delay time is measured as group delay, τ_d expressed in Eqs. (41), (42), and (45) will be multiplied by a factor v_g/v_k , where v_g denotes the group velocity ($=d\omega/dk$) and v_k denotes the phase velocity ($=\omega/k$) for wave propagation.

1.6. Spin-Wave Instabilities and Their Route to Chaos

In Fig. 1 the high- k regime where the wave dispersion curves show k^2 dependence is called the *spin-wave zone*. Although spin waves may not be directly exploited for device applications, they are important to influence device performances especially at high power, because they are intimately related to instabilities when a ferrite is excessively excited invoking nonlinearity. The quantized spin-wave particles are called *magnons*, which interact with the quantized electromagnetic-wave particles, or photons, through the nonlinear terms in the equation of motion [Eq. (7) or (61)]. Instabilities occur if energy transfer from the photon modes to the magnon modes, or among magnon modes themselves, becomes unstable [13], rendering

unpredictability resembling the turbulencelike behavior of chaos [14,15].

The concept of spin waves was first introduced by Bloch in 1930 to explain the thermodynamic properties of ferromagnets at low temperatures [16]. Suhl renewed the interest in spin waves and explained the saturation effects observed in ferromagnetic resonance (FMR) experiments [13]. As just stated, the spectrum of spin waves shown in Fig. 1 has proved to play a dominant role in the relaxation processes observed at high power. When an RF field is applied, it drives the spins into precessional motion, which in turn couples with spin-wave propagation, dumping energy into lattice vibration via spin-spin and spin-lattice relaxation processes. The coupling to spin waves must originate from the nonlinear terms in the equation of motion, Eq. (7). The quadratic interaction comes from $\mathbf{h} \times \mathbf{m}$ and the cubic interaction from either $\mathbf{h}\mathbf{m} \cdot \mathbf{m}$ or $\mathbf{m}\mathbf{m} \cdot \mathbf{m}$, inducing the so-called first-order and second-order spin-wave instabilities, respectively. For a spin wave component, \mathbf{m}_k , it induces two \mathbf{h} fields, denoted as \mathbf{h}_E , from the definition for \mathbf{H}_E following Eq. (18), and the dipolar field, \mathbf{h}_d , from Eq. (23). These two \mathbf{h} fields then feed back and couple nonlinearly with the original \mathbf{m}_k field to generate instability if a threshold power is reached. The $\mathbf{m} \cdot \mathbf{m}$ term arises from the constraint that the magnitude of \mathbf{M} needs to be a constant (equal to M_S); that is, in Eq. (8) the longitudinal component M_0 is replaced by

$$M_0 \approx \left(1 - \frac{\mathbf{m} \cdot \mathbf{m}}{2M_S^2}\right) M_S \quad (46)$$

As a consequence, the DC demagnetizing field, if not zero, will add cubic nonlinearity to the equation of motion, giving rise to adverse effects in influencing the spin-wave instability.

Under FMR measurements, the experiments showed a subsidiary absorption at high excitation power that occurs at a DC field less than that required by the resonance condition. Also, as the input power increases, the resonance absorption peak broadened accordingly rendering premature saturation of the main resonance. Suhl [13] showed that the subsidiary peak arises from a spontaneous transfer of energy from the uniform precessional motion of spins to spin waves of half the resonance frequency, $\omega_k = \omega/2$. This instability is caused by the first-order (quadratic) interaction between the dipolar field \mathbf{h}_d and the spin wave \mathbf{m}_k . The second instability responsible for the broadened and declined saturation of the main resonance peak comes from a catastrophic energy transfer from the uniform precessional motion of spins to spin waves of the same frequency $\omega_k = \omega$. This instability is brought about by the second-order (cubic) interaction between the exchange field \mathbf{h}_E and the spin waves, \mathbf{m}_k and \mathbf{m}_k . The resultant input field thresholds for these two instabilities are, respectively [17]

$$h_{SA}^{\text{th}} = \frac{2\Delta H_k}{\omega_m \sin 2\theta_k} \sqrt{(\omega - \omega_z)^2 + \omega_{\Delta H}^2} \quad (47)$$

$$h_{RS}^{\text{th}} = \Delta H \sqrt{\frac{2\Delta H_k}{M \cos 2\theta_k}} \quad (48)$$

where the subscripts SA and RS stand for subsidiary absorption (first-order instability) and resonance saturation (second-order instability), respectively. In Eqs. (47) and (48) ΔH is the FMR linewidth

$$\omega_{\Delta H} = |\gamma| \mu_0 \Delta H_k \quad (49)$$

and ΔH_k is the linewidth of the spin wave that is introduced phenomenologically to parametrize the energy transfer rate from the spin wave \mathbf{m}_k to lattice vibration. Thus, once excited, a spin wave will decay according to the following equation

$$\mathbf{m}_k(t) = \mathbf{m}_k(0) \exp(-\omega_{\Delta H} t) \quad (50)$$

assuming that it does not couple to other magnetic modes.

In addition to Suhl's instabilities, Morgenthaler [17] and Schloemann [18] found that spin waves could also be parametrically excited by an RF field applied parallel to the static field, known as *parallel pumping*, as in contrast to the transverse RF field configuration assumed by FMR measurements. Similar to Suhl's first-order instability, parallel pumping can impose an instability that occurs at a spin-wave frequency equal to half the frequency of the RF pumping signal $\omega_k = \omega/2$. The threshold for parallel pumping instability is

$$h_{PP}^{\text{th}} = \frac{2\Delta H_k \omega}{\omega_m \sin^2 \theta_k} \quad (51)$$

which compare closely in magnitude to h_{SA}^{th} , the threshold for Suhl's first-order instability shown in Eq. (47). In Eq. (51) the subscript PP denotes parallel pumping.

Parallel pumping excites spin waves via the cubic interaction term $\mathbf{h}\mathbf{m} \cdot \mathbf{m}$. However, in contrast to perpendicular pumping assumed by Suhl's instabilities, parallel pumping requires no involvement of the Kittel uniform mode and the pumped photon energy or electromagnetic energy is directly imparted to the creation of two spin-wave magnons of opposite wavevectors $\pm \mathbf{k}$, called *Cooper pair magnons*. For the case of perpendicular pumping, the pump signal is to first induce the Kittel uniform mode followed by conversion into either a single magnon at wavevector \mathbf{k} or Cooper pair magnons at $\pm \mathbf{k}$ for the first-order and the second-order processes, respectively. In Eqs. (47), (48), and (51), θ_k denotes the angle between the wavevector \mathbf{k} and the z axis \mathbf{e}_z . From these three equations, minimum threshold pump fields occur when θ_k equals 0, $\pi/4$, and $\pi/2$ for resonance saturation, subsidiary absorption, and parallel pumping instabilities, respectively. These energy transfer diagrams are shown schematically in Fig. 4, in which the spin-wave band is redrawn from Fig. 1 with the retarded zone omitted, but extended in both $\pm k$ directions. In Fig. 4 the Kittel uniform mode is also shown, whose frequency is

$$\omega_0 = \gamma \{ [H_a + H_A + 4\pi M_s \times (N_x - N_z)] [H_a + H_A + 4\pi M_s (N_y - N_z)]^{1/2} \} \quad (52)$$

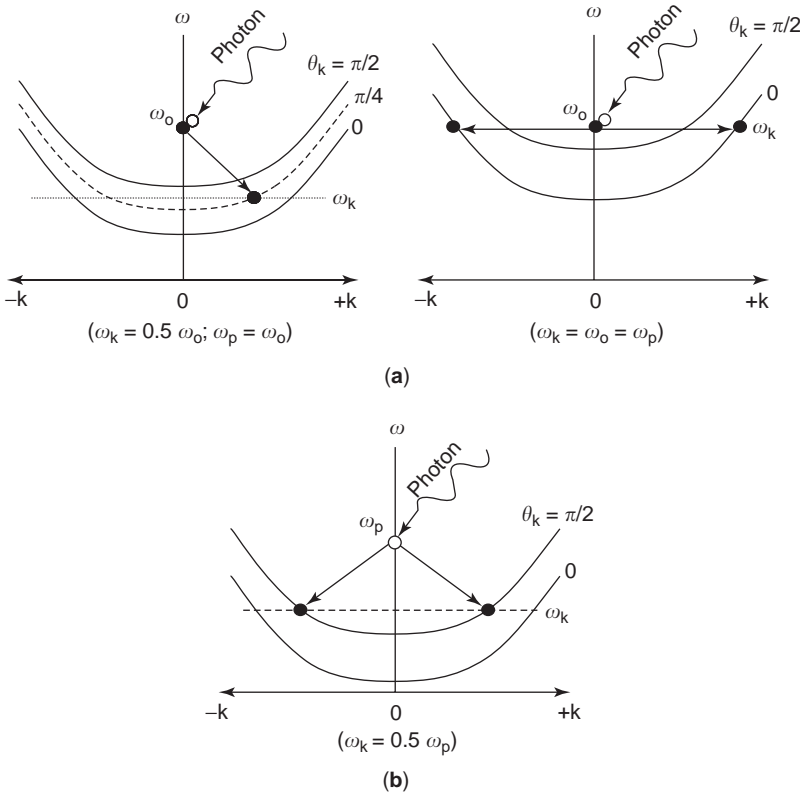

Figure 4. Photo-induced magnon transitions responsible for the observed instabilities for perpendicular pumping [first-order (left) and second order (right)] (a), and parallel pumping (second order) (b) of a nonlinear ferromagnetic spin system.

which can be derived by using the linearized equation Eq. (9) assuming the following dipole field for the uniform precessional mode

$$\mathbf{h}_d = -\underline{N}_D \mathbf{m} \quad (53)$$

see Eqs. (19) and (23). Note that in Fig. 4 Kittel uniform mode is not excited during parallel pumping, since the former requires transverse components of the RF magnetization field that are not able to be supplied by the latter. In Fig. 4 the wavy arrows indicate photon transitions, and solid arrows indicate magnon transitions; only the critical transitions are illustrated in Fig. 4, giving rise to minimum values in the pumping field responsible for the onset of instabilities.

The turbulencelike behavior of magnetic excitations after spin-wave instabilities have set in and their routes to chaos have been studied using the generic numerical analysis [14,15]. The responses of a nonlinear system, such as spins in a ferromagnet, can be totally unpredictable, due to amplification of errors made in the initial states. Such an error amplification mechanism, which is characterized by Lyapunov exponents for trajectories in state space during time evolution, renders randomness to the system's response leading to the violation of the causality principle; namely, the connection between the past and the future of the system is lost after a short transient period. However, in more recent decades, researches have found regularities in irregular systems and randomness appears to have a deterministic underpinning; even the random events

such as water dripping from a leaking faucet has been shown to show similarities with other irrelevant chaotic processes such as stretching and folding a plane (Héno attractor) or kneading a piece of dough (Lorentz attractor). Universal rules have thus been developed that govern the intrinsic structure of a chaotic system or a random process in a manner analogous to the scaling rules developed by using the renormalization group theory for phase transitions observed in condensed-matter physics.

Research in chaos has resulted in a common language suitable for the description of chaotic systems or random processes. This language applies to the universal structure of the limiting curves traced out by trajectories of a dynamic system or process embedded in state space. With dissipation these trajectories will, after a transient period, settle into limiting curves or cycles called *attractors*. If the system or the process is regular with its response predictable, state space trajectories will remain converged and confined all the time and the dimension of the resultant attractor will necessarily be an integer, for example, given by a circle, a torus, or another configuration. However, when chaos or turbulence launches, nearby trajectories in state space diverge and the attractor shows strange behavior, thereby called *strange attractors*. For a strange attractor, its dimension is not an integer and its appearance shows repeated resemblance after it has been continuously magnified, a scenario implied by a fractal. A similar fractal structure can be attributed to the strange basin boundaries separating the domains for different attractors settled in the state space of a chaotic system or process.

The usefulness of the language developed for describing chaos are twofold:

1. It allows a general erratic time-sequenced data or dynamically fluctuating picture to be categorized, according to the appearance of the associated attractors and/or basin boundaries in state space, analogous to the fact that phase transitions are classified according to their order in transformation. As such, routes to chaos can be visualized, and only a few routes have been found available for general random processes or phenomena to follow, including frequency-doubling bifurcation, intermittence, and crises. Similarly, thousands of kinds of phase transitions take place in the physical world, but only a few transformation orders are generally deduced for phase transitions. Universal scaling rules are concluded for both the chaotic/random systems and for the phase transition systems, which describes the rate at which instabilities or critical phenomena are approached by the change in system-pumping parameters or order parameters, respectively.
2. From the dimension or the size of the resultant attractors and/or the basin boundaries in state space, it is possible to determine the degree of randomness or agitation inherent in the chaotic system or process under study, enabling extraction of the maximum amount of information out of irregularity: the larger the entropy or the information content of the system or the process, the more complicated and involved structure will be implied by the strangeness of the attractors and/or the basin boundaries. When the nature of randomness is better known, which is clearly described in terms of the language of chaos, weather prediction and broadcast in the future, say, can then be much more reliable although still perhaps unable to yield 100% accuracy.

It has been shown that spin-wave instabilities resulting from parametric transverse and parallel pumping display chaotic dynamics characterized by the universal routes such as period-doubling bifurcation [14] and subharmonic generation [15]. In general, when the pumping field was increased beyond a threshold value [e.g., see Eq. (47), (48), or (51)], modulation in self-oscillation of the ferrite spin system set in at a low frequency; the amplitude of this low-frequency modulation oscillation grew steadily with pumping power until frequency doubling bifurcation occurred before leading to a full-scale chaotic state. For parallel pumping subharmonic generation routes were also observed from windows of the Feigenbaum scenario [15]. Strange attractors associated with computer-generated time sequences from the nonlinear coupled spin-wave modes, or the so-called two-mode model, showed fractal scenarios common to a generic chaotic system. A scaling parameter $\delta = 4.675$ was found for perpendicular pumping, which is close to the Feigenbaum universal value, indicating the success in adopting the chaotic language in describing the unstable dynamics of the nonlinear spin-wave system [14].

2. FERRITE JUNCTION CIRCULATORS

A *circulator* is defined as a device with ports arranged such that energy entering a port is coupled to that of an adjacent port but not to that of the remaining ports. A ferrite junction circulator has become a versatile microwave device because, in addition to its use as a circulator, it also can be used as an isolator or as a switch. Depending on the bias field direction onto the junction area, either upward or downward, the output ports operate in turn each time an input port is selected, either clockwise or counterclockwise, respectively, so that the junction is said to provide the circulation operation. The three-port version of the ferrite junction circulator, usually called the *Y-junction circulator*, is most commonly used. It can be realized by feeding the junction with three joining transmission lines, including waveguides, striplines, microstrips, CPWs (coplanar waveguides), and slotlines. The waveguide version is usually an *H*-plane junction, although an *E*-plane junction circulator can also be created. The stripline ferrite junction circulator is usually made with coaxial connectors facilitating its use as a discrete component at the UHF, microwave, and millimeter-wave frequencies.

Early experimenters found that waveguide T junctions having a transversely magnetized ferrite slab suitably placed in the junction could, with proper matching and adjustment of the magnetic field, be changed into circulators. The bandwidth of such devices was very narrow. Refinements producing better symmetry were found to broaden the bandwidth so that useful devices were obtained. The first commercial microwave circulator appeared in the early 1950s, while a full theoretical account of its operation was not published until 1962 by Bosma [19,20].

The stripline Y-junction ferrite circulator consists of two ferrite disks filling the space between a metallic center disk and two conducting ground planes. The static magnetic field is applied parallel to the axis of the ferrite disks. In Bosma's theory TEM Voigt modes were assumed propagating clockwise/counterclockwise in the region between the two conductor planes possessing no variation along the applied field direction [19,20]. Magnetic wall boundary conditions were assumed by Bosma at the ferrite disk periphery not adjacent to the circulator ports. Impedance boundary conditions were then imposed on the periphery areas defined by the circulator ports. Under these assumptions the RF magnetic field inside a 2D ferrite junction can be solved analytically, involving Bessel functions of the first kind to be cast in the series form. The circulation conditions were then postulated by Bosma, resulting in two real equations allowing for determination of two circulator design parameters. Bosma chose the radius of the junction R and the dielectric constant of the matching dielectric material surrounding the junction ϵ_d as the two independent parameters [19,20]. Therefore, at the circulation frequency the junction will yield 0 dB insertion loss and infinite isolation with all the input electromagnetic energy dumped into the output port without attenuation. Note that a circulation condition can be formulated only with respect to an ideal lossless junction with perfect impedance matching at all ports.

Fay and Comstock [21] presented a practical model for the operation of a Y-junction circulator. In their treatment the circulator circuit is approximated by a pair of slightly detuned RCL resonators connected in parallel to account for the two counterrotating dipole modes of the ferrite disks in the presence of a bias field. Participation from high orders has thus been ignored. At circulation the two dipole modes are nondegenerate, and the splitting between their (detuned) resonant frequencies Δf is proportional to the resultant gyrotropy $p = \kappa/\mu$ of the junction circuit. Here, κ and μ are the off-diagonal and diagonal elements of the Polder tensor of the ferrite material, respectively [Eqs. (11) and (12)]. Fay and Comstock have shown that it is imperative to incorporate moderate p of the ferrite material to obtain broadband operation of the circulator junction [21].

Fay and Comstock have also proposed RF field patterns responsible for the circulation operation of a ferrite junction [21]. This is shown in Fig. 5, where dipole-mode

excitations are shown as standing waves in an isotropic junction (Fig. 5a), and in a ferrite junction at circulation (Fig. 5b); the junction assumes a thin-disk geometry of a negligible aspect (thickness to diameter) ratio whose periphery is defined by the magnetic wall boundary conditions. In Fig. 5 solid curves with arrows depict RF magnetic field lines, and crosses and dots represent electric lines entering and exiting the junction area, respectively. For an isotropic junction the input field will excite a symmetric field pattern with respect to the output and the isolated ports attaining an equal intensity (Fig. 5a). Energy entering the input port, which has been shown with the most field intensity, will split in two equal halves reaching the output and isolated ports undergoing reciprocal operation. However, for a ferrite junction biased at circulation the dipole pattern of Fig. 5a is rotated 30° counterclockwise such that the input and the output ports are at an equal field intensity; the isolated port is averaged to zero, since an equal number of positive and negative electric field lines appears at the isolated port (Fig. 5b). Thus, electromagnetic energy entering the input port feeds the output port directly, leaving behind the isolated port essentially electronically insulated. The circulator operation is nonreciprocal in the sense that the circulation action takes place in a cyclic order among the three circulator ports, $1 \rightarrow 2$, $2 \rightarrow 3$, $3 \rightarrow 1$, and so forth.

The continuous “frequency tracking” conditions for the operation of a broadband junction circulator were first reported by Wu and Rosenbaum [22], whose design requires the junction to operate below FMR with the magnetization magnetized slightly above saturation. The other design parameters postulated by Wu and Rosenbaum are as follows:

$$\theta = 0.5 \text{ rad} \quad (54)$$

$$\epsilon_d = \epsilon_f \quad (55)$$

$$\omega R(\mu_0 \mu_{\text{eff}} \epsilon_f)^{-1/2} = 1.82 \quad (56)$$

where θ is half the port suspension angle, ϵ_f (ϵ_d) is the permittivity of the ferrite (dielectric matching) material, μ_{eff} ($= 0.556$) is the effective permeability of the ferrite junction, R is the junction radius, μ_0 is the permeability of air, and ω is the angular frequency (at the center of the transmission band). Equation (55) implies that the ferrite and the dielectric-matching material, also called the dielectric-matching “sleeve,” are characterized by the same dielectric constant. Thus, the junction and the sleeve can be conveniently fabricated using the same piece of ferrite, which needs to be magnetized slightly above saturation so as to avoid domain wall loss. As such, there is no need to separately fabricate a dielectric-matching sleeve surrounding the ferrite junction thereby reducing the fabrication costs. The thickness of the junction is not specified by the design, whose value is based on matching of the circulator port impedance:

$$Z_{\text{in}} = \left(\frac{\mu_{\text{eff}}}{\epsilon_f} \right)^{1/2} \quad (57)$$

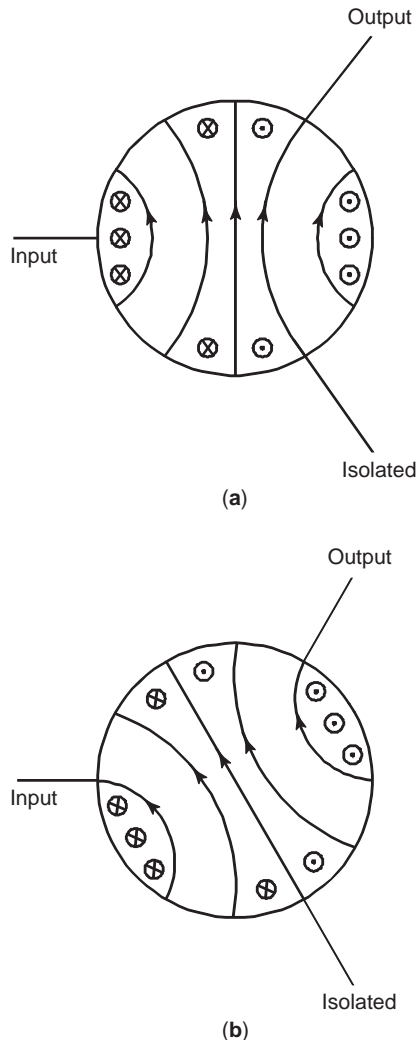

Figure 5. Field pattern for dipole excitations in an isotropic junction (a) and in a ferrite junction at circulation (b). Solid lines represent magnetic field lines; crosses/dots, electric lines entering and exiting the plane of the drawings.

The Wu–Rosenbaum circulator design provides an octave bandwidth extending from ω_m to $2\omega_m$ [22]. Here, $\omega_m = |\gamma| \mu_0 M_S$ and γ is the gyromagnetic ratio and M_S , the saturation magnetization [Eq. (14)].

Schloemann and Blight [23] have improved the Wu–Rosenbaum circulator performance [22] by extending the transmission band at a lower frequency limit. Schloemann and Blight were able to calculate the junction response in the FMR region where the effective permeability becomes a negative number [22]. To proceed, they employed the modified Bessel functions of the first kind to account for the evanescent modes excited during FMR. They also claimed that the measured bandwidth by Wu and Rotenbaum was narrower than that calculated, due to the nonuniform magnetic bias field accidentally introduced with the measurement. To prove their assertion, Schloemann and Blight [23] fabricated two semispherical domes using the same ferrite material as in the junction to cover the junction from above and below so as to ensure a uniform demagnetizing field within the junction area. By so doing, they successfully measured a 3:1 bandwidth for a crystal YIG (yttrium iron garnet) junction circulator (2.8–10.2 GHz) and for a crystal lithium ferrite junction circulator (5.8–18 GHz) [23].

All ferrite circulators are functional utilizing the non-reciprocal property for wave propagation in ferrites, providing low insertion loss and high isolation over a broad frequency band. The bandwidth is proportional to the inverse of the Q value of the cavity resonator formed by the circulator junction, namely, the region of the ferrite bound by metal boundaries at top and bottom and by a magnetic wall at periphery. Typically the bandwidth is about 5–15% of the center frequency, depending on the deployed suspension angle of the ports, unless the frequency-tracking conditions are enforced as postulated by Wu and Rosenbaum [22]. The circulator junction is a low- Q device, since the three coupling ports bestow the junction an open structure, allowing electromagnetic waves to leak from the junction area; the larger the port suspension angle, the broader the transmission bandwidth that will result. It is thus desirable to adopt the Wu–Rosenbaum parameters [Eqs. (54)–(56)] to achieve the broadest transmission band, unless the circulator operation is attempted at high power (or if one attempts to minimize the junction size as discussed later).

To design a circulator junction at high power we must consider the following issues: heat production, intermodulation, spin-wave generation, and thermal stability. There are two kinds of magnetic loss. The first kind is associated with magnetic domain wall motion, and the second kind relates to the intrinsic magnetic relaxation processes underlying the magnon–phonon interactions. To eliminate magnetic loss of the first kind, the ferrite junction needs to be magnetically biased well above saturation. This eliminates residual domains existent with a barely magnetized ferrite junction, thereby reducing heat. For this reason, a power circulator circuit should be biased well above FMR. The second kind of magnetic loss is characterized by a material parameter called *FMR linewidth* (ΔH) Eq. (26). To minimize magnetic loss of the second kind, one prefers to employ low-loss ferrites such as

crystal YIG and lithium ferrite, since these materials have shown the lowest ΔH values at the X-band and at the Ka -band frequencies, respectively.

The second issue relates to nonlinear coupling of electromagnetic signals at high power. This gives rise to intermodulation noise. In a ferrite junction intermodulation noise grows quickly with power, identified as clicking noises in a telephone line, which must be minimized, if not totally eliminated, to ensure quality communication. In the following we argue how intermodulation noise can be minimized in a semiquantitative manner. Let the power be applied to the input port of a circulator junction as

$$P = i^2 Z_{in} \quad (58a)$$

$$= h^2 w^2 Z_{in} \quad (58b)$$

$$= M_s^2 \left(\frac{h}{M_s} \right)^2 4R^2 \sin^2 \theta Z_{in} \quad (58c)$$

$$= M_s^2 |\mu_{eff} - 1|^{-2} \left| \frac{m}{M_s} \right|^2 4R^2 \sin^2 \theta Z_{in} \quad (58d)$$

$$= M_s^2 |\mu_{eff} - 1|^{-2} \delta_m^2 4R^2 \sin^2 \theta Z_{in} \quad (58e)$$

where i denotes the RF current flowing into the input port of impedance Z_{in} , h is the transverse RF magnetic field at the junction edge adjacent to the input port, w is the width of the input port, R is the radius of the junction, θ is half the port suspension angle, μ_{eff} is the effective permeability of the junction defined by

$$\mu_{eff} = 1 + \frac{m}{h} \quad (59)$$

and δ_m denotes the excursion angle of the magnetization vector away from the DC bias field direction, or the deviation or inclination angle of the precessional motion of electron spins in the ferrite junction around the DC bias field direction

$$\delta_m \approx \left| \frac{m}{M_s} \right| \quad (60)$$

where δ_m measures the extent that linear approximation of magnetic excitation remains valid inside the ferrite junction. In other words, if δ_m is large, linear approximation no longer holds true and nonlinear effects become noticeable. As a general rule, the onset of nonlinearity, or intermodulation coupling, is given by

$$\delta_m \leq 0.1 \text{ rad} \quad (61)$$

beyond which nonlinear effects set in, giving rise to appreciable amount of intermodulation noise. In Eq. (58e) δ_m denotes the excursion angle of the magnetization vector near the input port. However, the circulation mode assumes mostly the dipole mode, which implies the largest magnetic excitation near the input and the output ports (see Fig. 5). As such, the threshold condition of Eq. (61), which was derived at the input port, can be applied within

a multiplication constant (≈ 0.6) over the whole junction area, denoting the worst situation invoking the nonlinear interaction. Thus, we define the following parameter F denoting the figure of merit of a power circulator design characteristic of the amount of intermodulation noise as

$$F = 4\pi M_s R \sin \theta Z_{in}^{1/2} \tag{62}$$

by which Eq. (58a) becomes

$$P \propto F^2 \delta_m^2 \tag{63}$$

From Eq. (63) it is understood an effective power circulator design requires the value of F , the figure of merit, to be minimized, so as to yield minimum intermodulation manifested by δ_m under a given power excitation P .

Alternatively, the circulator junction problem at high power can be solved quantitatively, as proposed in [24]. By keeping high-order terms up to the third power of small-field quantities in Eq. (4), Eq. (9) becomes

$$\begin{aligned} \frac{-1}{\gamma} \frac{d\mathbf{m}}{dt} = & \mathbf{e}_z \times [H_{in} \mathbf{m} \\ & - M_s \mathbf{h} - (h_z + 4\pi N_z m_z) \mathbf{m} + m_z \mathbf{h}] \end{aligned} \tag{64}$$

where

$$m_z = M_s - M_z \approx \frac{\mathbf{m} \cdot \mathbf{m}}{2M_s} \tag{65}$$

denotes the z component of the RF magnetization vector that has been neglected in Eq. (9) under the first-order approximation [see Eq. (49)]. In Eq. (64) H_{in} is the internal DC field given by

$$H_{in} = H_0 - 4\pi N_z M_s \tag{66}$$

where H_0 is the applied DC field along the z axis and N_z is the axial demagnetizing factor [see Eq. (18)]. The schematic drawing at the bottom of Fig. 6 illustrates the relationship between intermodulation signals and the applied RF signals, where two RF signals are applied at two nearby carrier frequencies f_1 and f_2 , which are coupled via the (cubic) nonlinear terms in Eq. (64) so as to generate intermodulation signals at $2f_1 - f_2$ and $2f_2 - f_1$. At the top of Fig. 6 the ferrimagnetic amplifying echo signals are also shown; their significance will not be discussed until Section 7, where nonlinear magnetic microwave devices are introduced. Here we want to contrast both phenomena with the same physical origin with which intermodulation and ferrimagnetic echoing are driven by the same cubic nonlinear terms in the equation of motion [Eq. (64)] but with their respective responses expressed in the frequency domain and in the time-domain characteristic of different device applications.

It has been shown [24] that the nonlinear demagnetizing term in Eq. (64) plays a crucial role in bringing in intermodulation noise in a ferrite junction; the larger the demagnetizing field, the larger the intermodulation noise

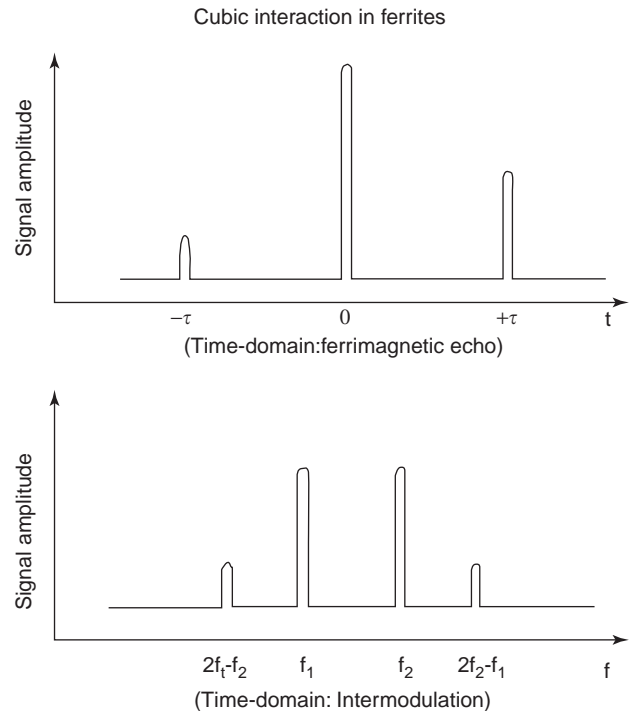

Figure 6. Nonlinear (cubic) coupling in an echo line and in a ferrite junction expressed in time domain and in frequency domain, giving rise to ferrimagnetic echo signals and intermodulation signals, respectively.

will be generated. This suggests the following bias configuration, which is thought to be effective in reducing intermodulation noise. As shown in Fig. 7, the two ferrite junctions implied by a stripline circulator are clamped

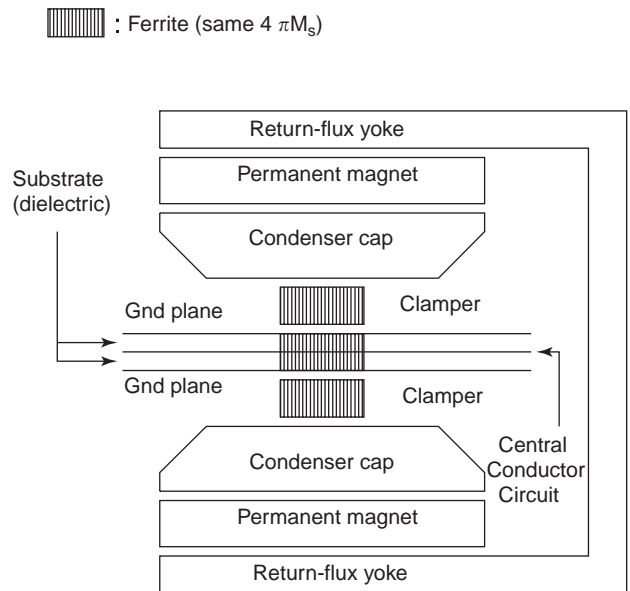

Figure 7. A ferrite junction is clamped between two ferrite cylinders having the same magnetization and cross-sectional area as the junction, and the clamped junction-cylinder assembly is biased by a permanent magnet pair included with flux condenser caps and return contour yoke.

between two cylindrical ferrite poles, which are placed outside the respective ground planes of the stripline circuit having the same saturation magnetization as the junction material and the same cross-sectional area as the junction geometry. While these two ferrite poles have no effect whatsoever in influencing the RF performance of the circulator junctions, they are effective in reducing the DC demagnetizing field within the junction areas so that $4\pi N_z$ in Eq. (64) becomes nearly zero, thereby minimizing intermodulation noise. Here we assume the thickness of the clamping ferrite poles to be much greater than the diameter of the junctions. In Fig. 7 a magnetic yoke (providing magnetic flux closure contour) and condensers (providing magnetic focusing) are used so as to facilitate the bias of the circulator junction circuit incorporating clamping ferrite poles.

We must point out here that the same ferrite clamping technique has been used by the ferrimagnetic echo experiments that reduced the demagnetizing field within an echo line such that an echo gain larger than unity can be realized [25,26]. More detail on ferrimagnetic echo amplification can be found in Section 7. The additional advantage associated with the magnetic bias configuration of Fig. 7 is that it is effective in inhibiting the onset of spin-wave instabilities occurring within the ferrite junction, thereby stabilizing its operation at high power. It is known that the demagnetizing field term in Eq. (64) can adversely affect the spin-wave instabilities at high power [13] and hence must be minimized; see discussion following Eq. (46). This constitutes the third issue, namely, that a ferrite junction to be applied at high power necessitates spin-wave stabilization. Furthermore, besides minimizing spin-waves, reducing the content of magnetostatic surface waves (MSSWs) is also necessary. We know that surface waves are inherent to a guiding structure possessing 2D discontinuities in magnetic or dielectric quantities [8]. In the microstrip geometry surface waves always exist whose modal spectrum depends on the thickness and the dielectric constant of the substrate material; the thicker the substrate and the larger the dielectric constant, the more surface modes will appear [8]. Analogously, one expects MSSWs to abound in a thick ferrite junction showing high saturation magnetization. This situation should be avoided if high power is attempted. Also, a thin ferrite junction facilitates heat removal via conduction so that it favors high-power applications.

The fourth issue on power circulator operation concerns thermal stability. Figure 8 shows four types of magnetization curves exhibited by magnetic materials with qualitatively different temperature dependence. The Q type represents the normal temperature dependence usually observed for metals and alloys. Almost all ferrites (e.g., Mn-Zn ferrite, Ni-Zn ferrite, Co ferrite) and garnets show the R-type temperature dependence. P-type and N-type temperature dependence were observed for some concentration ranges of Ni-Mn-Ti, Ni-Al, and Mn-Fe-Cr ferrites and for garnets in general [27]. In Fig. 8 Q and R types always show a negative slope for their magnetization curves. However, for P and N types the magnetization curves are possible to show a positive slope at certain temperature ranges. If positive slopes occur near room

Figure 8. Temperature-dependent magnetization curves: Q type is normally observed for magnetic metals and alloys, and R type for ferrites; both of them show normal temperature dependence. P type and N type occur for some ferrites that show positive slopes at certain temperature ranges near room temperatures; they are termed *temperature-compensated ferrites*.

temperature, the ferrite is then called a *temperature-compensated ferrite*, which provides advantages when the ferrite is used at high power.

When applied at high power, the axial component of the magnetization vector decreases, since the spin's precessional motion dictates the magnetization vector to deviate or incline farther away from the direction of the DC bias field: the more the power applies, the further the deviation or inclination will result [Eq. (60)] in addition to more heat generated in the junction area. This causes the temperature of the junction to rise. However, for a P- or a N- type ferrite, the temperature rise is accompanied by an increase in saturation magnetization, which compensates for the decrease in its axial component expressed in Eq. (46), ensuring that the circulation conditions do not drift away as a result of thermal heating, thereby stabilizing the circulator operation at high power. It is thus clear that temperature-compensated ferrites are preferred when a circulator junction is to be applied at high power.

The size of a ferrite junction can be considerably reduced if the junction is biased above FMR providing directly 50Ω impedance at the junction ports. The advantage of using the bias-below FMR configuration is that it is then possible to realize the frequency-tracking conditions so as to enable the broadband operation of a ferrite junction [22,23]. However, the drawback is that, to invoke a bias-below FMR configuration, the junction acquires a large area, since the junction is then characterized by a relative permeability value considerably smaller than unity (≈ 0.556). In order to reduce the junction size, the junction has to be biased above FMR, utilizing an effective permeability value appreciably larger than unity ($\approx 5-6$). Furthermore, if the circulator design directly

provides $50\ \Omega$ impedance at junction ports, there is no need for transformers, resulting in miniaturization of the circulator circuit at low frequencies. By using these two techniques Hotech has fabricated 5-mm circulator junctions at the ISM (industrial–scientific–medical) band providing 15% bandwidth in transmission. The ISM band includes the frequency ranging from 902 to 928 MHz and from 2.4 to 2.48 GHz, which do not require a FCC (U.S. Federal Communications Commission) license. Even smaller circulator junctions are currently attempted by Hotech incorporating high-dielectric materials so that miniaturized UHF circulators in the order of 1 mm can be potentially fabricated in the future.

A conventional Y-junction circulator utilizes a low-Q resonator that causes the standing modes to couple in and out electromagnetic energy in a nonreciprocal manner [21]. To admit ultrabroadband operation of a circulator junction, one must abandon the conventional standing-mode picture to allow for traveling waves. Broadband two-port isolators using the traveling displacement modes or edge modes were first reported by Hines in 1961 [28]. In Fig. 9 a stripline is fabricated on top of a ferrite substrate and a dissipation pad, such as a thin layer of poor conductor, is deposited at one side of the substrate next to the stripline circuit. The superstrate, which consists of the same ferrite material, stacks above the substrate, and ground planes are attached to the substrate and superstrate at their outer surfaces. Superstrate and ground

planes are not shown in Fig. 9. In the presence of a vertically applied bias magnetic field, wave propagation along the stripline is nonreciprocal: highly transmitting along one direction, but highly attenuating along the other direction. Thus, the RF magnetic field pattern shown as dashed curves in Fig. 7 displaces toward the edge of the stripline in the presence of the bias magnetic field, which is either shifting away from the dissipation pad (top drawing), or onto the dissipation pad (bottom drawing), resulting in little attenuation, or heavy attenuation, respectively. Hynes [28] has shown the operation of an edge-mode isolator providing a 3–1 transmission band, which is about the same bandwidth measured by Schloemann and Blight in 1986 wherein the frequency-tracking conditions were enforced employing the conventional (standing-mode) resonator-type circulator junctions [24].

Edge-mode traveling-wave operation can also be realized by three-port junction geometry. In Fig. 10, three adjoining ports exhibiting a three fold symmetry rather than two aligning ports are shown depositing on top of a triangularly shaped ferrite substrate. Again, a similar superstrate covers the substrate on top and two ground planes are applied at their respective outer surfaces. Superstrate and ground planes are not shown in Fig. 10. To operate, a bias

Figure 9. Operation of edge-mode isolator. In the presence of a bias magnetic field, the RF magnetic field pattern is shifted toward the edge of a stripline fabricated using ferrite materials deposited with dissipation pad at one side. As such, propagation of electromagnetic waves along the stripline is nonreciprocal, transmitting along one direction, top, but attenuating along the other direction, bottom.

Figure 10. Operation of edge-mode circulator. In the presence of a bias magnetic field, the RF magnetic field pattern shifts toward the edge of a stripline fabricated with ferrite materials, which couples strongly to one joining line (top) but decouples to the other joining line (bottom), resulting in circulation action over a broadband.

magnetic field is applied along the junction thickness direction inducing the displacement modes or the edge modes to propagate in a manner analogous to Hines' isolator circuit shown in Fig. 9. As a consequence, edge modes couple strongly between ports 1 and 2, due to overlapping of their respective propagation electromagnetic waves with phase coherency, but decouple also strongly between ports 1 and 3 due to lack of the required wave overlapping. This results in the desired circulator operation in which electromagnetic signals entering port 1 can exit only from port 2, and so forth. In comparison to Fig. 9, the dissipation pad is not needed by Fig. 10; rather, the wave propagation direction, or the circulation direction, is dictated by the coupling/decoupling mechanism imposed by the ports. In Fig. 10 the dashed curves depict schematically the RF magnetic field pattern illustrating the coupling and decoupling of the propagation waves in ports.

In order to broaden the transmission band of an edge-mode circulator, it is necessary to enforce phase coherency for wave propagation between the input and the output ports across a broad frequency range; that is, phase coherency needs to be maintained over a wavelength distance denoted as λ in Fig. 10. Therefore, high-frequency signals couple more strongly near the center of the junction and low-frequency signals, near the side edge of the junction. Since the operation of a ferrite device requires the magnetization to scale with frequency [this ratio is known as *gyromagnetic ratio*; see Eq. (13)], one expects an ultrabroadband edge-mode circulator to occur if the ferrite junction shows different magnetizations scaled with the propagation wavelengths: large at the center but small at the side edge. This ultrabroadband circulator geometry is shown in Fig. 11, in which a composite substrate is illustrated consisting of five triangular shells of different ferrite materials, labeled as μ_1 to μ_5 , respectively, whose saturation magnetization decreases from center to edge progressively. In Fig. 11 the metal strip has been tapered accordingly from edge to center to accommodate the change in saturation magnetization, assuming that the ferrite materials are characterized by the same dielectric constant. Again, a similar geometry is assumed by the superstrate. Initial studies on circulators of Fig. 11 have shown a 10–1 transmission band. A U.S. utility patent application for ultrabroadband edge-mode circulator operation has been filed by Hotech.

An asymmetric circulator junction can be used as a broad stopband filter [29,30]. Broad stopband filters are required by radome applications protecting the receiver circuits from high-power incidence over a broad frequency band. The traditional filters utilizing coupled resonators can hardly provide the broad stopband operation, since high-order harmonics will inevitably appear at high-order harmonic frequencies. By using an asymmetric ferrite junction it is possible to induce the broad stopband operation. This is seen in Fig. 12, where an asymmetric ferrite junction is shown similar to that in Fig. 5 except that the cyclic symmetry has been removed. Instead, the input and the output ports still show the left-right (image) symmetry so as to allow the circulation conditions to occur. As shown in Fig. 12, at circulation, electromagnetic energy enters the input port and exits from the output port, with

Figure 11. Operation of edge-mode circulator employing a composite substrate/superstrate structure containing five triangularly shaped shells labeled as μ_1 to μ_5 . The magnetization is increased from the side edge μ_5 toward center μ_1 to accommodate the phase-matching requirement to achieve ultrabroadband circulator operation.

the isolated port being connected with a matched dummy load. However, due to the asymmetric arrangement of the ports, high-order harmonics are effectively suppressed, resulting in broad stopband operation as desired. Broad stopband operation revealing a 10–1 bandwidth has been

Figure 12. Dipole field pattern for an asymmetric ferrite junction excited at circulation. The field pattern still shows symmetry between the input and the output ports so that energy entering the input port is dumped into the output port, with the isolated port essentially electronically insulated from the input port. Asymmetric junction will provide a broad stopband.

measured by using an asymmetric circulator junction [29,30].

When biased above FMR, a three-port ferrite junction normally shows a transmission band no broader than 15% of its center frequency. However, this bandwidth can be increased if additional tuning ports are added to the junction geometry. This is shown in Fig. 13, where three tuning ports, called tuning “stubs,” have been added to the junction circuit still exhibiting the threefold symmetry of the ports. This allows the circulation conditions to occur as usual. However, the added three tuning stubs are effective in broadening the bandwidth if their length and impedance have been properly designed. It has been shown [31] that the added capacitance from the tuning stubs in Fig. 13 has broadened the bandwidth to 30% of its center frequency when biased above FMR.

Difficulty in using a ferrite substrate is that the bias magnetic field is required to have a magnitude of at least several thousand oersteds to effectively change the permeability of the substrate at X-band frequencies, [e.g., see Eq. (13)]. In order to reduce this bias field requirement, it is desirable to utilize the internal anisotropy field associated with a hexaferrite material to substitute, at least partially, the external field. In a ferrite material exhibiting hexagonal symmetry the internal crystalline anisotropy field can be as high as 50 kOe, admitting device applications even beyond 100 GHz [27]. For a hexaferrite material crystalline anisotropy causes the energy of magnetization direction along the c axis to differ from energies in the directions lying on the ab plane. For an M -type hexaferrite the c axis is an easy axis, and the magnetization vector favors alignment along the c axis. This implies that in an M -type hexaferrite the crystalline anisotropy behaves like an external field aligning the magnetization along the c axis [see the definition for H_A below Eq. (18)].

Figure 13. Three additional tuning ports, called *tuning stubs*, are added to a three-port circulator junction. By carefully designing the width and length of the tuning stubs, the added capacitances from the tuning ports can effectively broaden the transmission band.

Important device applications for M -type hexaferrites include circulators and isolators, wherein the easy axes coincide with the thickness direction of the substrates so as to eliminate, or at least reduce, the bias field requirement at high frequencies. Using M -type hexagonal ferrites, barium–strontium magnetoplumbites, a practical self-biasing stripline circulator, has been fabricated at 37 GHz, exhibiting 1 dB insertion loss and 15 dB isolation [32].

The performance of a circulator junction can be numerically simulated by assuming a 2D geometry [33–35]. Dielectric loss can be accounted for by assuming a complex permittivity for the ferrite junction

$$\varepsilon = \varepsilon_0 \varepsilon_r (1 - j \tan \delta) - \frac{j \sigma_f}{\omega} \quad (67)$$

and magnetic loss due to domain-wall motion by a complex permeability

$$\mu = \mu_0 (\mu' + j \mu'') \quad (68)$$

where $\tan \delta$ denotes the dielectric loss tangent, σ_f the conductivity, and ε_r the dielectric constant, and μ' and μ'' are the real and imaginary parts of permeability, respectively. Magnetic loss due to the intrinsic relaxation processes can be included by modifying the bias field to include an imaginary part proportional to the FMR linewidth ΔH [Eq. (26)]. Conductor loss due to imperfect metal boundaries of the ground planes and the stripline central conductor patch can be modeled by using the mean-field theory [36]; that is, the metal boundaries are withdrawn a distance δ_c into the interior of the imperfect metal bulk with the recessed volume to be filled by air [36]. Here δ_c denotes the (complex) skin depth

$$\delta_c = (1 + j) \sqrt{\frac{2}{\omega \mu_0 \sigma}} \quad (69)$$

and σ denotes the conductivity of the metal bulk. This procedure is analogous to Wheeler’s incremental impedance [37,38], and the resultant permittivity of the junction structure, which is viewed as an air–ferrite–air composite, is obtained as an average by using the mean-field theory [36]. As an example, numerical calculations have been applied to a microstrip circulator fabricated on top of an M -type Sc-barium hexaferrite characterized by the following parameters: $4\pi M_s = 2400$ G, $H_A = 19$ kOe, and $\varepsilon_r = 22$. Calculations compared nicely with measurements, shown in Fig. 14. Note that in performing calculations in Fig. 14 no adjustable parameters have been used (Fig. 14 appeared in an internal report from Hotech).

3. LUMPED-ELEMENT CIRCULATORS

The linear dimension of a distributed-element microwave device is comparable to the wavelength of the RF signal propagating in the device, for example, a ferrite junction circulator. At UHF/VHF frequencies the size of a distributed-element device sometimes turns out to be too bulky

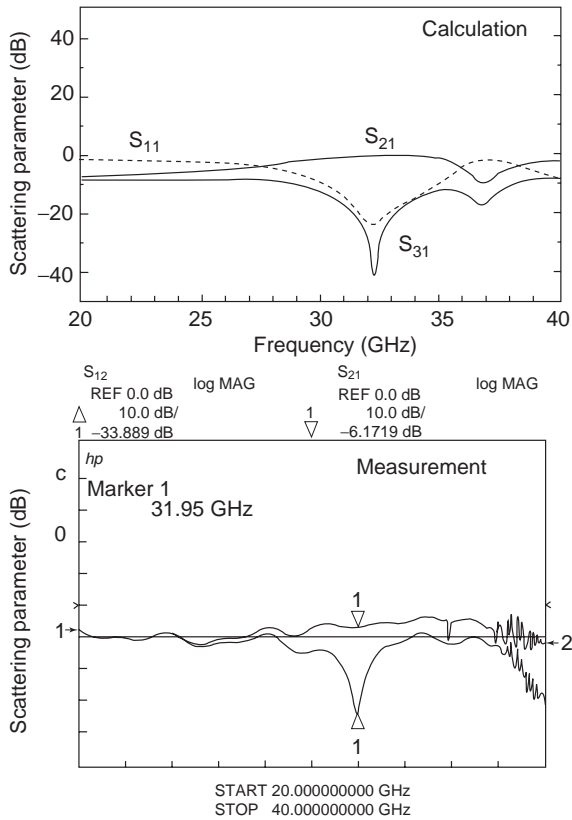

Figure 14. Calculated and measured scattering parameters of a self-biasing hexaferrite circulator.

to be handled practically, and hence the need for lumped-element devices arises. A *lumped-element device* is defined as having a linear dimension much smaller than the wavelength, and its performance can be analyzed in terms of the classical electric components, including resistors, capacitors, and inductors.

The original design of a lumped-element circulator consists of three coils wound around a common ferrite disk/puck intersecting each other at a 120° angle. The modern design makes use of the printed-circuit technique, and the three coils have been replaced by three interwoven microstrips deposited directly on top of the ferrite puck. The other side of the puck is deposited with a copper ground plane. The top view of the circuit is shown in Fig. 15, where the three microstrips intersect each other at 120° angles interwoven to retain the complete threefold symmetry. The importance of the interwoven geometry is that, besides maintaining the cyclic order of the circulator ports as defined by a circulator, interport capacitive coupling can be minimized to facilitate more precise designs of lumped-element circulators. In Fig. 15 the microstrips are grounded at their respective ends to complete the current loops for return paths (shown as heavy arcs in Fig. 15). Matching capacitances are inserted at the entrances of the microstrips to match the input impedance of the circulator to $50\text{-}\Omega$ feeder lines. The DC magnetic field is applied in the direction normal to the ferrite puck surfaces, which is designated as the z axis. A lumped-element circulator usually operates under the bias-above FMR conditions.

Figure 15. Top view of a lumped-element circulator fabricated using the printing circuit technique. The microstrips are interwoven with each other, rendering a threefold symmetry. The microstrips are electrically grounded on one end and connected with matching capacitances on the other end.

The voltage drop across the k th port microstrip or inductor is

$$\Delta v_k = j\omega \int_{A_k} \mathbf{b} \cdot \mathbf{e}_n da, \quad k = 1, 2, 3 \quad (70)$$

where A_k denotes the area enclosed by the feeding current of the k th strip. To be specific, we define A_k as the area bounded by the line along the center of the k th strip. When a ground plane is used for the current return path, the image strip will be included in conjunction with the original strip to totally specify the current path, and, hence, A_k . In Eq. (70) \mathbf{e}_n denotes the unit vector normal to the surface element da .

When the Polder permeability tensor is used, the \mathbf{b} field in Eq. (70) can be rewritten as

$$\mathbf{b} \cdot \mathbf{e}_n = \mu_0 [\mu \mathbf{h} \cdot \mathbf{e}_n - j\kappa \mathbf{h} \cdot (\mathbf{e}_z \times \mathbf{e}_n)] \quad (71)$$

where \mathbf{e}_z denotes the unit vector along the z axis. Here, μ and κ respectively are the diagonal and off-diagonal elements of the Polder tensor, Eqs. (10)–(12). The \mathbf{h} field can be written as

$$\mathbf{h} = \sum_{k=1}^3 \frac{i_k}{4\pi} \int_{S_k} \frac{d\mathbf{w}}{W_k} \frac{d\ell \times \mathbf{r}}{r^3} \quad (72)$$

where we have assumed the current to flow uniformly in the strips parallel to the length element $d\ell$. The total current in the k th strip is i_k , and W_k denotes the width of the

k th strip not necessarily a constant, for example, for the interwoven strips shown in Fig. 15. The k th strip is defined by the area S_k . In Eq. (72) dw is the width element, and vector \mathbf{r} connects the source point of the current to the observer point. Combining Eqs. (70) and (72), we obtain the following equation

$$\Delta v_i = \sum_{k=1}^3 Z_{ik} i_k \quad (73)$$

where the interport impedance Z_{ik} is given as

$$Z_{ik} = \frac{j\omega\mu_0}{4\pi} \int_{A_i} da' \int_{S_k} \frac{dw''}{W_k} \times \frac{\mu[d\ell'' \times (\mathbf{r}' - \mathbf{r}'')]\mathbf{e}_n - j\kappa[d\ell'' \times (\mathbf{r}' - \mathbf{r}'')] \cdot (\mathbf{e}_z \times \mathbf{e}_n)}{|\mathbf{r}' - \mathbf{r}''|^3} \quad (74)$$

The interport impedance of a cyclic three-port lumped-circuit element circulator can then be written as

$$\underline{\mathbf{Z}} = j\omega L \begin{pmatrix} 1 & \alpha + j\beta & \alpha - j\beta \\ \alpha - j\beta & 1 & \alpha + j\beta \\ \alpha + j\beta & \alpha - j\beta & 1 \end{pmatrix} \quad (75)$$

where

$$L = \frac{\mu\mu_0}{4\pi} \int_{A_1} da' \int_{S_1} \frac{dw'' [(d\ell'' \times (\mathbf{r}' - \mathbf{r}''))\mathbf{e}_n]}{W_1 |\mathbf{r}' - \mathbf{r}''|^3} \quad (76)$$

$$\alpha = \frac{1}{L} \left[\frac{\mu\mu_0}{4\pi} \int_{A_1} da' \int_{S_2} \frac{dw'' [(d\ell'' \times (\mathbf{r}' - \mathbf{r}''))\mathbf{e}_n]}{W_2 |\mathbf{r}' - \mathbf{r}''|^3} \right] \quad (77)$$

$$\beta = \frac{1}{L} \left[\frac{\kappa\mu_0}{4\pi} \int_{A_1} da' \int_{S_2} \frac{dw'' [(d\ell'' \times (\mathbf{r}' - \mathbf{r}'')) \cdot (\mathbf{e}_z \times \mathbf{e}_n)]}{W_2 |\mathbf{r}' - \mathbf{r}''|^3} \right] \quad (78)$$

and

L = self-inductance of each of the current strips

αL = mutual inductance between each pair of the current strips

$\mp j\beta L$ = gyromagnetic inductance between each pair of the current strips

We note that the gyromagnetic component of the interport inductance is nonreciprocal under port exchange. This renders the circulation action for the circulator device. Once the interport impedance matrix is known [Eq. (75)], the circuit of Fig. 15 can then be fully analyzed by using Kirchhoff's law as performed by a classical circuit. Or, one can follow the route adopted by Bosma [19,20] to solve the circulation conditions for a given lumped-element circulator circuit. Literature on lumped-element circulators is cited in Refs. 39 and 40.

4. HEXAFERRITE WITH EASY PLANE

For a Y-type hexaferrite the c axis turns out to be a hard axis and the magnetization vector tends to lie in the ab plane, which is termed the “easy plane”. While it is thought M-type hexaferrite is appropriate for circulator and isolator applications requiring out-of-plane magnetic bias, Y-type hexaferrite is adequate as the substrate material for microwave tunable filters because of its large magnetization and in-plane anisotropy, as well as the ease in use—the demagnetizing field is negligible along the transverse directions of a planar device [41]. Also, elimination of the external magnets represents a significant step toward more compact circuit design, allowing for integration of the device with future semiconductor circuits.

The effective field associated with an easy plane can be derived from using Eqs. (15) and (21). However, this would result in a magnetization–orientation–dependent effective field, as first demonstrated by Schloemann et al. [42], which is in contrast to the conventional concept of a magnetic field [see Eq. (85)]. In the following we define a mean effective field characteristic of the anisotropy of an easy plane from an operational point of view. The precessional motion of the magnetization vector is depicted in Fig. 16 for both cases of an easy axis (top) and an easy plane (bottom). For an easy axis the magnetization vector undergoes a uniform precessional motion around the easy axis, experiencing a uniform torque exerted by the anisotropy, resulting in a constant angular velocity. This is shown in a polar plot at the top of Fig. 17, where the loci of the angular velocity ω traces a circle. However, for the case of an easy plane (Fig. 16, bottom), the precessional motion of the magnetization vector is not uniform. The anisotropy field exerts no torque at all on the magnetization vector at points A and A' lying on the easy plane, and a maximum

Figure 16. Precessional motion of the magnetization vector around an easy axis (top) and an easy plane (bottom).

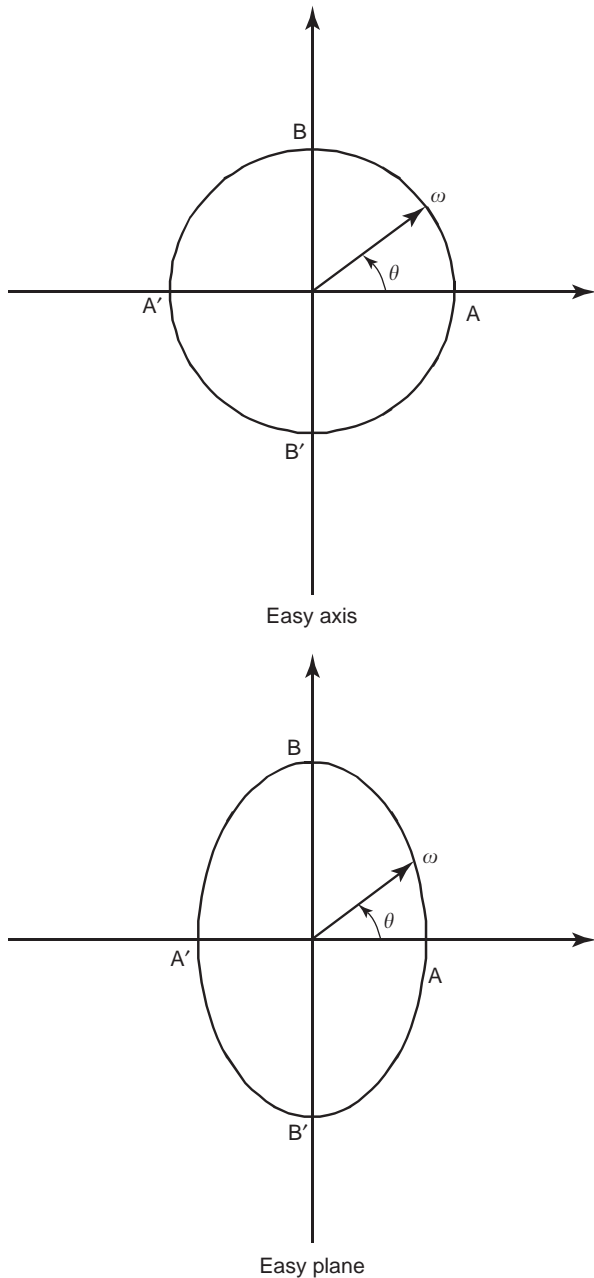

Figure 17. Polar plots of the instantaneous angular velocity of the magnetization vector precessing around an easy axis (top) and an easy plane (bottom).

torque is exerted by the anisotropy at the vertical positions marked as *B* and *B'* at the bottom of Fig. 16. Thus, in the presence of an easy plane the loci of the angular velocity traces out an ellipse, as shown at bottom of Fig. 17, whose semi-major and semi-minor axes are, respectively

$$\omega_{\max} = \gamma(H_0 + H_A), \quad \omega_{\min} = \gamma H_0 \quad (79)$$

Here, H_0 denotes the external field; H_A , the anisotropy field measured by Vibrational Sample Magnetometer (VSM); and γ , the gyromagnetic ratio. The period of the

nonuniform precessional motion is

$$T = \int_0^{2\pi} \frac{d\theta}{\omega} \quad (80)$$

where θ denotes the precessing angle of the magnetization vector shown in Fig. 17. Let this nonuniform magnetization vector precessional motion be associated with an effective internal field H_i whose Larmor frequency γH_i coincides with the period given by Eq. (80):

$$\gamma H_i = \frac{2\pi}{T} \quad (81)$$

We derive, therefore

$$H_i = \left[\frac{\gamma}{2\pi} \int_0^{2\pi} \frac{d\theta}{\omega(\theta)} \right]^{-1} \quad (82)$$

When the functional form of $\omega(\theta)$ is specified as an ellipse in the polar plot whose semi-major and semi-minor axes are given by Eq. (79), respectively, we obtain the following analytic equation from Eq. (82):

$$H_i = [H_0(H_0 + H_A)]^{1/2} \quad (83)$$

Figure 17 shows how the anisotropy field H_A adds to the external field H_0 for both the cases of an easy axis and an easy plane. For a cubic material, or an isotropic material, the anisotropy field is insignificant comparing to H_0 , and the magnetization vector undergoes a uniform precessional motion whose angular velocity is a constant, tracing out a circle of radius γH_0 , denoted as ω_{\min} in Eq. (79). For an easy axis pointing along the *c*-axis of an *M*-type hexaferrite, H_A adds to H_0 arithmetically, wherein the magnetization vector still undergoes a uniform precessional motion whose angular velocity traces out a circle of radius $\gamma(H_0 + H_A)$, denoted as ω_{\max} in Eq. (79). However, for an easy plane coincident with the *ab* plane of a *Y*-type hexaferrite, the magnetization vector no longer performs a uniform precessional motion, and the loci of the angular velocity becomes, instead, an ellipse whose semi-major and semi-minor axes are respectively ω_{\max} and ω_{\min} given by Eq. (79). These three kinds of magnetization vector precessional motions are shown as solid curves in Fig. 18.

Now, Eq. (83) dictates that in the presence of an easy plane the magnetization vector can still be visualized as if it were performing a uniform precessional motion as long as the associated hypothetical motion is characterized by a Larmor frequency whose period is given by Eq. (80). This hypothetical motion is depicted in Fig. 18 as a dashed circle whose radius is γH_i , as specified by Eq. (83). This gives rise to an expression for the effective internal field H_i characteristic of an easy plane, Eq. (83). Note that H_i assumes a magnitude between the two fields corresponding to the isotropic case H_0 and the case of an easy axis $H_0 + H_A$. Actually, H_i happens to be the geometric mean of these two fields: H_0 and $H_0 + H_A$ [Eq. (83)]. In other words,

Figure 18. Loci of the angular velocities for an isotropic material, an M-type hexaferrite, and a Y-type hexaferrite, and construction of the effective internal field for the Y-type hexaferrite.

H_i can be constructed in a geometric manner such that in Fig. 18 a hypothetical circle is drawn whose area equals that of an ellipse representing the actual loci of the angular velocity. In this discussion we have assumed the other DC effective fields to be zero, including the DC demagnetizing fields. In case there are nonzero DC fields other than H_0 , they need to be added to H_0 arithmetically before the geometrical construction of H_i giving rise to the total effective internal field in a Y-type hexaferrite exhibiting a magnetic easy plane. The effective field expression [Eq. (83)], applies to wave propagation of arbitrary polarization, as long as the longitudinal component of the magnetization vector does not couple into the precessional motion, as assumed by the small-signal approximation in deriving linearized equations of motion.

By using Eq. (83) the resonant frequency of the uniform mode in a Y-type hexaferrite can be written as

$$\omega_0 = \gamma \{ [H_a + 4\pi M_s(N_x - N_z)][H_a + H_A + 4\pi M_s \times (N_y - N_z)] \}^{1/2} \quad (84)$$

which was derived by Schloemann et al. [42]. However, we must point out that in deriving Eq. (84) those authors have used the following effective field for the planar anisotropy [37]

$$\mathbf{H}_i = \mathbf{e}_A \mathbf{H}_A \cdot \frac{\mathbf{M}}{\mathbf{M}_s} \quad (85)$$

whereas the effective field we used in deriving Eq. (84) is Eq. (83). The difference is that Eq. (83) is a mean effective field, and Eq. (85) is an instantaneous effective field. In Eq. (85) \mathbf{H}_A denotes the anisotropy field along the hard axis whose unit vector is \mathbf{e}_A , and \mathbf{M} is the magnetization vector. In comparison, the corresponding resonant frequency of

Kittel uniform mode for an M-type hexaferrite showing an easy axis is given by Eq. (52). The magnetization properties of an easy-plane Y-type hexaferrite including instability studies and spinwave linewidth measurements are discussed in further Refs. 43–46.

5. FERRITE NONRECIPROCAL RESONATORS

Microwave and millimeter-wave (MMW) devices and systems are becoming increasingly important today for both the defense and the commercial applications. For example, in the collision avoidance industries, low-profile conformal antennas are needed to provide electronically steerable radiations to detect and identify obstacles and extrusions in front of moving vehicles. On navigation the receiver antennas need to follow and trace the motion of GPS (global positioning system) satellites so as to continuously monitor and update their positions. Also, there is a need to create radiation nulls along certain spatial directions for an antenna transmitter/receiver to warrant secure and covert communications. Other applications can be found in target searching/tracking radars for surveillance, satellite communication systems, and TV program broadcasting antennas installed with civilian jet carriers. All of these applications require microwave phase shifters to participate at affordable prices.

Traditional approaches include the use of frequency-agile materials (varactors, ferroelectrics, and ferrites) so that the electrical length of a transmission line, and hence the propagation phase of an electromagnetic signal, can be electronically tuned by applying a voltage, a current, or a magnetic field. Microwave phase shifters thus obtained are expensive, requiring manual tuning or adjustment of the fabricated devices. Furthermore, the resultant phase shifting function is nonuniform, as it is dependent on the derived phase shift angle, since the impedance of the transmission line is inevitably changed accompanying the intended phase shift operation, in addition to the desired change in electrical length. This section introduces an innovative method permitting the phase-shifting function to be realized at microwave frequencies whose operation is independent of the phase shift angles. This method is based on the use of a nonreciprocal ferrite resonator that has been patented by Hotech [47].

For an isotropic resonator showing circular symmetry, for example, an isotropic dielectric microstrip/stripline disk/ring resonator, the excited modes contain both clockwise and counterclockwise rotational modes, because these two mode types are degenerate in frequency, and wave propagation is reciprocal with respect to rotation around the axial direction of the resonator. As such, phases are ambiguous if one attempts to couple out the excited modes from the resonator. This is no longer true for an anisotropic resonator in which the rotational symmetry for wave propagation is removed. As a consequence, the two eigenmodes associated with clockwise and counterclockwise rotations occur at different frequencies, and excitation of one mode excludes the other, and vice versa. This implies that the resonant modes are definite in phase, allowing the resonator to be effectively used as a

phase shifter. Most importantly, the eigenmodes excited in a nonreciprocal resonator are traveling waves, in contrast to the standing eigenmodes excited in a conventional isotropic resonator supporting reciprocal propagation of electromagnetic waves. This traveling-wave nature ensures that when used as a phase shifter, output from a nonreciprocal resonator is uniform or identical in amplitude, except for the desired change in phase, as imposed by the circular symmetry of the resonator circuit.

Among many possible solutions, an explicit example is discussed in this section utilizing a ferrite microstrip/stripline disk/ring resonator [47]. As stated above, in a ferrite disk/ring resonator magnetized along the axial direction the degeneracy between the two counterrotational modes is removed, and the resonant frequencies of these two eigenmodes occur at different frequencies, denoted as f_+ and f_- for the clockwise and the counterclockwise rotational modes, respectively [21]. While the operation of a ferrite junction circulator is designated at a frequency midway between these two frequencies, $f = (f_+ + f_-)/2$ [21], circularly polarized radiations are obtained from the disk/ring resonator if the excitation frequency is located near one of these two frequencies, f_+ or f_- [48]. This implies that at resonance the resonant mode in a ferrite resonator exhibiting circular symmetry consists of only one eigenmode whose phase can thus be determined without ambiguity, allowing the device to be used as a phase shifter.

For a 2D ferrite junction Maxwell equation, Eq. (1) reduces to the following form [19,20]:

$$\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \phi^2} + k^2\right) e_z = 0 \quad (86)$$

$$h_\phi = \frac{j}{\omega \mu_0 \mu_{\text{eff}}} \left(\frac{\partial e_z}{\partial r} - \frac{j\kappa}{\mu} \frac{1}{r} \frac{\partial e_z}{\partial \phi} \right) \quad (87)$$

$$h_r = \frac{-j}{\omega \mu_0 \mu_{\text{eff}}} \left(\frac{1}{r} \frac{\partial e_z}{\partial \phi} + j \frac{\kappa}{\mu} \frac{\partial e_z}{\partial \phi} \right) \quad (88)$$

$$e_r = e_\phi = 0 = h_z \quad (89)$$

Here (r, ϕ, z) are the cylindrical coordinates, k relates to the angular frequency ω by the dispersion relationship [Eq. (37)], and the effective (relative) permeability μ_{eff} is [Eq. (38)]

$$\mu_{\text{eff}} = \frac{\mu^2 - \kappa^2}{\mu} \quad (90)$$

where κ and μ are the Polder permeability tensor elements [Eqs. (10)–(14)]. The normal-mode solution of a thin ferrite disk/ring resonator can thus be solved assuming the magnetic wall boundary conditions at the peripheries, resulting in analytic solutions involving the Bessel and the Neuman functions.

For a disk resonator of radius R , the magnetic wall boundary conditions require

$$h_\phi(R) = 0 \quad \text{for } n = \pm 1, \pm 2, \dots \quad (91)$$

or

$$\left[J'_n(kR) - \frac{\kappa}{\mu} \frac{n J_n(kR)}{kR} \right] = 0 \quad (92)$$

from which the normal-mode frequency ω or k can thus be solved as a function of H_{in} , or H_0 , Eq. (18). For a ferrite ring resonator of inner radius R_1 and outer radius R_2 , the magnetic wall boundary conditions require

$$h_\phi(R_1) = 0, \quad h_\phi(R_2) = 0, \quad \text{for } n = \pm 1, \pm 2, \dots \quad (93)$$

or

$$\left[J'_n(kR_1) - \frac{\kappa}{\mu} \frac{n J_n(kR_1)}{kR_1} \right] + \alpha \left[N'_n(kR_1) - \frac{\kappa}{\mu} \frac{n N_n(kR_1)}{kR_1} \right] = 0 \quad (94)$$

$$\left[J'_n(kR_2) - \frac{\kappa}{\mu} \frac{n J_n(kR_2)}{kR_2} \right] + \alpha \left[N'_n(kR_2) - \frac{\kappa}{\mu} \frac{n N_n(kR_2)}{kR_2} \right] = 0 \quad (95)$$

Here α denotes an unknown mode-mixing parameter. By solving Eqs. (94) and (95) simultaneously, k and α are determined, giving rise to the normal-mode frequency as a function of H_{in} , or H_0 , Eq. (18). In the above equations J_n denotes the Bessel function of order n , and N_n the Neuman function or order n , and $n = 1, 2, 3, \dots$ for the dipole, quadrupole, and octopole modes, respectively.

A gyromagnetic medium, or a ferrite, is characterized by a nonvanishing off-diagonal element of the Polder permeability tensor κ [Eqs. (10) and (12)]. If κ is zero, the medium becomes isotropic, and wave propagation is reciprocal with respect to the wave traveling direction, or the sign of the modal number n in the equations above. For an isotropic medium, Eq. (92) and Eqs. (94) and (95) reduce to those ordinary equations describing the normal-mode solutions of an isotropic disk resonator and ring resonator, respectively. However, if κ is nonzero, wave propagation is nonreciprocal and the normal-mode solutions become dependent on the wave traveling directions, or the sign of the modal number n , as implied by Eq. (92) and Eqs. (94) and (95) for a ferrite disk resonator and ring resonator, respectively. This forms the basis for the operation of a phase shifter using a nonreciprocal ferrite resonator.

Thus, by coupling out the resonant mode selectively from a sequence of positions of the resonator showing circular symmetry, the output phase can be varied, but keeping the output amplitude at a rather constant level. In making this statement we have assumed that the input position is fixed. The reverse also holds true. That is, by keeping the output position fixed, the output phase, but not the amplitude, can be varied if the input position is selectively changed from a sequence of positions showing circular symmetry, exciting the resonant mode with a definite phase. Since the ferrite operation is designed away from ferrimagnetic resonance (FMR), low insertion loss is thus possible. Note that a ferrite junction circulator, which makes use of the standing modes excited inside a ferrite

resonator (rather than the aforementioned traveling waves excited inside a nonreciprocal ferrite phase shifter), has generally shown an insertion loss less than 0.5 dB, and an even smaller insertion loss, say, less than 0.1 dB, can be obtained if the circulator operates over a narrow frequency band. This implies that phase shifts obtained from using a nonreciprocal ferrite resonator can potentially show low insertion loss, if the coupling impedance has been well matched at the input/output ports.

Depending on the speed requirement, the output phase from the ferrite resonator can be coupled out using switches of various kinds, including mechanical switches, optical switches, electronic switches, or electromechanical switches. A mechanical switch might be slow, but it is nevertheless cost-effective. Electronic switches can be fabricated using semiconductor junctions located in close proximity to the resonator ports to be integrated with the other phased-array elements. Microelectromechanical switches (MEMSs) provide high isolation between ports. Optical/superconducting switches are fast devices, and a response time shorter than 1 nsec can be readily achieved.

Phase shifters using ferrite resonators are narrowband devices whose bandwidth is typically 5% of the transmission frequencies. However, one is allowed to vary the bias field magnitude so as to alter the resonant mode of the resonator, resulting in continuous tuning of the transmission frequency. In this sense, phase shifters using ferrite resonators are operational as broadband devices. However, if broadband transmission is not a requirement, the resonator can be fabricated using a self-biasing hexaferrite so that the need for external bias is eliminated. Also, the fabrication of a phase shifter utilizing a ferrite resonator is cost-effective, since, once it is fabricated, there is no need for individual tuning for performance adjustment, because the transmission amplitude is a constant, as implied by the resonator's circular geometry. Phase shifters using ferrite resonators can be fabricated over all the microwave bands, from UHF to millimeter-wave frequencies.

Figure 19 shows an example that a ferrite-ring resonator serves to provide phase shifts invoking a rotating arm as the coupling mechanism. Unlike the other electronic/optical/MEMS coupling mechanisms, a rotating arm gives continuous change in phase shift angles. In Fig. 19 a hole is drilled with the ferrite substrate that constitutes the central hole of the ring resonator, as shown in Fig. 19. In Fig. 19 port 0 is not fixed in position, and is allowed to rotate around an axis at the center of the resonator, contacting loosely, but coupling tightly to, the inner periphery of the ring patch of the conductor circuit of the resonator. Air is used as the substrate material for port 0 so as to facilitate the mechanical motion of the rotating arm intended there. The other end of port 0 is connected to the central conductor of a coaxial cable, which penetrates through the ground plane of the resonator from below, protruding into the hole region formed by the ferrite resonator, joining port 0 and making a 90° angle at the point of joint. This forms a rotating arm, consisting of port 0 and the central conductor of the coax cable, shaped as the letter "L" but upside down. Via a gear assembly, the coax cable, and hence the rotating arm, is loaded into a step motor that drives the rotating arm to perform

rotational motion, as shown in Fig. 19. A rotary joint is used to isolate the rotational motion of the coax cable from the coax launcher, which serves as the entrance for the input signal.

A prototype phase shifter device, whose schematic is shown in Fig. 19, has been fabricated and tested by Hotech. The resonator used garnet G1010 (Trans-Tech, Adamstown, MD) biased by a magnet located under the resonator (Fig. 19). The bias field was measured to be 1050 kOe, and the resonant mode was identified as the 1^+ mode at 3.78 GHz (clockwise rotating dipole mode). The measured transmission phases, as well as amplitudes, are shown in Fig. 20 at the resonant frequency, as a function of the rotating arm positions, normalized with respect to those values when the rotating arm is located along the output port direction (Fig. 19). From Fig. 20 it is seen that

Figure 19. An example of microwave phase shifter construction using a nonreciprocal ferrite resonator. Due to the removed degeneracy in wave propagation, the phase of the resonant mode can thus be uniquely determined. The resonant mode is coupled out via the use of a rotating arm driven by a stepped motor to select the output phase via mechanical means.

Figure 20. Transmission phase and amplitude at the resonant frequency plotted as a function of the rotating arm position. The measured phase and amplitude values have been normalized with those when the rotating arm is located at the 0° position, that is, when the arm is pointing toward the output port shown in Fig. 15.

the output phase from the phase shifter follows exactly the rotating arm position. Note that in Fig. 20, the measured transmission amplitudes of the phase shifter fluctuate slightly, to an extent of about ±2 dB, due to the imperfection impressed with device fabrication (the rotating arm was fabricated a bit off center). The measured bandwidth of the phase shifter was about 5% of the center transmission frequency, as expected. The minimum insertion loss was measured to be 0.33 dB when the rotating arm was located pointing along a 90° angle (see Fig. 20).

Instead of adopting mechanical means, the phase of the resonant modes excited with the ferrite ring resonator of Fig. 19 can also be coupled in and out using switches, as shown in Fig. 21. Although the construction of a mechanical rotating arm is cost-effective (Fig. (19)), its operation is slow, in the order of milliseconds, suffering from potential problems such as worn-out materials and hence mechanical breakdown. By using electronic switches, the phase shifter becomes more reliable and its response time greatly improves, in the order of microseconds for semiconductor junctions or MEMSs, and nanoseconds for superconducting or optical switches. The phase shifter, circuit shown in Fig. 21 consists of 64/8 switches at the inner/outer ports capable of providing 512 discrete phase angles in operation, if both the inner and outer port switches are under selection at the same time. Most importantly, the input/output ports are all symmetric with respect to one another, ensuring the transmission amplitude from the phase shifter to be uniform and independent of the angle in phase shifting. By applying a magnetic field perpendicular to the ring plane, one can vary the effective permeability of the ferrite resonator, resulting in tuning in the transmission frequencies. The tuning range of an octave band can be readily obtained from UHF to beyond Ka-band frequencies. A U.S. patent for the shifter circuit shown in Fig. 21 is currently pending (Hotech, 2004).

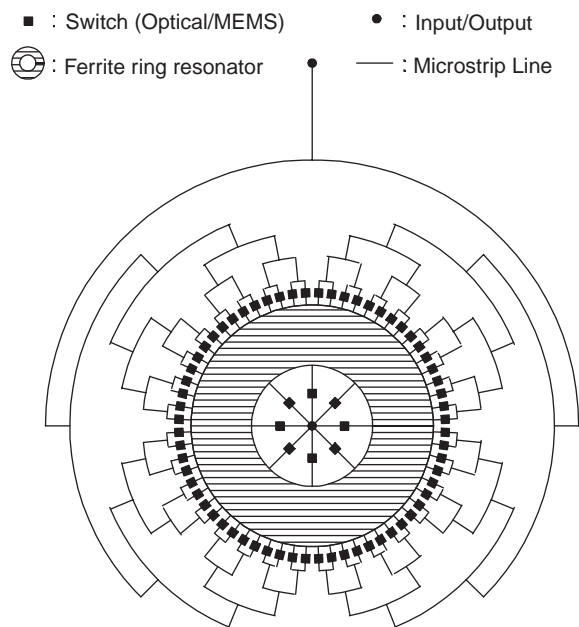

Figure 21. Novel ferrite phase shifter allowing for 512 phase values subject to frequency tuning capability. Isotropic symmetry of the device circuit ensures the phase shifting function to be uniform independent of the derived phase values.

6. MAGNETOSTATIC WAVES AND YIG FILM DEVICES

There exists an ever-increasing demand for signal processing devices that can be used for radar detection, electronics communication, and instrumentation applications. At UHF frequencies surface acoustic wave (SAW) devices have been widely used, providing phase shifting, time delaying, and other analog signal processing functions. However, at higher frequencies (>2 GHz), SAW devices are inefficient because of device fabrication and increased insertion loss. At microwave or even millimeter-wave frequencies signal processing devices have been largely achieved utilizing the newly developed magnetostatic wave (MSW) technology providing similar functional performance as SAW devices. Additional advantages include lower insertion loss, large bandwidth up to 1 GHz, ease of fabrication, frequency tuning, dispersion shaping, and nonlinear operation.

In contrast to SAWs, MSWs are very disperse and can be controlled readily by means of an external magnetic field. In principle, three basic types of MSWs are distinguished: forward volume MSW (MSFVW), backward volume MSW (MSBVW), and surface MSW (MSSW). An MSFVW is excited in the ferrite material, usually a YIG film, magnetized perpendicularly to the film plane. An MSBVW is excited in a YIG film and the magnetization direction is in the film plane along the wave propagation direction. An MSSW is also associated with a transverse magnetization, but the wave propagation is perpendicular to the direction of magnetization. For detailed discussions about excitation and dispersion trends of these three types of MSWs, see text discussion following Fig. 2. All three types of MSWs can be effectively used in fabricating

microwave devices, such as delay lines, tunable filters, phase shifters, resonators, noise suppressers, and amplitude correctors.

In order to reduce wave propagation loss, high-quality single-crystal yttrium iron garnet (YIG) films are usually used for the fabrication of MSW devices. When YIG single-crystal films are epitaxially grown on gadolinium gallium garnet (GGG) substrates, the ferromagnetic resonance (FMR) linewidth ΔH can be as narrow as 0.3 Oe at 9 GHz and 0.6 Oe at 20 GHz. Using Eq. (45), the propagation loss in an MSW delay line is 23 and 46 dB per μs at 9 and 20 GHz, respectively. Therefore, for a typical delay-line application, the propagation loss requiring 200 ns delay will be, respectively, 4.6 and 9.2 dB at 9 and 20 GHz. This compares very favorably with other kinds of delay lines such as a coaxial cable; at 9 GHz, a 200-ns coaxial cable would require a length of 50 m long, resulting in 30 dB loss in propagation.

MSWs are excited within YIG films using either microstrips or striplines as the transducer circuits. The guided electromagnetic modes of the transducers couple with the intrinsic excitations of the YIG films to launch magnetostatic waves traveling down from the input to the output transducers to perform the signal processing functions. In addition to straight microstrip/stripline transducers, meander lines, gratings, and interdigital and unidirectional transducers can also be used to couple in and out the MSW signals. Transducers involving short-circuited and open-circuited microstrip lines are commonly used for broadband MSW device applications. The entire MSSW, MSFVW, or MSBVW frequency band can be excited by using a narrow (10- μm) microstrip transducer. For narrowband devices, meander lines and gratings can be used. These transducers can be designed with 50–75 Ω input impedance over broad frequency bands, and matching circuits can be used to reduce mismatch losses.

In order to reduce spurious reflection of MSWs from the YIG film edges, MSW terminations or absorbers need to be utilized. These terminations can appear in the form of ferrite powders, or iron/permalloy rods, or even recording tapes, or GaAs thin films may be placed at the YIG edges.

However, the simplest way to avoid MSW interference is to cut the YIG edges into angles other than 90° such that the reflected beam is directed away from the active area of the MSW device [49]. Among the many MSW applications discussed in this section, we will briefly discuss the operation of MSW delay lines, filters, directional couplers, and resonators. Other nonlinear and magneto-optic MSW devices will be discussed in Sections 7 and 9, respectively.

6.1. MSW Delay Lines

Figure 22 shows the commonly used flip-over configuration for MSW delay lines. Microstrip lines serving as the transmitter and receiver for MSWs are fabricated using photolithographic technique on top of a dielectric superstrate such as alumina, sapphire, fused silica, or duroid material. The high-quality crystal YIG film epitaxially grown on GGG substrate is brought in contact with the transducers via a spacer layer and the overall dielectric-spacer–YIG–GGG assembly is placed between the poles of the biasing magnet. The biasing magnetic field can be directed either on the YIG film plane parallel to or perpendicular to the microstrip lines, or perpendicular to the YIG film plane, to provide MSBVW, MSSW, or MSFVW delay-line operation, respectively. Therefore, due to the coupling between the electromagnetic waves (EMWs) induced by the microstrip lines and the MSWs, the microstrip transmitter will excite MSWs that travel down the delay-line structure to be picked up by the microstrip receiver. Letting the distance between the transmitter and the receiver be D , the time delay for this device is

$$\tau_d = \frac{D}{v_g} \quad (96)$$

where $v_g = d\omega/dk$ denotes the group delay velocity of MSWs.

Delay-line elements exhibiting a linear dependence of the delay time τ_d on frequency are key components in pulse compression radar, microscan receiver, and Fourier transform systems. In general τ_d is highly dispersive, depending nonlinearly on frequency. There exists various methods that allows τ_d to show linear dependence on

Figure 22. Schematic showing the MSW delay-line configuration. Microstrip transducers are used to couple in and out the MSWs. Depending on the direction of the bias magnetic field, all types of MSWs can be excited and detected using the present circuit configuration.

frequency over broad-frequency bands [50,51]. For example, at X band it is possible to show 1 GHz bandwidth for a linearly dispersion delay line by using a thin YIG film with thickness 20 μm covered with a thin dielectric superstrate of the same thickness [50]. Alternatively, the linear dependence of τ_d on frequency can be obtained by varying the separation distance between the ground plane and the YIG film [51], using the bias field gradients [52], or deploying multiple YIG films [53].

Nondispersive broadband delay lines are potential devices replacing phase shifters at microwave frequencies, providing electronically tuning capability for phased-array antenna and other signal processing component applications. Therefore, we require the time delay τ_d to be independent of the bias field strength and, hence, the frequency over a broad frequency bandwidth. A possible solution to this requirement is to cascade two broadband linearly dispersive delay lines with opposite propagation characteristics; that is, the first device operates for forward volume MSWs and the second, for backward MSWs such that they compensate each other to provide nondispersive dependence on frequencies. Other methods make use of nonuniform bias field [52] and multilayer structure [53], as discussed for the construction of a linearly dispersive delay-line device.

6.2. MSW Filters

Filtering of electronic signals is performed as a frequency-selective process realized in the frequency domain. In principle, any delay-line configuration can be viewed as a frequency filter structure provided that the following features are emphasized: low insertion loss occurring at the passband and high attenuation occurring at the stopbands. The filter characteristics can be feasibly obtained by controlling the transducer dimensions and the YIG/ground-plane separation. While short-circuited straight microstrip lines are generally used as transducers for a broadband filter, multielement grating transducers, such as those shown in Fig. 23, are used to synthesize narrowband filters. As such, narrowband filters of bandwidth 30 MHz tunable from 3 to 7 GHz have been successfully demonstrated [54]. Similarly, by carefully adjusting the width of the short-circuited microstrip transducer and the YIG film thickness, a broadband filter tunable from 0.3 to 12 GHz with stopband rejection better than 45 dB has been shown [55]. The advantage of using a MSW filter is that the passband can be tuned by varying the strength of the bias magnetic field.

6.3. MSW Directional Couplers

Figure 24 shows the schematic of an MSW directional coupler, with which two YIG films are deployed face to face, separated by a dielectric spacer. Ground planes are deposited on the outer sides of the GGG substrates and two multistrip lines are used as transducers, coupling in and out microwave energy through exchange of MSWs. By careful design of the microstrip line spacing as well as the dimensions of the dielectric spacer, the characteristic of a directional coupler can be obtained. Operation at full power coupling is possible [56]; hence, the directional coupler

Figure 23. Microstrip circuit showing the geometry for multielement grating transducers used for excitation and receiving MSWs over a narrow frequency band for tunable filter applications.

Figure 24. Schematic showing the MSW directional coupler configuration. Microstrip multistrip transducers are used to couple in and out the MSWs. All types of MSWs are possible depending on the bias field direction. The coupling coefficient between the input and output ports can be varied by changing the strength of the bias magnetic field.

can be equivalently used as a bandpass filter. Also, by varying the bias field strength the power transferring coefficient of the directional coupler can be consequently adjusted.

6.4. MSW Resonators

Although the MSW bandpass filters discussed above are useful for many applications, occasionally, considerable signal selectivity may be required over as narrow a pass-band width as possible. For example, tunable MSW resonators can be used as the frequency-selective elements in tunable oscillator circuits in the microwave frequency bands. MSSW resonators can be constructed by placing reflective metal gratings at the edges of the resonating cavity. Alternatively, grooves may be cut on the YIG film surface using wet etching or ion bombardment to form an MSSW cavity. This is shown in Fig. 25, in which two arrays of straight grooves are etched parallel to but on the two sides of the microstrip transducer lines, and, MSSWs, once generated, bounce back and forth indefinitely between these two groove arrays at resonance. As reported by Castera [57], MSSW resonators fabricated in this manner have shown a tuning capability between 2 and 5 GHz, exhibiting a loaded Q of 500 and an off-resonance rejection level of 15 dB.

For MSFVWs the bias magnetic field is perpendicular to the YIG film plane, and hence the propagation of MSFVWs is isotropic in all directions in the film plane. As such, the MSSW resonator shown in Fig. 25 is not suitable for MSFVW applications; it will result in poor off-resonance isolation, since at off resonance the propagation of MSFVWs at slightly tilted angles may still satisfy the

resonance condition. To avoid this drawback, a new configuration that involves two cavities coupled by MSFVWs has been proposed [58], as shown in Fig. 26. Each cavity consists of two etched-groove gratings and a single microstrip transducer. The two cavities are placed at a 90° angle and are coupled by a 45° obliquely oriented gratings capable of deflecting the incident MSW beam by a 90° angle. The resonators reported by Castera and Hartemann [58] exhibited insertion losses between 20 and 32 dB and a loaded Q value of 290–1570 over a tuning range of 2–11 GHz.

The resonator structures discussed so far involve reflection surfaces or mirrors, which is complex in the sense that they require groove or metal-strip arrays to be fabricated on the YIG film surface. To avoid this complexity, it is also possible to directly use the straight edges of the YIG film to form a MSW cavity resonator. Figure 27 shows such a straight-edge resonator (SER) device, where the YIG/GGG resonator, which is of a rectangular shape cut by a dicing saw, is placed on top of the dielectric substrate coupled in and out by the short-circuited microstrip transducers on both sides of the resonator. Depending on the bias field direction, both MSSW and MSFVW SERs can be constructed. Thus, MSSWs propagate along the surface of the YIG film and are reflected back onto the surface at the straight edges. A standing-wave pattern results and a high- Q resonance is obtained. In this manner a MSSW SER has been reported [59], exhibiting an insertion loss of 3.1 dB and a sideband suppression level better than 20 dB tunable from 1 to 22 GHz.

Finally, we consider the MSW structure of Fig. 28, which depicts a one-port resonator circuit. The circuit of Fig. 28 can be fabricated using photolithographic technique, and, hence, cutting of reflective grooves on the YIG film is avoided. In Fig. 28 MSSWs are excited within the metal window coupled in and out via the microstrip transducer. In order to form total reflection of the MSWs at the window boundary, and hence to achieve a high Q value, the geometry of the resonator needs to be carefully designed. The circuit of Fig. 28 allows for operation for all types of MSWs, and simple MSW resonators can be constructed.

7. MAGNETIC MICROWAVE NONLINEAR DEVICES

As discussed in Section 1, nonlinear terms appear in the equation of motion whenever the small-signal assumptions no longer hold true for the magnetization vector. Under these conditions, the magnetization field will couple to itself, resulting in spin-wave interactions between different wavenumbers and frequencies [Eq. (64)]. In this section we discuss how this nonlinear phenomena can be utilized for device applications. Among many important nonlinear devices, we will discuss frequency-selective limiters, signal-to-noise enhancers, amplitude correctors, and ferrimagnetic echoing devices.

7.1. Frequency-Selective Power Limiter

Frequency-selective limiters have been demonstrated using YIG spheres and ferrite slabs in the waveguide, coax,

Figure 25. Schematic showing the configuration of an MSSW resonator. Reflecting arrays of grooves are cut on the YIG film surface to form an MSSW cavity resonator. The bias field is applied parallel to the microstrip transducer direction.

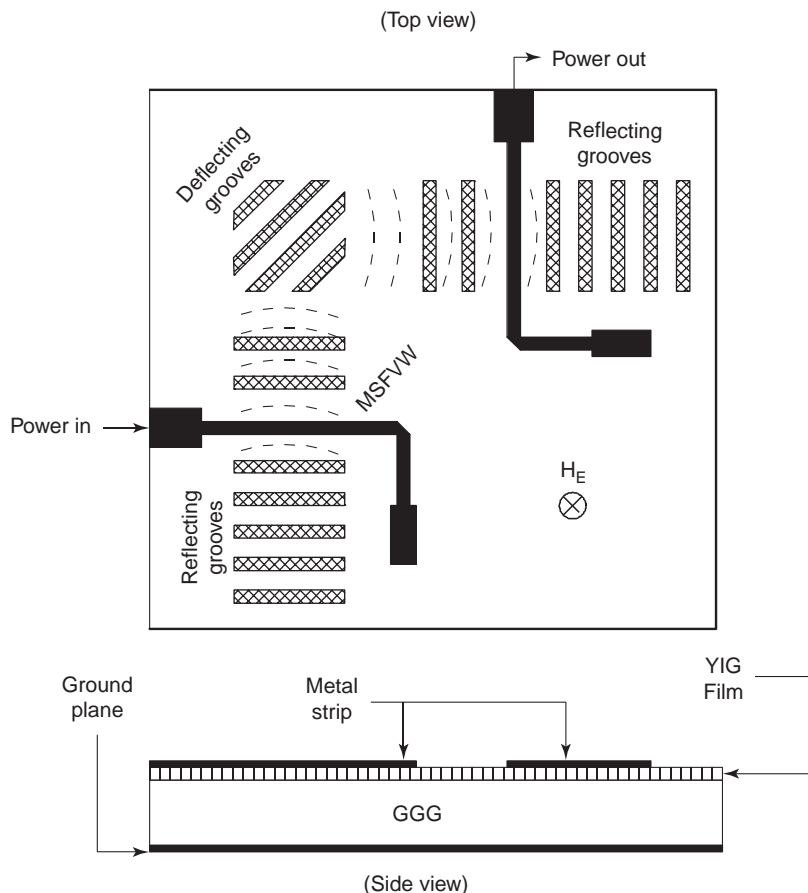

Figure 26. Schematic showing the configuration of an MSFVW resonator. Two cavities are placed at a 90° angle, and are coupled via MSFVWs passing through an obliquely oriented groove grating array. The bias field is applied perpendicular to the YIG film plane.

and stripline configurations [60]. We will discuss here the limiter operation using a single-crystal YIG film arranged in the configuration shown in Fig. 3 of Section 1, except that a meander line is normally used instead of a straight microstrip line. Also, a thick YIG film is preferred, because it implies an abundant spin-wave spectrum allowing the guided electromagnetic waves to react sufficiently with spin waves to induce instability at high power. All types of ferrite frequency-selective limiters operate analogously; when a transmission line is loaded with a ferrite element, the transmitted power cannot exceed a threshold value beyond which catastrophic energy transfer occurs between the guided RF electromagnetic fields and the spin precessional motion. This phenomenon has been discussed in Section 1, and it is generally known as the *Suhl spin-wave instability* [13]. Parallel pumping instability is irrelevant, since it requires the RF magnetic field to be applied parallel to the applied DC field direction, and this is not the case here.

Figure 29 depicts a simple picture explaining the operation of frequency-selective power limiter. As shown at the top left of Fig. 29, the relationship between the input power P_{in} and the output power P_{out} is roughly linear only when P_{in} is smaller than P_{th} , the threshold power. When P_{in} is larger than P_{th} , we observe that P_{out} becomes gradually saturated at P_s , and the excess power, $P_{in} - P_{out}$, couples into spin-wave motion to be ultimately converted

into lattice vibration, and hence dissipated as heat. Thus, when P_{in} is given as a function of frequency, as shown at the bottom left of Fig. 29, the excess power of $P_{in} - P_{th}$ will be removed by the limiter and the resultant output characteristic will be as shown at the top right of Fig. 29. We note that Fig. 29 shows only an idealized operation. In reality, the P_s level shown in the P_{out}/P_{in} diagram is not a constant; it increases slightly with P_{in} when P_{in} exceeds P_{th} . As such, instead of showing chopped-head peaks, the output will consist of rounded-head transmission peaks in the P_{out}/P_{in} diagram shown in Fig. 29.

As an example, in Ref. 61 a 57- μm -thick YIG film was coupled to a 25- μm -wide microstrip meander line of characteristic impedance 50 Ω fabricated on a high-dielectric-constant substrate. This limiter, which operated in the 2–4 GHz range showed a limiting range of 25 dB, a threshold input power level of 0 dBm, and a small-signal loss of 7 dB. The upper frequency limit was not sharply defined, since the limiting power decreased with increasing frequency, but operation up to 8 GHz is possible with this device.

The failure of the limiter device reported by Stizer and Goldie [61] to operate at high frequencies can be explained in terms of the onset condition giving rise to Suhl's spin-wave instabilities. As discussed in Section 1, Suhl's first-order instability occurs for spin waves possessing a frequency equal to half the applied RF frequency. Thus, above 8 GHz, the instability will occur in spin waves of

Figure 27. Schematic showing the configuration of a two-port MSW straight-edge resonator. The bias field can be applied perpendicular to the microstrip transducers in the YIG film plane, or perpendicular to the YIG film plane for MSFVW or MSSW operation, respectively.

Figure 28. Schematic showing the configuration of a one-port MSW groove-free resonator. The bias field can be applied either perpendicular to the microstrip transducer in the YIG film plane, or perpendicular to the YIG film plane for MSFVW or MSSW operation, respectively.

frequencies exceeding 4 GHz, which are located above the spin-wave manifold extending the frequency range from 2 to 4 GHz. The second-order spin wave instability, which involves spin waves of the same frequency as the applied RF signals, has a higher threshold and is not used in frequency-selective power limiters. Thus, a power limiter is operational only when half the applied frequency falls within the spin-wave manifold region bounded by the two frequencies ω_1 and ω_2 shown in Fig. 1. Since ω_1 and ω_2 can be tuned by varying the applied field strength, the limiter is therefore termed a *frequency-selective device*.

7.2. Signal-to-Noise Enhancers

Epitaxially grown single-crystal YIG films have been used to fabricate frequency-selective limiters and signal-to-noise enhancers. Although the construction of these two devices is very similar, as shown in Fig. 3, they perform opposite signal processing functions. The limiter presents low attenuation to low-intensity signals and high attenuation to high-intensity signals while the signal-to-noise enhancer attenuates weak signal more severely than strong signals. However, the major difference results from the origin of nonlinearities admitting the operation of these two devices. For a limiter the nonlinear coupling is related to the onset of spin-wave instabilities, whereas the nonlinear behavior of a signal-to-noise enhancer comes from the generation of magnetostatic waves (MSWs). The occurrence of the latter is at a power level much lower than that of the former.

Although a power limiter and a signal-to-noise enhancer are constructed using a configuration similar to that shown in Fig. 3, they are operational under different

physical principles. While the former device requires the insertion loss to increase with input power, the latter requires the insertion loss to decrease with input power. A power limiter circuit will couple most efficiently with spin waves, whereas a signal-to-noise enhancer will avoid this by operating at a frequency ω so that $\omega/2$ is located well beyond the spin-wave manifold region. On the contrary, a signal-to-noise enhancer will couple tightly with magnetostatic waves, for example, MSSW, while for a power limiter this is seldom the case. As a result, meander lines are commonly used in power limiter circuits.

Let us examine the configuration of Fig. 3. Here we assume that the biasing magnetic field is applied parallel to the microstrip direction such that MSSWs are excited propagating perpendicular to the strip. Since the generation of MSSW in this configuration is very efficient, the input RF power is almost entirely consumed for the generation of MSSWs at low input-power levels. However, as the input power increases, the amplitudes of MSSWs increase accordingly until reaching saturation beyond which no more conversion into MSSWs is appreciable. Figure 30 shows that P_{MSSW} increases with the input power P_{in} linearly in the initial region but saturates at large P_{in} . The functional dependence of P_{MSSW} is similar to that of the output power from a limiter device shown in Fig. 29. The output power from the signal-to-noise enhancer is $P_{\text{in}} - P_{\text{MSSW}}$, which is shown as the heavy line in Fig. 30. Thus, from Fig. 30 we conclude that low-intensity signals will be damped more by the generation of MSSWs than high-intensity signals.

The top diagram in Fig. 31 shows the power spectrum output from a signal-to-noise enhancer device based on the input spectrum shown at the bottom of the figure. It is seen in Fig. 30 that noises, appearing at low power levels, are damped out, leaving alone the high-level signals with improved signal-to-noise ratio. Again, Fig. 30 shows an idealized situation in which P_s does not depend on the

Figure 30. The relationship between the input power P_{in} and the output power P_{out} of a signal-to-noise enhancer. The converted MSSW power P_{MSSW} is also shown, and $P_{\text{out}} = P_{\text{in}} - P_{\text{MSSW}}$.

Figure 31. The input power spectrum, bottom, and the output power spectrum, top, applied to and transmitted from a signal-to-noise enhancer, respectively.

input power level P_{in} . In reality P_s will increase slightly with P_{in} when saturation is approached. As an example, Adam and Stizer [62] show a signal-to-noise enhancer device centered at 3.3 GHz with a bandwidth of 800 MHz that exhibited 16 dB less attenuation when the input power increased from -6 to $+10$ dBm.

7.3. Amplitude Correctors

For signal processing at microwave frequencies broadband amplifiers are needed whose characteristics are desired to show linear dependence on the amplitude of the input signals. However, for most power amplifiers including microwave traveling-wave tubes (TWTs), the amplification is deteriorated at high power, resulting in reduced power amplification for high-power input signals. One possible way to resolve this problem is to compensate the input power with a corrector that attenuates more input power at low input power levels. This is exactly the same characteristic that we have discussed for a signal-to-noise enhancer, and, hence, it can be equally used as an amplitude corrector device. It was shown [63] that an amplitude corrector operated at 3 GHz with low and high signal suppression level of 4.2 and 1 dB, respectively, and the threshold power level was 100 mW. This device was equipped with an O-type TWT operating from 2.5 to 3.6 GHz, and corrected output characteristics have thus been obtained.

7.4. Nonlinear Ferrimagnetic Echoing Devices

Echo phenomena are characterized by reradiation of the input signals stored in a nonlinear system through the agitation of a consequently applied pump pulse. Observation of ferrimagnetic echoes was first reported in 1965 by Kaplan in polycrystalline YIG samples [64]. Amplified echoes were thereafter reported in cylinders and truncated spheres of YIG crystals [65] and in single-crystal YIG films [66]. Echo experiments offer a possibility of a novel approach to performing important signal processing functions, such as nondispersive time delay and pulse correlation in the frequency range below 10 GHz. Within the demand of electronic technology advances there is now a

renewed interest in the use of ferrimagnetic echoing devices.

Among many nonlinear systems capable of producing an echoed signal (e.g., cyclotron echo, plasma echo, molecular echo, phonon echo, and spin echo), only ferrimagnetic echo can show amplification. This feature renders the ferrimagnetic echo phenomena in a very unique position for device applications. Ferrimagnetic echo is concerned mainly with the reservoir of the electron spin system provided by a YIG crystal that is nearly the perfect medium for signal storage. Thus, in view of the extremely narrow FMR linewidth (0.3 Oe at X band) the damping action accompanying the spin motion in the YIG crystal is very small; once the spins are put in motion, they will continue the motion indefinitely in time exhibiting very little attenuation. The lifetime of the magnons in a YIG crystal is very long, usually exceeding $1\ \mu\text{s}$. Ferrimagnetic echo signals are shown at the top of Fig. 6 in conjunction with intermodulation signals shown at bottom that are induced by a ferrite junction when excited at high power. We imagine that at the time instant $t = -\tau$ a signal pulse is applied to the YIG crystal setting the spins in precessional motion. Before the spin motion damps out, a pump pulse is applied at the time instant $t = 0$, which is so intense that nonlinear interaction is aroused in the spin system. Due to the (odd) cubic nature of the interaction, the process of time conjugation is recalled, which reverses the timescale for the stored signal such that the spins begin to precess in the opposite direction. As a consequence, at time $t = \tau$ ($\leq 1\ \mu\text{s}$) the original signal pulse recovers, which appears as the image, or replica, of the original signal echoed back by the pump pulse (see Fig. 6, the top diagram).

However, we must emphasize that if the cubic interaction is local in nature, no amplification is possible for the echoed signals, as occurs in the other nonlinear systems involving only isolated echoing sites. For ferrimagnetic echo the nonlinear interaction is brought about by the dipolar field interacting with the nonlocal spin waves showing a long-range dependence (this nonlocal interaction can be described in terms of a Green function whose kernel shows a $1/r$ dependence [25,26], see Eq. (100) below). As such, the echoed signal can show amplification, receiving power from the pump pulse not only to duplicate the signal waveform to result in an echo but also to amplify the echoed signal to high intensity. The amplification gain can be as large as 100, as measured experimentally [64] and calculated theoretically [25,26].

Ferrimagnetic echo experiments are carried out using crystal YIG bulk or thin-film materials in the presence of a high-magnetic-field gradient ($\approx 1\ \text{kOe/cm}$). In order to obtain high amplification gain, the YIG material needs to be clamped between two polycrystalline poles to effectively suppress the demagnetizing field. Theoretically it has been demonstrated that the DC demagnetizing field has adverse effect in reducing the echo gain to zero [25,26]. This result is consistent with Suhl's finding [13] that the DC demagnetizing field is apt to enhance spin-wave instability resulting in subsidiary absorption during microwave resonance measurements.

Finally, we want to point out the similarities between the ferrimagnetic echo signals and the intermodulation

noise observed in a ferrite circulator junction [24]. As shown at bottom of Fig. 6, two RF signals at adjacent frequencies f_1 and f_2 will couple each other to form intermodulation noises at frequencies $2f_1 - f_2$ and $2f_2 - f_1$. Intermodulation signals grow rapidly with power, which may be identified as clicking noises in a telephone line. Actually, both the echoing signals and the intermodulation noises are generated through the same cubic interaction terms in the equation of motion, Eq. (64). The only difference is that echo is a phenomenon in the time domain, whereas intermodulation is manifested in the frequency domain. While the DC demagnetizing field has been shown to have adverse effects in influencing the echo gain in the time domain, it has also been demonstrated that the same demagnetizing field will enhance the intermodulation level in a circulator junction [24]. Therefore, the DC demagnetizing field needs to be suppressed or minimized in nonlinear studies of ferrites applied at high power concerning the phenomena of spin-wave instabilities, the echo gain, and the intermodulation noise.

8. MAGNETIC SOLITONS

It is widely recognized that the study of nonlinear equations and their solutions is of great importance in many areas of physics. Of particular importance are nonlinear wave equations that admit large-amplitude solitary wave or soliton solutions that retain their shape during propagation. Such solutions have received considerable attention by elementary particle physicists since they may be regarded as extended particle-like solutions of nonlinear field equations. The study of solitary waves has proved fruitful in many areas of condensed-matter physics as well, for example, in theories of Bloch walls that separate domains in magnetic materials [3], structural phase transitions [67], liquid helium ^3He [68], 2D fluxons in Josephson weak-link junction [69], and low-temperature charge density wave condensates [70]. Engineering applications prefer solitonlike wavepackets or pulses to be formed in materials allowing the carried information to be transmitted over long distance without experiencing much attenuation and dispersion, such as for the study of optical [71] and microwave [72] magnetic envelope solitons. In this section Bloch wall solitons and magnetic microwave envelope solitons, referred to in general as *magnetic solitons*, are briefly introduced.

The first documented observation of the solitary wave was made in 1834 by the Scottish scientist John Scott Russell [73]. While observing the movement of a canal barge, Scott Russell noticed a novel type of water wave on the surface of the canal, in the form of a long bell-shaped wave that emerged and traveled down the channel—it did not cause rippling of the water, instead it remained stable and localized without change of waveform and diminution of speed over a distance about 2 miles in propagation. This type of water wave is now known as KdV solitons, short-named for Kortweg and de Vries, who first successfully demonstrated the underlying mathematical solutions in 1895. The other two well-known soliton systems are associated with the sine Gordon and the nonlinear Schrödinger

equations, describing the kinetics and dynamics of magnetic Bloch walls and microwave magnetic envelope solitons, respectively, discussed in the section.

In a nonlinear system that admits soliton-like solutions, two kinds of elementary excitations are possible: (1) particles with a finite amplitude in excitation called soliton/antisoliton, or bright/dark solitons, which possesses a finite mass; and (2) massless particles, with an infinitesimal excitation amplitude, called quasiparticles. Examples of solitons/antisolitons are electrons/positrons, and so forth, and quasiparticles are phonons, magnons, photons. Solitons and anti-solitons are topological entities, sometimes called “kinks”, whose waveform shapes are self-balanced so that dispersion imposed by the wave equation cancels exactly the nonlinear contribution from the amplitude of wave excitation. Thus, solitons and antisolitons carry shape integrity along with their motion, retaining their respective waveform shapes after the collision processes, similar to those massive particles observed in the physical world. Furthermore, like particles and antiparticles, a soliton can collide with an antisoliton, resulting in pair annihilation, ending up with radiations in the form of massless particles. Although losses can be readily added to the system, they will not affect the waveform shapes of solitons and antisolitons. Rather, the added loss terms in the equation of motion can merely introduce damping forces impeding the particles’ mobility in their kinetic motion. At a given temperature the thermodynamic quantities of the system, which describe the equilibrium states of solitons/antisolitons and the massless particles, can all be calculated, and phase transition can result at a Currie temperature in a manner analogous to that induced by soft-phonon/displacive modes, as described in Ref. 67. The following section describes domain wall solitons and microwave envelope solitons.

8.1. Magnetic Bloch Wall Soliton

A Bloch wall defines a magnetic transition layer that separates two magnetic domains of opposite magnetization. That is, inside a magnetic Bloch wall the magnetization vector reverses its direction undergoing 180° in-plane rotation in a manner so as to minimize the total free energy imposed by the uniaxial anisotropy and the exchange terms defined for H_A and H_E , respectively, following Eq. (18). Besides Bloch walls, the process of magnetization reversal can also take place by assuming 180° out-of-plane rotation, giving rise to Neel walls, which are not discussed in this section. After applying the Lagrangian equation utilizing the energy densities given by Eq. (15), one obtains the following equation governing the dynamic motion of a magnetic Bloch wall [3]

$$\begin{aligned} \frac{\partial^2 \Psi}{\partial t^2} + \sin \Psi - \frac{\partial^2 \Psi}{\partial x^2} = -f \sin \frac{\Psi}{2} - \Gamma \frac{\partial \Psi}{\partial t} \\ + B \left[\cos \frac{\Psi}{2} \frac{\partial^2 R_y}{\partial x \partial t} + \sin \frac{\Psi}{2} \frac{\partial^2 R_z}{\partial x \partial t} \right] \end{aligned} \quad (97)$$

where ψ denotes twice the azimuthal angle of the magnetization vector swinging away from the easy axis, the z

axis, and R_y and R_z are the y and z components of the displacement fields. In Eq. (97) f , Γ , and B are dimensionless parameters characterizing the magnitudes of the other coupling terms, including the external driving force (the Zeeman field), the Gilbert damping term, and the magnetoelastic constant of the medium, respectively. Here, x denotes the direction normal to the Bloch wall surface. In Eq. (97) the right-hand-side (RHS) terms may be treated as perturbations to the left-hand-side (LHS) terms, which renders the original sine-Gordon equation, describing and defining the unperturbed profile, kinetics, and dynamics of magnetic Bloch wall solitons/anti-solitons. Namely, the first term is associated with the kinetic energy of a sine-Gordon soliton (of a unified mass or inertia), and the second and the third terms are potential energies, arising from the uniaxial anisotropy, and the normalized exchange interaction, respectively. The effects of external magnetic driving f , the Gilbert damping Γ , and the magnetoelastic coupling B in influencing the soliton’s profile and its subsequent motion can thus be calculated [3]. A stability analysis on the mobility of a Bloch wall soliton/anti-soliton has also been performed in Ref. 3, discussed in conjunction with Slonzewski’s formula, which assumed the low-magnetization limits.

8.2. Magnetic Microwave Envelope Soliton

In the absence of an externally applied RF signal field the resultant equation of motion up to the third order in RF magnetization \mathbf{m} is, from Eq. (9)

$$\frac{d\mathbf{m}}{dt} = \gamma \mathbf{e}_z \times \left[H_0 \mathbf{m} - \left(M_s - \frac{\mathbf{m} \cdot \mathbf{m}}{2M_s} \right) \mathbf{h}_d - \left(\frac{2A}{M_s} \right) \nabla^2 \mathbf{m} + \frac{\lambda}{\gamma} \frac{d\mathbf{m}}{dt} \right], \quad (98)$$

where H_0 denotes the externally applied DC magnetic field normalized with respect to M_s , the saturation magnetization, and A and λ denote the exchange stiffness and Gilbert damping constant introduced following Eq. (18), respectively; the nonlinear term comes from Eq. (46) assuming large excursion angle of the magnetization vector away from the z axis, the applied field direction. In Eq. (98) \mathbf{h}_d denotes the dipole field induced by the rf-magnetization \mathbf{m} , all normalized with respect to M_s . Assuming the magnetostatic limit, the relationship between \mathbf{h}_d and \mathbf{m} is specified by Eq. (24). Or

$$\mathbf{h}_d = (1/\mu_0) \nabla \mathfrak{C} \nabla \cdot \mathbf{m} \quad (99)$$

where the Green function operator \mathfrak{C} is defined, upon operation on a regular function $f(\mathbf{r})$ as

$$\mathfrak{C}f(\mathbf{r}) = \int_{\text{all space}} d^3\mathbf{r}' \frac{1}{|\mathbf{r} - \mathbf{r}'|} f(\mathbf{r}') \quad (100)$$

which represents the nonlocal effect characteristics of a dipole field [25,26]. However, if one insists on a local approximation enforcing the dipole field to be equal to the rf

magnetization, or

$$\mathbf{h}_d = (1/\mu_0) \mathbf{m} \quad (101)$$

Eq. (98) becomes

$$\frac{d\phi}{dt} = -j\gamma \left[H_o \phi - \frac{M_S}{\mu_0} \left(1 - \frac{|\phi|^2}{2} \right) \phi - \frac{2A}{M_S} \nabla^2 \phi + \frac{\lambda}{\gamma} \frac{d\phi}{dt} \right], \quad (102)$$

where

$$\phi = (m_x - jm_y)/M_S \quad (103)$$

denotes the (normalized) circularly polarization field. From Eq. (102) one recognizes immediately the (damped) nonlinear Schrödinger equation [73], which admits solutions for microwave magnetic envelope solitons whose existence has been reported by various authors [74–76].

Although we have derived the desired equation of motion characteristic of microwave magnetic envelope solitons [Eq. (102)], caution is needed regarding use of the nonlinear term that was derived on the basis of the local assumption of the dipole field, Eq. (101), which was proposed intuitively without justification. Actually the same local assumption, Eq. (101), was used by Hermann in formulating the ferrimagnetic echo-gain calculations [77]. Although Hermann was able to predict the existence of ferrimagnetic echos, the calculated echo gain factors were two orders smaller than actually measured [64,65], indicating the insufficiency or inadequacy of the local dipole field assumption, Eq. (104). As such, Eq. (102) can pose only limited value; it at best leads to heuristic conclusions that in Eq. (102) the cubic interaction term, due to the large excursion angle of spins performing precessional motion, and dispersion, due to the exchange coupling among spins, constitute the two necessary ingredients for the generation of solitonlike solutions coincident with the nonlinear Schrödinger equation under the very crude assumptions. Only after the nonlocal nature of the dipole field rigorously treated in the equation of motion, can the formulation predict reliable results, Eqs. (99) and (100). Also, Eq. (98) assumes an infinite system for which the boundary conditions have been ignored. In real measurements finite samples such as single-crystal YIG films are normally used in conjunction with the microstrip launcher circuits shown in Fig. 24. As such, boundary conditions need to be included and the demagnetizing field effects to be explicitly considered [Eq. (66)]. The demagnetizing field has been found effective in triggering profound processes in ferrite samples undergoing high-power excitations, as observed in ferrimagnetic echo, intermodulation, and stabilities measurements. More work in these areas is needed.

Two different types of envelope solitons, bright solitons and dark solitons, or solitons and antisolitons, can propagate in nonlinear waveguiding dispersive media. Bright and dark solitons may be classified as dynamical and topological, respectively. The term “dynamical” for bright

solitons means that these pulses are essentially nonlinear wavepackets for which the carrier signal maintains a constant phase over the pulse. The term “topological” denotes the fact that the passage of a single dark soliton modifies the medium or the medium response in some critical way. “Dark envelope” solitons may be described in terms of a carrier signal of constant amplitude that has a dip in amplitude at the soliton position. If this dip goes completely to zero, one has a black soliton. If the minimum power at the dip is nonzero, one has a gray soliton. Dark envelope solitons have a nonzero jump in phase for the carrier signal as one crosses the dip. In the case of black solitons, this jump in phase is exactly 180° .

Observation of self-generated bright and dark microwave magnetic envelope solitons in ferrite films can be found in Refs. 75 and 76, respectively. Interaction between microwave magnetic envelope solitons and between microwave magnetic envelope solitons and continuous magnetostatic waves can be found in Refs. 74 and 78, respectively. Before ending this section, we note that it was generally observed that formulation, propagation, and decay of microwave magnetic envelope solitons were always accompanied by the generation of high-wavenumber spin waves, indicating that the equation of motion of the system is more involved than described by the simple nonlinear Schrödinger equation, Eq. (102), which allows for isolation of stable clean solitons and continuous waves. Thus, a complete description of the nonlinear spin system has to recruit the long-range dipole field, Eqs. (99) and (100), not only to faithfully describe soliton behaviors but also to understand interactions between themselves and between themselves and continuous waves, including the scattering processes involving three magnons and the resultant (modulation) instabilities of the system. These areas are discussed further in Refs. 79–81.

9. MAGNETOOPTIC DEVICES

At optical frequencies the Polder permeability tensor of a ferrite specimen is nearly isotropic with the diagonal element $\mu \approx 1$ and off-diagonal element $\kappa \approx 10^{-5}$, as can be calculated from Eqs. (11) and (12). Although small, the resultant magnetic anisotropy or gyrotropy can be measured using a laser optical beam. On incidence, the reflected and the transmitted beams will carry the magnetization information of the specimen, resulting in not only a rotation in polarization but also a change in reflectivity and transmission. These are called *magneto-optic Kerr* and *Faraday effects* for reflection and transmission measurements, respectively. Kerr and Faraday effects have been used in observing the dynamic processes of domain wall motion in a ferromagnetic metal or a ferrimagnetic insulator sample, respectively [82].

The most important devices utilizing magneto-optic coupling for electronic signal processing applications concern the scattering process between photons and magnons. This process is called *Bragg diffraction*, where in a ferrimagnetic medium a photon of momentum \mathbf{P} is scattered by a magnon of momentum \mathbf{k} , resulting in a photon of momentum $\mathbf{P} + \mathbf{k}$. This interaction is second order in

nature and is described a term of $\gamma\mu_0 \mathbf{m}_k \times \mathbf{h}_P$ included with the right hand side of Eq. (7). Here \mathbf{m}_k denotes the magnetization field of the magnon and \mathbf{h}_P is the magnetic field of the photon. As such, the photon wave is said to be modulated by the magnetization wave, carrying along with it the electronic information after scattering. Because of the nature of a second-order interaction, Bragg diffraction between photons and magnons, or MSWs in a magnetic film, is not very prominent, and only about 4% light diffraction was observed experimentally with a 7-mm interaction length for MSSW excitations approaching saturation [83].

Optical techniques are being increasingly utilized to meet the ever-growing data rate requirements of signal processing and communication applications. A key element to such applications has been acoustooptic modulators based on Bragg diffraction between photons and phonons. A large time–bandwidth product (TBW; i.e., time delay of acoustic signal in traversing the optical beam times signal bandwidth) is usually desirable. However, acoustic waves cannot be efficiently excited at frequencies above 2 GHz. Instead, magneto-optic devices offer the potential of large TBW modulation directly at microwave frequencies. The diffraction of guided optical waves by MSW is analogous to optical diffraction by a SAW and has the potential to enhance a wide variety of integrated optical applications such as spectrum analyzer, optical filters, deflectors, switches, and convolvers.

The basic theories of the MSW–optical interaction, including the development of expressions for optical diffraction efficiency and coupling factor as a function of the MSW power and other relevant parameters, has been derived by Fisher [83]. The theory applies to the collinear configuration, shown in Fig. 32, with the MSW traveling in a direction parallel or antiparallel to the optical beam, as well as to the transverse configuration, shown in Fig. 33, where the MSW travels at a 90° angle to the optical beam. In Figs. 32 and 33 prisms are used to guide optical beams onto the YIG layers that are transparent

Figure 32. Collinear configuration with codirectional MSW and optical beams. Due to Bragg diffraction between the optical beam and the MSWs, the original TM guided optical beam is scattered into a TE beam with deflected angle of propagation.

Figure 33. Transverse configuration for MSW and optical beams. Bragg diffraction of the guided optical wave by an MSW induces conversion between orthogonally polarized optical modes.

to lightwave propagation. In Figs. 32 and 33 the MSW configuration may be replaced by the superstrate structure shown in Fig. 3. To achieve good optical properties, the YIG film is usually highly doped, mainly by bismuth. As such, Bragg diffraction of guided optical waves by MSSWs and MSFVWs has been demonstrated in the configurations shown in Figs. 32 and 33, and the conversions between TE and TM modes have been experimentally observed from 1 to 6.5 GHz [83].

In experimental solid-state physics photons are used as instrumentation tools to probe the phonon spectra in solids. This is termed *Brillouin light scattering*. Analogously, Brillouin light scattering can be applied to a ferrite sample to study the magnon or spin-wave spectrum in the presence of solitons as well as to investigate the role of spin waves at the onset of instabilities [84,85]. In a ferrite a photon can create or absorb a magnon. The photon will be scattered in the process; its wavevector will change from \mathbf{k} to \mathbf{k}' and its frequency from ω to ω' . Suppose a magnon is created with a wavevector \mathbf{K} and angular frequency Ω . The kinematics of the collision or scattering event are simple. According to the conservation of energy

$$\omega = \omega' + \Omega \tag{104}$$

and per the wavevector selection rule

$$\mathbf{k} = \mathbf{k}' + \mathbf{K} \tag{105}$$

where, for simplicity, we do not include the possibility that the scattering may be combined with a Bragg diffraction involving a reciprocal lattice vector of the crystalline structure of a ferrite crystal. When ω , ω' , \mathbf{k} , and \mathbf{k}' are known, Ω and \mathbf{K} can thus be determined.

In conclusion, MSW optical devices are currently in an early stage of development, and their basic feasibility has been demonstrated. However, they are expected to lead to a variety of high-performance integrated optical signal processing devices.

10. ANTIREFLECTION LAYERS AND ABSORBING LAYERS

To date microwave or millimeter-wave antireflection layers and absorbing layers are almost exclusively used for radome design applications. Because of the highly classified nature of this topic, not much data have been published in the literature. In this section we discuss only the concepts that lead to the construction of microwave or millimeter-wave antireflection and absorbing layers. No explicit design parameters are given here. By definition, an antireflection/absorbing layer is placed on top of a substrate such that an incident microwave or millimeter-wave beam will be totally transmitted/absorbed when passing across the layer without causing reflection. The layer should be functional over a frequency range as broad as possible to be independent of the incident angle and polarization of the incident beam.

To realize the design of an antireflection layer, we consider first the case of normal incidence of the incident beam. According to the transmission-line theory, one concludes immediately that the first-order solution would require the layer to behave like a quarter-wave transformer. This implies that the layer shall possess a thickness equal to one quarter the wavelength with a characteristic impedance

$$Z_L = (Z_0 Z_S)^{1/2} \quad (106)$$

where

$$Z_0 = \left(\frac{\mu_0}{\epsilon_0} \right)^{1/2} \quad (107)$$

$$Z_S = \left(\frac{\mu_S}{\epsilon_S} \right)^{1/2} \quad (108)$$

where Z_0 (Z_S) is the characteristic impedance of air (substrate) and ϵ_0 (ϵ_S) and μ_0 (μ_S) are the permittivity and permeability of air (substrate), respectively. When broader bandwidth is desired, higher-order solutions are required, and this results in a multilayer system with progressively changing electromagnetic parameters matching the impedance difference between air and substrate.

For an absorbing layer design the air impedance can also be matched by a multilayer system with progressively increasing damping parameters such that the series of the layers satisfies the transformer matching requirement. Thus, we use the same impedance transformer theory for the design of absorbing layers, except that the impedances of the layers are now complex numbers, since the permittivity and permeability of the layers are complex numbers. As such, the incident wave damps out when it passes through the layer system before arriving at the substrate.

When oblique-angle incidence is considered, the impedance transformer theory can be generalized using the transfer matrix technique [41,86]. The present problem is to determine an optimal layer system design allowing for polarization independent operation over a frequency band and angle range on beam incidence as broad as possible. Also, the design task is subject to a very important constraint requiring the thickness of the layers to be

minimal, since at microwave and/or millimeter frequencies a practical layer system should be thin enough compared to the wavelength of the waves propagating in air. The design is in general not a trivial problem, and efficient computer algorithms are needed.

Once an optimal multilayer system is determined, the remaining task is to synthesize it using real materials. Unfortunately, nature does not provide general materials covering the whole range of electromagnetic parameters. Instead, artificial materials need to be developed. The first kind of artificial materials include particle composites where dielectric particles [87], metal-shelled particles [88], ferrite particles [89,90], and graphite powders are embedded in a matrix epoxy such that the effective permittivity, permeability, and/or conductivity of the composite can be controlled over the desired frequency band by adjusting the mixing fraction of the particles.

The second class of artificial materials is quite new; it involves periodic patterns of metal strips or grooves (surface relief gratings) to be fabricated on top of a layer surface. In fact, when electromagnetic waves interact with periodic structures much finer than the wavelength, they do not diffract, but instead reflect and transmit as if they were encountering a nonstructured medium. Effective field theory describes the interaction between electromagnetic waves and such subwavelength structures by representing a region of subwavelength heterogeneity in terms of a homogeneous material possessing a single set of effective electromagnetic parameters: permittivity, permeability, and conductivity [91]. Actually, the antireflection structures consisting of surface relief gratings can be found on the cornea of certain night-flying moths, and the first scientists to investigate antireflection-structured surfaces for application in the visible or near-infrared portion of the spectrum worked to replicate moth eye surfaces [92].

Antireflection means establishing a resonant structure on the substrate surface that is able to “capture” the incident electromagnetic signal forming standing modes so as to dissipate the captured energy, converting it into heat before it reaches the substrate. In this sense an antireflection layer is a sheet of absorbent. Two kinds of resonant structures are possible. Standing modes can be formed along the propagation direction, or the longitudinal direction, of the signal by constructing a quarter-wave transformer [Eq. (106)] or a transformer of high order, as discussed previously. Alternatively, standing modes can be formed along the transverse directions. For example, metal patches or meshes of a diameter equal to one-half the wavelength of the incident electromagnetic waves can be deployed in front of the substrate surface accompanied by an dissipation layer responsible for wave damping. Multiple antireflection layers can be stacked together to jointly capture and damp a broadband signal, thereby realizing the broadband operation.

MAGNETIC RESONANCE IMAGING

ANDREW WEBB
 University of Illinois at
 Urbana–Champaign
 Urbana, Illinois

1. INTRODUCTION

Magnetic resonance imaging (MRI) is one of the major radiological diagnostic modalities in the clinic. More than 20 million exams per year are carried out in the United States alone. A large number of academic and commercial laboratories are involved in the development of new hardware, data processing algorithms and applications. Studies can be performed on size scales ranging from humans to single neurons. One factor linking many of the most recent developments in MRI is the trend towards higher static magnetic fields. Higher fields provide many benefits, which will be outlined in this article, but also present considerable challenges in engineering design. Since the “operating frequency” of the system and associated hardware is proportional to the strength of the static magnetic field, high-frequency analysis of system design, as well as the interactions between electromagnetic radiation and the human body are increasingly important areas of research. As shown in Fig. 1, MRI now spans almost the entire radiofrequency spectrum.

The MRI signal arises from protons in the body, primarily water but also lipid. The patient is placed inside a superconducting magnet, which produces a static magnetic field several tens of thousands times stronger than Earth’s magnetic field. Each proton, which is a charged particle with angular momentum, can be considered as acting as a small magnet. The protons align in two configurations, with their magnetic fields aligned either parallel or antiparallel to the direction of the large static magnetic field, with slightly more found in the parallel state. The protons precess around the direction of the static magnetic field, analogously to a spinning gyroscope under the influence of gravity. The frequency of precession is proportional to the strength of the static magnetic field. Application of a weak radiofrequency (RF) field causes the

protons to precess coherently, and the sum of all the magnetic moments of the precessing protons is detected as an induced voltage in a tuned detector coil. Spatial information is encoded into an image using magnetic field gradients [1,2]. These impose a three-dimensional linear variation in the magnetic field present within the patient. As a result of these variations, the precessional frequencies of the protons depend on their position within the body. The frequency and phase of the precessing magnetization are detected by the RF coil, and the analog signal is digitized. An inverse two-dimensional Fourier transform is performed to convert the time-domain signal into the spatial domain to produce the image. By varying data acquisition parameters, differential contrast between soft tissues can be introduced into the image. Figure 2 shows a block diagram of an MRI system. Many of the subsystems are described in detail later in this article.

2. BASIC PRINCIPLES

For this article, only proton MRI will be considered, although useful spatial information from other nuclei such as ²³Na, ¹⁹F, and ³¹P can also be obtained. In proton MRI the signal comes essentially from the protons in water, with a minor component from those in fat. From a quantum mechanical standpoint, the proton possesses two nuclear energy levels, which correspond to the z component of the magnetic moment of the proton being aligned either parallel or antiparallel to the applied static magnetic field, as shown in Fig. 3.

The energy gap between the two energy levels is given by

$$\Delta E = \frac{\gamma \hbar B_0}{2\pi} \tag{1}$$

In order to stimulate transitions between the two energy levels, an oscillating magnetic field must be applied at a frequency ω , such that

$$\frac{\hbar \omega}{2\pi} = \frac{\gamma \hbar B_0}{2\pi} \Rightarrow \omega = \gamma B_0 \tag{2}$$

Figure 1. Operating frequencies of human and animal MRI systems. The corresponding static magnetic field strengths are given in tesla (T).

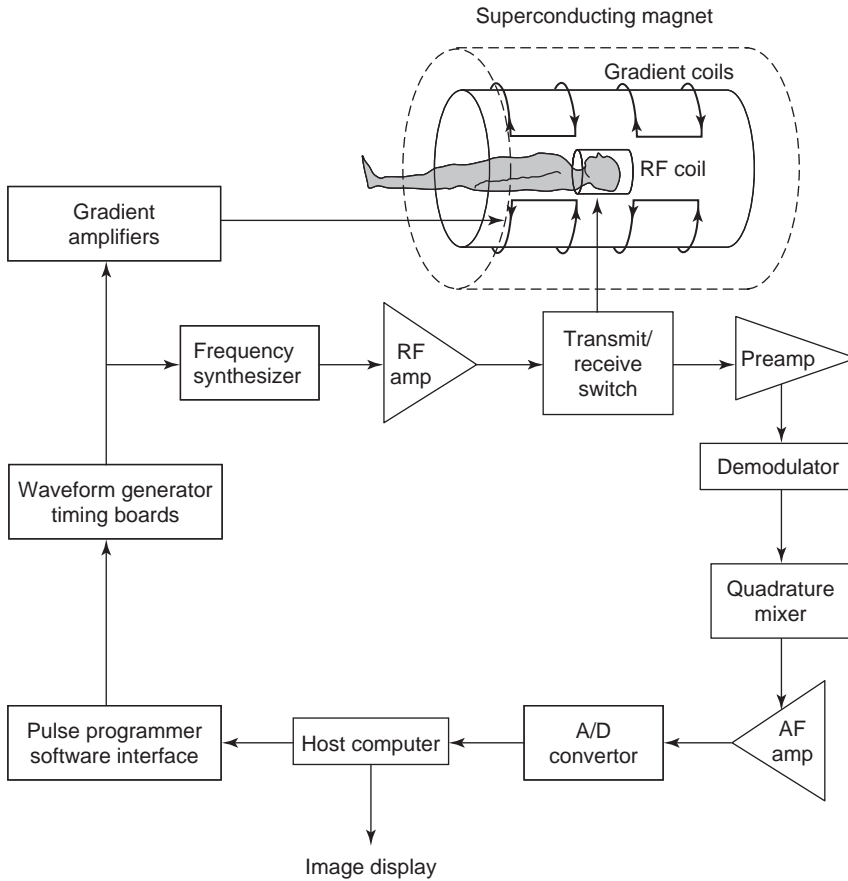

Figure 2. Block diagram of an MRI scanner.

The Boltzmann equation can be used to calculate the relative number of protons in each energy level

$$\frac{N_{\text{antiparallel}}}{N_{\text{parallel}}} = \exp - \left[\frac{\Delta E}{kT} \right] = \exp - \left[\frac{\gamma \hbar B_0}{2\pi kT} \right] \quad (3)$$

where k is the Boltzmann coefficient with a value of 1.38×10^{-23} J/K and T is the temperature measured in degrees Kelvin. Applying the approximation $e^{-x} \approx 1 - x$, we can calculate the net magnetization of the object as

$$M_0 = \frac{\gamma \hbar}{4\pi} (N_{\text{parallel}} - N_{\text{antiparallel}}) = \frac{\gamma^2 \hbar^2 B_0 N_s}{16\pi^2 kT} \quad (4)$$

Therefore, the higher the static magnetic field B_0 , the greater is the equilibrium magnetization, and, as will be seen later, the higher the MRI signal. It is also useful to consider, from a classical description, the motion of the individual magnetic moments. As derived in the previous section, the proton magnetic moment μ is aligned at an angle of 54.7° to the axis of the external magnetic field B_0 . This magnetic field attempts to align the proton magnetic moment parallel to the direction of B_0 , and this action creates a torque C , given by

$$\mathbf{C} = \mu \times \mathbf{B}_0 = i_N |\mu| |B_0| \sin \theta \quad (5)$$

where i_N is a unit vector normal to both μ and \mathbf{B}_0 . The result of the torque is that the proton precesses around the

axis of the magnetic field, keeping a constant angle between μ and \mathbf{B}_0 , at an angular frequency given by

$$\omega = \gamma B_0 \quad (6)$$

where B_0 is universally used to represent \mathbf{B}_0 . Classical mechanics, therefore, shows that the effect of placing a proton in a magnetic field is that it precesses around the axis of that field, at a frequency that is proportional to the strength of the magnetic field. This frequency is termed the *Larmor frequency*.

2.1. Application of a Radiofrequency Pulse

Although all of the protons precess around B_0 , they are randomly oriented around a cone, as shown in Fig. 4, and therefore the net magnetization is aligned along the $+z$ axis, that is, there is no transverse component. In order to create a transverse component, an oscillating electromagnetic field (B_1), linearly polarized in the x direction, is applied.

$$B_1 = \hat{x} B_{10} \cos \omega t = \frac{1}{2} B_{10} (\hat{x} \cos \omega t - \hat{y} \sin \omega t) + \frac{1}{2} B_{10} (\hat{x} \cos \omega t + \hat{y} \sin \omega t) \quad (7)$$

where B_{10} is the magnitude of the magnetic field. The right-hand side of Eq. (7) shows that the B_1 field consists

Figure 3. (a) Quantization of the magnitude of the z -component of a proton’s angular momentum means that the z component of the proton’s magnetic moment (μ_z) has two possible physical orientations, parallel and antiparallel, with respect to the direction of the main magnetic field—the value of the angle θ is 54.7° ; (b) in the absence of an external magnetic field, there is only one energy level. When an external magnetic field is present, “Zeeman” splitting results in two energy levels, with more protons occupying the lower energy level, corresponding to the proton magnetic moments being aligned parallel to the main magnetic field, than the higher energy level, corresponding to an antiparallel alignment.

of the sum of two rotating magnetic fields, one rotating clockwise and the other anticlockwise. It can be shown that only the clockwise rotating field interacts with the nuclear spins. Application of the B_1 field at the Larmor frequency rotates the net magnetization M_0 toward the y axis, creating a component of magnetization M_y , given by

$$M_y = M_0 \sin(\gamma B_1 \tau_{B1}) = M_0 \sin \alpha \tag{8}$$

where α is the excitation tip angle. This process of tipping the magnetization is shown in Fig. 4. After the RF pulse, the component of magnetization in the xy plane precesses around B_0 at the Larmor frequency.

2.2. Signal Detection

Signal detection involves placing an RF coil close to the sample. In its simplest form, this coil can be a single loop of wire. Faraday’s law states that, when the magnetic flux enclosed by a loop of wire changes with time, a current is produced in the loop, and a voltage is induced across the

ends of the loop. The induced voltage E is proportional to the negative of the time rate of change of the magnetic flux ($d\phi/dt$):

$$E \propto -\frac{d\phi}{dt} \tag{9}$$

The time-varying magnetic field produced by the precession of the magnetization vectors results in a voltage induced in the RF coil. The requirement for a time-varying magnetic flux is the reason why only precessing magnetization in the xy plane gives rise to an NMR signal; the z component does not precess and therefore produces no voltage. At higher strengths of the B_0 field, the protons precess at a higher frequency [Eq. (6)], and the value of $d\phi/dt$ increases. Therefore, higher magnetic fields produce higher signal not only because of greater nuclear polarizations [Eq. (4)] but also because of the higher voltage induced in the RF coil. Overall, we obtain

$$E \propto \frac{\gamma^2 h^2 B_0 N_s}{16\pi^2 kT} \gamma B_0 \sin \alpha \tag{10}$$

Figure 4. (a) Application of a B_1 field ($B_{1,x}$) along the x axis rotates the individual proton magnetic moments about the x axis toward the y axis; (c) After applying the B_1 field for a certain time duration, the “cone” of magnetic moments has been rotated by 90° (the magnetic moments continue to precess around the B_0 axis); (b,d) the vector model representations of the effect of the B_1 field. The initial longitudinal magnetization (M_z) has been rotated into the transverse plane and has been converted into transverse magnetization (M_y) along the y axis.

2.3. Relaxation

Each of the magnetization components M_z , M_x , and M_y must return to their thermal equilibrium values over time. The time evolutions of M_z , M_x , and M_y are characterized by the Bloch equations [3]

$$\begin{aligned} \frac{dM_x}{dt} &= \gamma M_y \left(B_0 - \frac{\omega}{\gamma} \right) - \frac{M_x}{T_2} \\ \frac{dM_y}{dt} &= \gamma M_z B_1 - \gamma M_x \left(B_0 - \frac{\omega}{\gamma} \right) - \frac{M_y}{T_2} \\ \frac{dM_z}{dt} &= -\gamma M_y B_1 - \frac{M_z - M_0}{T_1} \end{aligned} \quad (11)$$

where T_1 is the spin–lattice relaxation time and governs the z component of magnetization and T_2 is the spin–spin relaxation time governing the transverse component. In the well-known rotating reference frame—a frame of reference where the $x'y'$ axes rotate around B_0 at the Larmor frequency—simple expressions can be obtained for the time evolution of longitudinal and transverse magnetization:

$$M_z(t) = M_z(t=0) + [M_0 - M_z(t=0)](1 - e^{-t/T_1}) \quad (12)$$

$$M_y(t) = M_y(t=0)e^{-t/T_2} \quad (13)$$

$$M_x(t) = M_x(t=0)e^{-t/T_2}$$

As seen later in the article, image contrast depends strongly on the different T_1 and T_2 values for various tissues in the human body.

2.4. Magnetic Field Gradients

Three separate gradient coils are required to encode unambiguously the three spatial dimensions within the body. Since only the z component of the magnetic field interacts with the proton magnetic moments, it is the spatial variation in the z component of the magnetic field which is

important. Image reconstruction is simplified considerably if the magnetic field gradients are linear over the region to be imaged:

$$\frac{\partial B_z}{\partial z} = G_z \quad \frac{\partial B_z}{\partial x} = G_x \quad \frac{\partial B_z}{\partial y} = G_y \quad (14)$$

By convention, for human studies the z direction lies along the head-to-foot axis, the y axis corresponds to the vertical (spine-to-abdomen) direction, and the x axis extends from side to side. The gradient coils are designed (as discussed later in this article) such that there is no additional contribution to the static magnetic field at the isocenter ($z = 0$, $y = 0$, $x = 0$) of the magnet, which means that the magnetic field at this position is simply B_0 . If a gradient G_z is applied, the magnetic field B_z experienced by all nuclei with a common coordinate z is

$$B_z = B_0 + zG_z \quad (15)$$

where G_z has units of tesla (T) per meter or gauss (G) per centimeter (cm). The corresponding precessional frequencies (ω_z) of the protons, as a function of their position in z , is given by

$$\omega_z = \gamma B_z = \gamma(B_0 + zG_z) \quad (16)$$

In the rotating reference frame the precessional frequency is

$$\omega_z = \gamma zG_z \quad (17)$$

Analogous expressions can be obtained for the spatial dependence of the resonant frequencies in the presence of the x and y gradients.

The process of image formation can be broken down into three components: slice selection, phase encoding, and frequency encoding. Examples of common imaging sequences are shown in Fig. 5. In the gradient echo sequence the combination of a frequency-selective 90° pulse

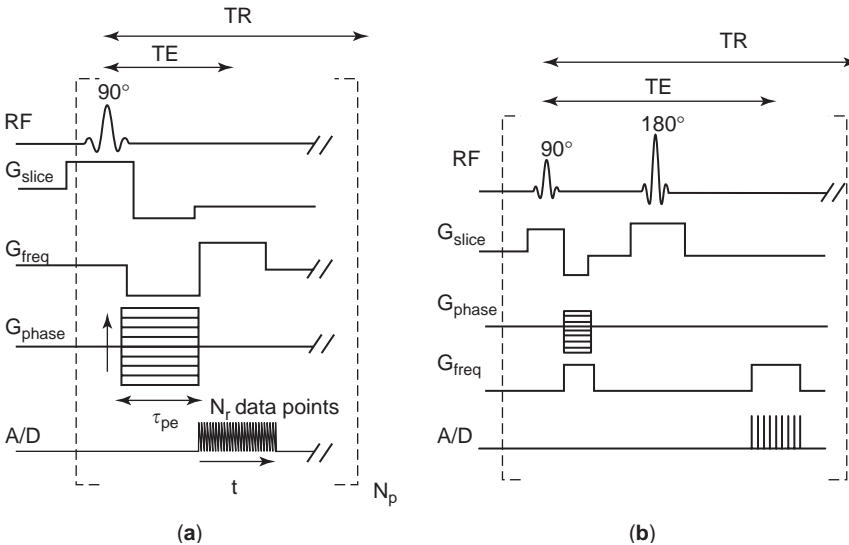

Figure 5. (a) Basic scheme for a gradient-echo imaging sequence and (b) for a spin-echo sequence. In both cases the acquisition matrix size is $N_r \times N_p$ data points.

and the slice gradient tips protons within a thickness $\Delta\omega/\gamma G_{\text{slice}}$, where $\Delta\omega$ is the frequency bandwidth of the pulse, into the transverse plane. Protons outside this slice are not excited. Application of the phase encoding gradient G_{phase} , denoted as the y direction here, imparts a spatially dependent phase shift into the signal. During signal acquisition, the frequency encoding gradient (x direction) generates a spatially dependent precessional frequency in the acquired signal. Overall, ignoring relaxation effects, the detected signal is given by

$$s(G_y, \tau_{\text{pe}}, G_x, t) \propto \int_{\text{slice}} \int_{\text{slice}} \rho(x, y) e^{-j\gamma G_x x t} e^{-j\gamma G_y y \tau_{\text{pe}}} dx dy \quad (18)$$

where $\rho(x, y)$ is the spatially dependent proton density, specifically, the number of protons at a given x, y coordinate. Using the k -space formalism [4], this signal can be expressed as

$$S(k_x, k_y) \propto \int_{\text{slice}} \int_{\text{slice}} \rho(x, y) e^{-j2\pi k_x x} e^{-j2\pi k_y y} dx dy \quad (19)$$

where the two variables k_x and k_y are defined as

$$k_x = \frac{\gamma}{2\pi} G_x t, \quad k_y = \frac{\gamma}{2\pi} G_y \tau_{\text{pe}} \quad (20)$$

This representation of the acquired data is particularly useful since the image can simply be reconstructed by an inverse two-dimensional Fourier transform.

$$\rho(x, y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} S(k_x, k_y) e^{+j2\pi(k_x x + k_y y)} dk_x dk_y \quad (21)$$

The k -space representation of the data is shown in Fig. 6. In the k_x dimension N_r data points are acquired (see Fig. 5). The imaging sequence is repeated N_p times, with the phase encoding gradient incremented for each repetition. This results in N_p lines being acquired in the k_y direction.

If the effects of T_1 and T_2 relaxation are taken into account, it can be shown that in a gradient-echo sequence, the image intensity $I(x, y)$ is given by

$$I(x, y) \propto \frac{\rho(x, y)(1 - e^{-\text{TR}/T_1})e^{-\text{TE}/T_2^*} \sin \alpha}{1 - e^{-\text{TR}/T_1} \cos \alpha} \quad (22)$$

where T_2^* is the spin-spin relaxation time, including the effects of magnetic field inhomogeneity. For a spin-echo imaging sequence, the corresponding expression is

$$I(x, y) \propto \rho(x, y)(1 - e^{-\text{TR}/T_1})e^{-\text{TE}/T_2} \quad (23)$$

The times TR (repetition time) and TE (echo time) within the imaging sequence can be chosen to give different contrasts in the image. For example, Fig. 7 shows the effects of increasing the TE on a simple brain scan.

The ability to produce many different contrast characteristics in images is one of the major advantages of MRI as a clinical diagnostic technique. Clinical applications include brain scanning (for tumors, hematomas, astrocytomas, etc.), musculoskeletal (shoulder, knee, etc.), cardiac, and liver/kidney imaging. Contrast agents such as gadolinium DTPA and superparamagnetic iron oxide are often used to highlight pathological features from surrounding healthy tissue [5]. Detailed descriptions of clinical MRI can be found in Ref. 6.

3. HARDWARE DESIGN

The major hardware components of an MRI system are the magnet, magnetic field gradients, and RF coil, in addition to the receiver. The first three components involve similar analytical methods [7,8] to design, respectively, a homogenous DC static magnetic field, linear spatially dependent rapidly switched magnetic fields, and high-frequency (60–750 MHz) resonators producing a uniform magnetic field.

Figure 7. Axial images of the brain acquired at 1.5 T. The image in (a) is acquired with a TE value of 34 ms. Increasing the TE value to 102 ms produces the image in (b).

3.1. Superconducting Magnets

For all imaging studies performed at field strengths above ~ 0.5 T, a superconducting magnet is required. For fields below this, permanent magnets can be used. In either case the critical factors in magnet design are high homogeneity of the field [<1 part per million (ppm) over the sample], and a high degree of temporal stability (<50 Hz drift per hour). Almost all clinical superconducting magnets have a cylindrical bore, approximately 1 m in diameter, which encloses the magnetic field gradients, radiofrequency coil, and patient, as shown in Fig. 1. In order to create high static magnetic fields, it is necessary for the superconductor to carry a large current, and this capability is possessed only by certain alloys, particularly those made from niobium–titanium. Below a critical temperature (9 K) and critical magnetic field (10 T), once current has been fed into such an alloy, this current will run through the wire with constant magnitude essentially indefinitely. The superconducting alloy is formed into multistrand filaments and interspersed within a conducting matrix. This arrangement can support a much higher critical current than a single, large-diameter superconducting wire. The superconducting coils shown in Fig. 8 are housed in a stainless-steel can containing liquid helium at a temperature of 4.2 K. This inner container is surrounded by a series of radiation shields and vacuum vessels to minimize heat transfer to the liquid helium. Liquid nitrogen is used to cool the outside of the vacuum chamber and the radiation shields. Since heat transfer cannot be completely eliminated, liquid nitrogen and liquid helium must be replenished on a regular basis.

The exact placement of the superconducting filaments within the magnet is designed to give the maximum field homogeneity over the patient. The basic design consists of a number of wire helices, or solenoids, of different diameters and separations, each wound along the major axis of the magnet. A typical layout is shown in Fig. 8.

For a single loop of wire, the field can be expressed as

$$B_z(r, \theta) = \sum_{n=0}^{\infty} \left(\frac{r}{r_0}\right)^n B_n P_n(\cos \theta) \quad (24)$$

where r_0 is half the length of the region of interest and $P_n(\cos \theta)$ is the standard Legendre polynomial of degree n . The design problem is to determine the optimum number, spacing, and diameter of wire loops such that the B_n coefficients are zero up to the maximum order. The larger the number of current-carrying elements that are present, the higher the order of the harmonics that can be minimized; however, one constraint is the total length of the magnet.

Slight errors in positioning the wires can lead to significant variations in the field uniformity, in which case the B_z field is given by the complete solution to Laplace's equation. Additional coils of wire are added in series with the main coil as superconducting correction coils. After the magnet has been energized by passing current into the major filament windings, the current can be changed in these correction coils to improve the homogeneity. Fine tuning is performed by using a series of independently wired coils at room temperature, termed "shim coils." The operator can adjust the current in these coils for each clinical examination, and so the magnet homogeneity can be optimized for individual patients.

A strong magnetic field is also present outside the magnet, and this can interfere with any electronic equipment nearby. Machines with moving parts, such as induction motors, or any object with metallic elements must be placed outside the fringe field; this creates an effective "dead space" around the magnet. In many clinical and academic institutions space is limited, and so a reduction in the extent of the "stray" field is highly desirable. "Active shielding" of a magnet uses secondary windings, placed outside the primary magnet windings, with the current traveling in the opposite direction, in order to minimize the fringe field. Clearly, the presence of these secondary windings also reduces the field within the patient, and so an increased current is now needed in the primary windings. The alternative method of "passive magnet shielding" incorporates iron plates into the magnet exterior. The disadvantage of this method of shielding is that the mass of the magnet is increased significantly.

3.2. Magnetic Field Gradient Coils

Three separate "gradient coils" are required to encode the x , y , and z dimensions of the sample. The requirements for gradient coil design are that the gradients are as linear as possible over the region being imaged, that they are efficient in terms of producing high gradients per unit current, and that they have fast switching times for use in rapid imaging sequences. Copper is used as the conductor, with chilled-water cooling to remove the heat generated by the current. Since the gradient coils fit directly inside the bore of the cylindrical superconducting magnet, the geometric design is usually also cylindrical. The simplest configuration for a coil producing a gradient in the z direction is a "Maxwell pair," shown in Fig. 9a, which consists of two separate loops of multiple turns of wire, each loop containing equal currents I flowing in opposite directions. In order to estimate the distance between the two loops that maximizes the linearity of the gradient, the value of B_z is

Figure 8. Schematic of the layout of the superconducting wires to produce a homogeneous magnetic field B_z within the patient.

Figure 9. (a) Schematic of a Maxwell gradient set that produces a linear magnetic field gradient in the z direction; (b) schematic of a saddle geometry gradient set producing a linear magnetic field in the y direction.

first calculated

$$B_z = \frac{\mu_0 I a^2}{2[(d/2 - z)^2 + a^2]^{1.5}} - \frac{\mu_0 I a^2}{2[(d/2 + z)^2 + a^2]^{1.5}} \quad (25)$$

where μ_0 is the permeability of free space and a is the radius of the gradient set. The first term that can give a nonlinear contribution is the third derivative, given by

$$\frac{d^3 B_z}{dz^3} = \frac{15\mu_0 I a^2}{2} \left\{ \frac{4(d/2 - z)^3 - 3(d/2 - z)a^2}{[(d/2 - z)^2 + a^2]^{9/2}} + \frac{4(d/2 + z)^3 - 3(d/2 + z)a^2}{[(d/2 + z)^2 + a^2]^{9/2}} \right\} \quad (26)$$

This term becomes zero at a value of $d = a\sqrt{3}$. The magnetic field produced by this gradient coil is zero at the center of the coil, and is linearly dependent on position in the z direction over about one-third of the separation of the two loops. The region over which the gradient is linear can be extended by adding other sets of coils in the axial dimension.

The x - and y -gradient coils are completely independent of the z -gradient coils. The derivation of gradient field linearity for the transverse gradients is somewhat more complicated than for the Maxwell pair. The usual configuration is to use four arcs of wire as shown in Fig. 9b. The wire segments in the z direction do not produce a transverse component to the field, and the four outer arcs provide return paths for the current. The B_z field produced by an arc on a cylinder of radius a is given by

$$B_z(r, \theta, \phi) = \sum_{n=0}^{\infty} \sum_{m=0}^n r^n P_n^m(A_{nm} \cos m\phi + B_{nm} \sin m\phi) P_{nm} \cos \theta \quad (27)$$

If the four inner arcs are placed symmetrically around $z = 0$, then $A_{nm} = 0$ for all m , and $B_{nm} = 0$ if n or m is even. Equation (27) can now be expanded as follows:

$$B_z(r, \theta, \phi) = -B_{11}r \sin \theta \sin \phi + B_{31}r^3 P_3^1 \cos \theta \sin \phi + B_{33}r^3 P_3^3 \cos \theta \sin 3\phi + \dots \quad (28)$$

The first term is a linear function of y , but the other terms are nonlinear. The term in B_{33} can be made zero by setting the angle $\psi = 120^\circ$, and the term in B_{31} can be eliminated by setting $\theta_0 = 21.3^\circ$ for $z_0 = 2.57a$. These results mean that the separation between the arcs along the z axis is ~ 0.8 times the radius of the gradient coil. From symmetry considerations the same basic design can be used for coils producing gradients in the x direction with the geometry simply rotated by 90° .

A second design criterion is that the current in the gradient coils should be switched on and off in the shortest possible time. This reduces the time that must be allowed for gradient stabilization in imaging sequences. This criterion is achieved by minimizing the inductance L of the gradient coils. A related issue is achieving high efficiency η , where η is defined as the gradient strength per unit current at the center of the gradient set. These three criteria (homogeneity, switching speed and efficiency) for judging gradient performance can be combined into a so-called figure of merit β , defined as

$$\beta = \frac{\eta^2}{L \sqrt{\frac{1}{V} \int \left(\frac{B(r)}{B_0(r)} - 1 \right)^2 d^3r}} \quad (29)$$

where $B_0(r)$ is the “desired” magnetic field, $B(r)$ is the actual magnetic field, and V is the volume of interest over which the integral is evaluated.

When the current in the gradient coils is switched rapidly, eddy currents can be induced in nearby conducting surfaces, such as the radiation shield in the magnet. These eddy currents, in turn, produce additional unwanted gradients in the sample that may decay only very slowly, even after the original gradients have been switched off. These eddy currents can result in image artifacts, and are particularly problematic for sensitive measurements of diffusion coefficients and in localized spectroscopy. All gradient coils in commercial MRI systems are now “actively shielded” to reduce the effects of eddy currents. Active shielding uses a second set of coils placed outside the main gradient coils, the effect of which is to minimize the stray gradient fields.

3.3. Radiofrequency Coils for MRI

Radiofrequency coils for MRI differ from conventional antennas in that they are designed to maximize the near-field magnetic energy that is stored in the patient. The desirable properties of such a coil include: (1) a homogeneous B_1 distribution within the patient, (2) minimum electric fields within the patient since these lead to signal-to-noise ratio (SNR) losses and also to an increased specific absorption ratio (SAR; i.e., patient heating), (3) maximum B_1 intensity per unit driving current, and (4) minimum resistive losses in the RF coil.

Since most RF coils are used to image either the brain or torso, the form of the coil is usually cylindrical as shown in Fig. 1. Assuming that this cylinder is infinitely long and carries a surface current J_s , given by

$$J_s = \hat{z} J_0 \sin \phi \quad (30)$$

the field inside the cylinder is given by

$$\begin{aligned}
 B(\rho, \phi) = & -\hat{\rho} \sum_{m=1}^{\infty} m\rho^{m-1}(A_m \cos m\phi + B_m \sin m\phi) \\
 & + \hat{\phi} \sum_{m=1}^{\infty} m\rho^{m-1}(A_m \sin m\phi - B_m \cos m\phi)
 \end{aligned}
 \tag{31}$$

By applying boundary conditions at the cylinder surface (considering the B_1 field created outside the cylinder), all the B_m coefficients must be zero, and the only nonzero A_m coefficient is given by $A_1 = -\mu_0 J_0/2$. Therefore

$$B(\rho, \phi) = \frac{\mu_0 J_0}{2} (\hat{\rho} \cos \phi - \hat{\phi} \sin \phi) = \hat{x} \frac{\mu_0 J_0}{2}
 \tag{32}$$

This shows that a perfectly uniform B_1 field, directed along the x direction, is produced by a sinusoidal current along the surface of a cylinder of infinite length. Of course, this configuration cannot be realized in practice, but the basic tenet of coil design is to approximate this sinusoidal surface current. The most common such realization is called the “birdcage” resonator [9], which is shown in Fig. 10. The resonator is usually constructed in a high-pass configuration, with a series of equidistantly spaced “rungs” and two “end rings.”

The birdcage coil has multiple resonant modes. For an n -rung highpass birdcage the highest-frequency mode is the so-called end-ring mode, the next $n - 2$ modes are each

doubly degenerate (the highest-frequency one produces a homogeneous transverse B_1 field), and there is a single mode at the lowest frequency. Since the birdcage coil has two orthogonal, degenerate homogeneous modes, it can be operated in quadrature; that is, it can produce a circularly polarized B_1 field. This reduces the power required for RF transmission by a factor of 2, and increases the image SNR also by a factor of $\sqrt{2}$. Practical implementation simply involves splitting the transmitter pulse through a quadrature hybrid, the two outputs of which are connected to the coil at feedpoints that are physically 90° apart.

Impedance matching of the coil must be performed in order to ensure maximum power transmission and efficient reception. Since amplifier outputs, transmission cables, and preamplifier input impedances are almost exclusively 50Ω , this is the impedance to which the coil is matched at the Larmor frequency. A balanced impedance-matching network should be used to reduce electric field losses in the sample, and the most common is a standard pi-matching network, with variable capacitors to adjust for different sample-dependent loads. Often, baluns or cabletraps are used to reduce currents traveling on the outside of the transmission cable connecting to the coil.

Noise in MRI originates from the sample and also the RF coil. Coil losses are linearly dependent on the operating frequency, and sample losses in human patients increase as the square of the operating frequency. In general, at low frequencies coil losses are dominant, whereas at high frequencies sample losses are the dominant factor. In all cases it is desirable to minimize the loss

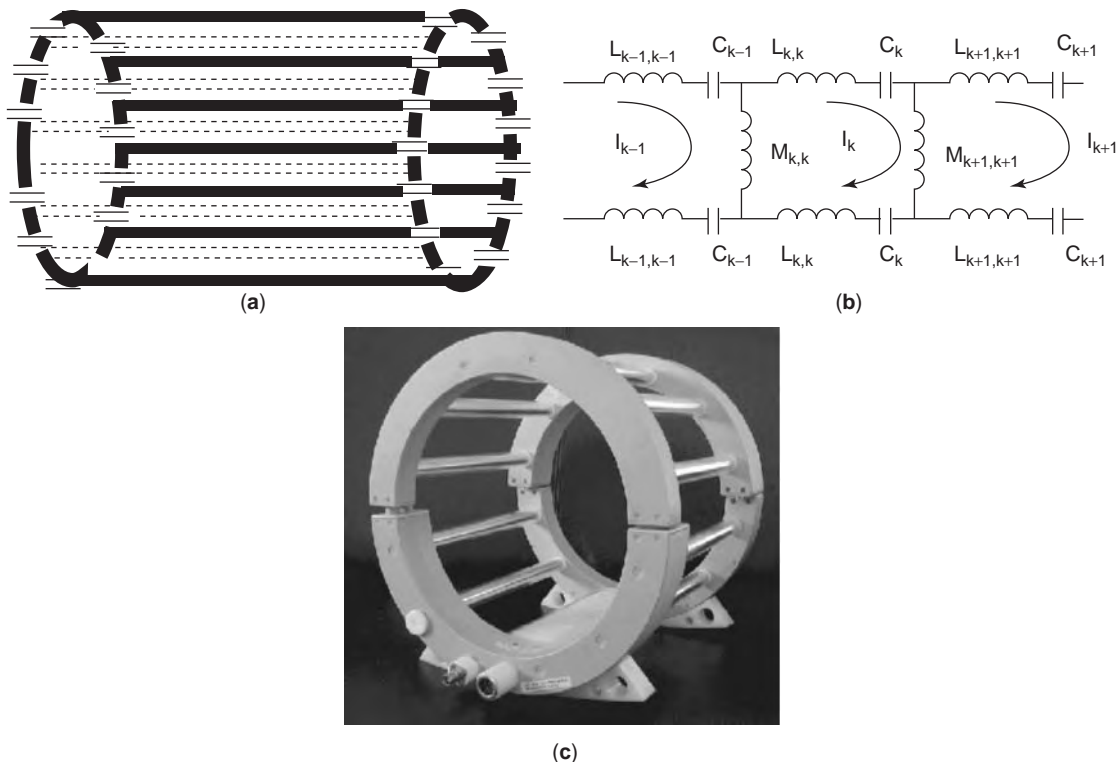

Figure 10. (a) Highpass birdcage coil; (b) equivalent circuit model for the highpass birdcage including the mutual inductance between individual loops; (c) photograph of a 12-leg birdcage coil for a 1.5-T system.

inherent in the coil, that is, to maximize the quality factor Q of the tuned circuit. At high magnetic field strengths the dimensions of the RF coil constitute a substantial fraction of the wavelength of the electromagnetic wave inside the patient. This leads to a number of problematic issues, including increased radiative losses and nonuniform current distribution along the conductors, which reduces the B_1 homogeneity. One way to minimize these effects is to design the coil using distributed capacitance rather than discrete lumped elements. Thus, familiar elements in microwave technology, such as transmission lines and cavities, will potentially play an increasingly important role in the design of high frequency coils. For example, one such design, termed a transverse electromagnetic (TEM) resonator, has been used for human studies up to frequencies of 300 MHz [10].

3.4. Mutually Decoupled Coil Arrays

In many MRI applications, it is not necessary to acquire signal from the entire patient, but only from a localized region. In this case, a small “surface coil” can be placed next to the region of interest. Typically, this surface coil is a simple circular or square loop. Since the B_1 field produced from such a coil is very inhomogeneous, a larger-“volume” coil, such as the birdcage described previously, is used for transmitting a homogeneous B_1 field, and the surface coil is used to receive the signal. Using the small surface coil in this way gives a local SNR much higher than that from the volume coil alone, due to both the high intrinsic sensitivity of the small surface coil and the reduced noise contribution from the patient. However, since there are now two circuits impedance-matched at the same frequency in relatively close proximity, there can be considerable coupling between the two circuits. This coupling must be minimized, and is normally achieved using active detuning of the surface coil during transmission, and the volume coil during signal reception, via PIN diodes.

An extension of the surface coil concept is the design of arrays of mutually decoupled surface coils [11,12], often misleadingly called “phased arrays,” as shown schematically in Fig. 11. The use of many coils requires that the imaging system has multiple receiver channels; as of 2004, most commercial vendors have up to 32 such receiver channels. Each coil in the array is connected to a separate preamplifier and receiver. Using such arrays, much larger imaging fields of view can be covered than with a single small coil, while maintaining the high sensitivity of the individual small surface coils. Image reconstruction is normally implemented using a simple sum-of-squares algorithm. The major engineering challenge is to reduce the coupling between individual coils; this coupling introduces noise correlation into the reconstructed image and reduces the image SNR. Effective coil decoupling can be achieved by optimal overlapping of the coils, a process that minimizes the mutual impedance between neighboring coils, and also by using high-input impedance preamplifiers for each of the coils, which minimizes the currents present in the individual coils, and therefore the intercoil coupling [11].

Figure 11. Schematic of a four-element one-dimensional MRI coil array (a) and an eight-element two-dimensional MRI coil array (b).

3.5. The MRI Receiver

The basic elements of an analog MRI receiver chain are a preamplifier, a one- or two-stage demodulator, a quadrature-phase-sensitive detector, lowpass filters, two second-stage audio amplifiers with variable gain, and finally two analog-to-digital converters; the MRI receiver as such is very similar to a conventional superheterodyne radio receiver.

Figure 12 shows the first stage of the receiver chain and the connections to the MRI coil. The purpose of the transmit/receive (Tx/Rx) switch is to ensure that the high-power transmitted RF pulse does not leak into the receiver, and also that during signal reception all of the signal passes to the preamplifier. During transmission of the RF pulse, diodes D_1 and D_2 are turned on and therefore conduct. Diodes D_3 and D_4 are also in ON state, and the quarter-wavelength cable to ground provides a high impedance, preventing current from traveling to the preamplifier. The received signal (typically of the order of millivolts) is several orders of magnitude lower than the transmitted pulse, and so, during signal reception, all diodes are OFF. The transmitter chain presents a high impedance, and all the signal passes through the quarter-wavelength cable to the preamplifier. In certain implementations the quarter-wavelength cable can be replaced by a lumped-element circuit, typically a “pi” network with two capacitors and one inductor. Rather than the single set of diodes shown in the diagram, in practice many sets of diodes are used.

The second stage of the receiver chain is shown in Fig. 13. The first stage demodulates the signal from the Larmor frequency to an intermediate frequency (IF), typically ~ 10.7 MHz. A second demodulation stage to baseband can be used, but most modern scanners directly sample at the intermediate frequency. The signal enters a quadrature mixer to produce real and imaginary

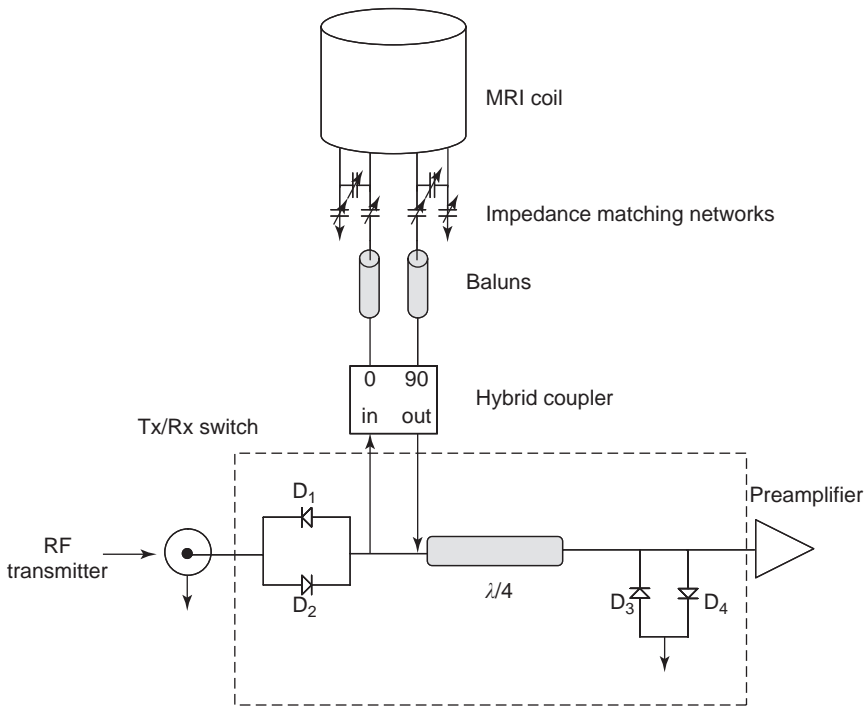

Figure 12. A schematic of the first stage of the receiver chain with a Tx/Rx switch used to isolate the receiver from the transmitter.

outputs. These pass through lowpass filters, the cutoff frequency of which depends on the particular data acquisition parameters used in the image. After final amplification, the signal is digitized, typically with a resolution of 16 bits.

3.6. Direct Digital Synthesis and Digital Detection

The rapid spread of digital transmission and reception in the communication industry has recently been mirrored in the design of MRI systems, in particular the receiver. Using digital filters, for example, enables a much better filter shape than for the analog case. In addition, the data can be oversampled many times, which provides a higher SNR in the reconstructed image. Direct digital synthesis (DDS) has the advantage of faster frequency- and phase-continuous switching than does its analog counterpart. A complete DDS unit is available on-chip (e.g., the AD9854 from Analog Devices, with 48 bit frequency resolution and 14

bit phase resolution). A DDS chip typically consists of an address counter, a lookup table for production of the sine wave at the frequency of interest, and a digital-to-analog converter. Although such chips are currently limited in the highest frequency that can be produced, the image frequency output can potentially be used for such applications.

4. ADVANCED TOPICS

4.1. Parallel Imaging

One of the major limitations of MRI, particularly in comparison with computed tomography and ultrasonic imaging, is the relatively slow data acquisition. The fundamental limits on imaging speed are the time required for current switching in the gradient coils, and the relatively large number of phase encoding steps (typically

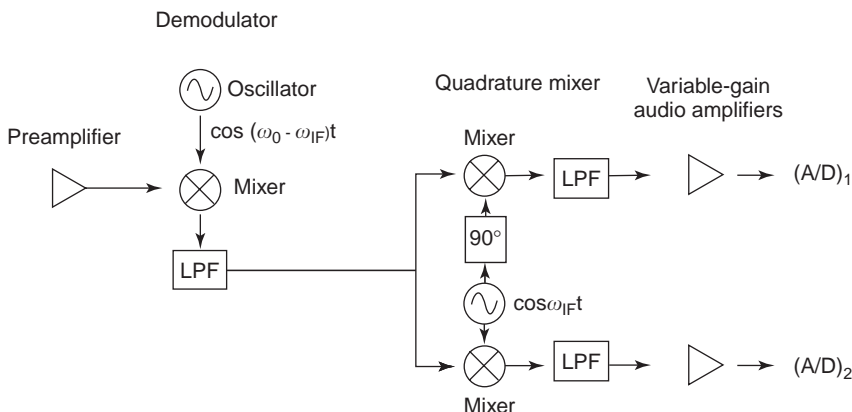

Figure 13. A schematic of the second stage of the receiver chain and analog-to-digital (A/D) conversion, where ω_0 is the Larmor frequency, ω_{IF} the intermediate frequency, and LPF a low-pass filter.

128–256) required for reasonable spatial resolution. More recently, a general class of imaging techniques, termed *parallel imaging*, have been developed that use the spatial information from an array of mutually decoupled coils to reduce the number of acquired phase encoding steps, and therefore increase the imaging speed. Acceleration factors of 4 in one-phase-encoding direction, and up to 10 in two-phase-encoding directions have been achieved.

The basic principle of parallel imaging is that it is possible to reconstruct many lines of k space from a single acquired line. The original method, termed *simultaneous acquisition of spatial harmonics* (SMASH) [13], achieves this by using combinations of signals from an array of surface coils to directly mimic the spatial encoding normally performed by phase encoding. In analogy to Eq. (19), the k -space signal acquired in the p th coil is given by

$$S_p(k_x, k_y) \propto \int_{\text{slice}} \int_{\text{slice}} \rho(x, y) C_p(x, y) e^{-j2\pi k_x x} e^{-j2\pi k_y y} dx dy \quad (33)$$

where $C_p(x, y)$ is the spatial distribution of the RF sensitivity for the p th coil in the array. If the array is constructed appropriately, then a linear combination of the individual coil sensitivities can be used to produce shifts in k_y that are identical to acquiring different phase encoding steps

$$\sum_p n_p^{(m)} S_p(k_x, k_y) \approx \sum_p n_p^{(0)} S_p(k_x, k_y + m\Delta k_y) \quad (34)$$

where m is an integer, either positive or negative. For example, if $m = +1$, then the even lines in k_y space could be acquired, and the odd lines synthesized from the (measured) coil sensitivity profiles, thus reducing the data acquisition time by a factor of 2.

For image reconstruction without artifacts, the SMASH technique relies on accurate knowledge or a good estimate of the relative RF sensitivities of the component coils in the array in order to determine the optimal complex weights $n_p^{(m)}$. Many improvements have been made to the original implementation; for example, the technique known as *generalized autocalibrating partially parallel acquisitions* (GRAPPA) acquires additional autocalibration scan (ACS) lines. Data from multiple lines from all the coils are used to fit ACS lines in a single coil. This fit gives the weights, which are then used to generate the missing k -space lines from that particular coil. After this procedure has been performed for each coil in the array, the full set of images can be combined using an optimal sum-of-squares reconstruction. Using GRAPPA several problems such as sub-optimal image reconstruction, phase cancellation and inexact estimates of coil sensitivities are minimized.

An alternative parallel imaging strategy is the sensitivity encoding (SENSE) method [15], which provides an optimized reconstruction if a perfectly accurate complex coil sensitivity map can be obtained. If the acquired k -space data are reduced by a factor of R by skipping certain k -space lines, then inverse Fourier transformation of the data leads to aliased images from all the coils in the array.

Figure 14. Single-shot inversion recovery HASTE images in the lungs of a healthy volunteer acquired with an eight-element cardiac array: (a) conventional acquisition matrix 128×256 (207 ms imaging time, interecho spacing 2.88 ms); (b) GRAPPA acquisition (acceleration factor 3) with matrix 256×256 (150 ms imaging time, interecho time 0.96 ms). (Reproduced from Ref. 14, copyright 2002, with permission from John Wiley & Sons.)

In order to reconstruct an accurate image of the sample, the true signals and folded signals have to be separated. This can be achieved since, in the image from each individual coil, signal superposition occurs with different weights according to the local coil sensitivities. The unaliased components v of every aliased pixel can be obtained by an appropriate linear combination of the pixel values in the various single-coil images

$$v = (S^H \Psi^{-1} S)^{-1} S^H \Psi^{-1} a \quad (35)$$

where vector v contains the unaliased pixel values, a the aliased values, and S the complex coil sensitivities; the superscript H represents the transposed complex conjugate, and Ψ noise correlation in the receiver channels.

In addition to speeding up data acquisition, partial parallel imaging can also be used to improve image quality in single-shot imaging techniques, where short T_2 values lead to image blurring. An example is shown in Fig. 14.

4.2. Dielectric and Penetration Effects at High Frequencies

As described previously, higher static magnetic fields result in a higher image SNR, and are particularly advantageous in functional magnetic resonance imaging, for example. However, as the Larmor frequency increases, the dimensions of the human patient (head or torso) become a significant fraction of the radiofrequency wavelength, and the B_1 field distribution is distorted significantly by the patient [16,17]. In general, two competing effects arise from the dielectric and conductivity properties of the patient. Materials with a high dielectric constant, for instance water with $\epsilon_r = 80$, reduce the effective wavelength within the patient, and can give rise to dielectric resonances that produce areas of high signal intensity at the center of the object. For a dielectric cylinder with radius a cm and length L cm, the resonant frequency of the $TE_{01\delta}$ mode is given by

$$f_{\text{MHz}} = \frac{3400}{a\sqrt{\epsilon_r}} \left(\frac{a}{L} + 3.45 \right) \quad (36)$$

Figure 15. Magnetic resonance images acquired at (a) a field strength of 4 T (proton Larmor frequency 170 MHz) and (b) at a field strength of 7 T (proton Larmor frequency 300 MHz). The presence of a dielectric resonance at the higher field strength is clearly visible. (Reproduced from reference 18, copyright (2001), with permission from John Wiley & Sons.)

The conductivity of the sample, however, dampens this effect and reduces the penetration of the RF field. Since both effects are highly frequency-dependent, the relative effects are manifested very differently at different field strengths. Specifically, the wavelength is given by

$$\lambda = \frac{2\pi}{\sqrt{\omega^2 \mu_0 \epsilon_0 \epsilon_r - j\omega \mu_0 \sigma}} \quad (37)$$

At field strengths up to 7 T, the dominant effect is from the dielectric “focussing,” which is typically seen as a bright area in the center of the patient, as shown in Fig. 15 [18].

MAGNETIC SHIELDING

DAVID W. FUGATE
Electric Research and
Management, Inc.
FRANK S. YOUNG
Electric Power Research
Institute

Shielding is the use of specific materials in the form of enclosures of barriers to reduce field levels in some region of space. In traditional usage, *magnetic shielding* refers specifically to shields made of *magnetic* materials like iron and nickel. However, this article is more general because it covers not just traditional magnetic shielding but also

Figure 1. (a) Shielding the source—placing a shield around a field source reduces the fields everywhere outside the shield; (b) shielding the subject—a shield placed around a sensitive device reduces the fields from external sources.

shielding of alternating magnetic fields with conducting materials, such as copper and aluminum. In typical applications, shielding eliminates magnetic field interference with electron microscopes, computer displays (CRTs), sensitive electronics, or other devices affected by magnetic fields.

Although shielding of electric fields is relatively effective with any conducting material, shielding of magnetic fields is more difficult, especially at extremely low frequencies (ELFs). The ELF range is defined as 3 Hz–3 kHz [1]. The selection of proper shield materials, shield geometry, and shield dimensions are all important factors in achieving a specified level of magnetic field reduction. Placing a shield around a magnetic field source, as shown in Fig. 1a, reduces the field magnitude outside the shield, and placing a shield around sensitive equipment, as shown in Fig. 1b, reduces the field magnitude inside the shield. These two options are often called “shielding the source,” or “shielding the subject,” respectively.

Both examples in Fig. 1 illustrate shield geometry. In many applications, it is impractical or impossible (due to physical constraints) to use an enclosure, and open shield geometries, also called *partial shields*, are required. Figure 2 shows two basic partial shield geometries, a flat-plate shield (a), and a channel shield (b). For these configurations, the region where shielding occurs may be limited because the shield does not fully enclose the source or the subject, resulting in *edge effects*. A discussion of the geometric aspects of shielding is contained in Ref. 2.

1. ELF SHIELDING VERSUS HIGH-FREQUENCY SHIELDING

Electric and magnetic fields radiate away from a source at the speed of light c . In the time it takes a source alternating with frequency f to complete one full cycle, these fields have traveled a distance λ , known as the *electromagnetic*

Figure 2. Examples of open shield geometries: (a) flat plate shield, (b) inverted channel shield.

wavelength:

$$\lambda = c/f \quad (1)$$

At distances from a field source on the order of one wavelength and larger, the dominant parts of the electric and magnetic fields are coupled as a propagating electromagnetic wave. If a shield is placed in this region, shielding involves the interaction of electromagnetic waves with the shield materials. Any mathematical description must be based on the full set of Maxwell's equations, which involves calculating both electric and magnetic fields. Shielding of electromagnetic waves is often described in terms of reflection, absorption, and transmission [3]. Because wavelength decreases with increasing frequency, shielding at radio frequencies in the FM band (88–108 MHz) and higher typically involves the interaction of electromagnetic waves with shield materials.

At distances much less than one wavelength, the non-radiating portion of the fields is much larger than the radiating portion. In this region, called the “reactive near-field region,” the coupling between the electric and magnetic fields can be ignored, and the fields may be calculated independently. This is called a quasistatic description. At 3 kHz (the upper end of the ELF band), a wavelength in air is 100 km. Thus, for ELF field sources, one is in the reactive near-field region in all practical cases, and a full electromagnetic solution is not required. Instead, one need focus only on interaction of the magnetic field or the electric field with the shield material, depending on which field is being shielded. In some cases, shielding of the electric field with metallic enclosures is required. This article deals specifically with the shielding of DC and ELF magnetic fields.

2. MAGNETIC FIELDS

Moving electric charges, typically currents in electrical conductors, produce magnetic fields. Magnetic fields are defined by the Lorentz equation as the force acting on a test charge q , moving with velocity \mathbf{v} at a point in space

$$\mathbf{F} = q(\mathbf{v} \times \mu\mathbf{H}) \quad (2)$$

in which \mathbf{H} is the magnetic field strength with units of amperes per meter and μ is the permeability of the medium. By definition of the vector cross-product, the force on a moving charge is at right angles to both the velocity vector and the magnetic field vector. Lorentz forces produce torque in generators and motors and focus electron beams in imaging devices.

Unwanted, or stray magnetic fields deflect electron beams in the same imaging devices, often causing interference problems. Sources that use, distribute, or produce alternating currents, like the 60 Hz currents in a power system, produce magnetic fields that are time-varying at the same frequency.

Magnetic fields are vector fields with magnitude and direction that vary with position relative to their sources. This spatial variation or field *structure* depends on the

Figure 3. The lines of magnetic flux illustrate the field structure associated with one or more sources. The density of flux lines indicates the relative field strength and the tangent to any line indicates the field direction at that point.

distribution of sources. Equal and opposite currents produce a field structure that can be visualized by plotting lines of magnetic flux, as show in Fig. 3. The spacing between flux lines, or line density, indicates relative field magnitudes, and the tangent to any flux line represents field direction. Another way to visualize field structure is through a vector plot, shown in Fig. 4. Lengths of the arrows represent relative field magnitudes, and the arrows indicate field direction.

Shield performance, or field reduction, is measured by comparing field magnitudes before shielding with the field magnitudes after shielding. In general, field reduction varies with position relative to the source and shield. The shielding factor s is defined as the ratio of the shielded field magnitude \mathbf{B} to the field magnitude \mathbf{B}_0 without the shield present at a point in space:

$$s = |\mathbf{B}|/|\mathbf{B}_0| \tag{3}$$

The shielding factor represents the fraction of the original field magnitude that remains after the shield is in place. A

Figure 4. A vector plot graphically illustrates both field strength and direction as a function of position.

shielding factor of zero represents perfect shielding. A shielding factor of one represents no shielding, and shielding factors greater than one occur at locations where the field is increased by the shield. It is incorrect to define the shielding factor as the ratio of the fields on opposite sides of a shield. Shielding factor is often called *shielding effectiveness* (SE), expressed in units of decibels (dB):

$$SE \text{ (dB)} = -20 \log_{10} |\mathbf{B}|/|\mathbf{B}_0| \tag{4}$$

Shielding effectiveness is sometimes alternatively define as the inverse of the shielding factor, the ratio of unshielded to shielded fields at a point, but it is really a matter of preference. For example, a shielding effectiveness of two defined in this manner represents a twofold reduction, that is, the field is halved by the shield and the shielding factor is 0.5. When fields are time-varying, shielding is typically defined as the ratio of RMS magnitudes.

3. SHIELDING MECHANISMS

Although shielding implies a *blocking* action, DC and ELF magnetic field shielding is more aptly described as altering or restructuring magnetic fields by the use of shielding materials. To illustrate this concept, Fig. 5a shows a flux plot of a uniform, horizontal, magnetic field altered (Fig. 5b) by the introduction of a ferromagnetic material.

These are two basic mechanisms by which shield materials alter the spatial distribution of magnetic fields, thus providing shielding. They are the flux-shunting mechanism and the induced-current mechanism [5].

Figure 5. (a) Horizontal uniform field (b) altered by introduction of a ferromagnetic material; illustrates the concept that shielding is the result of induced sources in the shield material.

3.1. Flux Shunting

An externally applied magnetic field induces magnetization in ferromagnetic materials. (All materials have magnetic properties, but in most materials these properties are insignificant. Only ferromagnetic materials have properties that provide shielding of magnetic fields.) Magnetization is the result of electrons acting as magnetic sources at the atomic level. In most matter, these sources cancel one another, but electrons in atoms with unfilled inner shells make a net contribution, giving the atoms a magnetic moment [6]. These atoms spontaneously align into groups called *domains*. Without an external field, domains are randomly oriented and cancel each other. When an external field is applied, the Lorentz forces align some of the domains in the same direction, and together, the domains act as a macroscopic magnetic field source. A familiar magnetic field source is a bar magnet, which exhibits permanent magnetization even without an applied field. Unlike a permanent magnet, most of the magnetization in ferromagnetic shielding materials goes away when the external field is removed.

Basic ferromagnetic elements are iron, nickel, and cobalt, and the most typical ferromagnetic shielding materials are either iron-based or nickel-based alloys (metals). Less common as shielding materials are ferrites such as iron oxide.

Induced magnetization in ferromagnetic materials acts as a secondary magnetic field source, producing fields that add vectorially to the existing fields and change the spatial distribution of magnetic fields in some region of space. The term *flux shunting* comes from the fact that a ferromagnetic shield alters the path of flux lines so that they appear to be *shunted* through the shield and away from the shielded region, as shown by the example in Fig. 6. Flux-shunting shielding is often described in terms of magnetic circuits as providing a low-reluctance path for magnetic flux.

Permeability μ is a measure of the induced magnetization in a material. Thus, permeability is the key property for flux-shunting shielding. The constitutive law

$$\mathbf{B} = \mu \mathbf{H} \quad (5)$$

relates magnetic flux density \mathbf{B} to the magnetic field strength \mathbf{H} . More typically used, relative permeability is

Figure 6. Example of the flux-shunting mechanism. The region inside a ferromagnetic duct is shielded from an external, horizontal magnetic field.

the ratio of permeability in any medium to the permeability of free space, $\mu_r = \mu/\mu_0$. Nonferrous materials have a relative permeability of one, and ferromagnetic materials have relative permeabilities much greater than one, ranging from hundreds to hundreds of thousands. In these materials, permeability is not constant but varies with the applied field \mathbf{H} .

The nonlinear properties of a ferromagnetic material can be seen by plotting flux density \mathbf{B} , as the applied field \mathbf{H} is cycled. Figure 7 shows a generic \mathbf{B} - \mathbf{H} plot that illustrates hysteresis. When the applied field is decreased from a maximum, the flux density does not return along the same curve, and plotting one full cycle forms a hysteretic loop. A whole family of hysteretic loops exists for any ferromagnetic material as the amplitude of field strength \mathbf{H} is varied. The area of a hysteretic loop represents the energy required to rotate magnetic domains through one cycle. Known as *hysteretic losses*, this energy is dissipated as heat in the shield material.

For effective flux-shunting shielding, the flux density in a magnetic material should follow the applied field closely. However, it is obvious from the hysteretic loop of Fig. 7 that \mathbf{B} does not track \mathbf{H} . \mathbf{B} lags \mathbf{H} , as seen by the fact that there is a residual flux density (nonzero \mathbf{B}) when \mathbf{H} has returned to zero and that \mathbf{B} does not return to zero until \mathbf{H} increases in the opposite direction. Thus, *soft* ferromagnetic materials with narrow hysteretic loops are best for shielding, in contrast to *hard* ferromagnetic materials with wide hysteretic loops, typically used as permanent magnets and in applications such as data storage. Hysteretic curves illustrating “soft” and “hard” ferromagnetic materials are shown in Fig. 8.

At very low field levels relative permeability starts at some initial value (initial permeability) increases to a maximum as the applied field is increased, and then decreases, approaching a relative permeability of one as the material saturates, as shown in Fig. 9. Saturation occurs because there is a limit to the magnetization that can be induced in any magnetic material. In Fig. 7, the decreasing slope at the top and bottom of the curves occurs as the limit of total magnetization is reached. When a material saturates, it cannot provide additional shielding.

For shielding alternating magnetic fields via flux shunting, the key property is AC permeability, $\Delta B/\Delta H$ through one cycle. Although Fig. 7 shows a hysteresis

Figure 7. Typical \mathbf{B} - \mathbf{H} curves showing how nonlinear properties of ferromagnetic materials result in a hysteretic loop as the applied field \mathbf{H} is cycled.

Figure 8. Examples of hysteretic loops for *soft* and *hard* ferromagnetic materials.

curve that swings from near saturation to near saturation in both directions, a hysteresis curve caused by a very small alternating field in the presence of a large DC field might look like Fig. 10. In this case, the ac permeability is less than the DC permeability, B/H . In addition, the DC field creates a constant magnetization that affects the time-varying magnetization. Figure 11 shows how AC permeability for a small alternating field is reduced with increasing DC field. This plot, called a “butterfly” curve, is generated by measuring the AC permeability at different levels of DC field. The DC field is increased from zero to a maximum, reversed to the same maximum in the opposite direction, and then reduced to zero, and the AC permeability is measured at different points to generate the “butterfly” curve. The extent to which the AC permeability is affected depends on the properties of each ferromagnetic material. In general, the better ferromagnetic materials are more sensitive. This type of curve is relevant for shielding small AC fields in the presence of a larger DC field.

To gain an understanding of how flux shunting varies with shield parameters, one can look at the analytical expression for the shielding provided by a ferromagnetic spherical shell with radius a , shield thickness Δ (that is much smaller than the radius), and relative permeability μ_r :

$$s = \frac{3a}{2\mu_r\Delta} \tag{6}$$

Figure 9. Permeability as a function of applied field strength.

Figure 10. Hysteretic loop formed by a small AC field in the presence of a large DC field.

Equation (6) shows that shielding improves (shielding factor decreases) with increasing relative permeability and increasing shield thickness. It also shows that shielding gets worse with increasing shield radius. From the perspective of magnetic circuits, shielding improves as the reluctance of the flux path through the shield is lowered. Increasing permeability and thickness reduce the reluctance, improving shielding. Increasing shield radius increases reluctance by increasing the pathlength of the magnetic circuit, making shielding worse. In short, the flux-shunting mechanism works best in small, closed-geometry shields.

Flux-shunting shielding has been studied for a long time. A journal article [7] dating back to 1899 describes an effect whereby increased shielding is obtained using nested shells of ferromagnetic material with nonmagnetic materials or air gaps between the ferromagnetic shells. In other words, by changing the shield form a single thick layer to thinner double or triple layers, one can in some cases enhance the shielding effectiveness although using the same amount or even less ferromagnetic material. This effect occurs mainly with configurations where the total shield thickness is within an order of magnitude of the shield radius.

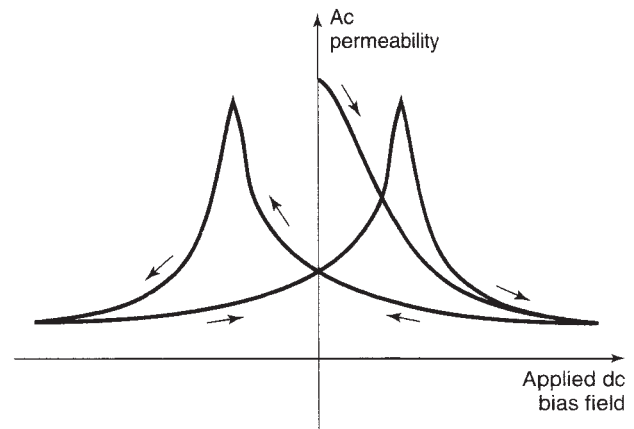

Figure 11. “Butterfly” curve illustrates how the AC permeability changes as a much larger DC field is applied and removed.

Table 1. Properties of Typical Shielding Materials

Name	Material Type	Maximum Relative Permeability	Saturation Flux Density (T)	Conductivity (S/m)	Density (kg/m ³)
Cold-rolled steel	Basic steel	2,000	2.10	1.0 × 10 ⁷	7880
Silicon iron	Electrical steel	7,000	1.97	1.7 × 10 ⁶	7650
45 Permalloy	45%nickel alloy	50,000	1.60	2.2 × 10 ⁶	8170
Mumetal	78%nickel alloy	100,000	0.65	1.6 × 10 ⁶	8580
Copper	High conductivity	1	NA	5.8 × 10 ⁷	8960
Aluminum	High conductivity	1	NA	3.7 × 10 ⁷	2699

From Hoburt (8).

In some cases, a double layer shield is used to avoid saturation of the layer closest to the field source where the fields are strongest. For example, a steel material might be used as the first shield layer, whereas a high-performance nickel alloy is used as the second layer. The steel lowers the field enough that the nickel alloy layer is not saturated. Saturation flux densities of typical shield materials are listed in Table 1.

3.2. Induced-Current Mechanism

Time-varying magnetic flux passing through a shield material induces an electric field in the material according to Faraday’s law:

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{7}$$

In electrically conducting materials, the induced electric field results in circulating currents, or eddy currents, in the shield according to the constitutive relationship

$$\mathbf{J} = \sigma \mathbf{E} \tag{8}$$

where \mathbf{J} is the current density, σ is the material conductivity, and \mathbf{E} is the electric field induced according to Eq. (7). The fields from these induced currents oppose the impinging fields, providing field reductions. Figure 12 shows a flat plate in a uniform field. Induced-current shielding appears to exclude flux lines from the shield, providing field reductions adjacent to the shield on both sides. Because the induced currents are proportional to the time rate of change of the magnetic fields, induced-

Figure 12. Conducting plate in an alternating vertical field tends to exclude flux from passing through the plate, thus providing shielding.

current shielding improves with increasing frequency. Thus, at higher frequencies, magnetic fields are more easily shielded via the induced-current mechanism. In the limit of infinite conductivity or infinite frequency, flux lines do not penetrate the shield as shown in Fig. 13.

In a conducting shield, the magnetic field and induced-current magnitudes decrease exponentially in the direction of the shield’s thickness with a decay length called the *skin depth* δ

$$\delta = \sqrt{\frac{1}{\pi f \sigma \mu}} \tag{9}$$

which involves not only frequency f and conductivity σ but also permeability μ because it affects the flux density, which induces the circulating currents. Because of exponential decay, shield enclosures with thickness on the order of a skin depth or thicker provide good shielding. For shield thicknesses much less than a skin depth, the induced current densities are constant across a shield thickness. However, significant shielding can still be obtained from thin conducting shields in some situations where the shield is sized properly. In these cases the shielding is a result of induced currents flowing over large loops.

The shielding factor equation for a nonferrous, conducting, spherical shield with radius a , thickness Δ , and conductivity σ provides insight into how these parameters affect the induced-current mechanism:

$$s = \frac{1}{\sqrt{1 + \left(\frac{2\pi f \mu_0 \sigma a \Delta}{3}\right)^2}} \tag{10}$$

Because all parameters are in the denominator of Eq. (10), induced-current shielding improves (shielding factor

Figure 13. In the limit of zero resistivity or infinite frequency, a conducting shield totally excludes flux lines.

decreases) with increasing frequency f , increasing shield thickness, and increasing shield radius. The effect of shield radius is opposite to that for flux shunting shielding, and although flux shunting shields static fields, the induced-current mechanism does not. In general, induced-current shielding is more effective for larger source shield configurations whereas flux shunting is more effective for smaller shield configurations.

3.3. Combined Shielding Mechanisms

Until now, the shielding mechanisms have been discussed separately. Equations (6) and (10) are the shielding factor equations for flux shunting and induced-current shielding alone. In many shields, both mechanisms are involved. For example, most ferromagnetic materials, being metals, also have significant conductivity in addition to high permeability. Or a shield might be constructed using two materials, one layer of a high permeability material and one layer of a high conductivity material. In these cases both shielding mechanisms contribute to the shielding to an extent that depends on material properties, frequency of the fields, and details of the shield configuration.

To illustrate the combined effect of both shielding mechanisms, Fig. 14 shows the shielding factor, calculated by a method described in Ref. 8, as a function of shield radius for a spherical steel shield in a 60-Hz uniform field. For these calculations steel is assigned a conductivity of 6.76×10^6 S/m, a relative permeability of 180, and the shield thickness of 1 mm is held constant as the shield radius is varied. Flux shunting dominates at the smaller radii, induced-current shielding dominates at the larger radii, and there is a worst-case radius of about 0.4 m, where a transition occurs between the dominant shielding mechanisms.

The combined effect of both flux shunting and induced-current shielding can be exploited with multilayer shields made from alternating ferromagnetic and high-conductivity materials. Also using the method described in Ref. 8, one can explore this type of shield construction. Alternating thin layers of high permeability and high conductivity

perform like a single-layer shield made with a material with enhanced properties.

4. SHIELDING MATERIALS

Basic magnetic field shielding materials can be grouped in two main categories: ferromagnetic materials and high-conductivity materials. For DC magnetic fields, ferromagnetic materials are the only option. They provide shielding through the flux shunting mechanism. For AC magnetic fields, both ferromagnetic and high-conductivity materials may be useful as shielding materials, and both shielding mechanisms operate to an extent determined by the material properties, operating frequency, and shield configuration.

The practical high-conductivity materials are those commonly used as electrical conductors, aluminum and copper. Copper is almost twice as conductive as aluminum, but aluminum is about 3.3 times lighter than copper and generally costs less than copper on a per pound basis. For shielding that depends on the induced-current mechanism, conductivity across a shield is paramount and copper has the advantage that it is easily soldered whereas aluminum is not—it should be welded. Mechanical fasteners can be used for connecting aluminum or copper sheets, but the longevity of these connections is questionable because of corrosion and oxidation.

Although there appears to be a large variety of ferromagnetic shielding materials, most fit into one of five basic types:

- Basic iron or steel—typically produced as coils and sheet for structural uses
- Electrical steels—engineered for good magnetic properties and low losses when used as cores for transformers, motors, and other components
- 40–50% nickel alloys—moderately expensive materials with very good magnetic properties
- 70–80% nickel alloys—highest cost materials with the best magnetic properties, often referred to generically as *mumetal*, although this was originally a trade name.
- Amorphous metals—noncrystalline metallic sheet formed by an ultrarapid quenching process that solidifies the molten metal; the noncrystalline form provides enhanced ferromagnetic properties.

Different manufacturers produce slightly different compositions of these basic materials, and they have different procedures for heat treating, but the percentages of the main elements, iron or nickel, are similar. There are only a few large producers of nickel alloy materials. Shielding manufacturers typically purchase materials from a large producer, heat the materials in a hydrogen atmosphere (hydrogen annealing) to improve the ferromagnetic properties, and then utilize the metal to fabricate a shield enclosure or shield panels. Smaller shields are often annealed after fabrication because the fabrication process may degrade the magnetic properties.

Figure 14. Calculated 60 Hz shielding factor for a spherical steel shell in a uniform magnetic field as a function of shield radius. The shield thickness of one millimeter is held constant.

Important properties for ferromagnetic shield materials are the initial permeability, the maximum permeability, and the magnetic field strength (or flux density) at which the material saturates and further shielding cannot be obtained. Because the ferromagnetic properties are nonlinear, the operating permeability depends on the magnitude of the magnetic field being shielded. In general, increasing magnetic properties go hand in hand with increasing cost, lower saturation levels, and lower conductivity. Table 1 shows nominal values of maximum permeability, saturation flux density, conductivity, and density for basic shielding materials including copper and aluminum [9]. Note that the initial permeabilities of ferromagnetic materials are often one and two orders of magnitude smaller than the maximum permeabilities (see Table 1).

5. SHIELDING CALCULATIONS

Because there are an infinite variety of shield source configurations and a wide variety of shield materials for building effective magnetic field shields, shielding calculations are a key part of practical shield design. Elaborate experiments need not be made to characterize the performance of each unique shield design. Extensive experiments are not only impractical but also unnecessary. However, closed-form analytical expressions exist only for a limited set of ideal shield geometries, such as cylindrical shells, spherical shells, and infinite flat sheets. Even for these ideal shield geometries, the expressions can be quite complicated, especially solutions for shields with more than one material layer. For general shielding calculations, one must either select a simple approximation to obtain an order-of-magnitude shielding estimate or utilize more complex numerical methods to solve the shielding problem.

In high frequency shielding, calculations for plane waves propagating through infinite sheets are used to arrive at shielding estimates. Because the resulting equations are analogous to transmission line equations, this method is often called the *transmission-line approach* [10]. As described previously, this approach is not relevant to ELF shielding except for a limited set of conditions. Reference 8 describes a technique similar to the transmission-line approach, but specifically tailored to ELF magnetic field shielding calculations for ideal shield geometries with multiple layers having different material properties. This method is well suited for calculations involving nested cylindrical or spherical shields or shields constructed from alternating layers of conducting and ferromagnetic materials.

Another technique found in literature is the circuit approach [11]. In this method, typically used to calculate ELF induced-current shielding, the shield enclosure is viewed as a short-circuited turn that can be characterized by an inductance and resistance. This method suffers from the assumption that significant details of field structure for the shielding problem are known a priori to properly set the circuit parameters. This severely limits application of the method.

General modeling of ELF magnetic field shielding amounts to calculating magnetic fields in the presence of

conducting and ferromagnetic materials. The computation must account for induced currents and magnetization throughout the shield material. This involves solutions to the quasistatic form of Maxwell's equations for magnetic fields over a continuum that represents the problem region. In differential form the basic equations to be solved are

$$\nabla \times \mathbf{H} = \mathbf{J} \quad (11)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (12)$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (13)$$

along with the constitutive relationships for permeability, Eq. (5), and conductivity, Eq. (8), which describe the macroscopic properties of shield materials. This quasistatic description, which ignores the displacement current term $\partial \mathbf{D} / \partial t$, normally on the right-hand side of Eq. (11), is valid as long as an electromagnetic wavelength is much larger than the largest dimension of the shield. General solutions to these equations are often called *eddy-current* or *magnetic diffusion* solutions. At zero frequency or zero conductivity in the shield, there are no induced currents. Only permeability restructures the magnetic field. This simplification is called the *magnetostatic case*, and solutions must satisfy only Eqs. (11) and (12), along with the constitutive relationship that defines permeability, Eq. (5).

In finding exact solutions to the governing magnetic field equations previously described, one approach is to define a vector potential \mathbf{A} that satisfies Eq. (12):

$$\nabla \times \mathbf{A} = \mathbf{B} \quad (14)$$

Substituting Eq. (14) in Eq. (13), we obtain

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} \quad (15)$$

Combining Eqs. (8), (11), (14), (15), and using a vector identity gives the following

$$\nabla^2 \mathbf{A} - \mu \sigma \frac{\partial \mathbf{A}}{\partial t} = -\mu \mathbf{J}_s \quad (16)$$

in which \mathbf{J}_s is the known distribution of source currents producing magnetic fields that require shielding.

When the source currents are sinusoidal, \mathbf{A} and \mathbf{J}_s can be represented as phasors, and the time derivative in Eq. (16) is replaced by $j\omega$:

$$\nabla^2 \mathbf{A} - j\omega \mu \sigma \mathbf{A} = -\mu \mathbf{J}_s \quad (17)$$

When the shield material has zero conductivity or the magnetic fields are constant (zero frequency), Eq. (17) becomes

$$\nabla^2 \mathbf{A} = -\mu \mathbf{J}_s \quad (18)$$

Equation (17) can be used for the general case where a shield provides field reduction through both flux shunting

and induced-current mechanisms. Equation (18) is only for flux shunting. The shielding factor for a specific source shield configuration is determined by first solving for the magnetic vector potential \mathbf{A} without the shield in the problem and then solving for \mathbf{A} with the shield. Using Eq. (14), one calculates the flux densities from both vector potential solutions. Ratios of the field magnitudes as in Eq. (2) define the field reduction provided by the shield as a function of position.

6. NUMERICAL SOLUTIONS FOR SHIELDING

Except for the ideal shield geometries mentioned previously, solving the governing equations requires numerical methods. Two common numerical techniques are the finite-element method and the boundary integral method [12–14].

In the finite-element method, the problem region is subdivided into elements—typically triangles for two-dimensional problems and tetrahedra for three-dimensional problems—that form a *mesh*. The continuous variation of vector potential \mathbf{A} over each element is approximated by a specified basis function. Then the unknowns become the coefficients of the basis function for each element. Variational concepts are used to obtain an approximate solution to the governing partial-differential equation, for example, Eq. (17), across all elements. The net result is a system of algebraic equations that must be solved for the unknowns. Finite-element software is commercially available, and features that provide automatic meshing, graphical pre-processing, and visualization of results make it an accessible and useful general shield calculating tool for some shield problems, especially problems that can be modeled in two dimensions or problems with symmetry about an axis. Figures 3, 5, 6, 12, and 13 were produced with finite-element software.

However, there are weaknesses to the finite-element method. Shield geometries typically involve very thin sheets of materials with much larger length and width dimensions. This, along with the need to accurately model significant changes in field magnitudes across the shield thickness, requires large numbers of elements in the shield region. Shielding problems are also characterized by large regions of air and complicated systems of conductors that are the field sources for the problem. In terms of energy density, the fields in the shielded region are negligible compared with fields near the sources, so one cannot rely on energy as the criterion for determining when an *adequate* solution has been obtained. Finally, solving the partial-differential equations means that the problem region must be bounded and a boundary condition must be specified at the edges. The problem region must be made large enough that the boundary conditions do not affect the solution in the region where shielding is being calculated. This results in more unknowns and a larger problem to solve.

Instead of differential equations, it is also possible to use the integral form of the quasistatic equations. For determining magnetic fields in air due to some distribution of currents, one can derive an integral equation, often

called the *Biot–Savart law*, which gives the magnetic field contribution at a point in space due to a differential *piece* of current density

$$\mathbf{H} = \frac{1}{4\pi} \int_V \frac{\mathbf{J}(\mathbf{r}') \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} dv' \quad (19)$$

in which $\mathbf{J}(\mathbf{r}')$ is the current density in the problem as a function of position defined by the vector \mathbf{r}' (from the origin to the integration point) and \mathbf{r} defines the point where the magnetic field is being evaluated (vector from origin to the field evaluation point). Integrating over all of the currents in the problem gives the total field at one point in space. This equation is not valid when shield materials, that is, conducting and ferromagnetic materials, are introduced into the problem region. The boundary integral method overcomes this difficulty by replacing the effect of magnetization or induced currents within the materials with equivalent sources at the surface of the materials where discontinuities in material properties occur. In contrast to the finite-element method, only the surfaces are divided into elements. Basis functions are used to approximate a continuous distribution of equivalent sources over these surfaces, and a system of equations is developed in which the unknowns are the coefficients for the basis functions. After solving for the unknown sources on the shield surface, one can then calculate the new magnetic field at any point by combining the contributions of all sources—the original field sources and the induced sources in the shield—to obtain the *shielded* magnetic field distribution.

The key advantages of the boundary integral method are that only the surfaces of the shield need to be subdivided into elements and that the method is ideal for open boundary problems with a large air region. The method is also ideally suited for complex systems of currents. Thus, the boundary-element method is better suited for three-dimensional problems than the finite-element method. The main weakness of the boundary integral method is that it results in a full system of equations that is more difficult to solve than the sparse system produced by the finite-element method. An integral method based on surface elements, developed expressly for solving three-dimensional quasistatic shielding problems, is described in Ref. 15.

The underlying theoretical basis for shield calculations is as old as electricity itself and goes back to Faraday and Maxwell. Although materials science is a rapidly changing area with developments in composite materials and materials processing, the basic materials for shielding of DC and ELF magnetic fields have, for the most part, remained unchanged. For basic shield configurations, calculations are straightforward. However, actual application of shielding requires practical expertise in addition to theoretical knowledge. For example, construction methods used to fabricate a shield from multiple sheets must ensure that conductivity and permeability are maintained across the entire shield surface, especially in critical directions. Edge effects and holes in shields for conduits, doors, windows, and so on degrade shield performance and must be accounted for early in the design process. With proper shield calculating tools and proper construction practices, shields can be designed that attenuate magnetic

fields by factors ranging from 10 to 1000 (shielding factors ranging from 0.100 to 0.001), thus eliminating problems with stray or unwanted magnetic fields.

1. INTRODUCTION

The magnetron is a unique surviving example of an electron tube, or vacuum-electronic device, in the modern age of RF and microwave semiconductor devices. Its definition

is complicated in historical length (back to 1921) and breadth, types, and derived devices. In this review the term “magnetron” usually connotes a source (oscillator) of microwave power, where “microwave” is used to designate frequencies between roughly 300 MHz and 300 GHz. Practical application is dominated by its use in the microwave oven, although a significant number of other military and industrial applications remain.

In the IEEE dictionary (1997 edition), “magnetron” is defined as “An electron tube characterized by the interaction of electrons with the electric field of a circuit element in crossed steady electric and magnetic fields to produce alternating current power output”. If “alternating current” is replaced by RF/microwave, then this definition is roughly equivalent to the one used here with some further caveats. The IEEE definition would apply to amplifiers as well as oscillators. Also, a strict reading would allow its application to a possible class of “cyclotron resonance” devices, which would not generally be termed as *magnetrons*. If the interaction mechanism is restricted to the class of “velocity synchronism,” then the IEEE definition would be apt. It should be noted that in modern technology the term “magnetron” also applies to devices not covered by the IEEE definition but that demonstrably are derived from the basic elements of the magnetron, which are depicted in Fig. 1. A uniform static magnetic field B is applied parallel to a cylindrical (generally) cathode, of radius r_c , which is an effective emitter of electrons when a voltage V_a is applied between the concentric anode, of radius r_a , and the cathode, with conventional polarity. Axial confinement of the electrons is achieved by the presence of end shields or end hats, which are attached to the cathode as depicted in Fig. 1, where the distance between end shields is denoted as L . The anode electrode, of height H in the axial direction, could be merely a solid (generally copper) block, in which case the term “magnetron diode” is used. Alternatively the anode could be made of a circuit, or periodic structure for the purpose of achieving interaction of circuit and electron cloud. The cathode is shown as a uniform cylindrical tube heated by an internal filament (usually tungsten) and thus dubbed an “indirectly heated” cathode. Alternatively, which is the case for most magnetrons in “power applications,” the cathode itself could be directly heated when it itself consists of a tungsten (or thoriated tungsten) helix or coil.

MAGNETRONS

1. INTRODUCTION

The magnetron is a unique surviving example of an electron tube, or vacuum-electronic device, in the modern age of RF and microwave semiconductor devices. Its definition

is complicated in historical length (back to 1921) and breadth, types, and derived devices. In this review the term “magnetron” usually connotes a source (oscillator) of microwave power, where “microwave” is used to designate frequencies between roughly 300 MHz and 300 GHz. Practical application is dominated by its use in the microwave oven, although a significant number of other military and industrial applications remain.

In the IEEE dictionary (1997 edition), “magnetron” is defined as “An electron tube characterized by the interaction of electrons with the electric field of a circuit element in crossed steady electric and magnetic fields to produce alternating current power output”. If “alternating current” is replaced by RF/microwave, then this definition is roughly equivalent to the one used here with some further caveats. The IEEE definition would apply to amplifiers as well as oscillators. Also, a strict reading would allow its application to a possible class of “cyclotron resonance” devices, which would not generally be termed as *magnetrons*. If the interaction mechanism is restricted to the class of “velocity synchronism,” then the IEEE definition would be apt. It should be noted that in modern technology the term “magnetron” also applies to devices not covered by the IEEE definition but that demonstrably are derived from the basic elements of the magnetron, which are depicted in Fig. 1. A uniform static magnetic field B is applied parallel to a cylindrical (generally) cathode, of radius r_c , which is an effective emitter of electrons when a voltage V_a is applied between the concentric anode, of radius r_a , and the cathode, with conventional polarity. Axial confinement of the electrons is achieved by the presence of end shields or end hats, which are attached to the cathode as depicted in Fig. 1, where the distance between end shields is denoted as L . The anode electrode, of height H in the axial direction, could be merely a solid (generally copper) block, in which case the term “magnetron diode” is used. Alternatively the anode could be made of a circuit, or periodic structure for the purpose of achieving interaction of circuit and electron cloud. The cathode is shown as a uniform cylindrical tube heated by an internal filament (usually tungsten) and thus dubbed an “indirectly heated” cathode. Alternatively, which is the case for most magnetrons in “power applications,” the cathode itself could be directly heated when it itself consists of a tungsten (or thoriated tungsten) helix or coil.

Figure 1. Basic structure of a magnetron: (a) midplane cross section; (b) longitudinal cross section through axis.

¹Section 3,5, and 7 were contributed by Thomas E. Ruden.

The schematic of Fig. 1 applies not only to the magnetron diode and magnetron oscillator but also to a number of derived devices not discussed in detail here. These include the “vac-ion” pump, Penning discharge tubes in which the cathode is reduced only to endplates and “planar magnetrons” used for sputtering and thin-film deposition in the semiconductor industries. Furthermore, even within the class of microwave oscillators there are variations such as the inversion (spatial) of cathode and anode as well as special experimental devices in which the polarity of voltage is reversed—namely, with an interacting periodic structure at or near cathode potential and a positive anode with or without a periodic structure. Ground is at either cathode or anode potential.

2. EARLY HISTORY

In 1921, Dr. A. W. Hull of the General Electric Company published a paper [1] on the magnetron, as depicted in Fig. 1. He studied its basic properties as an electron tube. The key concept he presented was that of the *cutoff* condition, or the boundary of parameters that permit electron flow from cathode to anode and those that do not permit electron flow. This condition was given by the following formula for the Hull cutoff voltage V_{ac} :

$$V_{ac} = (\eta/8)(B)^2(r_a)^2[1 - (r_c/r_a)^2]^2 \quad (1)$$

where MKS units are used, and $\eta = e/m$, the ratio of electron charge to mass, 1.76×10^{11} C/kg (coulombs per kilogram). Neglecting space charge effects and any axial motion (i.e., an assumption of axial uniformity), then, at voltages greater than the cutoff value, an electron will flow directly from cathode to anode, albeit with a curved trajectory, the more so as the magnetic field is increased or voltage decreased. Just at the cutoff condition an electron will just graze the anode and return to the cathode, theoretically with zero energy— that with which it began its trajectory. At anode voltage below the cutoff value the electron trajectories will be confined to some limiting radius r_m , whose value is less than r_a and goes to r_c with decreasing voltage (see the trajectory depicted in Fig. 1).

In the pre-World War II era, little attention was given to the linear version of magnetron devices, but it is useful at this point to point out the simple relation that ensues for cutoff and trajectories in the linear case where r_c and r_a go to infinity and $d = r_a - r_c$, the space between cathode and anode in the linear case. One finds the following for the cutoff voltage in the linear case:

$$V_{ac} = \eta(Bd)^2/2 \quad (2)$$

As shown by Harman [2] after World War II (WWII), the linear case provides a simpler and more easily expressed picture of electron motion, space charge effects, and interaction mechanisms. Thus in crossed fields (a two-dimensional view), E and B , it is found that in general, the average drift velocity of an electron is given by the simple ratio

$$v = E/B \quad (3)$$

and in some cases the trajectory then is a straight line perpendicular to both field directions, with spatial conventions corresponding to a right-hand rule coming from the underlying vector relation $\mathbf{v} = \mathbf{E} \times \mathbf{B}/|B^2|$. In general when the fields are uniform, there will be superimposed on this average drift a quasicycloidal component. For the case where this additional component is cycloidal, the radius of this orbital motion is

$$r = E/B\omega_c \quad (4)$$

where $\omega_c = \eta B$ is the cyclotron frequency corresponding to the magnetic field B . Then, if E is the field between two plates with anode voltage equal to the cutoff value (3), Eqn. (4) reduces to $r = d/2$ or the case of a cycloidal trajectory between cathode and anode at the grazing condition.

More sophisticated later analyses of magnetrons with the static effect of space charge addressed, for example, by Brillouin [3], found that the cutoff relations (1) and (2) remain valid even when space charge is accounted for, at least in the simplest models. In the popular (and neglecting small effects such as axial motion and magnetic field created by the rotating space charge) single-stream model of Brillouin the electron trajectories in the linear case are straight lines parallel to the electrodes and in the cylindrical case circles outside of the cathode. It is found that whatever the space charge distribution $\rho(r)$ is, the potential distribution in the space charge must satisfy the relation

$$V(r) \geq (r\omega_c)^2(1 - r_c^2/r^2)/8\eta \quad (5)$$

and for the single-stream model the equality applies at radii less than r_m , the outer limit of the space charge hub. Thus the anode voltage associated with hub radius r_m is

$$V_a = [\omega_c^2 r_m^2 / 8\eta](1 - r_c^2/r_m^2) \\ [(1 + 2 \ln r_a/r_m)(1 - r_c^2/r_m^2) + 4(\ln r_a/r_m)r_c^2/r_m^2] \quad (6)$$

and the space charge density ρ_0 in the hub is

$$\rho_0 = -(\epsilon_0 \omega_c^2 / 2\eta)(1 + r_c^4/r^4) \quad (7)$$

where ϵ_0 is the dielectric permittivity of free space, 8.86×10^{-12} F/m (farads per meter). The square of the velocity of an electron at radius r is

$$(rd\theta/dt)^2 = 2\eta V(r) = (\omega_c^2 r^2 / 4)(1 - r_c^2/r^2)^2 \quad (8)$$

For the linear case, relations (5)–(8) simplify to the following, respectively, where x is the distance above the lower cathode electrode and x_m denotes the upper boundary of the space charge slipping stream:

$$V(x) \geq (\omega_c x)^2 / 2\eta \quad (9)$$

$$V_a = (d/x_m)(\omega_c x_m)^2 / 2\eta \quad (10)$$

$$\rho_0 = -\epsilon_0 \omega_c^2 / \eta \quad (11)$$

$$v(x)^2 = (\omega_c x)^2 \quad (12)$$

Thus the velocity at the upper edge of the stream x_m is always greater by a factor of 2 than the velocity of an electron without space charge (i.e., $\omega_c x_m$ vs. $\omega_c x_m/2$).

Before WWII the understanding of magnetron space charge did not go much beyond this description with the question of instability and chaos still far in the future for consideration. Nevertheless considerable progress was made in experimental production of magnetron oscillations. At that time these were divided into three categories:

1. *Cyclotron Frequency Oscillations.* In almost any magnetron device evidence of such oscillations can be perceived. In the 1930s various studies showed such oscillations regardless of whether the anode was solid or segmented. The most dramatic report was the production of usable power (for scientific studies) at 50 GHz [4] with powers up to 100 W at low frequencies below 1 GHz. In most cases it was believed that the oscillation was optimum near the cutoff condition where phase sorting could remove unfavorable electrons. This type of oscillation was not pursued much, although it could be considered a precursor of the oscillation type in the modern gyrotron (see GYROTRON article).

2. *Negative-Resistance Oscillations.* This type oscillation occurred when the magnetic field was very high (i.e., $\omega_c \gg \omega$). In this case studies by Kilgore [5] showed favorable electrons performing many gyrations or cycles (at cyclotron frequency) during the transit from cathode to anode. Some commentators suggest that this type is a special case of the more general “traveling wave” oscillations, but in any case applied only to low frequency. More recently, however (see theoretical discussions in Section 5) it appears that there may be some relevance to interaction in relativistic magnetrons.

3. *Traveling-Wave Oscillations.* For many years before World War II many investigators succeeded in producing oscillations in magnetrons where the anode was segmented— for example, into two, four, six, eight, or more segments and various circuits connected to these segments. The theories were not sufficient, but there slowly was an appreciation of the concept of “velocity synchronism” in

which electrons when moving at the same speed as a traveling wave can become phase focused in such a way as to deliver energy to the wave. As depicted in Fig. 2, such a wave that can travel around the anode or interaction space is a “slow wave” supported by “periodic structures” [6,7]. From the principle that electrons in crossed fields move perpendicular to the E field, one can see that certain favorable electrons move toward the anode and give up energy. At the same time unfavorable electrons move a limited distance toward the cathode and possibly gain some energy, which then trigger backbombardment of the cathode, heating and secondary electron emission to add to the presumed thermionic emission. If the circuit, as well as the electron flow, is reentrant, as in the cylindrical magnetron, then oscillations can and should build up.

As documented by Harvey, Guerlac, and others [8,9], all the activity before 1940 resulted in many papers showing traveling-wave oscillations but mostly with modest power of watts up to 100 W and predominantly at low frequency below 1 GHz. The real breakthrough credited as the birth of the microwave magnetron was done in the United Kingdom in response to urgent wartime needs for radars— particularly search and fire control. Boot and Randall [10,11] are credited with this work, which demonstrated the feasibility of generating watts of average power and tens of kilowatts peak power (with microsecond pulses) at high frequencies, around 3 GHz (S band) with good efficiency: 10–50%. The importance of this “cavity magnetron” in winning the war for the United Kingdom and the United States has been well documented [9,12]. Important features introduced by Boot and Randall included the recognition that multiple resonators in a copper block could yield the high Q (low loss) important for extension of performance to higher frequencies (important for radar resolution, etc.). Years later, some decry [13] the credit uniquely given to the British for this development while not recognizing the prior reports of magnetron oscillations in Russia, Germany, Japan, and France. But it has been explained in rebuttal [13] that only when the British demonstrated the breakthrough levels of power at high frequencies was there practical recognition of its importance. Indeed, history [9,12] records the dramatic program to manufacture in large quantity the magnetrons need by the Allies in World War II. (It is ironic that various reports [14] state that in Germany governmental policies in the 1930s and early 1940s had prevented the concentrated attention to high frequencies, which triggered the British milestone.)

An immense amount of research and development on the cavity magnetron for military applications took place during World War II, and unclassified documentation was possible only after then. Concerning the magnetron, that work is described in Volume 8 [15] of the celebrated Radiation Laboratory series of books on radar, microwave technology, and the various associated components such as the magnetron and other devices. As described by Collins [15], many physicists contributed greatly to the theories and experimental magnetron development between 1940 and 1946, and even a bit later. Here we will only summarize the key theoretical principles and experimental results codified during the war effort.

Figure 2. Depiction of RF interaction electric fields in a magnetron.

The copper anode structures consisting of an even number of vanes, or variously shaped resonators were analyzed as reentrant periodic structures with principal modes $n = 0 \cdot \cdot \cdot N/2$ where N is the number of vanes or resonators. For a given mode n there would be $2n$ half-wave fringing fields as depicted in Fig. 2. It was soon found that the best mode of operation was that of the π mode with 180° phase shift between adjacent resonators or cavities and hence $n = N/2$. Also it was found that a “strapping” technique was very effective in providing “mode separation,” allowing stable magnetron operation in that mode.

Key concepts of “instability” voltage and “threshold” voltage were developed [15] by many led by Buneman and Hartree, respectively. The more useful concept is the latter, which describes the minimum voltage at which current can be drawn for a given mode. The Hartree voltage was given by

$$V_H = [\omega B(r_a^2 - r_c^2)/2n](1 - \omega/n\omega_c) \quad (13)$$

where n is the mode number corresponding to the number of periods or wavelengths of the field pattern in the interaction space from the anode structure. In almost all cases the value of n is for the π mode or $n = N/2$, where N is the number of vanes, cavities, or resonators. For the linear case the Hartree voltage becomes

$$V_H = \omega B d / \beta - \omega^2 / 2\eta \beta^2 \quad (14)$$

where $\beta = 2\pi/\lambda$ is the phase parameter for the interacting slow wave where λ is its wavelength or period along the direction of electron or beam flow.

It can be shown that at the Hartree condition in the cylindrical magnetron the azimuthal velocity of the outermost electrons in the space charge hub, is greater than the corresponding azimuthal velocity of the interacting slow wave. This signifies that extra energy must be available for the electrons as they drift radially out from the hub, requiring a continuously increasing azimuthal velocity if the electrons are to stay synchronized with the rotating wave. One speaks of the bunched electron spokes rotating in synchronism with the rotating wave.

For the linear case, however, it can be seen that the voltage for synchronism (or velocity resonance) is the same as the Hartree voltage. Once in synchronism at the outer edge of the sheath of electrons, the electrons or spokes require no increase in velocity along the y direction as they move toward the anode, in the x direction.

We have described the basic concepts underlying the modern microwave magnetron. Later we review practical designs, the use of the “performance chart” and Rieke diagram to describe the magnetron operating results and the actual results achieved in the field during and since World War II. For the most part the magnetron circuit (anode) represents a resonant circuit. Its characterization is required before the full electron cloud-circuit interaction is understood as to its dependence on the load where the output power is delivered and the portrayal of same on the “Rieke diagram”—namely, power and frequency data plotted on the classical “Smith chart” (see SMITH CHART).

3. MICROWAVE MAGNETRONS

3.1. Synopsis of Magnetron and Crossed-Field Amplifier Development

Pre-World War II magnetrons were of the so-called split-anode type [16]. A resonant circuit was formed by coupling the anode segments to a short-circuited Lecher wire transmission line. Operating in the VHF and UHF regions, these magnetrons produced continuous-wave (CW) power of hundreds of watts and could be mechanically tuned over a wide range of frequencies. Short transit time of the electrons from cathode to anode was necessary to obtain efficiencies of 60% and was achieved by the use of a strong magnetic field. Split-anode magnetrons were employed in the early 1940s primarily in radar and UHF electronic countermeasures. It was not practical to use this type of device as a source of high power at microwave frequencies because of the power dissipated in the anode and cathode, and the high magnetic field requirement. However, operation at lower magnetic field and with anodes consisting of multiple electrodes led Posthumous [17] to develop the concept of traveling-wave interaction between the electrons and the RF electric fields developed in the interaction space between cathode and anode. The electrons executed long transit-time orbits, allowing the electrons to efficiently transfer energy from the DC field directly into microwave energy. Traveling-wave interaction formed the basis for the design of high-power, high-frequency magnetrons.

A detailed and descriptive discussion of magnetron development during World War II and the subsequent development of the crossed-field amplifier (CFA) is given in a paper by Brown on the microwave magnetron and its derivatives [18]. Design and performance features of World War II magnetrons are described in a Bell Laboratories paper by Fisk et al. [19], and an MIT Radiation Laboratory Series text edited by Collins [15].

A synopsis of the early magnetron design and its role in crossed-field amplifier development is presented below. Particular crossed-field devices and their performance features are described that influence modern design and applications of magnetrons and crossed-field amplifiers.

3.2. Early Magnetron Design Features that Influence Modern Tube Design

High pulsed power was required at microwave frequencies to meet radar-ranging requirements. In 1939, a compact, mechanically and thermally robust hole and slot anode magnetron resonator was invented. The anode resonator is shown in Fig. 3. Early models of the magnetron employed a large-diameter oxide-type cathode to obtain the necessary electron emission current densities for high power operation. These tubes eventually developed peak power of 100 kW at 10 cm wavelength. However, the anode structure consisting of coupled resonators had multiple resonant frequencies that interfered with the desired oscillation frequency. This problem was resolved by modifying the anode circuit with the addition of metallic conductors called “straps”. Figure 4 shows a typical

Figure 3. Hole and slot magnetron anode.

early magnetron. The letter I identifies the interaction space between the cathode C and the anode A. The anode resonators are shown as R, and coupling between resonators is increased by the straps S shown electrically connecting alternate resonator cavities. The loop L connected to the end of a coaxial transmission line couples power from the resonator cavity. A second strap, not shown, connects the remaining resonators. Dual strapping was applied to either one end or to both ends of the anode. The effect of strapping was to lower the desired operating frequency and to displace potentially interfering frequencies well above the operating frequency.

Based on the early development work, the design of the anode resonator circuit was modified to include the vane and the slot (wedge) configurations shown in Fig. 5. Both these designs could be strapped as discussed above.

The manufacturing process for the anode block involved machining of OFHC (oxygen-free high-conductivity) copper. This process was time-consuming and costly. An alternate procedure used stamped copper laminations that could be stacked and brazed together with high-conductivity solders. This process was employed for production of tubes with wavelengths of 10-cm tubes and

(a)

(b)

Figure 5. Magnetron anode: (a) vane and (b) slot (wedge).

higher. Tubes operating at low wavelength still required machining to meet required tolerances.

Strapped anodes were difficult to fabricate at wavelengths shorter than 10 cm. The strapped anode was replaced by the unstrapped rising sun anode shown in Fig. 6. The rising-sun anode provided adequate frequency separation and could be fabricated at mm wavelengths by using a technique called "hobbing," in which a machine tool is driven into a block of copper to create the rising-sun anode shape.

A large number of fixed-frequency and mechanically tuned magnetrons that incorporated anodes of various designs [15,19] were developed during WWII and oscillated at wavelengths ranging from 40 cm to 10 mm.

Figure 6. Rising-sun anode.

3.3. Magnetron Tuning Techniques

It was recognized early that tuning of the magnetron was essential for military applications, which required frequency diversity for jamming and general radar applications, including FM altimeters. Tuning was achieved mechanically, electronically, and by voltage tuning [20]. Mechanical tuning involves changing the inductance or capacitance of the anode resonant circuit. This method typically provides a 10% tuning range prior to having mode interference. Nominal shift of frequency can also be obtained either by changing the load impedance of the magnetron or by coupling an external tunable cavity to one or more magnetron cavities.

A variety of other techniques have been used to provide tuning and frequency agility of the magnetron. These include electron-beam tuning of the resonators, change of the permeability of ferrite-loaded transmission lines coupled to the resonators, change of the electrical length of transmission lines coupled to the resonators by means of a multipactor discharge, and piezoelectric tuning [20]. A few examples of magnetron tuning are discussed below.

3.3.1. Voice Coil Tuning Reed. This approach was first incorporated into a low power CW magnetron for use as a frequency-modulated CW radar altimeter. This magnetron is the C-band, 4268–4350-MHz, 1.5-W RK6177 magnetron, which is frequency-modulated at a 300 Hz rate by a vibrating reed driven by a voice coil mechanism [21]. Another device using a voice coil is the frequency-agile MG5272 Ku-band, pulsed coaxial magnetron. This 50-kW peak, 50-W-average power device has a tuning range of 350 MHz and a tuning rate of 700 Hz [22].

3.3.2. Multipactor-Tuned Magnetron. Strapped-vane magnetrons have employed one or more external cavities coupled to individual anode resonators to provide tuning [23]. A modification of this technique is to employ a coaxially tuned circuit inductively coupled to the magnetron having a capacitive section in which an electron

discharge is created between the inner and outer coaxial conductors [24]. RF power coupled from the magnetron excites an electron multipactor discharge within the capacitor volume. The effect of the discharge is to reduce the capacity of this section by about 11%. Magnetron power loss due to the discharge is 5–10%. An X-band multipactor-tuned magnetron MG5286 operates at 22.5 kW with an efficiency of 34%. The tuning range is 9265–9315 MHz [25].

3.4. Coaxial Magnetron and Methods of Tuning

The development of the coaxial magnetron by Feinstein and Collier [26] has had a major impact on the upgrade of commercial and military radars because of its improved spectrum and operational life as compared to the strapped magnetron. In addition, advanced tuning techniques have been applied to this device, further enhancing its overall capability. The coaxial magnetron generally has larger size and weight than does the strapped magnetron to achieve a given power level.

The improved performance was obtained by symmetrically coupling the unstrapped magnetron anode resonators to a TE_{011} mode cavity having a low RF loss. The unloaded Q of the composite anode and cavity is approximately 4 times that of the strapped magnetron, which is a key factor in achieving improved spectrum. Symmetric coupling of the cavity and anode resonators ensured that the anode resonators were excited in the pi mode. The coaxial magnetron structure also has lower power density as compared to the strapped magnetron, thus reducing the tendency for arcing, which affects the performance of high-peak-power magnetrons. A concise description of the coaxial magnetron and performance features is provided by Gerard [27]. The design and performance of a 3-MW S-band coaxial magnetron incorporating mode perturbation techniques to achieve wide tuning range is discussed by Ruden [28], and a field analysis was developed for the mode spectrum of the coaxial magnetron that shows similarity to the mode spectrum of the rising-sun magnetron [29]. The coaxial magnetron has played a major role in the upgrade of existing radars in providing improved spectrum characteristics, enhanced reliability during operation, and exceptionally long operational life. The coaxial magnetron has a number of features that suggest that it may perform well at the multimewatt/gigawatt peak power level. Preliminary work on development a 100-MW relativistic positive anode coaxial magnetron is described in Section 7 on technological developments.

Various methods of tuning the coaxial magnetron are described by Gerard [30]. Slow, motor-driven, mechanical tuning is used to set the magnetron center frequency. A separate motor connected to the cavity tuning plunger is used to “dither” the frequency. At K band the coaxial magnetron is capable of a frequency excursion of 300 MHz at a dither rate of 150 Hz.

Other coaxial magnetrons employ a servocontrolled mechanism to provide accurate and fast frequency response to a variety of input tuning waveshapes, and variable-frequency excursion and tuning rate [31].

3.5. Cathode and Magnet Design

3.5.1. Cathode Design. A variety of cathodes have been used in the magnetron and crossed-field amplifier. The cathode is located directly in, and is integral to, the interaction space, which places unusual design constraints on the cathode. The DC–RF crossed-field interaction results in a percentage of the emitted electrons being returned to the cathode. The kinetic energy of these returning electrons is greater than the thermal energy of the emitted electrons. This is known as “backbombardment” of the cathode, and produces three effects:

1. There is heating of the cathode surface due the energy of the backbombarding electrons, which can result in a significant temperature rise of the cathode. In some magnetrons and CFAs, a precisely controlled change in the heater voltage is required to restore cathode to its original temperature.
2. Depending on the cathode materials, the electron energy may be enough to produce secondary electrons that contribute to the current delivered by the cathode.
3. Depending on the cathode materials and electronic and physical processes, the cathode-emitting surface may be modified by the energy of the returning electrons. Choice of cathode materials and type of cathode is therefore a critical item in magnetron and CFA design.

In general the thermionic emitter type cathodes used in magnetrons are either pure tungsten operating at very high temperatures to achieve the requisite emission densities with long lifetimes, versions of carburized thoriated tungsten operating at lower temperatures and having some reduction of life, or dispenser cathodes operating at much lower temperatures that depend on the constant evolving and migrating of an activating material to the emitting surface to mitigate the effects of evaporation and electron backbombardment.

One of the easiest and least expensive dispenser-type cathodes to manufacture and use is the oxide cathode. This cathode was typically used in low-power CW magnetrons for altimeter and FM transmitters. Originally developed for radio tubes, this cathode through chemical and thermal processes continually replenishes its semiconductor surface with barium ions evolved in the body of the oxide, which in conjunction with the oxide provide emission of electrons at a low temperature. The barium oxide cathode material is frequently used in either a nickel mesh or nickel matrix to enhance its chemical and mechanical properties. The oxide cathode can provide not only CW current but also high peak current at narrow pulsewidth. Currently, the oxide cathode is used in beacon magnetrons for transponder and weather radar applications.

Considerable effort has been devoted over many years to develop fast warmup cathodes for beacon and millimeter-wave magnetrons. In most instances the achievement of fast warmup requires changing many other features of the magnetron design and specifications besides just the

cathode emitter. A recent analysis discusses methods for reducing warmup time and heater power for a “semiindirectly heated” oxide coated cathode [32]. This paper also suggests that materials other than tungsten and molybdenum be used for the cathode heater.

The impregnated type cathode has replaced the oxide cathode in many high-power crossed-field tubes that require long life and wide pulsewidth. The particular type of impregnated cathode used is greatly influenced by the nature of the application of the magnetron or crossed-field amplifier.

Although other methods and materials have been used, in general the impregnated cathode uses a porous matrix of compacted and sintered tungsten into which a suitable barium oxide base compound is impregnated. The emitting surface may be polished or have various other materials deposited on it to stabilize thermionic or secondary emission characteristics. Operating at about 1050°C, this cathode, when applied properly, can supply copious emission for tens of thousands of hours in a crossed-field device.

A paper by Cronin [33] provides basic information on the impregnated cathode and describes various coating methods used to enhance the cathode current density. The impregnated cathode is highly reliable and is extensively used in high-power coaxial magnetrons and crossed-field amplifiers.

General description of cathode types, fabrication, and usage is provided by Gilmour [34], and a complete discussion of cathode fabrication and processing is given by Rosebury [35] and Kohl [36]. Djubua et al. [37] reviews the state of the art of the dispenser cathode to provide current density of 30 A/cm² (amperes per square centimeter) with a life of 10,000 hours for klystron usage. The combination of layered cathode materials and alternate surface coatings is discussed. This technology may be applicable to further improve the performance of cathodes in the magnetron and crossed-field amplifier.

The cathode workhorse for the kilowatt, S-band microwave oven magnetron is the carburized thoriated tungsten helix wire cathode where current density of 1–3 A/cm² is typical depending on whether the device operates CW or pulsed. Carburization reduces the amount of evaporation of thorium leading to enhanced reliability and life. A pure-tungsten cathode helix is used in the higher-power industrial magnetrons. L-band 100-kW CW magnetrons have a life of approximately 10,000 h. Most common failure modes are filament end of life, internal arcing, and moding phenomena. Limited data for L- and S-band 30-kW magnetrons show 6000–8000 h of life with filament end-of-life the most common failure mode [38].

Finally, some cathodes operate on secondary emission. The oxide cathode has a high secondary emission ratio and can provide high current under short pulsewidth conditions. Other secondary emission cathodes can operate stably at reasonably high emission densities and high average power. Pure metal cathodes of tantalum and molybdenum showed some early promise. These materials have been superseded by a cold, secondary emitting platinum cathode that meets the stability and life requirements for both high-CW power generation and combined

high peak and average power generation at wide pulse-widths [39].

Particular applications requiring low-voltage operation of the crossed-field device, long pulse operation dictated the use of metallic oxide films as beryllium oxide. The nature of these emitters is discussed by Shih et al. [40]. The oxide film degrades during operation, and an auxiliary oxygen dispenser is required to allow the oxide film to be continually replaced. This approach has been used successfully in crossed-field amplifiers employed in the AEGIS Weapon System [41].

3.5.2. Magnet Design. The magnetron and crossed-field amplifier have had a long history of using Alnico 5 and 7 magnetic material. Alnico 9 is also used in coaxial magnetrons at L and S band to achieve higher field strength, and to reduce volume and weight. As discussed in Section 7, magnets made of the rare-earth element samarium and cobalt [42] are used in beacon and millimeter-wave magnetrons where exceptionally small volume and low weight, freedom from demagnetization when in proximity to ferrous materials, and high-temperature operation are requirements. The use of temperature compensated samarium-cobalt magnets has achieved essentially zero temperature coefficients and provides long-term stability at 300°C [43]. These magnets have been employed in traveling-wave tubes. Information on usage in crossed-field tubes is not available.

The magnetrons used in microwave ovens typically use low-cost ferrite magnets; changes in temperature can affect the stability of this material.

3.6. Magnetron Performance Chart and Rieke Diagram

The magnetron performance chart shows the relationship between voltage, current, and magnetic field. Specific power data or contours of constant power and constant

efficiency are typically superposed on the voltage-current plot. Regions of high or low noise generation are sometimes identified. Figure 7 is of considerable historical interest in that it shows the “Gauss lines” of voltage versus current for different magnetic field levels for a 25-kW CW magnetron that has used as the base design for higher-power CW magnetrons. Note that as the magnetic field is increased, the efficiency approaches ~85%. This efficiency value includes the electronic conversion efficiency, circuit efficiency, and an efficiency term associated with back-bombardment power to the cathode. Note the wide range of current, which provides high efficiency at a higher than normal magnetic field level. Further investigation is required to establish the maximum efficiency obtainable from the magnetron [140].

The performance chart records the operation of the magnetron into a matched RF load. This chart also provides information on matching the static impedance of the magnetron to the power supply or modulator impedance. The dynamic impedance of the magnetron is of importance relative to the manner in which the magnetron voltage and current are affected by the dynamic impedance of the power supply/modulator. CW magnetrons typically have low dynamic impedance; hence optimum performance is obtained by operation of the magnetron under a condition of constant current. Note the dynamic impedance is sensitive to the heater power and cathode backbombardment power.

At a given magnetic field an increase in magnetron anode voltage produces a change in anode current that is a function of the dynamic impedance of the tube. The voltage and current will increase until a limit in current is reached. The voltage and current may markedly change depending on the nature of the power supply or modulator. This voltage-current change corresponds to a transition of operation into a non- π circuit mode at a different frequency. The current limit is termed a *current-mode boundary*, and the magnetron is said to have moded.

Figure 7. Performance chart: frequency 912 Mc/s, frequency-pulling figure 2.6 Mc/s. (Reproduced with permission from Proc. IEE, 1964, J.R.G. Twisleton, Ref. 56.)

Alternately, the magnetron may undergo a small percentage change in voltage at essentially constant current. This voltage change is accompanied by a shift in frequency. This is termed a “Gauss-line discontinuity,” which causes degradation of the magnetron spectrum.

Moding and the Gauss-line discontinuity can be influenced by the load conditions and is greatly affected by the available cathode emission current. If the maximum available emission current is approached the slope of the voltage-current curve will increase. It has recently been shown by numerical simulation of magnetron operation [79,104] that the magnetron is unstable under this condition. Once the transition into a regime of cathode temperature emission-limited operation has occurred, the magnetron resumes stable operation with typically lower noise generation than that associated with cathode space-charge-limited emission.

The effect of load (microwave oven, plasma reactor, antenna, etc.) mismatch that encompasses variation of both magnitude of load impedance and phase is described by the Rieke diagram, which provides contours of power and frequency as a function of load voltage standing-wave ratio (VSWR) and phase.

The Rieke diagram of Fig. 8 provides a description of the magnetron response to variation of the complex load impedance. Circles of load reflection coefficient or corresponding load VSWR are displayed. The contours of measured constant power output are shown as a function of load VSWR and phase. Note the region of high power corresponds to strong coupling of the magnetron to the load. Matched load is at the center of the diagram and represents zero reflection coefficient or VSWR equal to one. Operation of the magnetron at a power level greater than that at matched load can lead to moding. The region of

high power is called the “sink.” The lines of constant frequency tend to converge in the high-power region of the chart. Small changes in load impedance result in relatively large frequency shifts causing degradation of the spectrum. However, efficiency is high in the sink region.

The low-power region of the chart corresponds to reduced coupling to the load with greater energy storage in the magnetron circuit. While buildup of oscillation is improved in the low-power (antisink) region, the magnitude of the RF fields in the magnetron can lead to arcing and an increase in the missing pulse count. An increase of cathode backbombardment power also occurs in regions of the chart when the output power is less than the matched load power. For a given cathode heater power, the variation in cathode backbombardment power may vary the cathode temperature and thus cathode emission such that the cathode transitions back and forth between space-charge-limited operation and temperature-limited operation.

3.7. Modification of Magnetron Circuit to Create an Amplifier

3.7.1. The Amplitron Crossed-Field Amplifier. From the late 1940s to the early 1950s numerous research activities were in progress to develop a crossed-field amplifier. Magnetron amplifier concepts were in vogue [44], and an offshoot of Warnecke’s work led to the development of the M-type backward-wave oscillator (M-BWO) [45], which provided considerable insight into the crossed-field interaction process. A parallel investigation led to modification of the magnetron anode circuit, which resulted in an amplifying device called the Amplitron invented by Brown [46]. The theory of the Amplitron was developed by Dombrowski [47].

Figure 8. Rieke diagram with series field $V_s = 11.4$ kV, $I_a = 2.35$ A, frequency = 909.6 Mc/s. (Reproduced with permission from Proc. IEE, 1964, J.R.G. Twisleton, Ref. 56.)

Figure 9. Diagram illustrating the basic difference of construction and operation between the platinotron and the magnetron. (© Proc. IRE, 1957, W.C. Brown, Ref. 46.)

The Amplitron is best described in terms of the magnetron circuit modification as shown in Fig. 9, where the dual strapped circuit is severed. The anode-strap configuration is now representative of a broadband transmission line rather than the resonant structure of the magnetron. The anode vane count for the magnetron is an even number, while for the Amplitron the vane count is odd. The circuit has an input/output terminal. A drive signal impressed on the input is transmitted along the circuit to the output. Electrons created at the cathode rotate about the cathode in a direction opposite that of power flow on the circuit. This device is termed a “backward-wave device.” The power flow on the transmission line creates RF voltages on the anode electrodes. The time-varying electric field created in the interaction space is composed of two fundamental waves, one of which travels in the direction of electron flow. Interaction of this wave with the circulating electron stream is similar to that occurring in the magnetron. The mechanism of power buildup on the circuit is also identical to what occurs in the M-BWO where power flows on the circuit in a direction opposite that of the electron flow. The frequency of the Amplitron is determined by the drive signal and the magnitude of power gain is determined by the impedance of the transmission line.

Of importance is the reentrant nature of the electron stream in the Amplitron. “Reentrant” implies the space charge spokes created by the crossed-field focusing mechanism rotate about the cathode and pass without degradation from the region of low electric field of the input anode electrode to the region of high electric field of the output anode electrode. Typical overall efficiency for the backward wave Amplitron is between 45–80% depending on frequency, magnetic field level, and RF circuit resistive loss associated with the length of the circuit. In some applications the Amplitron can exhibit greater efficiency than the high- Q resonant magnetron due to its broadband, low- Q filter-type RF circuit.

Typical usage of the Amplitron is illustrated by the following examples. The Amplitron was used in the S-band,

CW, FM transmitter in the lunar excursion module of the NASA Apollo program. This Amplitron provided 17 dB of gain, power of 25 W, and operated at an efficiency of 55%. Note this tube employed a standard oxide-coated cathode with a nickel matrix that met the reliability and life requirements of the spaceborne telemetry mission.

For decades the Amplitron was the dedicated pulsed power source for the U.S. FAA Airport Surveillance Radar providing 4.5 MW of peak power at L band and operating at approximately 50% efficiency. An oxide cathode was used that consisted of a coating of barium-strontium oxide supported by a husky nickel sleeve. This cathode provided an operational life of 15,000 h. The drive power for this amplifier was provided by highly frequency-stable, mechanically tuned oscillator version of the Amplitron called the *Stabilotron* [46].

Typical of the many radar systems that have employed the Amplitron are the U.S. Navy 3 D air search SPS-48E and the surface search SPS-67, and the U.S. Army Patriot multifunction phased array radar MPQ-53 [48].

3.7.2. Forward-Wave Crossed-Field Amplifier. One of the many versions of the crossed-field amplifier is the forward-wave crossed-field amplifier. The direction of electron flow in the interaction space is in the same direction as the power flow on the RF circuit; hence the term “forward-wave interaction.” As with backward-wave interaction, the electrons interact with a component of electric field that travels in the same direction as the electron flow; thus the interaction and spoke formation is again similar to that of the magnetron. This device is “nonreentrant” in that a circulating spoke of charge is dispersed as the spoke passes from output to input electrodes. Ideally the dispersed electrons have no residual bunching and carry no modulation into the input region.

A forward-wave crossed-field amplifier is employed in the AN/SPY-1 multifunction, phased-array radar used by the U.S. Navy AEGIS Weapon System [49]. Crossed-field amplifier mean time between failures (MTBF) has reached 45,000 h, compared to a design requirement of 5000 h. As of 1998 the shelf life of AEGIS CFA tubes was ~10–12 years [41].

4. MAGNETRONS FOR POWER APPLICATIONS

The magnetron, per the review in the preceding section, has played a leading role in military and civilian radar applications, primarily in the pulsed mode. In such applications in many cases the magnetron was eventually replaced by magnetron derivatives, such as various forms of the crossed-field amplifier (See Section 7.), by klystrons or traveling-wave tubes (TWTs) and at the lower microwave frequencies by solid-state devices when the radar system is converted to a phased-array system, which uses many lower-power sources instead of one or a few high-power sources. CW applications for the magnetron were first sought in electronic countermeasures but later replaced by M-type backward-wave oscillators (carcinotrons) and TWTs. Magnetrons persisted in applications of beacon magnetrons and marine radar—especially for small boats.

In the 1960s, however, the tube industries in the face of successful replacement of tubes by new semiconductor devices looked for new application areas and recognized [50] the area of noncommunications or non-information-processing applications as a potential new-growth market for tubes. In the main this is equivalent to “power applications” reflecting the fact that tubes generally have much higher power capability than do solid-state devices. Power applications include medical procedures (diathermy, hyperthermia), power transmission as in the solar-satellite power system and microwave heating in the consumer area (the microwave oven), and industrial areas (a variety of tasks from bacon cooking to drying of wood and paper).

The history [51] of microwave heating is centered around the invention and growth of the microwave-oven market for both consumers and commercial sites. The magnetron plays the key role in the history of the microwave oven. The inventor of the microwave oven, Percy Spencer headed the World War II work at Raytheon, which resulted in that one company manufacturing over 80% of the magnetrons in the world in 1946. Naturally he looked for commercial applications of the magnetron following the War; included were the diathermy application, the microwave oven, and even, for a while, microwave relay applications for TV signals. The relatively low weight, size, and cost of the magnetron coupled with its unchallenged potential for efficiency made it the leading candidate for the microwave oven application. After the war, Raytheon successfully proposed to the FCC (Federal Communications Commission) in the United States for a new frequency allocation around 2.45 GHz for heating applications such as diathermy and the microwave oven. At the same time an allocation was made around 915 MHz in response to a request from GE. These two bands have become part of a series of ISM bands [industrial, scientific, and medical (ISM)] recognized by international treaty through the ITU (International Telecommunications Union). The 2.45-GHz band is used throughout the world and specifically is 2.4–2.5 GHz. The 915-MHz band is now 902–928 MHz but is approved for use only in region 1, the Western Hemisphere. Incidental emissions in these ISM bands is limited only by safety regulations and not the much more stringent limits to prevent RFI (radiofrequency interference). The relatively broad width of these bands is necessitated by the properties of inexpensive magnetrons, which include large values of frequency pulling, in response to load variation, large frequency pushing as a function of anode current, and thermal drift as the magnetron temperature varies with time and other parameters, including line voltage.

The magnetron, because of its inherent high efficiency, 90% theoretically and 60–90% in practice, has always been the leading candidate for use in the microwave oven. Early tubes [51] made by Raytheon during 1946–1966, however, still were relatively expensive and heavy—compared to today’s magnetrons. Beginning in the 1960s, contributions from engineers in Japan [52] led to the modern “cooker magnetron.” In the period between 1960 and 1975 the unit cost to OEM (original-equipment manufacturers) microwave oven companies dropped from over \$100 to close to \$10. This represents a cost of about \$0.01/W of microwave

power. The many steps, studies, and innovations by Japanese manufacturers (mainly Toshiba, Matsushita, and Hitachi) have been recorded mostly in papers published in the *Journal of Microwave Power*, published by the International Microwave Power Institute. The potential for further improvement was reviewed in 1995 [52].

By 1995 the characteristics of cooker magnetrons had evolved to essentially a standard design representing a consensus among manufacturers. Figure 10 is a photograph of three typical cooker tubes. As shown their weight is 1–2 lb and size less than a 4-in. cube. Their output powers generally are between 700 and 1000 W with peak anode voltage around 4 kV, peak anode current around 1 A, and a filament voltage around 3.0 V. The internal construction of any cooker magnetron is similar to that shown in Fig. 11 except for the number of vanes, which is now typically only 10. Not shown is the filter box, evident in Fig. 10, which encloses the high-voltage terminals (header) with insertion of series inductors and a shunt capacitance before the external terminals seen in Fig. 10. Ferrite magnets, shown in Fig. 10, provide the magnetic field, which is about 1850 G in the interaction space. The cathode is a carburized thoriated tungsten helix, and the anode structure is a strapped-vane periodic structure. The output is through an antenna shown contacting one vane and transmitting into a rectangular waveguide.

In the microwave oven application the waveguide then transmits the microwave power to the oven cavity and load with the possible utilization of randomizing elements like a rotating antenna, rotating turntable, stirrer, or other components such as multifeed apertures or use of more than one tube per oven. In the early days ferrite circulators were used to protect the magnetron, especially in commercial applications. It, however, has been the standard practice for many years to eliminate any ferrite protection device. The modern cooker tubes, of ceramic metal construction, are rugged enough to withstand such treatment even during no-load operation. The side effects, however, are that the magnetron “sees” a multitude of loads in a stirrer cycle. This and the variables of current and temperature create a complicated matrix of instantaneous operating conditions, which increases greatly the probability for some spurious effect, even if it is for a brief instant.

Figure 10. Photograph of several typical modern cooker magnetrons.

Figure 11. Drawings of typical cooker magnetron construction.

In a 1995 review [53] a comparison of tubes revealed the values shown in Table 1. The cost-reduced 10-vane models retained the approximate values of anode length and cathode length of previous vintage 12 vane tubes (viz., ~0.400 in. for anode length and 0.425 in. for cathode length). Changed were anode diameter, reduced to about 0.350 in. and cathode diameter reduced to about 0.155 in. In addition, the cathode helix wire diameter was reduced by about 20% to 0.020 in.

A very important and distinctive feature of cooker magnetron operation is its AC operation, wherein the tube is subjected to a rectified AC (50 or 60 Hz) voltage of a bit over 4.0 kV peak. This means that, in contradistinction to conventional operation at a DC current, the anode current in the cooker magnetron, each cycle, varies from 0 to a peak of over 1 A. This leads to very important differences in conventional magnetron operation versus that in the microwave oven. Figure 12 depicts typical Gauss lines recorded when a magnetron is operated with steady DC voltage and current. At normal filament voltage one

usually observes the lower Gauss line with significant noise. A higher Gauss line with reduced noise is achieved only after dropping the filament voltage through a critical value of filament voltage. In the AC operation of the cooker magnetron, however (see Fig. 13) the tube each cycle passes on the way up through first a preoscillation region, then a noise region, then a region of discrete spurious sideband oscillations, and finally at high current a region essentially free of noise—at least the noise associated with space charge effects. These regions are also influenced by change in filament voltage as depicted in the oscilloscope photographs in Fig. 14 of Gauss lines, showing at critical values of filament voltage Gauss line discontinuities associated with the boundaries of high-amplitude spurious signals. Figure 15 shows typical instantaneous spectra between 2 and 3 GHz at currents in the three principal regions of anode current

Almost all microwave ovens are operated with “cold start,” meaning that the high voltage (anode) and filament voltage are snapped on simultaneously. Thus, as shown in

Table 1. Summary of Key Tube Dimensions (inches)^a

Vane Number	Tube Type	Anode Diameter	Cathode Diameter	Anode Length	Cathode Length	Wire Diameter	Number of Turns
12	QKH1845	0.400	0.200	0.400	> 0.400	—	—

^aMeasurements indicate at least ± 0.010 " scatter in cathode axial position with respect to anode. Antenna pole in most tubes is "north," except for Panasonic designs:
 Toshiba: 2M172J, 2M172AJ(A), 2M229
 Hitachi: 2M107A-78 H, 2M107A-304, 2M214
 Panasonic: 2M167, 2M167A-M10, 2M203
 Samsung: OM75A.

Fig. 16, the waveform of anode voltage during cold start shows about a 1.5 s delay before steady cyclic operation is achieved with peak voltage of ~4 kV. Initially the magnetron is subjected to cold-state anode voltage values between 7 and 10 kV and just before full oscillation a ~0.5-s period of complicated moding states and transitions—with operating voltages between 5 and 7.5 kV. There is a small probability of voltage breakdown under the higher cold voltages with subsequent voltage transients generated by the presence of high inductance in power supply transformers. These could be damaging to oven components. Previously there were voltage transients triggered at the end of a spurious mode that occurred just before the moding period, which was the result of an electron discharge from one end shield to the opposite end shield. (This discharge is related to an axial double-stream interaction believed to play a role in the preliminary stages of cold-cathode emission in magnetron diodes [54].) The marking "F" and "FA" on filament leads previously served as a guide for preferred filament polarity for reduced transients of this type. Modern cooker tubes all incorporate the grooves in end shields, (see Fig. 11) as an effective means

of suppressing this spurious mode, making the utility of the F/FA codes academic.

Cooker magnetrons typically encounter only the lower (in terms of filament voltage) mode boundary during normal operation. That boundary, denoted by V_{fm} may typically be below 1 V at the start of life and rises to the normal value of filament voltage around 3.3 V at the end of life. Presumably this deterioration is the result of progressive loss of thorium under complicated processes of sputtering and other gas phenomena, even though the tubes incorporate getters (usually consisting of titanium or Zirconium on the cathode support rod and end shield, made of molybdenum). Less frequently encountered is the upper-mode boundary above which strong spurious sidebands ($f_0 \pm \Delta f$) and baseband signals (Δf) exist with Δf in the range of 200–300 MHz. This spurious modulation, when too strong, causes the magnetron to mode, not at peak current (as is the case for the lower-mode boundary) but at either discontinuity bounding the anode current

Figure 12. Depiction of low-noise and high-noise Gauss lines (states) in a magnetron when operated with DC anode voltage (taken from old data on CW magnetrons).

Figure 13. Regions of different noise characteristics during operation of a cooker magnetron with rectified AC voltage.

Figure 14. Gauss line traces [50 V/div(division); 0.1 A/div.] of a cooker magnetron at varying filament voltages (1.65, 2.0, 2.5, 3.0, and 3.6 V) showing presence of discontinuities associated with spurious oscillations (traces displaced for viewing purposes).

region of strong spurious. The cause is not too well understood but presumably is associated with excess emission, while the immediate solution is to reduce filament voltage.

Today's cooker magnetrons generally operate around 1 kW with efficiency into a matched load of >70% to permit 50% overall oven efficiency for large loads. The manufacturing volume per year, worldwide, is now (as of 2004)

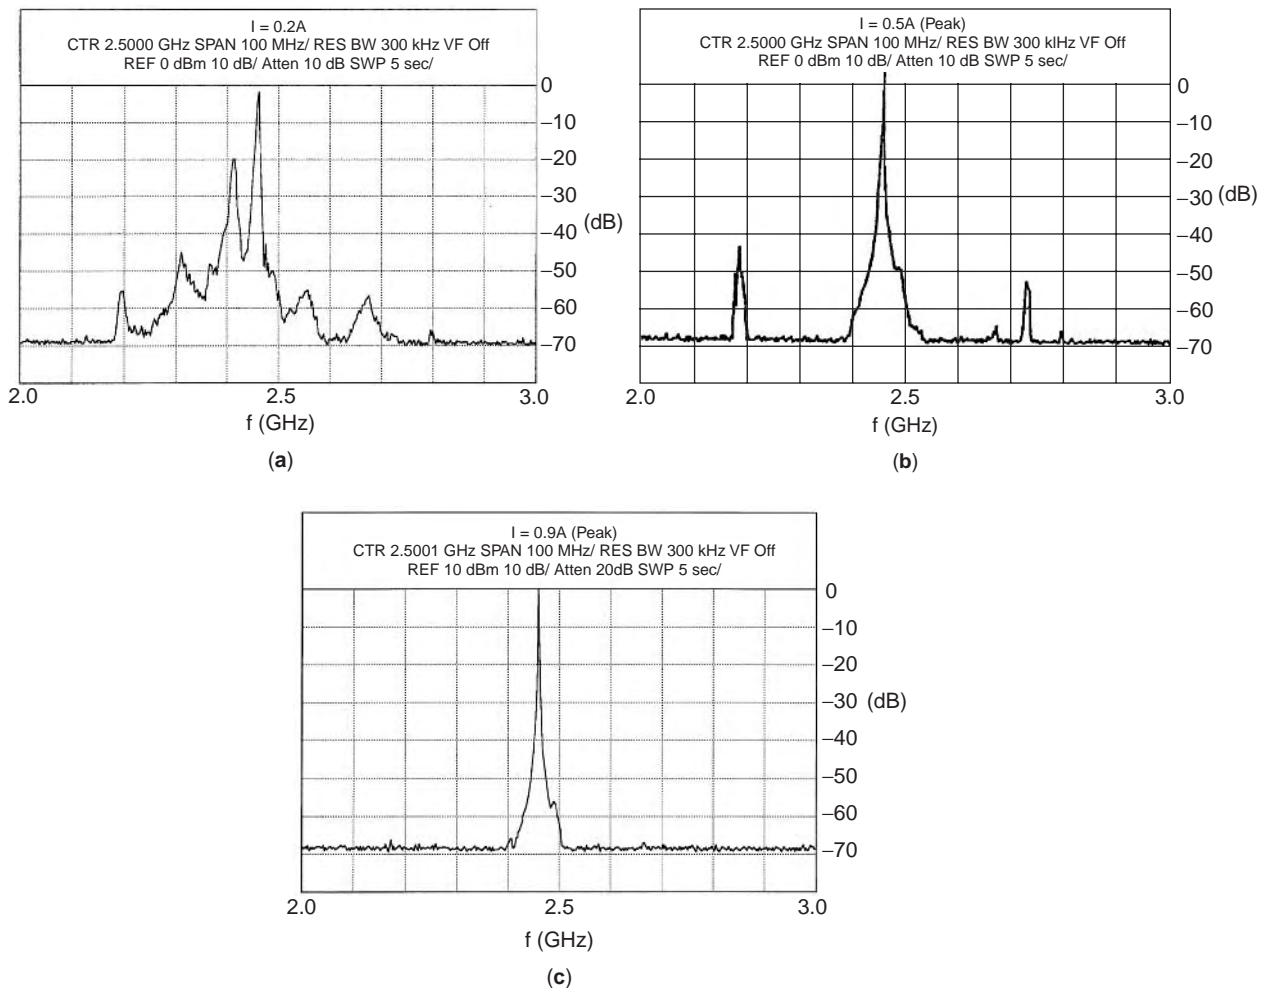

Figure 15. Typical cooker magnetron noise spectra at (a) low currents, (b) moderate currents, and (c) high currents.

Figure 16. Voltage waveform during cold start of a cooker magnetron. In this case a voltage transient due to end shield emission is present. (2 kV/div; 0.2 s/div).

over 60 million tubes per year. While Japan and Korea are still significant suppliers of cooker magnetrons, the majority are being made in the Third World in China, Indonesia, and Thailand with an unknown production in the former Soviet Union. Large quantity prices are now well below \$10 per tube.

Besides the microwave oven there are some industrial applications of microwave power [55] in which magnetrons play a key role. Some of these, for example, for powering plasma sources of ultraviolet energy, utilize magnetrons at the 2–5 kW level. Although these are not cooker magnetrons, they are closely related in design and performance.

Microwave power applications at power levels below 5 kW are almost all at 2.45 GHz. There are, however, many higher-power applications, up to 100 kW and higher, that operate at 915 MHz. The main uses are in the food industry for meat tempering and bacon cooking [55], although other applications for drying and even some military applications exist. The power source is a magnetron derived from the pioneering work of Twisleton [56] in the 1960s. Today the major suppliers are Burle Industries and California Tube Laboratories (CTL) in the United States, while EEV in the United Kingdom and Istok in Russia also have been suppliers. In Fig. 17 we show a recent photograph of this type of tube. It is large and weighs about 15–20 lb. It is typically operated around 18 kV and 5 A for

Figure 17. Photograph of a 75-kW 915-MHz magnetron.

75-kW applications with a large solenoid used for the magnetic field, which typically is around 1350 G. The magnetron in this application, in contradistinction to the cooker magnetron, is not operated cold-start, which is clearly impractical at the high voltage and current levels. Instead the cathode, made of tungsten, is preheated at 12 V filament voltage and roughly 100 A and then after start the filament current is programmed to decrease as power increases to, for instance, 75 A at the 75 kW operating point. The conventional supply used with this tube allows anode current to flow through the solenoid. Thus, as power is increased, the current from the separate solenoid current supply is decreased accordingly. The DC voltage is snapped on at start at high Gauss, and then the gauss level is dropped to permit current flow and power output. Typical efficiency is in the mid 80–90% percentage range, while in the laboratory, prototype tubes of the Twisleton variety have shown over 90% efficiency. The cathode is a helix and made of pure tungsten and of roughly 0.400 in. diameter. There is no getter in the tube.

This magnetron is operated in industrial systems only with a ferrite circulator to protect the tube, particularly against “moding,” which can be destructive to the tube. The recommended value of filament voltage versus output power is designed to be adequately separated from both a lower-mode boundary and an upper-mode boundary. The lower-mode boundary is related to inadequate cathode emission. It is believed that the upper-mode boundary is associated with spurious oscillations, as with the cooker tube. Little data exist to confirm this supposition, because of the restrictions involved in experimenting at high power levels. Even though the cathode is pure tungsten, the emission includes contribution from secondary electron emission as well as thermionic emission. The former is not well understood, so considerable variation in lower-mode boundary exists.

A significant field problem with this tube is that of “mag overloads.” Another problem is the methods to restore full power operation after momentary powerdown procedures triggered by arcs in the heating cavities. The mag overloads are not well understood but in the main are “moding” events, sometimes triggered by momentary drops in line voltage in industrial-level voltage lines.

Other magnetrons in industrial applications include tubes at the 600–1000 W level at 915 MHz and tubes at power levels of 5–25 kW at 2.45 GHz. There are also more recent reports of the development of a 1-kW 60% efficiency magnetron in Japan for 5.8 GHz. Little information about these magnetrons is generally available. There is little doubt that useful magnetrons for power applications could be developed over much wider ranges of frequency and power when the economic conditions are appropriate.

5. CROSSED-FIELD DEVICE THEORY AND DEVICE SIMULATION

5.1. Elementary Magnetron Theory

The elements of the magnetron consist of a cathode that emits electrons into a three-dimensional interaction space (r, θ, z) bounded by the cathode of radius r_c and an outer

electrode or anode of radius r_a . A potential difference between the anode and cathode is established by a DC power supply or by a modulator that provides a voltage pulse. The pulse repetition frequency (PRF) multiplied by the pulse length in seconds is called the *duty factor*. This is a measure of the percent time that the device is operating. If the average power delivered to the magnetron is P_{av} watts, then the instantaneous peak power is $P_{av}/(\text{duty factor})$ measured in watts. For continuous-wave (CW) operation, the duty factor is 1.

A magnetic field is applied axially in the z direction, which is in a direction parallel to the anode-cathode surfaces. The electrons emitted from the cathode experience a radial outward force $F = eE$ measured in newtons, where e is the magnitude of the charge on the electron in coulombs and E is the magnitude of the electric field in volts per meter created by the anode-cathode potential difference in volts within the region $(r_a - r_c)$ in meters. A radial inward magnetic force opposes the electric field force and is given by $F = evB$, where v is the azimuth velocity measured in meter per second and B is the applied axial magnetic field measured in teslas. The general motion of an electron within the interaction space is that of an epicycloid with radial acceleration determined by the net force exerted by the electric and magnetic fields; the net force provides the centripetal force $F = mv^2/r$, where m is the mass of the electron in kilograms and r is the radial position of the electron in meters, required for circular motion. The epicycloid motion of the electron consists of an azimuth drift with velocity $v = E/B$ with superposed circular motion with angular velocity $\Omega = v/R$, where R is the radius of the circle; $\Omega = (e/m)B$ is the cyclotron frequency.

The cycloidal motion is termed two-stream motion in that electrons travel outward and then return inward toward the cathode. This motion is modified by the presence of the electrons in that they contribute to the electric field in the interaction space. Thus the motion of the electrons is modified by the density of electrons as a function of radius, azimuth, and axial position such that various configurations of the electron motion can exist. If the number of electrons is minimum, then double-stream motion dominates with electrons traveling radially outward from the cathode and radially inward toward the cathode. This is called the “temperature-limited state” in that for a given cathode temperature the cathode will emit a limited number of electrons. If the number of electrons is large, then the motion of the electrons is greatly modified. A so-called single-stream state may exist when the cumulative effect of all the electrons reduces the electric field at the cathode to zero. The emission from the cathode is termed “space-charge-limited”. Under these conditions all electrons travel in circular orbits about the cathode with azimuth velocity increasing with the radius.

For a given magnetic field and anode voltage, electrons moving on a cycloidal orbit can just graze the anode. The magnetic field is specified as B_0 and the anode voltage as V_0 , and the condition of grazing is termed “cutoff.” Increasing the voltage above V_0 allows electrons to be collected on the anode and the condition is termed “above cutoff.” The device is a diode with current delivered to the anode as a function of the magnetic field and cathode

temperature. If the magnetic field is increased, the electrons can (ideally) no longer reach the anode. This is called a condition of “below cutoff.” In this state we may have the extremes of temperature-limited operation and space-charge-limited operation.

Let us assume in either extreme that we have an aggregate of electrons having a particular azimuth velocity and hence a particular angular velocity at a given radius. These electrons will induce charge on the anode circuit electrodes, which vary with time as the electrons pass by an electrode. The variation of the charge with time creates an induced current in the anode electrode. If, by Fourier analysis of the induced current, a frequency component exists that matches the resonant frequency of the magnetron, an RF voltage will be developed on the anode electrodes. This time-varying voltage will establish electric fields in the interaction space, which can be Fourier-analyzed into azimuth traveling electric field waves in the interaction space. If the electron angular velocity matches the angular velocity of one of these Fourier wave components, then a condition of synchronism is said to exist.

Assume at some radius r_0 that the electron moves with an angular velocity ω that is synchronous with that of the circuit wave. Electrons riding at the positive peak voltage of the wave will experience a force in a direction determined by the vector cross-product of $E_r \times B_z$ such that they will advance toward the zero voltage point of the wave. Electrons riding at the negative voltage of the wave will be retarded in their motion and coalesce about the zero voltage point. Crossed-field bunching of the space charge thus occurs and the angular velocity is constant. In the interaction space electrons at the zero voltage point on the wave will experience an angular component of electric field E_θ due to the circuit wave. The force on the electrons will be in a direction determined by $E_\theta \times B_z$ which is directed toward the anode. The electrons are thus forced radially outward while maintaining approximately constant angular velocity ω_{syn} while the azimuth velocity increases with r . During the radial drift toward the anode, the electrons traverse a potential difference ΔV with available energy $W = q\Delta V$, where q is the transported charge. The change in kinetic energy of the electrons however is $\Delta KE = (m/2)(v_f^2 - v_0^2) = (m/2)(\omega_{syn})^2(r_a^2 - r_0^2)$. It is found that ΔKE is less than W ; thus the potential energy transformed into RF energy is $W - \Delta KE$. The energy exchange mechanism is in contrast to the exchange that occurs in linear beam devices where potential energy is first converted into kinetic energy, which is subsequently converted into RF energy.

5.2. Recent Work on Extending the Theory of Magnetron and Crossed-Field Amplifier

5.2.1. Soliton Theory.

The development of an extension of basic magnetron theory has been minimal in more recent years. Work has been done in the application of soliton theory to the crossed-field device [57]. Early analysis as applied to the crossed-field amplifier in predicting performance was reviewed and found lacking in details [58]. Nonlinear analysis has been pursued by Kaup and Thomas [59] relative to the magnetron and provides

further insight into the complexity of the interaction. Analytical results support some measured data on CFA operation at reduced magnetic fields, which indicates a reduction in noise. This result is supported by measurements on millimeter-wave magnetrons operating at reduced magnetic field that show noise comparable to that of O-type tubes [60].

Usychenko [61] discusses the space charge structure and stability of solitary waves in the crossed-field diode. It is found that stable oscillations exist when the cathode emission is weak. Under high emission conditions the waves are unstable and may result in chaotic behavior of the space charge and excess noise generation. This behavior appears to be related to high noise generation in the magnetron under space-charge-limited operation of the cathode and low-noise generation when the cathode is operated under temperature-limited conditions.

5.2.2. Hartree Threshold Relationship. Lindsay et al. [62] suggested that the Hartree threshold voltage–magnetic field relationship may have a broader interpretation. Usually this relationship has been applied to the voltage–magnetic field relationship that must be met to initiate oscillation in the magnetron. The condition for start of oscillation in the magnetron has experimentally followed closely that predicted by the threshold relationship. It is found by numerical simulation under space-charge-free conditions that electrons can be collected on the anode at anode voltages well below the threshold value. This occurs at normal operating current values and at correspondingly high RF voltage levels. It is probable that the Hartree equation is satisfied under these conditions by the superposition of the reduced anode voltage and the large RF voltage. The range of anode voltage and RF voltage for which the above mentioned threshold condition might hold has not been determined. The extreme conditions for which this rule of thumb may not apply are a minimum RF voltage approximating the start of oscillation-synchronous threshold conditions and a maximum RF voltage approximating the DC anode voltage similar to that occurring in a high-power relativistic magnetron where the RF–electron interaction is highly nonsynchronous.

5.2.3. Radiation Generation in Crossed-Field Devices. An alternate way of looking at the RF generation mechanism in the crossed-field device is considered by Riyopoulos [63,64]. Consistent with elementary theory, electrostatic electron energy is converted into radiation. Total energy and momentum balance during the emission process requires that the change in electron canonical momentum and electrostatic energy be related to a shift of the guiding center location of the electron in a direction perpendicular to the drift velocity of the electron. The incremental change in the electrostatic potential and vector potential due to guiding center shift equal the energy and momentum of the emitted RF quantum. The combined drift plus cyclotron kinetic energy of electron motion are invariant during this interaction process. This analysis is correct to the first order, neglecting second-order effects in E_{rf}/B^2 .

The theory predicts that gain in the CFA is symmetric about the frequency corresponding to that at which perfect

beam–circuit reentrancy occurs. This result is in agreement with Amplitron theory [47] and simulation results [65]. The theory also provides information on the gain per wavelength as a function of the ratio of the height of the space charge hub above the cathode to the anode–cathode spacing.

5.3. Early Crossed-Field Trajectory Calculations; More Recent 2D and 3D Simulations

5.3.1. Analog Computer Computation: Magnetron and Amplitron. In the mid-1950s, prior to the general availability of the digital computer, Feinstein and Kino [66] used an analog computer to solve the equations of motion for electrons in a forward-wave amplifier and an M-type backward-wave oscillator. The computations predicted the performance of these devices under large-signal conditions. It was assumed that the space charge effect on the RF and DC fields could be neglected. Adiabatic motion of the electrons was also assumed. The DC current, generated power, and growth rate of the RF field along the length of the anode circuit were computed.

An alternate approach developed by Brown and described by Zettler et al. [67] employed a large plotting table driven by an analog computer to trace out the x and y positions of an electron in time. The recorder pen was replaced with a probe that sensed electric potentials on a resistive paper sheet placed on the plotting table. The anode–cathode geometry of the magnetron or Amplitron was outlined on the resistive sheet using conductive paint. Assumed RF vane voltages scaled in amplitude and time to give analog voltages were applied to the painted electrodes. Phase shift of the voltage between adjacent vanes was included. The potentials sensed by the probe were used to compute the x and y electric fields for use in solving the equations of motion. The computed x and y position was fed to the plotting table to achieve a closed-loop computation between position coordinates and sensed electric fields. This approach was used by Zettler and Ruden [67] to study the phase focusing mechanism in the magnetron and Amplitron assuming synchronous DC fields and to study the effect of changes of anode vane geometry on efficiency. Use of a slanted anode vane tip designed on the analog trajectory plotting equipment was incorporated into the QK470 magnetron. An efficiency improvement of 5% (absolute) was obtained, and frequency pushing was reduced by an average of 50%. This reduction in pushing provided superior performance of the magnetron in a moving-target-indication (MTI) radar.

Using this same vane shape the efficiency of the QK653 Amplitron, a device used in major airports in the U.S. FAA Air Route Surveillance Radar, was increased by 5–10%.

A round anode vane was also designed and incorporated in the S-band, 400-kW CW power Amplitron. The electronic efficiency of electrons collected on the vane surface was optimized and anode secondary emission energy losses were minimized.

This analog approach was also used to design a broadband VHF Amplitron that employed a single-electron spoke with 10–13 dB of gain occurring over only one guide wavelength of the circuit [68].

5.3.2. Early Self-Consistent Space Charge; 2D Digital Trajectory Calculations in Assumed Space Charge within the Spoke. In 1941 a numerical analysis of the steady-state operation of the magnetron was undertaken by Hartree and Stoner [69]. A relaxation method was employed to adjust the space charge in the interaction space to be consistent with the applied DC electric field, the anode current, and the generated RF electric field. Primary results of the computation were frequency, power, and efficiency. In 1945 self-consistent calculations performed by Tibbs and Wright [70] provided a description of the focusing of the electrons in the interaction space of the magnetron. An instantaneous snapshot of the electrons showed the space charge as having been focused into what were termed “spokes.” This is shown in Fig. 18 for the early British 10-cm, eight-vane, CV 76 magnetron. Although the calculation was run for only one iteration, it was believed that this picture represented steady-state operation.

Further numerical studies of the magnetron had to await the advent of the digital computer. Lehr et al. [71] began a series of computations in 1959 to extend the results of Tibbs and Wright. The computation failed after 36 iterations to converge to a steady-state solution for the imposed condition of space charge limitation of cathode emission. However, a steady-state space charge configuration was obtained under temperature-limited operation of the cathode. Note that magnetrons were normally run in the space charge-limited condition since temperature-limited operation led to degradation of the cathode emission due to ion bombardment of the surface of the oxide cathode. Controversy on operation of the magnetron cathode in the space-charge-limited versus temperature-limited regime had been ongoing since the early 1950s. Experimental confirmation as to the existence of a

low-noise state during temperature-limited operation of an injected-beam amplifier was provided by Little et al. [72]. Noise was high when the cathode was operated in the space-charge-limited state and low when in the temperature-limited state.

Analysis and digital trajectory calculations including space charge effects were made by Dombrowski in 1957 for the magnetron and Amplitron. These computations were based on adiabatic motion of the electrons, which requires constant space charge density within a spoke as predicated by Brown and discussed by Zettler and Dombrowski [67] and employed by Feinstein [66]. An important result of these trajectory calculations was the confirmation that the RF voltage increased linearly along the Amplitron circuit from input to output for a given value of gain as predicted by theory [47] and experimentally measured by Zettler [67]. The trajectory calculations demonstrated that high electronic efficiency occurs in the high-field-output section of the circuit, and provided information on cathode backbombardment power as a function of the assumed space charge distribution in the hub. A movie of the rotating spokes of charge dramatically showed electrons traversing the input-output vanes, thus moving from a low RF potential to a high RF potential region. Because of the inertia of the electrons, the maximum electron collection was not on the output vane but rather occurred downstream from the output. The computed distribution of anode electron collection had excellent agreement with experiment. In addition, details of the electron collection on the cathode were obtained. Information on impact energy, angle of incidence, and spatial distribution of electron collection about the circumference of the cathode provided the impetus to incorporate a cold, secondary emitting platinum cathode into high CW and pulsed power Amplitrons. A paper by Dombrowski and Ruden [73] describes the abovementioned results. Additional information on magnetron and Amplitron calculations can be found in a technical report [74] dealing with self-consistent and adiabatic space charge calculations, analog and digital trajectory calculations, and the early development of a transient space charge simulation program.

5.4. Transient Simulation

Transient calculations of the space charge in the crossed-field device were first applied to the injected-beam crossed-field amplifier by Sedin [75] followed by a magnetron calculation by Yu et al. [76]. Electron-RF wave interaction occurred over a single wavelength and competing circuit modes were not considered. A high degree of turbulence of the space charge was found that had originated in the hub of electrons surrounding the cathode.

Based on the Yu analysis, single moving wavelength particle-in-cell codes were developed by MacDowell [77] for study of the magnetron and the CFA. The magnetron simulations confirmed a turbulent hub condition and the fact that primary and secondary emission dominated states could exist. Turbulence was enhanced when

Figure 18. Electron orbits in an eight-segment magnetron. (© IEEE Trans. ED, 1976, H.A.H. Boot and J.T. Randall, Historical notes on the cavity magnetron.)

secondary emission was present; turbulence associated with primary emission was eliminated when a transition was made from the space-charge-limited to the temperature-limited operation of the cathode.

A 2D transient code for the analysis of both the magnetron and the Amplitron was developed by Dombrowski [78]. The code accounted for space charge effects and circuit modes but did not account for electromagnetic modes associated with the volume of the vacuum envelope. A few thousand electrons and timestep of 0.02 RF cycle were used. Simulation results for the 2J32 magnetron were in good agreement with experiment.

This code has been applied to a study of an X-band beacon magnetron [79]. Experimentally this tube showed the Gauss-line discontinuity phenomena. Computationally, the discontinuity occurred at the onset of transition from space-charge-limited operation of the cathode to temperature-limited operation.

Another transient code called MASK was developed by Chernin [80] to study the forward-wave crossed-field amplifier with space charge recirculating in the interaction space between the output and input anode vanes. Circuit properties are handled in a manner similar to that for the Dombrowski code, and the entire interaction space, including a drift space between output and input vanes, is taken into account. This simulation predicts the transition from a high-noise to a low-noise state at a given current level, and a similar discontinuity in voltage as noted above was also observed. Noise was about 20 dB lower than that normally computed for this amplifier design. This reduction of noise was achieved using a primary emitting cathode. The low-noise state was not observed when a secondary emission cathode was used. The results of this simulation are in agreement with measurements made by Ye et al. [81] showing the effect of secondary emission on creating fluctuations of the space charge. It was suggested in this paper that low noise in the crossed-field device might be achieved if the use of the thermionic cathode be reconsidered.

The above-described computations on low-noise, temperature-limited cathode phenomena were highly influenced by a series of measurements made by Brown on the microwave cooking magnetron using a thoriated-tungsten primary emitting cathode. A dramatic reduction of noise was observed by Brown when the cathode was operated in the temperature-limited state [82]. The details of this transition are not understood, but a key observation by Brown indicated that the transition from high to low noise is associated with an increase in anode voltage at a given current, and this appears to be supported by a number of simulations. This phenomenon is believed to be somehow related to the illusive Gauss-line discontinuity problem, where, for the magnetron operating at a given current level, the anode voltage will rise slightly and the magnetron frequency will shift by a few megahertz. The Gauss line discontinuity problem has not been observed in backward-wave Amplitron devices [82]; however, the MASK simulation for the forward-wave CFA shows this anomaly.

Analytic theory and an associated simulation code were used by Schuenemann et al. [83] to compute the steady-state spatial-harmonic operation of a K-band magnetron.

The $\pi/2$ mode of the first backward space-harmonic unit was employed. This mode is of interest for use in millimeter-wave magnetrons as it results in an increase in anode and cathode dimensions with corresponding reduction in power dissipation density. In addition, the strength of the magnetic field is markedly reduced hence minimizing size and weight. The mode separation is large such that a broad tuning range is possible. The computation was made for an 8-mm unstrapped magnetron having a secondary emission cathode that provides for longlived operation at these wavelengths. The anode vane count was 16, and for the $\pi/2$ mode the number of space charge spokes computed was 12 as observed in the interaction space near the anode. An important result was that additional bunching of the space charge occurred near the cathode. Depending on the circuit quality factor Q and level of the RF voltage, the number of bunches near the cathode varied between 4 and 6. The simulation thus predicted the presence of multistable states, the likelihood of which has concerned crossed-field researchers for many years.

Particle simulation studies on optimizing the performance the spatial-harmonic magnetron has concentrated on maximizing of the generated power as a function of the anode resonator dimensions and anode Q [84]. Computations was made for an 8-mm magnetron operating at a magnetic field of 0.5875 T with operation on the backward-wave space-harmonic. The presence of steady-state dual-space-charge configurations was observed in the vicinity of the cathode. The power generated for these two states differed by approximately 3 dB. Further understanding of these phenomena may provide insight into the magnetron problem areas of mode shift, delayed start of oscillation, high-cathode backbombardment at low currents, and noise and spurious signal generation.

5.5. 2D and 3D Electromagnetic Simulation of Crossed-Field Devices

The fully electromagnetic particle-in-cell simulation of the crossed-field device in general solves for electric and magnetic fields created by the charge in the interaction space by solving Maxwell's equations within the volume of the device. The equations of motion include the static magnetic field and account for relativistic effects. The simulation is thus self-consistent in solving both time-dependent and steady-state problems.

The early work of Palevesky et al. [85] on the relativistic magnetron used an electromagnetic code to compute the optimum power generated as function of magnetic field strength at a level somewhat higher than normally employed in S-band magnetrons. The magnetron anode was unstrapped, and it was determined early on that steady-state operation could be obtained in the conventional π mode or 2π mode depending on the cathode diameter. Electromagnetic 2D "Magic" code simulations by Stark et al. [86] and by Weatheral [87] using a single-wavelength, rotating frame-of-reference, 2D code showed that the RF magnetic field had little effect on the interaction process, and that the electron transit time was a fraction of an RF period. When the RF anode voltage is comparable to the applied DC voltage, the interaction is

no longer one of synchronism between the electrons and the RF circuit wave but one of short-transit-time negative-resistance oscillation [16] as proposed by Ruden [88]. Chan et al. [89], using the 2D Magic code to simulate the relativistic magnetron, examined RF output power and electron flow properties, scaling and dependence of emission on fundamental system parameters, and the effect of finite power-supply impedance.

Aspects of phase locking of a rising-sun, L-band, 100-MW pulsed magnetron were studied using the 2D Magic code by Chen et al. [90]. A technique was developed that reveals the dynamical behavior of frequency and phase during the phase-locking process. Without a drive signal, the development of an oscillation takes 50–100 RF cycles and low-level noise is generated during this time interval. With a locking drive signal the power buildup occurs within 20–30 cycles, and noise is almost completely eliminated.

An important application of the 2D Magic code by Jones et al. [91] has been to introduce an analytical expression for a variation of the axial magnetic field in azimuth in the interaction space of the magnetron. This perturbation selectively develops the pi-mode space charge configuration in the vicinity of the cathode. This prebunching action results in rapid buildup of the magnetron oscillation to steady state.

5.6. 3D Simulation

A revision of the Magic code allows analysis of three-dimensional structures and has been applied to the rising-sun magnetron, the strapped magnetron, and the relativistic magnetron. The time to complete a simulation run resulting in a steady-state solution is highly dependent on the number of particles employed; runs of 40–120 h are common such that obtaining the performance of a device over a wide range of operating parameters is rarely practical. It is difficult, therefore, to state whether the simulation truly represents the actual performance of the device. Perhaps limiting the number of particles is an option in obtaining a rough general view of the operation, but in dealing quantitatively with starting processes and noise generation mechanisms, it is probable that fine detail will be required, and hence will require many particles. Users of the code have suggested modifying the code to stop the computation after a number of cycles and then to be able to restart the calculation with a change in operating parameters such as, for example, voltage and magnetic field. This would allow a performance chart to be readily developed from the data.

Kim et al. [92] have used the 3D Magic code to simulate a 250-kW, 28-kV, X-band rising-sun magnetron. A study of the modes of the rising-sun structure showed a discrepancy between an analytic computation and the Magic simulation. The pi-mode frequency agreed with experiment, but experimental data for the other modes were not provided. At the start of oscillation, leakage current to the endspaces was reduced and single-frequency pi-mode oscillation was obtained. No other spoke configurations were reported as occurring during buildup of the oscillation. It is to be noted that the magnitude of the applied magnetic field and the anode voltage are ramped up in time. This

combination of time-varying voltage and magnetic field may inhibit the development of spokes (space charge perturbations) of varying periodicity in azimuth as the space charge hub develops.

The 3D Magic code is capable of analyzing the strapped magnetron. The understanding of the noise-generating mechanisms and the nature of low-noise operation of the microwave oven magnetron and commercial high-power CW magnetrons is important relative to the level of noise within the ISM band and at harmonic frequencies. Results of Kim et al. [93] using the Magic code confirm the pi-mode oscillation, and computed harmonics and higher modes as determined by Magic have been compared to experimental data. The possible competition of the adjacent $\pi - 1$ mode and details on other spurious oscillations are presently not available. Modeling of a high-power CW magnetron with and without straps has been done by Jung et al. [94]. Resonant frequencies, resonant modes, and higher harmonics of the fundamental frequency were identified.

These efforts have been directed mainly at demonstrating the basic performance of the tubes. The important issue of noise mechanisms has not been addressed at this time. This issue is highly dependent on the cathode emission algorithm, and it is not clear whether the present “explosive” and “thermionic” emission algorithms are adequate for the study of noise close to the carrier.

Modeling of a strapped X-band magnetron MG5241 using 3D Magic is discussed in a paper by Ma et al. [95]. Basic resonant frequency computations agreed well with experiment for both cold and hot tests. While experimental-versus-computed agreement was obtained for the input voltage and current, the electronic efficiency did not agree. This problem has been addressed in the simulation by accounting for leakage current due to end-hat emission [96]. Concerns with regard to the cathode electron emission model have also been addressed. The emission models as “explosive emission” and “space-charge-limited emission” are being replaced with a model that can be used to vary the cathode emission density. This later emission model has properties similar to those employed by the Dombrowski magnetron-Amplatron simulation [78]. Unpublished data obtained with the latter simulation code suggest that the starting time of the magnetron is highly dependent on the particular emission model. The space-charge-limited model has a factor of roughly twice the time delay of that of the temperature-limited model. Finally, a major improvement [95] in the 3D Magic code is the modeling of the cathode end hat, and modeling of the actual variation of magnetic field in the interaction space, which has yielded simulation results very different from those for the uniform field. The ability to fully model variations in both the electric and magnetic fields and end-hat geometry that affects electron leakage and confinement in the magnetron is important in the study of noise. (*Note:* Experimental changes in end-hat design and magnetic field uniformity in the region of the cathode endspace have reduced conductive noise in the microwave oven magnetron 2M172A as compared to its predecessor the 2M172 [97].)

Two analyses of the relativistic magnetron have been made using different 3D codes. Arter and Eastwood [98]

developed a 3D PIC code to model a mechanically-tuned rising-sun magnetron design. A comparison of results of the 3D simulation with a 2D simulation showed that maximum efficiency occurs close to the Buneman–Hartree threshold voltage. It is not clear whether this statement holds for conditions approximating negative-resistance oscillation. Simulation time corresponding to onset of oscillation was some 100 ns and computationally quite long, placing a limit on the amount of performance data that can be obtained. The simulations also show mode competition that may terminate operation. This observation may be related to one aspect of the upper current-mode boundary limitation that occurs in many magnetrons and CFAs. The simulations also indicate that one cause of pulse shortening in magnetrons may be related to droop of the voltage pulse. Suggested corrective action would be to tailor the anode voltage to increase during the pulse. Such pulseshaping may have application to the pulse shortening observed in relativistic magnetrons.

The 3D code Quicksilver developed by Lemke et al. [99] has also provided a detailed analysis of operation of the relativistic magnetron. The simulation addressed the reproduction of the experimental results of the Palevsky–Bekefi A6 magnetron [100]. The simulation provided close agreement with experimental results and confirmed that the use of endcaps markedly increases efficiency by reduction of leakage current. The pulse voltage feed to the cathode can be either single-ended or double-ended. From an electromagnetic perspective, potential problems as to the effect of single-versus double-ended voltage feed on the space charge close to the cathode have not been analyzed.

The operation of the relativistic magnetron at voltages substantially above the Buneman–Hartree threshold as compared to nonrelativistic magnetrons appears to suggest that nonsynchronous interaction may be dominant. Design criteria for high efficiency in this regime have not been met [88].

5.7. Analysis of the Crossed-Field Diode

The stability of the space charge in the crossed-field diode has been investigated over several years by researchers at the University of Michigan. Mechanisms that limit the current in a crossed-field gap were analyzed by Christenson and Lau [101] using PDP1, a one-dimensional electrostatic particle-in-cell (PIC) code [102], investigating the transition from laminar to turbulent flow in the space-charge sheath under conditions of cutoff and the excitation of a modulational instability caused by small AC voltages applied across the gap. Christenson et al. [103] also found that crossed-field cycloidal flows are extremely unstable even when the emission current density is a small fraction of the limiting value. A small resistance in the external circuit, a small RF voltage, or a small tilt in the magnetic field would disrupt the cycloidal flow; the end result is always a near-Brillouin state that consists of the classical Brillouin flow superimposed on a turbulent background.

The sensitivity of the crossed-field diode to asymmetry of emission about the cathode surface is illustrated by disturbing the uniform emission with nonemission sites, as shown by Ruden et al. [104]. This simulates nonuniform

emission from the surface of the cathode. It is found that a transition occurs from the stable diode state to one consisting of azimuthally bunched clusters with azimuth periodicity dependent on the time of evolution. This phenomenon is akin to that of the azimuth magnetic field effects described above. As time progresses, the perturbed diode states interact with one another, producing turbulence. This chaotic behavior leads to the creation of streams of secular electrons beyond the crude hub layer. Such bunching and secular electrons have been observed in both 2D electrostatic codes and 2D/3D electromagnetic codes but are not at all understood. These phenomena appear to have some relationship to that described by Schuenemann [83] and may be some what dependent on the model employed for electron emission from the cathode.

Luginsland et al. [105], applying the 3D Magic code to the strapped “cooker” magnetron, extended the 2D simulations described above [91] to show that the periodic placement of permanent magnets about the anode cylinder results in fast startup of the magnetron and demonstrated that under DC operating conditions both sideband spurious signals and noise generated at low anode currents can be eliminated or greatly reduced.

6. THE NOISE PROBLEM

The cooker magnetron is a great success because it is efficient besides being inexpensive. It seems, however, that a concomitant of efficiency is “noise” or an array of spurious signals. This subject has been prominent in all varieties of magnetrons and its derivatives and helped trigger the extensive computer modeling (see Section 5) of amplifier and oscillators derived from the magnetron. Even before World War II it was recognized [8] that the magnetron space charge was unstable without a circuit and that even with a circuit there remained numerous sources of anomalous noise—including discrete signals anywhere in the spectrum.

Many studies [106] of the magnetron diode showed that the magnetron space charge, through its instability, generated signals that were voltage-tunable and corresponded to conditions of “velocity resonance” of n spokes of space charge revolving around the cathode, thus yielding frequencies that obeyed empirical relationships such as

$$f_n = (k/n)(V_a/B) \quad (15)$$

where k is some constant, n is a mode number corresponding to the number of space charge perturbations or “spokes” around the cathode, and V_a and B are the anode voltage and magnetic field, respectively. This space charge instability in crossed fields was dubbed [106] the “diocotron” effect by researchers at CSF (Compagnie Générale de Telegraphie Sans Fil). Those workers in France along with counterparts in the United States [107] found that a satisfying theory could be found for the analogous instabilities in a thin beam moving through crossed fields, but theoretical studies of the full magnetron space charge remain controversial if not intractable to this day. In

addition such linear beam interaction theories were able to predict thresholds for spurious sidebands in M-type backward-wave oscillators (BWO). In this tube the basic issues are exactly when the beam-circuit interaction results in start of oscillations at the desired frequency and when it further allows “spurious” sidebands to be generated. The answers, in terms of “starting currents,” can be derived from the small-signal theories. One finds as beam current is raised first a starting current for the desired oscillation and at some higher starting current (perhaps 2–3 times higher) the generation of sidebands at a frequency Δf , which is of the order of 1–2% of the desired oscillation frequency. At still higher currents the sidebands may begin to show their own sidebands and soon there will be “noise” sidebands in place of discrete coherent spurious signals. This pattern corresponds to the general pattern of modern “chaotic” phenomena [108]. The small-signal theories [106,107] for the thin beam provide a satisfying framework for predicting the regions of current with different “noise.” This theory employs two parameters, one, which we call p , proportional to beam current and another, which we call q , which is proportional to circuit field strength or its “coupling impedance.” One finds that if $q \gg p$, then space charge effects are minimum, but if $p \gg q$, then space charge effects are dominant. No such theory exists for the magnetron (see Section 5). One can perceive, however, the pattern for “chaos” in the magnetron in analogy to the M-type BWO. In Section 4, we showed that as anode current is raised, we pass successively through preoscillation, noise, discrete spurious signals, and finally no-noise or low-noise (“quiet”) regions. Note that this succession with magnetron anode current is inverse to that in the M-BWO with beam current. This is because the true analog in the magnetron to beam current is not anode current but the rotating space charge current. This rotating current and the attendant space charge density is reasonably the highest before start of oscillation (at approximately zero anode current) and then decreases as anode current draws off some of the rotating current.

Space charge effects thus can cause the appearance of many spurious signals and noise in the cooker magnetron, especially because it passes through all regions from preoscillation to the “quiet” state during each cycle. (In contrast, Brown has proposed [82] DC operation of magnetronlike devices in the “quiet” region as a way of minimizing “noise.”)

Besides all the possible signals and noise deriving from space charge effects, there are also a multitude of signals that can result from more conventional electron–circuit interaction, recognizing that the anode structure is characterized by many resonant modes. Furthermore, even though the successful type of interaction in the magnetron is one of “velocity synchronism or resonance,” there are other modes of interaction related to the cyclotron interaction principle. We can most easily discuss the relevant principles by using the language of simple linear beam interaction, where there is a beam moving with velocity v_e and a circuit-supported wave of electric field moving at a speed (phase velocity) v_0 . It is necessary at this point to introduce some notation for this “wave” that derives from modern understanding of periodic structures [6]. When

power is transmitted through or along a periodic structure there is an infinite set of spatial harmonics that make up the total propagating disturbance. Some of these harmonics, which can include the “fundamental” with longest wavelength, propagate in the same direction as the power flow. We call these harmonics or waves “direct” spatial harmonics. There is also a corresponding set of harmonics, which can include the “fundamental” (but not at the same time as the alternate possibility referred to above) that propagate in the direction opposite to the power flow. We call these spatial harmonics “reverse.”

Now in general beam–circuit interaction there is the beam direction, which we will call “forward”; then there is the direction of power flow on the circuit, which we call “forward” if in the same direction as the beam and “backward” if in the direction opposite to the beam. Then there are several alternate resonance or interaction conditions. The first is velocity resonance:

$$V_e = V_0 \text{ or } c/v_e = c/v_0 \quad (16)$$

This corresponds to most conventional interactions in any circuit mode as described in the Hartree voltage relation (14). In addition there are “cyclotron-mode interactions” for which the resonance relations are

$$c/v_0 = c/v_e(1 \pm \lambda/\lambda_c) \quad (17)$$

where $\lambda = c/f$, where f is the operating or interacting frequency and $\lambda_c = c/f_c$, where f_c is the cyclotron frequency.

There are a considerable variety in the possible interactions for which the resonance relations (16) and (17) apply. These are depicted in Fig. 19, which is a $c/v-\lambda$ plot, the equivalent of the more popular ω/β chart, but in which the relations for resonance are more easily pictured. We see that for the velocity resonance condition (16) that the normal situation applies where a forward-wave amplifier exists only with interaction with a direct harmonic wave (FD0) and backward-wave oscillation occurs only with a reverse harmonic (BR0). But equation (17) shows that with the “fast wave” cyclotron resonance case [a minus in Eq. (17) and the downward branch in Fig. 19] we can have forward-wave amplification with a reverse harmonic (FR⁻) as well as backward-wave oscillation with a direct harmonic (BD⁻). We conclude that there is a rich variety of possible resonance interactions that could lead to signal generation in a magnetron during “moding” or even in the presence of the desired oscillation. Classical nonlinear theory [7,15,106] would suggest that the presence of a strong oscillation should suppress buildup of any competing oscillation. This may be true in general when the same interaction mechanism applies for the two competing modes. But because the “cyclotron resonance” is independent or in a sense orthogonal to velocity resonance, the two may possibly coexist. In any case there have been a number of experimental observations of simultaneous oscillations in magnetrons, and certainly they exist at serious “noise” levels of concern to regulators even though they are far from the power level in the π mode.

In addition, some oscillations are connected with endspace resonances. These were observed in early

Figure 19. Diagram depicting various interaction modes in a crossed-field tube on the $c/v-\lambda$ chart for periodic structure propagation.

magnetron work [15], and more recently they have been observed as out-of-band signals from cooker magnetrons [109]. Note that these “axial oscillations” tend to strengthen with current up to the peak current while many spurious signals occur only at low or moderate currents.

It is no surprise that the magnetron emits a copious amount of spurious signals and noise across the whole spectrum. In Fig. 20 we see a typical baseband spectrum measured near a microwave oven. Much, if not most, of this energy is associated with spurious space charge phenomena, but not all. Some of it is due to axial oscillations, and some signals defy explanation. In Fig. 21 we see a

Figure 20. A typical baseband spectrum measured near a modern microwave oven (lower curve is background). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 21. Typical spectrum around 2.45 GHz emitted by a modern microwave oven.

typical spectrum around the main signal at ~ 2.45 GHz. The expected sidebands are in evidence. In Fig. 22 we show a typical result of a compliance test for a microwave oven across the spectrum from 1 to 18 GHz. Only the more prominent signals are shown, signals at harmonic frequencies are expected, but their behavior is not always understood. Other signals are difficult to explain, and in some cases there is reason to believe that parametric interactions [110] may be operating. In Fig. 23 we see a typical waveform for an out-of-band signal, which occurs mostly at low and moderate anode current and thus occurs only during a millisecond or so at the beginning and end of the 50/60-Hz half-cycle when the tube is operating. This opens up the possibility of avoiding interference from the magnetron by transmitting information only when the magnetron is not emitting noise. It should not be forgotten that there are, however, signals, sometimes at peak currents—as in the case of axial oscillations.

The bottom line is that inherently the cooker magnetron is a prolific noise generator that is compounded in the microwave oven application by all variables such as current, stirrer positions, and temperature load changes. For this reason, special attention was devoted to the development of emission limits for microwave ovens. In Tables 2 and 3 we list the limits [111] issued by the CISPR committee of the IEC (International Electrotechnical Committee). Those in Table 2 are for the frequency range below 1 GHz and are quasipeak limits, while Table 3 applies to frequencies above 1 GHz and presents peak limits. While some relaxation is given in the lower sideband region, the limits are tightened elsewhere, particularly around the fifth harmonic, which is close to some satellite TV bands. Note that as of yet, the compliance tests apply only to time after the oven and magnetron have started. The noise and moding signals during the moding period shown in Fig. 16 are not measured or regulated.

Noise and radiofrequency interference are becoming more serious issues as expanding wireless systems [112] develop in the microwave bands above 1 GHz. Of particular concern are the systems that share the ISM band at 2.45 GHz, but there exists RFI potential in many other

Figure 22. Chart of measured microwave oven emissions in a test for compliance with CISPR 11 limits.

bands—For example, in the satellite radio band located between 2.3 and 2.4 GHz.

Heretofore magnetron developers and manufactures have found no easy solution to the “noise problem,” and it is not likely that one is forthcoming soon. In the meantime oven manufacturers must employ a wide variety of

fixes, sometimes with ingenuity, in the face of such a complex set of phenomena. Note that simple filtering is not the answer, even if it were cost-effective. Filters that reflect energy can also modify the harmonic levels and other signal levels in the magnetron as well. Still a better understanding of the origin of the signals in the magnetron will be helpful, and much work remains in this area.

7. TECHNOLOGICAL DEVELOPMENTS

Two devices that have demonstrated excellent performance employ technology that is important in obtaining low-noise operation of the crossed-field device and power generation at millimeter wavelengths. The voltage-tuned magnetron is discussed relative to both noise and a more recent millimeter-wave application, and the beacon magnetron for its high-frequency design features. Both devices have required marked attention to manufacturing details to achieve a high level of performance.

Technology developments for commercial, industrial, and military applications include injection locking of the magnetron, cathode-driven CFA, millimeter-wave tubes and harmonic generation, high peak and average power CFA, relativistic magnetron, and large anode area devices for high-power microwave (HPM) and millimeter-wave applications.

Table 2. CISPR 11 Limits on Microwave Oven Emissions at 10 m, and 0-1 GHz

7.1. The Voltage-Tuned Magnetron: Past Performance and Potential Application

The voltage-tuned magnetron (VTM) has had application as a low-power, CW, microwave signal source at frequencies extending from 200 MHz to above 10 GHz. At power levels of milliwatts to a few watts, these devices are capable of being tuned over a 2/1 and 3/1 range of frequency. High-power tubes have 10–30% tuning range, which depends on the frequency band. These tubes have been used in electronic countermeasures and as general sources of microwave power for test and evaluation of microwave systems. Typical VTM performance is 400 W (minimum) from 2.7 to 3.5 GHz at 65% efficiency and 100 W from 9 to 10 GHz at about 50% efficiency.

A paper by Weinstein and Winkowski [113] summarized the status of the VTM as of 1977. These devices are magnetically shielded, typically integrated with wideband isolators to permit operation into variable load impedance, can be conduction-cooled as a result of high efficiency, are robust in terms of operation under extreme vibration and shock conditions, generate very low noise, and have excellent shelf life.

To achieve wide tuning, the VTM employs an interdigital anode circuit [114]. The transmission-line circuit is closed on itself in a manner similar to that for the conventional magnetron anode with phase shift of 180° between anode electrodes thus operating in the pi mode. The transmission line can be heavily and uniformly coupled to the load for wide frequency tuning at low power, and nominally coupled for limited tuning at high power.

In the conventional magnetron operating under a condition of space-charge-limited emission an increase in anode voltage produces an increase in anode current. This is accompanied by a small shift in frequency termed “pushing.” In the VTM an electron gun injects electrons axially into the interaction space between a dummy cathode electrode and the anode. The current injected into the interaction space is controlled by adjustment of a voltage applied to a control electrode in the gun. A change in anode voltage at constant anode current produces a change in the azimuth angular velocity of the electrons with an associated increase in frequency such that synchronism is maintained between the rotating electrons and the RF voltage wave supported by the anode circuit. The oscillation frequency is directly proportional to the anode voltage. By sweeping the anode voltage, the frequency can be modulated at rates of 60 MHz. Higher rates can be obtained by aboveground operation of the anode (positive anode operation).

High-power CW tubes with tuning of 10–20% have a spectrum quality that exceeds that obtained from high- Q magnetrons. Limited published data [115] show a noise level of -110 dBc/Hz at 10 kHz offset from the carrier and -150 dBc/Hz extending from 100 kHz to 100 MHz. Other data at 30 MHz offset from the carrier the noise are -160 dBc/Hz and harmonic power -60 dBc [116]. The close-in noise data are consistent with those obtained from the microwave cooker magnetron when operated with a thoriated tungsten cathode operated in the temperature-limited regime. The data suggest that the VTM may be an

ideal vehicle for the study of crossed-field noise generating mechanisms.

It is expected that injection locking of the VTM would further reduce the noise close to the carrier. Since with an injected beam the electron stream is located at large radii, it is probable the locking gain will be higher than that of the conventional magnetron.

A possible application of the VTM principle is to excite multimode microwave cavities for improving the heating or processing of materials and for the generation of large-volume gaseous plasmas. Multikilowatt power can be generated using the vane and strapped S- and C-band magnetron circuits with an axially injected electron beam. The cost of a high-power VTM would be substantially lower than the cost of the traveling-wave tube previously considered for such applications.

Low unit cost, compact size, low weight, excellent spectrum quality, and high reliability under shock and vibration conditions suggest that the VTM is a potential competitor with the beacon magnetron in airborne transponder applications. The VTM should also have application as highly stabilized, tunable oscillator at millimeter wavelengths for radar applications. A high-power, injection-locked harmonic generator is based on the VTM principle is discussed below.

7.2. Beacon Magnetron

The beacon magnetron is a high-frequency, low-peak-power and average-power magnetron optimized for frequency and pulse stability, low jitter, ruggedness, and reliability, which are critical parameters for use in beacon, transponder, fuze, weather, and marine radar applications [117]. This is achieved by design improvements such as making the cathode more rugged, temperature compensation, and output matching to control frequency pulling (change in magnetron frequency with variation of load VSWR). Frequency pushing is controlled by careful interaction space design and by suitably mating the magnetron to the modulator to ensure generation of a flat-top current pulse. Low pulse to pulse frequency jitter and pulse starting-time jitter is obtained by ensuring adequate and uniform cathode emission, careful vacuum processing of the tube, and optimization of the rate of rise of the modulator voltage pulse. Size and weight reduction has been generally achieved with optimizing the design of magnet pole pieces and Alnico magnet location [118].

A design approach presented by Hobbs [119] that provides additional advantages is that of the positive anode magnetron. The magnetron anode is isolated from ground and pulsed positively; the cathode and magnet pole structure are grounded. Axial beam confinement is done by the magnet pole tips now placed closer to the anode. This reduces the amount of magnetic material required to provide the necessary field level and results in improved uniformity of the field. Use of the higher-reluctance Alnico materials or the rare-earth cobalt materials allows placement of the magnet close to the interaction space, reduces energy loss, and again reduces magnet and return path size and weight.

The cathode and the magnet pole tips are at the same DC potential, which allows more accurate centering of the cathode with respect to the anode via the use of thermally insulating spacers near the interaction space. Both electric and magnetic fields in the interaction space are more uniform with the result of reduced starting jitter and lower startup noise, lower frequency pushing, and cleaner spectra. Efficiency is improved by about 5% as compared to the conventional beacon structure. Typical peak power for fixed-tune devices at X band is 1–10 kW at 0.001 duty factor and 0.1–5.0 μ s pulsewidth, and weight and volume are approximately 0.6 lb and 7 in³.

The beacon magnetron design philosophy has been carried over to the millimeter-wave regime. Noise suppression and tuning over a finite frequency range is managed via injection locking as discussed below.

7.3. Injection Locking

Injection locking of the magnetron is the control the frequency of the free-running magnetron oscillation by means of an external drive signal. The magnitude of the locking signal affects the locking bandwidth; specifically, the change of oscillator frequency Δf controllable by the drive frequency is determined by

$$\Delta f = (2f_0/Q_e)[P_{in}/P_{out}]^{1/2} \quad (18)$$

where f_0 is the frequency of the free-running magnetron, the ratio P_{out}/P_{in} is the pseudogain, and Q_e is the external quality factor of the magnetron. Depending on the particular magnetron, the drive power necessary to provide frequency locking can vary from 10 to 30 dB below the carrier. Larger bandwidth is obtained at the higher drive levels. In addition, higher drive reduces both the time to achieve lock from the start of buildup of oscillations, and in the steady-state locked condition the noise level close to the carrier is reduced as compared to that of the free-running oscillator [118].

Data on phase noise–frequency offset from the carrier for a pulsed, 10 W, X-band positive anode magnetron MA2829 was obtained by Hobbs [120]. With a magnetron Q_e of 185 and gain of 10 dB, the coherent bandwidth was 0.34%. From 1 to 100 kHz offset the noise was reasonably flat at -113 dBc/Hz at center frequency while improving at the lower band edge to -115 dBc/Hz and degrading to -100 dBc/Hz at the upper band edge. With a Q_e of 80, corresponding to increased coupling to the load, the coherent bandwidth was increased to 4%. The noise over the same offset range as above was a minimum at -115 dBc/Hz at center frequency. The noise was -111 dBc/Hz at the lower band edge and -108 dBc/Hz at the upper band edge, representing an overall improvement at the lower value of Q_e .

These noise data are consistent with results of English [121] and Garrigus [122] where noise for injection-locked magnetrons lies within the range from -120 to -90 dBc/Hz.

A marked improvement in the noise of the injection locked microwave oven magnetron has been obtained by Brown [123]. The technique employed was to reduce the filament power to the magnetron such that the tube

operated in a temperature-limited emission regime as compared to the conventional a space-charge-limited regime. Historically, prior to 1958 it was recognized that operation of the magnetron had reduced noise when operated with the cathode temperature-limited as compared to the same magnetron operating in the space-charge-limited state. It was also recognized that cathodes available at that time tended to lose emission (*poison*) when operated temperature-limited. Concern on magnetron life and reliability hindered further research at that time. Research on developing a low-noise magnetron operating with space-charge-limited emission was pursued but has not been achieved to date.

The carburized thoriated tungsten cathode employed in the microwave oven magnetron is quite stable under temperature-limited operation. The low-noise performance potentially has application to commercial and industrial magnetrons and to crossed-field devices that might be considered for use in the area of microwave power transmission. CW testing of the oven magnetron at reduced magnetron filament power has shown improved noise performance for both the free-running oscillator and for the injection-locked oscillator (directional magnetron amplifier) with the lowest noise measured when the magnetron frequency is controlled by a drive signal. The measured noise can be as low as -197 dBc/Hz with the imposed conditions of temperature-limited operation of the cathode and the introduction of a cathode impedance that minimizes resonant coupling to the cathode.

A comprehensive historical review of magnetron and crossed-field amplifier noise has been prepared by Brown [123], and details of the experiments and noise measurements have been documented [124].

An approach to increase the locking bandwidth while maintaining the frequency and phase stability of the coherent drive source by the cascading of injection-locked magnetrons has been described [121]. The advantage of cascading is illustrated by the following example.

Example. A basic X-band 1-kW magnetron with a of Q_e 40 and coherent drive source of 10 W provides a 50 MHz locking bandwidth. The bandwidth is adequate to overcome environmental frequency drifts, resulting in a coherent frequency power source such as, for example, missile fuze systems and weather radar. If two magnetrons were cascaded, the 10 W drive source would produce a bandwidth of 158 MHz. It was projected that a fractional bandwidth of 2% at 10–13 dB gain per stage was achievable.

At Ku band the noise output of an injection-locked magnetron chain was less than -105 dBc/Hz. This value is within the general range of injection-locked noise from -120 to -90 dBc/Hz.

7.4. Cathode-Driven Crossed-Field Amplifier

Marked improvement in both gain and noise of the crossed-field amplifier has been obtained with a modified Amplitron experimental device where an RF drive signal is applied to both an anode and cathode slow-wave structure [125]. The standard S-band CFA typically operated at 10–15 dB gain and signal-to-noise ratio (SNR) of 45–50 dB/MHz. The modified S-band CFA provided gain of 20 dB

and noise-level values of 75 dB/MHz, which is comparable to that achieved by injection-locked magnetrons and linear beam devices. The noise level is consistent with that required for high-power radar applications.

These data are consistent with identifying the noise generating regime in the CFA as being related to mechanisms associated with the continuous cathode. The data are also in accord with previously described voltage-tunable magnetron low-noise data where the electron stream is provided by axial injection into the interaction space rather than a concentric anode-cathode geometry.

7.5. Voltage-Tunable Frequency Multiplier

The application of the principles of the voltage-tuned magnetron to achieve frequency multiplication has resulted in a tube design that has potential for millimeter-wave applications. Two VTM-like devices are cascaded within a single vacuum envelope. The coupling between the two circuits is performed by the rotating, bunched, and axially traveling space charge developed in the input VTM section. The input circuit consists of an interdigital line structure coupled to a quasitoroidal resonator. A low- Q composite resonator system is formed that supports a pi-mode voltage distribution on the interdigital fingers. The output structure has a similar circuit, but the number of interdigital fingers is multiplied by the harmonic number [126].

The harmonic operation of the device is dependent on creation of space charge spokes that have high harmonic content, which in turn is dependent on the spatial distribution of the electrons in the spoke. Numerical simulation of the space charge should play a role in determining the space charge harmonic content as a function of the design and operating parameters.

The device can operate in one of two ways: (1) the drive circuit can be allowed to oscillate, and the resultant space charge will drive the output circuit; or (2) alternatively a low-power locking signal can be applied to the drive circuit at the fundamental frequency. This signal is used to control the space charge and frequency of the input device and results in an effective power gain from the output circuit. The phase of the output signal is determined by the phase of the input signal.

An output power of 430 W was obtained in the 10 cm wavelength range when operating at the fourth harmonic of the fundamental frequency of the drive circuit. Gain was 23 dB, electronic efficiency was 52%, and the tube operated over a frequency band of 15%. The frequency was linear with a voltage that is consistent with voltage-tunable magnetron operation.

The pi-mode interdigital circuit provides bandwidth but will have limited average power capability at high frequencies. The use of the unstrapped-vane-type magnetron circuit, which is capable of high average power when operating in a non-pi space-harmonic mode, may be applicable to the dual-circuit VTM concept.

7.6. Millimeter-Wave Sources

7.6.1. Magnetron Millimeter-Wave Sources. Early millimeter-wave magnetrons used the rising-sun anode structure and operated in the pi mode. The Amperex DX287

developed in 1966 generated power at a fixed frequency close to 95 GHz. The tube delivered 10 kW of RF power at pulsewidths between 5 and 200 nanoseconds (ns) and at duty cycles up to 0.0002. Efficiency was about 8%, and using an impregnated type cathode the life was ~ 500 h. The tubes operated stably into a load VSWR of 1.5–1. Permanent, stabilized magnets of ticonal weighing 15 lb were employed [127].

Improvements in the millimeter-wave magnetron have focused on using samarium-cobalt magnet structures to reduce size and weight, cathode design capable of providing the high emission densities compatible with achieving high average power, high reliability, and long life. The EEV MG5294 95 GHz magnetron, delivers 2.5 kW, a 50 ns pulsewidth, and a duty cycle of 0.0002 corresponding to 0.5 W of average power. Maximum load VSWR is 1.3–1; typical test VSWR is 1.15–1. The tube has an overall length of 5.8 in. diameter of 2.6 in. and weight of 2 lb [128].

Substantial progress has also been made since the mid-1990s using the unstrapped magnetron anode operating in a space harmonic of the fundamental [129]. Typical performance at 95 GHz is 4 kW peak power and 2 W average power at a pulse duration of 50–200 ns and a pulse repetition frequency of 5 kHz (maximum). The magnetron is packaged with a solid-state modulator; total volume is 183 in.³ and weight is 8.8 lb. The transmitter is designed for airborne applications. Space-harmonic millimeter-wave magnetrons have also been employed in practical radar systems [130,131].

Research on alternate M-type oscillators at millimeter wavelengths is being carried out by Kulagin and Yeryomka [132]. The RF circuit is that of the unstrapped magnetron with an axial injected large-orbit electron stream. Operation at lower values of magnetic field and voltage is possible when compared to the magnetron operating in the pi mode with small-orbit electron streams originating from the conventional continuous cathode, which is concentric with the anode. Typical analytical results are wavelength of ~ 1.9 mm, anode voltage of 2 kV at a magnetic field of 0.5 T, and efficiency of 12%. Additional reduction in magnetic field is possible by the use of the interaction of the large-orbit stream with an anode space harmonic [133].

Typical applications for millimeter-wave magnetrons as sources are active missile terminal homing systems, detection of small stationary targets, high-resolution surveillance and MTI radar, and lightweight radars in remotely piloted vehicles.

7.6.2. Millimeter-Wave High-Gain Crossed-Field Amplifier. Research was undertaken in the late 1980s by Macmaster and Nichols [134] on a new approach for a crossed-field device to achieve high peak and average power at millimeter wavelengths. The device has a large-area anode consisting of axially aligned, staggered slots in the anode cylinder wall. A continuous cathode is mounted external to and concentric with the anode cylinder creating an inverted crossed-field interaction space. The anode cylinder with a center conductor forms a coaxial TE₀₁-mode waveguide that transforms to circular waveguide at the input and output. The slots couple RF energy from the

interaction space into the waveguide, and power growth occurs within the coaxial waveguide along the length of the anode. At 34 GHz a peak power of 15.5 kW and 140 W of average power was obtained at a gain of 10 dB. To demonstrate somewhat higher average power capability of the circuit and cathode, the tube was operated at 4 kW peak power, 200 W average power, and 8 dB gain. Earlier versions amplified a frequency between 35 and 36.25 GHz at a power of 50 kW peak, 88 W average, and 10 dB gain. Maximum recorded peak and average power was 58 kW at 230 W.

The geometry of this device is such that an RF circuit can be readily located on the cathode to enhance gain and overall performance. A cathode-driven Ka-band device has not been tested.

7.7. The Electromagnetic Amplifying Lens

A very-large-area anode–cathode crossed-field axial gain device with potential for generating exceptionally high peak and average power at millimeter wavelengths is the electromagnetic amplifying lens or “EAL” designed by Brown and Dombrowski [135]. A number of crossed-field tube research programs were carried out in parallel with the EAL design effort [136]. These programs have been briefly reviewed in a paper by Ruden et al. [137]. None of these efforts succeeded in developing a high-frequency, high-power amplifier. As discussed below, the evaluation of the EAL has yet to be completed.

An X-band, 100-MW-peak-power, prototype EAL employing a platinum secondary emitting cathode was fabricated and tested. However, the available drive power required the device to operate at greater than 20 dB gain. The device oscillated at a frequency well removed from the design frequency and failed to amplify. It was estimated that a drive power of 10 MW would be required to achieve a nominal gain of 10 dB. Other techniques that could be used to achieve amplification are the incorporation of an RF drive circuit on the cathode to provide strong RF fields at the cathode, operation of the device in the low-magnetic-field regime to enhance interaction near the anode between the electron stream and the RF circuit, and the use of an axial injected electron beam as in the voltage tuned magnetron to provide a temperature-limited, current-controlled electron beam.

7.8. Magnetron for Medical Applications

A 9.3-GHz magnetron of 1.8 MW peak power has been developed for radiotherapy [138]. The device uses rare-earth magnets, which results in a compact package meeting the system requirements. Lower-frequency magnetrons have been used extensively in this area. Operation of a representative pulsed S-band magnetron as described by Konrad [139] is 2.6 MW peak power and 3.1 kW average with a 4.2 μ s pulse duration, and a tuning range of 9 MHz. Electromagnets are used to provide the magnetic field, and adjustment of field allows operation at various power levels such that the X-ray energy can be varied. Projected need for peak power magnetrons are 3.5 and 6 MW at S band and 2.5 MW at X band. Increased tube reliability and lower unit cost are key manufacturing goals.

7.9. High-Peak- and Average-Power UHF Magnetrons

A paper by Wynn et al. [138] discusses the development of a 915-MHz pulsed magnetron operating at millisecond pulse length and high duty cycle. The magnetron is a strapped device and operates at higher than normal magnetic field levels, which enhance the efficiency of the device [52,140]. Various pulsed tubes have provided the following performance: magnetron with agile tuning of 60 MHz operated at 250 kW peak power at 25 kW average and an efficiency of 85%; fixed-frequency magnetron operation at 600 kW peak power at 300 kW average and 85% efficiency, and 1200 kW peak power at 300 kW average.

A 300-kW CW L-band magnetron, model CWM-300L, whose design was based on the commercially available 75-kW CW magnetron, model CWM-75L, has been developed [141]. The 300-kW tube operates at 32 kV and 10 A. The conversion efficiency is greater than 90%.

7.10. Relativistic Magnetron

In more recent years experimental work on the relativistic magnetron has centered on devices operating at pulsed voltages of a few hundred kilovolts and the generation of peak power from hundreds of kilowatts to gigawatts. A paper by Taylor and Younan [142] discusses the effects of high-power microwave illumination. Topics discussed are electrical effects, effects on electronics, hardening against high-power microwave illumination (including shielding and filtering), and high-power microwave weapons.

The technical status of the relativistic magnetron is reviewed by Saveliev [143]. Design issues as effective anode–cathode gap, uniformity of electron emission, anode–cathode gap closure velocity, voltage–current characteristics as a function of end caps, microwave characteristics as operating frequency and mode structure, and mode competition are discussed.

An alternate relativistic magnetron design is described by Schnitzer et al. [144], which combines coaxial magnetron and positive anode magnetron principles. Operation at 50 MW at 150 ns and 100 MW at 70 ns was achieved. The reduced power density in the structure is proposed as a possible reason for achieving the observed pulse length from a single device. Another cause of pulse shortening under consideration is failure to properly match the impedance of the modulator to the magnetron impedance.

Chen et al. [145] contend that pulse shortening is related to electron bombardment of the anode electrodes with subsequent generation of ions that are accelerated toward the cathode and modify the plasma at the cathode surface. This ion process is in accord with experimental observation of erosion of the platinum cathode surface in both 50–400 kW CW and 25–50 MW pulsed superpower, S-band Amplitron models [146]. The latter pulsed tubes operated at approximately 150 kV, 1–10 μ s pulse width, and average power \leq 200 kW. Axial striations on the cathode surface are observed directly opposite the gaps between anode electrodes. Computation of the ion trajectories showed that the DC fringing electric fields created by the anode electrode system focus the ions and produce the striations on the cathode surface [147]. In addition, electrons created near the anode by gas ionization can result

in electron bombardment of sections of the anode surface. Gas evolution can occur, which enhances vane-to-vane and single-surface anode multipactor, leading to further gas evolution.

The Chen paper also highlights the importance of pre-processing and proper storage of tube parts, and the following of microwave tube industry procedures of vacuum processing of the tube. (Note: Double-vacuum bakeout was standard procedure for the abovementioned superpower Amplitrons).

8. CONCLUSIONS

The magnetron has survived in an era when most electron tubes have been replaced by solid-state devices in modern electronic systems. In particular, the cooker magnetron is the power source for microwave ovens at power levels of 300–3000 W and its manufacturing volume, worldwide, is over 60 million tubes per year. This version of the magnetron preserves the classical strapped-vane anode design of World War II vintage. Because of its low cost and high efficiency (60–90%), it is unlikely to be replaced by other electron devices.

A wide spectrum of related devices is being developed for specialized applications. These include crossed-field amplifiers, voltage-tuned magnetrons, beacon magnetrons, and relativistic magnetrons. Applications range from the classical radar through industrial heating to microwave weapons.

Computer modeling of magnetrons and related tubes has become an extensive activity in many countries, including Russia, Korea, and Japan as well as the United States. Although considerable advances have been made in describing or predicting magnetron performance, computer calculations have not yet mastered the chaotic nature of electron–field interactions in the magnetron. The excess noise feature of magnetrons remains unconquered and very likely will be a potential radiofrequency interference threat to the expanding universe of modern microwave wireless systems.

Large-scale manufacturing of magnetrons has shifted to countries in the Far East such as China, Thailand, Indonesia, and Korea. More limited production and R&D continue in Japan, Russia, the United States, and a few other countries such as the United Kingdom. Trends in the modern global economy determine, in large measure, future R&D and manufacture of magnetrons.

Despite prediction, in the 1960s, of its obsolescence, the magnetron remains one of the electron tubes that survive because of its high efficiency, power capability, and low cost. Future applications remain unpredictable, but many are being explored. Advances in computer modeling will eventually produce success. It remains to be seen whether magnetron noise can be controlled to permit true electromagnetic compatibility in the new era of microwave wireless communications systems.

Acknowledgments

One of the authors, Thomas E. Ruden, wishes to express his appreciation for the technical assistance and helpful

comments provided by Mr. David Hobbs, Microwave Consultant, retired from Microwave Associates, Inc., Burlington, MA. John M. Osepchuk thanks all at Maytag/Amana Appliances who have supported and contributed to this work, particularly Ed Cook and Thomas L. Miller.

MAXWELLIAN CIRCUITS

KENNETH K. MEI
 City University of Hong Kong
 Zhejiang University
 Hangzhou, China

1. INTRODUCTION

The term *circuit* implies the involvement of Kirchhoff’s laws. The name Maxwell is associated with the partial-differential equations of electromagnetic theory. Most of us who have been doing research in electromagnetics believe that Maxwell’s equations are complete, in that they can formulate any problem related to electricity and magnetism including circuit problems, and that Kirchhoff’s theory is a simplified form of Maxwell’s equations, applicable at low frequencies when the circuit components and connecting wires are much smaller than a wavelength. However, a careful search of textbooks and journal papers reveals that many of our colleagues may not agree with these ideas. In fact, the most embarrassing moments for those of us who have taught electromagnetic theory may have been when we realized that the transmission-line equations, which are derived from Kirchhoff’s laws [1,2], have been an integral part of standard textbooks on electromagnetic theory. Indeed, the transmission-line theory is an important part of a course on electromagnetic theory, which students later apply in their careers as microwave engineers. However, deriving transmission-line theory from Kirchhoff’s laws in an electromagnetic textbook is inappropriate, to say the least, because it misleads our students to believe that Kirchhoff’s laws and Maxwell’s equations are really the same. The objectives of this article are (1) to show that some important part is missing from

Kirchhoff’s circuits so that they cannot be used to simulate solutions of Maxwell’s equations except in certain special cases, and (2) that the solutions of Maxwell’s equations of a structure can be simulated by circuits rendered Maxwellian by adding dependent sources, such that the solutions of voltages and currents of the circuits are identical to those of the original problem.

Before we discuss Maxwellian circuits, let’s review the textbook derivation of the transmission-line equation (TLE) from Kirchhoff’s laws, and rederive it from Maxwell’s equations in Sections 2.1 and 2.2.

2. TRANSMISSION-LINE EQUATION

2.1. TLE by Kirchhoff’s Laws

In the traditional derivation of the TLE, a transmission line is segmented into small identical pieces of Δz , and simulated by series inductor and shunt capacitor as shown in Fig. 1, where L and C are inductance per meter and capacitance per meter of the line, which can be calculated from the specific geometry of the line. Using Kirchhoff’s laws, the voltage and current differences between the nodes $i + 1$ and i are found to be

$$\Delta V = -j\omega L\Delta z(I + \Delta I) \tag{1a}$$

$$\Delta I = -j\omega C\Delta zV \tag{1b}$$

As $\Delta z \rightarrow 0$, and neglecting the second-order term, we get the TLE:

$$\frac{dV}{dz} = -j\omega LI \tag{2a}$$

$$\frac{dI}{dz} = -j\omega CV \tag{2b}$$

2.2. TLE by Maxwell’s Equations

Equations (2) can be derived from Maxwell’s equations of the vector and scalar potentials:

$$\nabla V = -j\omega \mathbf{A} - \mathbf{E} \tag{3a}$$

$$\nabla \cdot \mathbf{A} = -j\omega \mu \epsilon V \tag{3b}$$

On a straight conducting wire along the direction z , and assuming that

$$\mathbf{A} \cdot \mathbf{z} = LI \tag{4}$$

Figure 1. L, C circuit segment used in conventional TLE derivation.

where L is the inductance per meter of the line, which is exact for infinitely long straight wires. Equation (3a) becomes identical to Eq. (2a), since the electric field vanishes along the line. Using the relation

$$\frac{1}{\sqrt{LC}} = v = \frac{1}{\sqrt{\mu\epsilon}} \quad (5)$$

where v is the velocity of propagation, and assume L to be uniform, then, Eq. (3b) becomes the same as Eq. (2b).

2.3. Comparison between Kirchhoff and Maxwell Derivations

While we get identical results from the Kirchhoff and Maxwell theories, there are some differences in the procedures. Specifically, in the derivation by Maxwell's equations, we have to assume that

1. The line is straight and infinite.
2. The inductance and the capacitance per meter are uniform.

These assumptions are absent in Kirchhoff's derivation. This is so because solutions to Maxwell's equations are geometrically specific. Circuits have topology but no geometry; hence Kirchhoff's laws are blind to geometric variation. When L and C are not uniform, Eq. (3b) becomes

$$\frac{dI}{dz} = -j\omega CV - \frac{dL/dz}{L} I \quad (6)$$

The added term in (6) represents the effect of changing geometry in Maxwell's formulation. Since the textbook derivations of the TLE all use Kirchhoff's laws, it is absent from their equations for nonuniform lines. For example, the equations for nonuniform lines in Ref. 1 are

$$\frac{dV(l)}{dl} = -j\omega L(l)I(l) \quad (7a)$$

$$\frac{dI(l)}{dl} = -j\omega C(l)V(l) \quad (7b)$$

where l is the position along a curved line. Using Eqs. 7, the classical textbook [1], for example, went on to obtain the exact solutions to exponential lines. Many inquisitive students have tried to verify their MoM (method of moments) results using those exact solutions and found disappointing results. Of course, they would place the blame on their numerical results. How could one dispute against the exact solution? If the classical textbooks had derived the TLE from Maxwell's equations, such mistakes would not have occurred. Would the added term in Eq. (6) make the equations for a nonuniform line correct? No. As we mentioned earlier, solutions of Maxwell's equations are geometry-specific. So, the approximation of Eq. (4), which is good for a straight and infinite wire, may not apply. In this article, we shall show that wire structures of any shape may be represented by circuits, and are not limited to low frequencies. If the solutions of voltages and currents of a simulating circuit are identical to those of the solutions of the Maxwell's equations of the original

Figure 2. Schematics of a linear dipole

structure, we shall designate it of being *Maxwellian*. To understand the theory of Maxwellian circuits, we need to relate the integral equations of wire structures and differential equations.

3. INTEGRAL EQUATIONS OF WIRE STRUCTURES

The integral equation of a wire structure is derived from Maxwell's equations. The simplest integral equation of a wire structure is that of a straight-wire antenna in free space, driven by an infinitesimally thin gap electric field in the middle of the wire as shown in Fig. 2. The antenna is symmetric: $I(-z) = I(z)$. The simplified geometry will facilitate the ensuing discussions without any loss of generality. The theories can be readily adapted to wire structures of any shape [3].

The integral equation of the current on the antenna in Fig. 2 is

$$\mathbf{L}I(z) = B \cos kz - \frac{jV_0}{2Z_0} \sin k|z| \quad (8)$$

where V_0 is the driving voltage and \mathbf{L} is the integral operator

$$\mathbf{L}I(z) = \int_{-L}^L \mathbf{G}(|z - z'|) I(z') dz' \quad (9)$$

$G|z - z'|$ is the free-space Green function, if the structure is a straight-wire antenna in open air. For wire antennas of other shapes, this should be replaced by an integral of the free-space Green's function [2]. For microstrips of any shape, the integral equation of the thin-wire structure type can still be derived, where $G(|z - z'|)$ would be replaced by a kernel of integrals of a Sommerfeld-type Green dyadic. The constant B is a parameter adjusted to enforce the boundary condition of the vanishing current at the end of the antenna or any other impedance condition at the end of the wire.

4. THE DIFFERENTIAL OPERATOR \mathbf{D}

We have also chosen a delta generator as the source model [4,5] so that the incident field is zero everywhere on the wire except at the gap. Our objective is to find a differential operator \mathbf{D}

$$\mathbf{D}I(l) = \frac{d^2}{dl^2} I + U(l) \frac{d}{dl} I + T(l)I = 0 \quad (10)$$

where $U(l)$ and $T(l)$ are to be found such that the solution of (10) is identical to that of (8). In Eq. (10), the zero on the right-hand side (RHS) is justified because there is no

incident field on the wire owing to the delta source. In fact, for every function of ℓ , there are an infinite number of differential operators that can cause (10) to be zero. We wish to find one that is applicable to all solutions of (8) regardless of the terminating condition at $\ell = L$. Also, the solution of (10) should be the same as that of the integral equation (8) when the same terminating condition is applied. The proofs of the existence and uniqueness of such an operator and its invariance to the terminating conditions are given in the following sections.

Operators are in general not unique, in that the product of the operator of (10) with any other operator should include the same properties of the operator of (10). So, our uniqueness theorem is for \mathbf{D} to be the lowest-order differential operator. It is easy to eliminate a first-order operator as a possible candidate, so the second-order equation of (10) is the next possible candidate.

The theorems to be presented should rely on two assumptions:

1. The inverse operator of the integral operator L exists.
2. The current on the structure can be adequately represented by a complex Fourier series of finite terms.

4.1. Existence Theorem

Let I_i and I_j be two solutions of the integral equation 1 subject to different terminating conditions at $\ell = L$; then there exists a differential operator \mathbf{D} , defined in Eq. (8), such that $\mathbf{D}I_i = 0$ and $\mathbf{D}I_j = 0$.

We can prove the existence theorem by substituting these two solutions into (10) to get two equations from which we can solve for the coefficients U and T . The solutions for U and T should exist and be unique unless the following determinant vanishes:

$$\begin{vmatrix} \frac{dI_i}{d\ell} & I_i \\ \frac{dI_j}{d\ell} & I_j \end{vmatrix} = 0 \tag{11}$$

Vanishing of the determinant (11) means

$$\ln I_i - \ln I_j = \text{constant} \tag{12}$$

In other words, the ratio I_i/I_j must be a constant, which is not possible if I_i and I_j have different terminating conditions. Because a current can be approximated by finite terms of complex Fourier series, then for (4) to be true within a finite nonzero interval of $\Delta\ell$, say, at the neighborhood of a point $\ell = \ell_0$, it should follow that $I_i^{(n)}(\ell_0) = CI_j^{(n)}(\ell_0)$, for $n = 0, 1, 2, \dots, \infty$, where C is a constant. This implies that the Taylor expansions of $I_i(\ell)$ and $CI_j(\ell)$ are identical, which leads to $I_i(\ell) = CI_j(\ell)$ over the entire length of the wire, which again contradicts the assumption of the boundary conditions. Hence, (11) can be true only at discrete points where U and T may be singular but not in a finite interval $\Delta\ell$, and it follows that the existence of a differential operator valid for at least two solutions of (8) is proved.

4.2. Uniqueness Theorem

The differential operator D , defined in Eq. (10), is unique for all solutions of an integral equation shown in Eq. (9).

We can prove the uniqueness theorem by letting I_i and I_j be a pair of solutions of (9) from which we obtain an operator \mathbf{D}_{ij} , and letting L^{-1} be the inverse operator of the integral operator L :

$$\mathbf{D}_{ij}I_{(i)} = \mathbf{D}_{ij}\mathbf{L}^{-1}\left(B_{(i)} \cos k\ell - \frac{jV_0}{2Z_0} \sin k|\ell|\right) = 0 \tag{13}$$

The RHS of (13) must vanish for two different values of B because the left-hand side (LHS) must vanish for both I_i and I_j , which satisfy different terminating conditions. For (13) to vanish for two different values of B , it is necessary that the two terms on the RHS of (13) vanish separately after being operated on by $\mathbf{D}_{ij}\mathbf{L}^{-1}$. It follows that

$$B_{(i)}\mathbf{D}_{ij}\mathbf{L}^{-1} \cos k\ell = 0 \tag{14}$$

Since $B_{(i)}$ govern the terminating conditions and $B_i \neq B_j$, at least one of them does not vanish. Therefore, $\mathbf{D}_{ij}\mathbf{L}^{-1} \cos k\ell = 0$ is independent of the parameter B and $\mathbf{D}_{ij}I_{(i)} = 0$ has to be an invariance of the terminating conditions.

Since \mathbf{D}_{ij} exists and is unique between I_i and I_j , the same is true for \mathbf{D}_{ik} between I_i and I_k . But \mathbf{D}_{ij} is also applicable to I_i and I_k because of its invariance to the terminal condition. It follows that $\mathbf{D}_{ij} = \mathbf{D}_{ik}$. It is thus proved that \mathbf{D} is the same for all solutions I , since \mathbf{D}_{ij} is unique for I_i and I_j and \mathbf{D}_{ik} is unique for I_i and I_k .

4.3. Finding the Operator \mathbf{D} from Numerical Results

The integral equation of the type in (1) is most conveniently solved numerically [2]. To find the operator \mathbf{D} numerically, we assume the wire structure to be subdivided into equal segments, and the values of the currents are found numerically at the middle of each segment. A second-order differential operator may be represented by the linear equation

$$I_{n+1} + a_n I_n + b_n I_{n-1} = 0 \tag{15}$$

at a point n ($n = 1, 2, \dots, N$). Substituting two numerical solutions for I into (15), we can solve for a_n and b_n . The values of U_n and T_n can be obtained readily by comparing (15) to the finite-difference form of (10), which yields

$$U_n = 2 \frac{(1 - b_n)}{(1 + b_n)\Delta\ell}, \quad T_n = \frac{2(1 + a_n + b_n)}{\Delta\ell^2(1 + b_n)} \tag{16}$$

5. OTHER NUMERICAL RESULTS

We have used MoM and the terminating conditions, $I(L) = c$ and $I'(L) = \alpha I(L)$ with various values of c and α to find the current along the wire. Values of coefficients U and T obtained from different pairs of current are all the same, just as the theorem predicts. The values of current, T , and U for a wire antenna with two right angle bends are given in Fig. 3. It is interesting to observe that the value of U is practically zero in the midsection of the straight wire.

The value of T there is the square of the free-space wave-number, which indicates that the current travels along a straight-wire antenna with the velocity of light, almost without attenuation. Most of the radiation, therefore, takes place near the bends and ends of the antenna, where both U and T change drastically. Another interesting feature of the differential equations is that the coefficients U and T are very sensitive functions of the local geometry of the wire. From the currents it is difficult to see where the bends are, but from U and T it is quite obvious where the bends are located. Conversely, the currents are not very sensitive to the errors of the differential equations. Since the functions U and T near the bends are characterized fairly easily, one can make use of their approximations to form the differential equation of the current [6]. Figure 4 shows the values of the current on a rectangular helical antenna as calculated by the MoM and those reconstructed by the differential equation. They are practically identical, just as the theorem has predicted.

5.1. Extraction of Maxwellian Circuit Parameters from Full-Wave Results

One important application of the differential equation formulation is that it is amenable to the extraction of circuit

components from the full-wave results that might be found, for example, by the MoM. Actually, wire antennas and microstrips belong to the same class of problems that can be solved by integral equations of the type in Eq. (8). Circuit parameter extraction is important for IC interconnects, which is done traditionally from static results [7,8] on open transmission systems. Although several researchers have succeeded in obtaining full-wave solutions of microstrips of various shapes [9,10], none has made any attempt to extract circuit parameters from the dynamic results. Using the differential equation of the current, we are able to extract circuit parameters for both transmission and radiating systems at any frequency.

Having shown that the solution of the differential equation (10) truly reproduces the MoM solution, our next step is to split Eq. (10) into two coupled first-order equations involving current and voltage. The general homogeneous first-order linear system of differential equations [11] that can reproduce Eq. (10) may be written in the form

$$\frac{dV}{d\ell} = -j\omega L(\ell)I + \alpha(\ell)V \quad (17)$$

$$\frac{dI}{d\ell} = -j\omega C(\ell)V + \beta(\ell)I \quad (18)$$

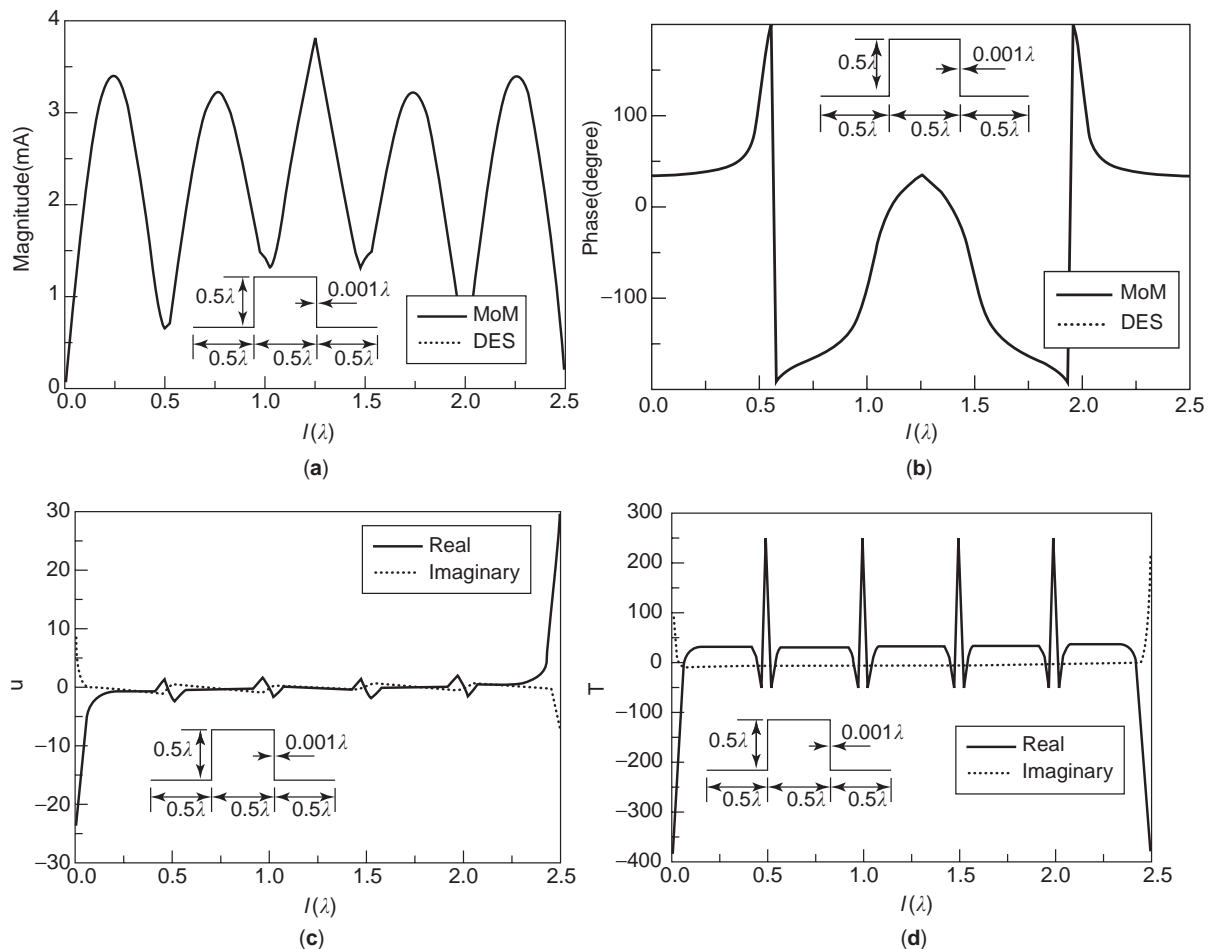

Figure 3. (a) Current $|I|$ on a double-bend wire antenna; (b) phase angle of the current of (a); (c) coefficient $U(\ell)$ of a double-bend wire antenna; (d) coefficient $T(\ell)$ of a double-bend wire antenna.

Figure 4. Currents on a rectangular helical antenna driven at node 5, computed by MoM and by solution of the wire differential equation.

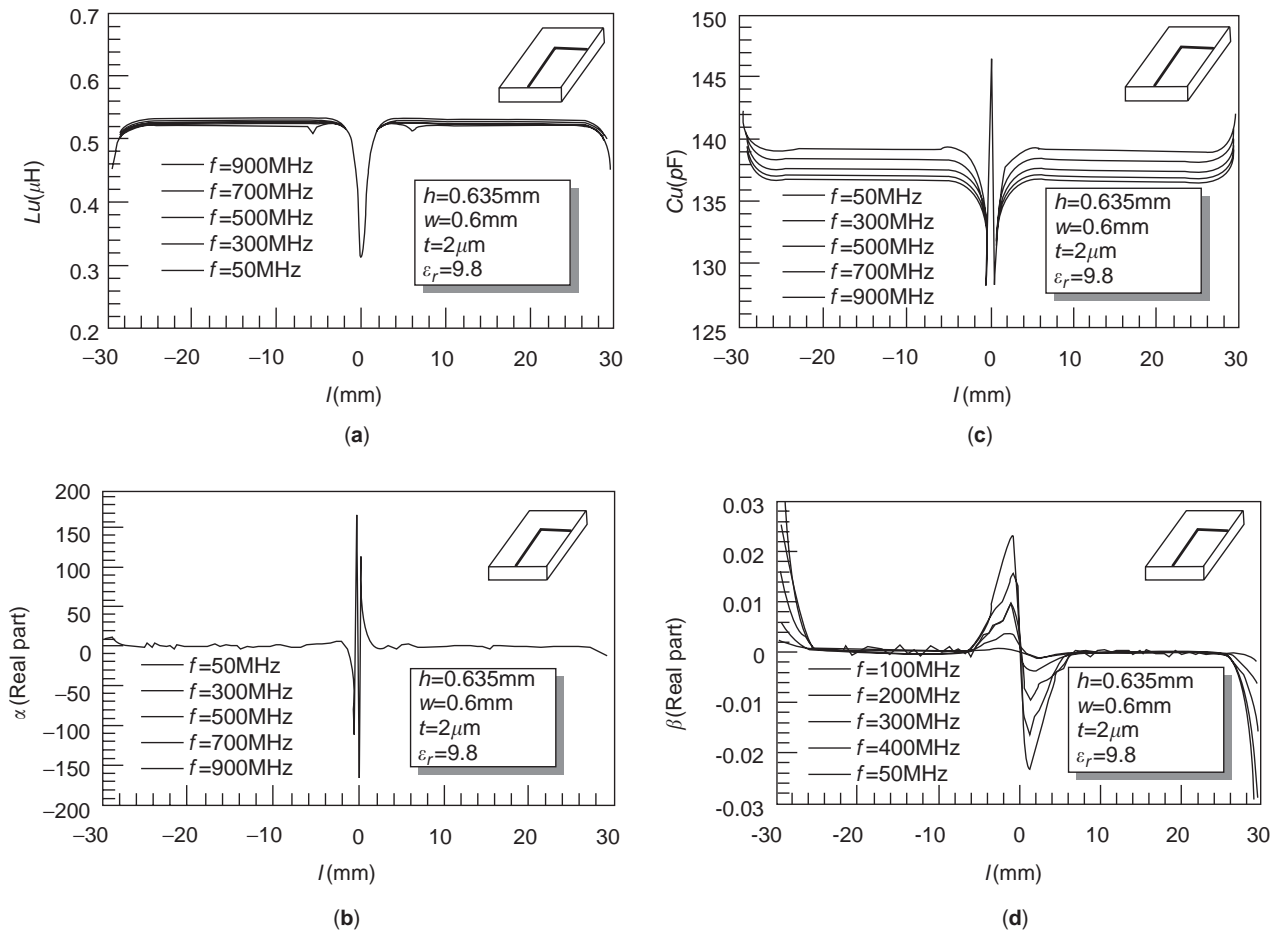

Figure 5. Circuit parameters (a) $L(\ell)$, (b) $\alpha(\ell)$, (c) $C(\ell)$, and (d) $\beta(\ell)$ of a 90° bent microstrip of $\epsilon_r = 9.8$ for $f = 50\text{--}900$ MHz, applicable to all loads.

Figure 6. Schematics of a microstrip of double-bend discontinuity.

where the factor $j\omega$ is inserted for convenience in the ensuing discussions relating L and C to circuit elements. Since $I(\ell)$ is found by MoM and $V(\ell)$ can be found from $I(\ell)$, we need two independent solutions of $I(\ell)$ to find L and α from (17), and C and β from (18). After the parameters are found, V may be eliminated from (17) and (18) to get a

Figure 7. S_{11} of microstrip discontinuities of Fig. 6, computed by Maxwellian circuits with parameter s extracted at 3GHz, and comparison with those by MoM.

second-order differential equation of $I(\ell)$, which, by the uniqueness theorem, should be identical to Eq. (10).

Since D is proved to be invariant to the terminating conditions, so should be the parameters L , C , α , and β , from which we can derive D . The L , C , α , and β are circuit components familiar to circuit engineers, where α and β are parameters of the voltage- and current-dependent sources, respectively. The novelty is that the exact solution of an antenna problem can now be obtained by solving a circuit problem. Since such circuits are formulated via solutions of Maxwell's equations instead of the conventional Kirchhoff's laws, they are termed "Maxwellian circuits."

5.2. Line and Load

In the classical theory of uniform transmission lines, an infinite line is indistinguishable from a finite-length line with a matched load. In this new formulation, we should note that a load has to be different from a line.

The parameters L , C , α , and β are invariants of the load, but they are not invariants of the length or shape of the line. A pure load is defined as a circuit parameter, which does not produce external fields to influence the other parameters of the system. Since a piece of open transmission line is considered to be a radiating or receiving element, it cannot be considered as a pure load. The combination of a load and a transmission line is not a pure load. The attached transmission line must be accounted for in the determination of equivalent-circuit parameters. For the same reason, an antenna is not a pure load unless it can be shown that its radiation has no effect on the transmission system. Because of the variation of the equivalent-circuit parameters near the line termination, an exact matching load may not be easy to find. The conventional matching load, the characteristic impedance, may be a good approximation, but there is no guarantee that it is the optimum.

5.3. Numerical Results on Circuit Parameters

The circuit parameters are not calculated from the second-order differential equations. They are calculated directly from the solutions $I(\ell)$ as mentioned in the previous section. To show the versatility of the theory, we present the circuit parameters of microstrips, where they are most needed.

Figure 5 shows L , C , α , and β of a microstrip with a 90° bend. An interesting feature of these figures is that L and C are now almost independent of frequency. There are small drifting changes, which may be partially attributed to the numerical inaccuracies in the computation. An average value within an operating band may be adequate for most applications. The parameter α is essentially frequency-independent. Only β is dependent on frequency, and our calculations show that its variation is in proportion to ω^2 . Even the ω dependence of β can be avoided if we choose to use a mitered 90° bend. β is independent of ω if the bend is 45° . A 90° bend can be achieved by two 45° bends. β becomes ω dependent when the two varying parts of β overlap, which happens when the inner mitered distance is less than the width of the strip. Using these parameters to solve for the current on the bend microstrip, one should obtain results identical to those from MoM. It is noted

that, in the computation of the parameters, all are considered to be complex, but the results show that all are real. Using these real parameters, one can readily calculate the current of any load. Figure 6 shows the geometry a double-step discontinuity of a microstrip. Figure 7 shows the comparisons of the results calculated by the equivalent circuits and those by MoM of absolute values of S_{11} of the structure. The Maxwellian circuit parameter of Fig. 8 is calculated at 3 GHz. The total time for 20 sample points of calculation using MoM is 1025 s, while the same

calculation using the Maxwellian circuits including one solution of MoM at 3 GHz is 65.87 s.

6. MAXWELLIAN CIRCUITS OF LINEAR ANTENNAS

With the theory of Maxwellian circuits, we can now represent a long dipole by circuits. The only approximation is the discretization in the numerical process. The circuit parameters of a resonant dipole are shown in Fig. 8. There

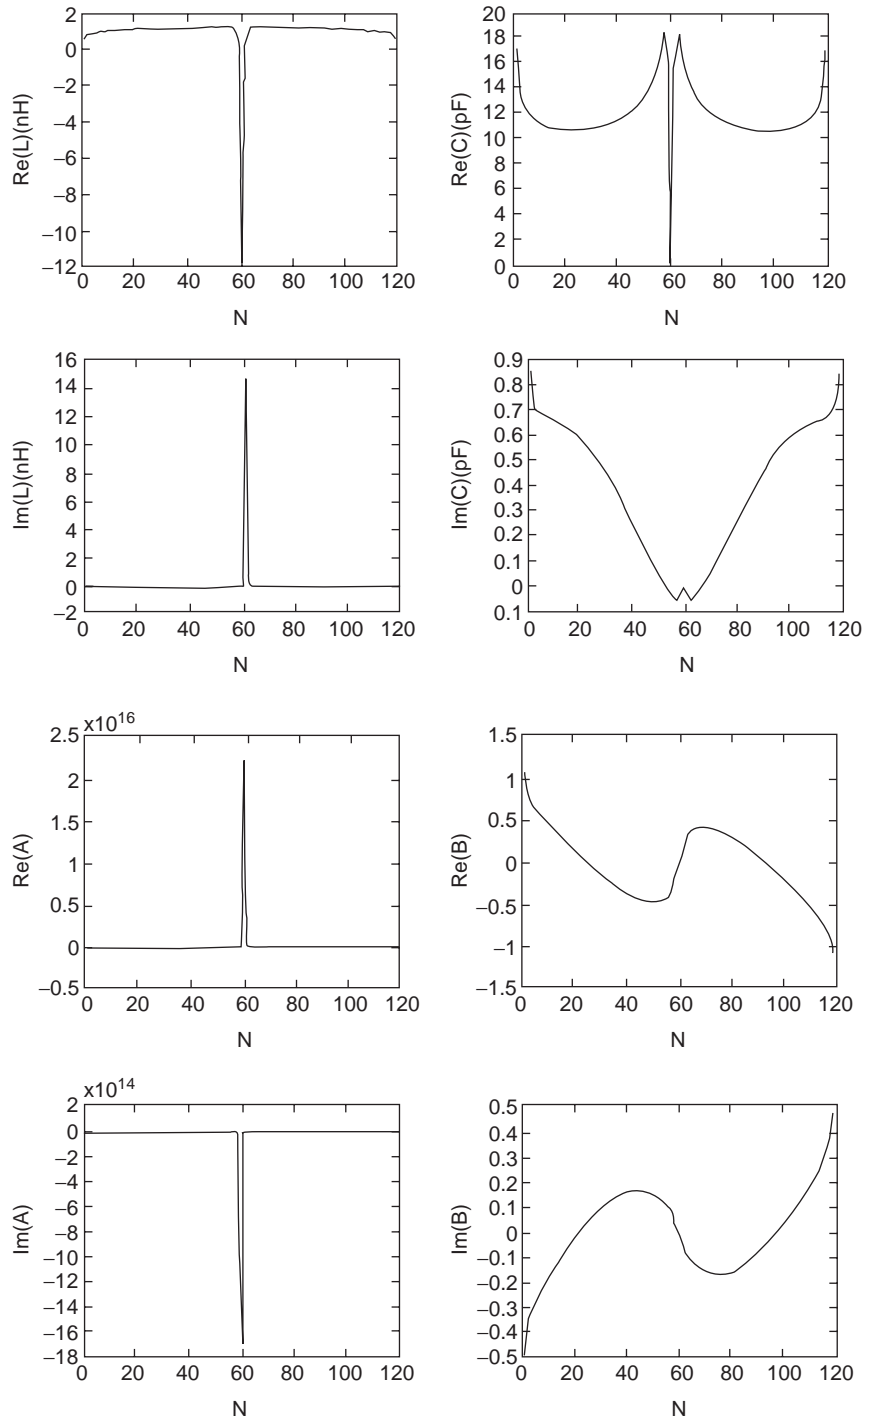

Figure 8. Maxwellian circuit parameters of a resonant dipole.

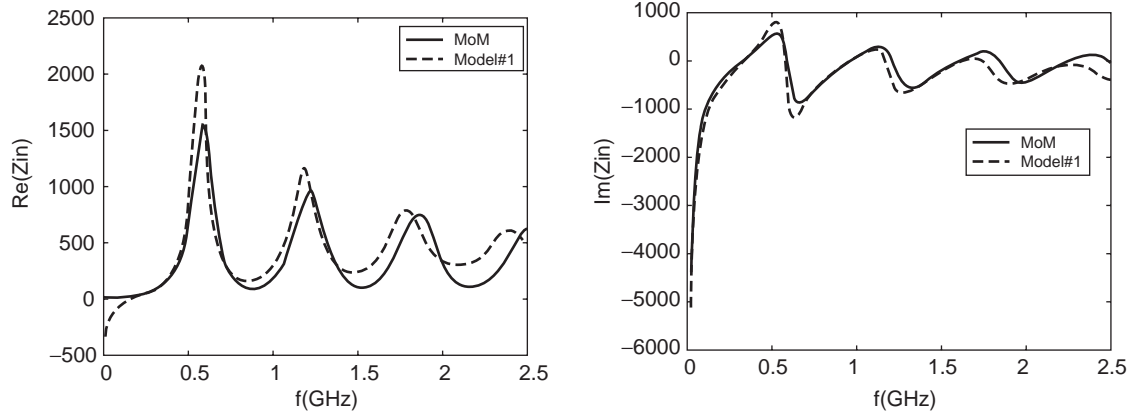

Figure 9. Input impedances of a dipole antenna of the Maxwellian circuits, the parameters of which are extracted at 300 MHz.

are some obvious differences between the parameters of a dipole and those of a transmission line. The parameters α and β of a transmission line are essentially real and appear only near the discontinuity or truncation, but those parameters of the dipole are complex and are spread all over the antenna. The role of those parameters in the radiation process is not exactly known, but one may speculate that they are influential. The input impedances of the equivalent circuits of a dipole, the parameters of which are calculated at 300 MHz, are shown in Fig. 9. Comparing the results of exact MoM calculations, we find the equivalent circuit to be fairly broadband. One may readily broaden the bandwidth by replacing the simple L, C circuits by impedance and an admittance ladder network and match the results at a few frequency points [12].

7. INTERPRETATION OF THE DEPENDENT SOURCES

Without α and β , (17) and (18) are the textbook equations of nonuniform transmission lines [1], which are derived from Kirchhoff's laws. By including the dependent sources, we have essentially modified Kirchhoff's laws, but the physical conditions we have used to replace Kirchhoff's laws are not explicit here. However, the dependent sources α and β are not arbitrary. They are found by fitting the equations to the solutions of Maxwell's equations. The significance lies in the fact that one pair of α and β is sufficient for all solutions of Maxwell's equations of the specific system, which implies that the pair (α, β) is a part of Maxwell's equations. In contrast to Kirchhoff's laws of current conservation, Maxwell's equations stipulate the conservation of charge, so α and β must be there to maintain this physical condition. Another interpretation of the role of the dependent sources is that an open transmission line is not a purely passive system. When a section of line radiates, it behaves like a sink to the system because it takes energy away. Conversely, when a segment of line receives energy from outside, it behaves like a source. So, a section of line can be passive or active depending on the direction of current flow—a role that cannot be fulfilled by an active or passive component. But a dependent source fits naturally. There is very strong evidence to support the claim

that the missing links between a theory based on Maxwell's equations and one based on the laws of circuits are the dependent sources. Without them the model is incomplete and the discrepancies arise as erratic frequency and load dependencies of the circuit parameters. With the dependent sources, the solutions of the equivalent-circuit problem become the same as those of Maxwell's equations for all loads over a wide band of frequencies.

8. FURTHER RESEARCH

The concept of Maxwellian circuit is new. There are only a few published articles on this subject, scattered in journal and conference papers [6,13,14]. The basic theory, presented in this article, is the same as those in Refs. 6 and 13. Reference 14 contains an extension of the theory of Maxwellian circuits to multiwire systems. An extension of the theory from frequency domain to time domain is contained in Ref. 15. The theory is still in its infancy. The direction of further research must depend on the acceptance of the new concept by the microwave and circuit community in either computation or computer-aided design. It is hoped that the theory will soon be extended beyond the thin-wire structures, such as patches and multilayer systems. Since the Maxwellian circuits are obtained from solution of Maxwell's equations, they are only as good as the software that provides the solutions. Most commercial Maxwell's equation solvers provide accurate current densities but not voltages. Thus, the applicability of Maxwellian circuits also depends on the availability of new software, which provides both accurate voltages and currents.

9. CONCLUSION

We have shown that, to every integral equation of the thin wire structure type, there exists a unique second-order differential operator, the solutions of which are identical to those of the integral equation if identical boundary conditions are applied in the solution to the integral and differential equations. Existence and uniqueness theorems are proved. When the second-order differential equations

are rewritten as two first-order differential equations involving voltage and current, equivalent circuits evolve naturally. We have shown that the telegrapher's equations for nonuniform lines, given by most textbooks of electromagnetic field theory, are incomplete. We have appended dependent sources to the equations to make them complete, and the ensuing results are most remarkable. It renders the passive components almost independent of frequency, thus preserving the simple relation between voltage and current of circuit theory without invoking the complicated process of convolution. The dependent sources appear to be the missing link between circuit theory and electromagnetic theory. Only by including them can the currents in a circuit obtained from the solution of equations based on circuit laws be the same as currents obtained from the solution of Maxwell's equations. The theorems and ensuing equivalent circuits have not only improved our physical insights but also accelerated computations because of the broadband nature of the circuit parameters.

MEASUREMENT OF NEAR FIELDS USING A MODULATED SCATTERER

FRED GARDIOL
Swiss Federal Institute of
Technology
Lausanne, Switzerland

1. INTRODUCTION

In the close vicinity of electrical equipment, electronic devices, and antennas, the electric and the magnetic fields often exhibit a complex behavior, in particular when guided, radiated, surface, and leaky waves are simultaneous present. The fields of the different waves combine and may form complicated patterns.

The usual measurement techniques determine signal amplitudes and phases at the ports of a device and in the far field of an antenna. They do not show what happens inside the device itself, or just next to an antenna, how signals travel along transmission lines and across junctions, mysteriously vanishing at some ports, and what parts of an antenna actually contribute to radiation.

For practical purposes, it would be most valuable to know how the fields are distributed in the close vicinity of a device, for instance, to determine the presence of leaks in shielded enclosures, or of hotspots and of potential trouble areas in printed and monolithic circuits. For some large antennas and arrays, the far-field region starts at very large distances, so that measurements have to be made within the near-field region. The far-field behaviour is then derived with the help of mathematical transforms.

One can use a small probe antenna and a receiver to carry out near-field measurements, and this is commonly done in compact antenna test ranges. Unfortunately, the introduction of a probe, together with the transmission line (coaxial line or waveguide) required to connect it to the receiver, perturbs to some extent the measurement, because the presence of metal locally short-circuits the tangential electric field. In addition, the transmission properties of flexible transmission lines vary somewhat with the shape of the line—as the antenna is moved around—and this effect becomes significant at high frequencies. This means that the direct measurements of the fields might yield unreliable data. This can be avoided to some extent by placing the receiving probe far enough

from the element under test, for instance, in the Rayleigh and Fresnel regions of an antenna.

The issue to be resolved is then how can one accurately determine the field distribution that would exist if the probe and its connecting line were not there. Within a complex field environment the answer is by no means obvious, because the field changes with the position of the probe. Only for some simple situations can one determine correction factors to account for its presence.

An indirect measurement approach introduces a small but well-defined perturbing element. Measurements are made with and without this element, and the difference between the two sets of measured values yields the desired information. However, the field distribution must not be significantly modified by the introduction of the element, so that it must remain very small—but at the same time it must also be large enough to produce a detectable response. The two requirements are clearly contradictory! In addition, the need to carry out two sets of measurements tends to be impractical, in particular when one wishes to obtain the distribution of a field component at many locations over a specified region of space.

The perturbing element should be provided with additional information that would attach some kind of “tag” to it, in order to detect its presence more clearly. This is done by applying a modulation by mechanical or electrical means. In this manner, one can discriminate the signal coming from the perturbing element from background reflections and noise. This is the basis of the *modulated scatterer technique* (MST).

The technique was first developed in 1955 by Cullen and Parr [1], with a vibrating and rotating dipole, and by Richmond [2], who electrically modulated a scatterer. At that time measurements had to be carried out manually; they were therefore impractical and time-consuming, and the new technique did not meet with much success.

Since the advent of computers, the measurements can now be completely automated—directed and controlled with the help of dedicated software and directly yielding field plots and associated quantities. The modulated scattering technique now provides a flexible, fast, and efficient way to analyze systems, becoming a useful tool for researchers and designers. Its low invasiveness makes it particularly attractive for particular situations where the element under test must not be disturbed.

The modulated scatterer technique can be used to measure all kinds of antennas and high-frequency printed and monolithic circuits, to test for electromagnetic compatibility, to characterize material properties, and to control industrial processes. In biomedical applications, it plays an important role in microwave tomography. Unfortunately, the information and the results obtained with this technique are widely spread out within the technical publications of the specialized fields involved, and are therefore not easy to locate for “outsiders.” To overcome this hurdle, Bolomey and Gardiol collected the most significant informations related to the modulated scatterer technique and regrouped them within a book, making them more readily available to the general public [3].

2. PRINCIPLE OF OPERATION

When a scatterer is introduced into an electromagnetic field, currents are induced on its metallic parts, which then transmit a scattered signal; thus the scatterer behaves like a radar target. One can use either a short dipole—which couples to the electric field parallel to it—or a small loop, which interacts with the magnetic field perpendicular to the plane of the loop. The scattered field depends on the amplitude of the field at the scatterer location. By moving the scatterer, one can determine the field distribution along a line, over a surface, or within a volume.

When a suitable nonlinear element is placed within the scatterer and a modulating signal applied to it, the scattered field is modulated, and it is then more easy to detect with a receiver tuned at the modulating frequency (coherent detection). In principle, the modulation could be provided by illuminating a photodiode with a laser beam, but this approach proved rather difficult to implement in practice for a mobile scatterer. It is more practical to transmit the modulating signal through an optical fiber illuminating a photodiode (Fig. 1), or still to apply a low-frequency modulation to a mixer diode with high-resistivity wires—in both cases the source of the modulating signal is physically connected to the scatterer, but the dielectric and the highly resistive connections do not significantly affect the electromagnetic field.

The device under test, which may be an antenna or a circuit, creates in its vicinity an electromagnetic field. The

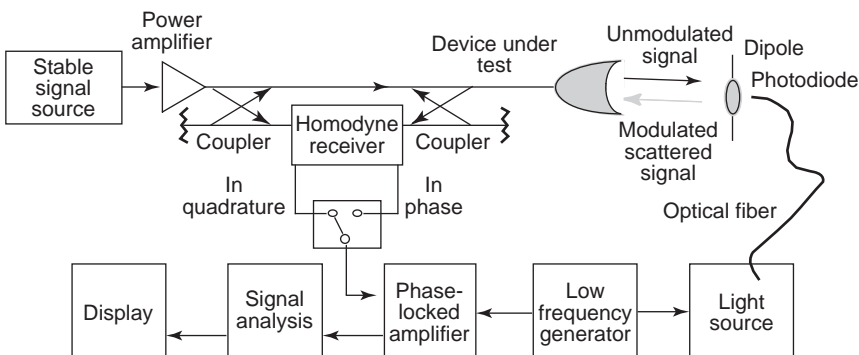

Figure 1. Basic test setup making use of the reflection from a loaded dipole modulated through an optical fiber (monostatic configuration).

scatterer (shown in Fig. 1 as a short dipole loaded by a photodiode) picks up a signal, modulates a portion of it, and reflects it back toward the device under test. The homodyne receiver compares the reflected signal with the signal fed by the source, and provides low-frequency phase and quadrature signals to the phase-locked amplifier. In this way it is possible to retrieve a quantity related to the electric field component parallel to the dipole. When the dipole is replaced by a small loop, the quantity retrieved is related to the magnetic field perpendicular to the plane of the loop.

In the setup of Fig. 1, called *monostatic*, analogously with radar, the same device is used to transmit and to receive, yielding the reflection from the scatterer. The forward and the return signals travel over the same path, so that the transmission factor from the device to the scatterer appears twice in the reflection relationship—a complete mathematical derivation, based on reciprocity and making use of the scattering matrix formulation, is provided in Ref. 3. As a result, the quantity measured in this configuration is proportional to the square of the field component. The amplitude is then determined by taking the square root of the module, but the phase is known only with an uncertainty of $\pm 180^\circ$. This is not too bothersome for field diagnostics, where knowledge of the amplitude of a single field component is generally sufficient to provide the desired information. But the knowledge of the amplitude and phase of two field components is required to determine the antenna pattern with near-to-far-field transformations.

To determine the field pattern over a region of space (line, surface, or volume), the probe is moved, and measurements repeated at a suitable number of locations selected to provide an adequate coverage. A mechanism holding the probe is provided to move it along one, two or three dimensions (not shown in Fig. 1). The probe movement and all the measurements are directed and controlled by a computer, which also treats the information obtained, providing amplitude and phase plots for the electric or magnetic field component considered. When knowledge of more than one field component is desired, it is possible to combine several orthogonal scatterers—but particular care is then required to avoid spurious interactions.

In an alternate approach, transmission and reception functions are treated separately, introducing an additional collector antenna (Fig. 2). By analogy with radar, this

configuration is called *bistatic*. The collector must be placed sufficiently far from the device under test to avoid perturbing the very near field.

In the bistatic configuration, the signal travels only once between the device under test and the scatterer, and therefore the measured values are linearly proportional to the field component (assuming that the transmission from scatterer to collector remains constant during the measurements). This means that the phase is determined without ambiguity, and this configuration is therefore preferred when near-to-far-field transformations are involved later on. This configuration is, however, somewhat more complicated to assemble than the monostatic setup.

Moving the probe from one point to another takes some time, as one must ensure that the probe has reached a stable position when the measurement is taken (residual vibrations would introduce noise, which would be particularly bothersome if it fell within the same frequency range as the modulation). This means that, typically, only a few points can be covered in one second; when measurements are to be made over a large surface, they can become quite time-consuming. This would remain acceptable for simple diagnostic applications, but it would make complete antenna measurements quite impractical.

To reduce the measurement time when many points are involved, the mechanical movement of the scatterer is replaced by electronic switching between many scatterers grouped in an array. Very fast measurements can then be made, but since an array tends to become considerably larger than a single scatterer, its presence will more significantly disturb the field distribution.

Depending on the application considered, arrays of scatterers can lie along a line (one-dimensional scan) or on a surface (two-dimensional scan). They are most often used in a bistatic configuration, as sketched in Fig. 3. In this particular configuration, the modulated scatterers form a linear array, providing a vertical scan, while the antenna under test is rotated for azimuthal scanning [4]. In other measurement setups, the antenna remains steady while two-dimensional scanning is carried out by a surface array of scatterers.

Material measurements are another important field of application of the modulated scatterer technique that also used bistatic array configurations [5]. For instance, one can continuously keep track of manufacturing processes. Three possible schemes are schematically represented in Fig. 4: reflection (for highly lossy and reflecting materials),

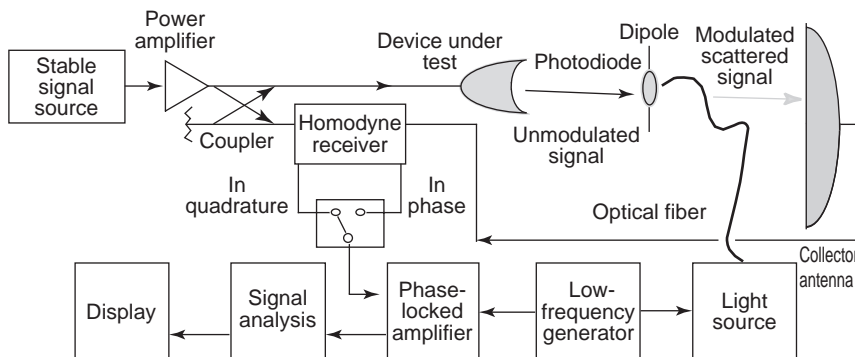

Figure 2. Basic test setup making use of the scattering from a loaded dipole modulated through an optical fiber (bistatic configuration).

Figure 3. Near-field bistatic test setup making use of a vertical linear array of modulated scatterers while the antenna under test is rotated.

transmission, and double transmission (for transparent materials). Similar arrangements are also used to measure radar cross sections [6] and to detect buried objects.

3. EQUIPMENT

The monostatic mobile probe configuration was implemented at the National Physical Laboratory in Great Britain, where a broadband instrument was designed for operation between 2 and 18 GHz [7]. It was used to analyze the operation of rectangular horn antennas, by measuring the field patterns in the plane of the aperture, and to determine diffraction effects produced in the near-field region by combinations of slits. The measurement results were used to verify existing theories and to validate computer simulations. Considerable work was carried out to characterize close-range interactions between probes and conductor edges.

A similar setup was developed at the Swiss Federal Institute of Technology in Lausanne, Switzerland [8], to measure more particularly microstrip patch antennas and circuits. The project started quite modestly for demon-

stration purposes, making use of material available in the microwave laboratory—except for the homodyne receiver and the scatterers, which were specifically realized for this equipment. High-resistivity wires are used to feed the modulating signal to the scatterer, taking particular

precautions to avoid high-frequency leakage along the wires (by adding resistors and ferrite beads). A standard x - y plotter was used at first to provide a two-dimensional scan; it was later on replaced by a more sophisticated 3D coordinating table (Fig. 5). The instrument proved quite valuable to design a variety of complex antennas, for which simulation softwares did not always provide satisfactory information.

Along similar lines, a miniaturized probe was developed at the University of Michigan in Ann Arbor, in order to test more specifically microwave monolithic circuits and filters [9]. Both a dipole antenna and a monopole antenna were integrated within the probe, so that vertical and horizontal electrical field components could be measured at the same time.

The development of compact near-field ranges using modulated scatterer arrays to measure large antennas was carried out extensively at Supelec (École Supérieure d'Électricité) near Paris, in France, under the direction of Professor Jean-Charles Bolomey. The various array geometries that can be used in a wide range of situations were carefully analyzed and their respective merits compared: in which cases should one use two-dimensional electronic scanning, in which ones should one combine a one-dimen-

sional electronic scan with a mechanical scan (rotation or translation). Several measurement ranges were built to test large antennas used for military radar and space applications, for instance, at the ESTEC research center of the European Space Agency in Noordwijk, the Netherlands [10]. This research was reported in many technical publications [3].

The complete measurement of an antenna in an modulated scatterer facility takes on the order of 30 s, as compared to one hour or more to achieve the same accuracy in a standard test facility [11]. Since measurements are made in such a short time, one can determine the radiation of a cellular phone together with its user—sitting on the rotating platform. The company SATIMO was actually created to further develop, produce, and sell microwave equipments based on Supelec's inventions, in particular those making use of the modulated scatterer technique. Complete near-field measurement facilities are now commercially available (Fig. 6).

Arrays of modulated scatterers also found applications in the measurement of a wide variety of materials, using the geometries depicted in Fig. 4. Among many others, they control the manufacture of textiles, wooden boards [12], paper, composite materials, and rock fiber [3]. Modulated scatterer arrays are also used to analyze the field distribution within TEM cells used for electromagnetic compatibility (EMC) testing [13], and to detect the presence of buried objects [14].

Last but by no means least, one must mention the important role of modulated scatterer arrays in the field of microwave tomography [15]. A "microwave camera" was developed at Supelec (Fig. 7). Operating at 2.45 GHz, its scatterer array is made of $32 \times 32 = 1024$ short dipoles loaded by pin diodes, which can be individually modulated through a line/row-addressing scheme. The biological target is immersed in a water tank, to optimize the penetration of the beam and to prevent parasitic contributions of waves propagating around the target. Initially developed in the very early 1980s, the camera was constantly updated with the advent of new technology. It provides reconstructed patterns at the rate of 15 images per second, including both acquisition and data processing.

Figure 7. Schematic of the 2.45-GHz microwave camera developed at Supelec in France.

Figure 8. Amplitude of the longitudinal electric field over a rectangular patch antenna with a rectangular slot at three frequencies of resonance, showing how the field component is concentrated next to the edges of the patch and of the slot. (Courtesy of J.-F. Zürcher.)

4. SOME EXPERIMENTAL RESULTS

This section presents some results (For a few among many, see Ref. 3) obtained using the modulated scatterer technique.

At the Swiss Federal Institute of Technology, the test configuration shown in Fig. 5 was used to measure the electric and the magnetic fields over microstrip antennas and circuits. Figure 8 shows the amplitude of the tangential electric field slightly above a rectangular patch in which a rectangular slot was cut out. As can be expected, the field is concentrated mostly close to the edges of the patch and of the slot, whereas it vanishes on the metal surface. Distributions for three modes of resonance are

shown. At the lowest frequency, the antenna edges are active, while radiation at the edges of the slot becomes more important at the higher frequencies.

A planar inverted-F antenna (PIFA) was developed for dual-frequency operation in GSM cellular phones, at 900 MHz and 1.8 GHz (Fig. 9). The upper conductor strip is divided into two sections, which are connected by an LC filter. The lower frequency lies within the passband of the filter, and the currents then flow over the entire structure. On the other hand, the upper frequency is located in a stopband of the filter, so that only a part of the antenna is active in this case. Measured near fields show the distribution of the magnetic field component over the strip, illustrating the principle of operation.

Figure 9. Amplitude of the normal magnetic field over a dual-frequency PIFA at the two frequencies of operation. (Courtesy of J.-F. Zürcher.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 10. Amplitude of the normal electric field over a hybrid ring for two excitations. The port at the left on the left-hand figure is excited, while the port at the bottom right is excited on the right-hand figure. (Courtesy of J.-F. Zürcher.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The distribution of the normal electric field over a microstrip hybrid ring (ratrace) is shown in Fig. 10 for two excitations. The distance between successive ports in the lower part of the device is a quarter-wavelength, and 3 times that in the upper part. As a result, the signal fed at the input is evenly distributed among two output ports, while the fourth port lies in a trough of the standing wave, so that no signal comes out of it.

A similar behaviour appears in a directional coupler made of two coupled parallel transmission lines, as shown in Fig. 11 [9]. The signal propagates mostly on one transmission line (the mainline), while a small part of it is coupled to the second one. The coupled port is here the one located across from the input, while the fourth port is isolated.

A measurement setup, based on the reflecting configuration shown in Fig. 4a, was developed specifically to detect the presence of buried objects. Figure 12 shows several metal bars inside reinforced concrete, as detected by an array of 32 modulated scatterers with illuminating frequencies ranging from 7 to 13 GHz. Measurements were carried out at various frequencies within that range and then compared by a dedicated data processing software, which extracted the salient features [16]. The apparatus used was optimized for a spatial resolution smaller than 1 cm and an investigation depth of 10 cm.

Figure 13 shows the “microwave radiography” of a human hand as it appears in real time on the screen of

the microwave camera specifically developed for medical applications at the ISM frequency of 2.45 GHz (Fig. 7). The microwave beam propagates in a water tank, in which the object is immersed. Since water is highly lossy, it reduces spurious effects of waves propagating around the target and reflecting on the tank walls. The use of a water medium reduces surface reflections on many biological tissues, because these have a high water content. Finally, the use of a high-dielectric medium yields a much better spatial resolution—in this case, it is increased by a factor of 10 with respect to air.

5. EVALUATION

For many electrical engineering applications, it is useful, necessary, or at least interesting to know how electric and magnetic fields are distributed over some regions of space. One may indeed wish to dispose of some detailed information that the ubiquitous network analyzer simply cannot provide.

While one may directly measure near-field components with small antennas, the signals picked up must then be transmitted to a receiver, and the presence of connecting lines tends to disturb the field. In the modulated scatterer technique, one removes the high-frequency transmission lines entirely, replacing “wired” by “wireless” transmission; the probe antenna picks up the signal at the point of interest and reflects it, or radiates it toward some collector antenna located far enough not to perturb the measured field. Low-frequency modulation and coherent detection can detect very weak signals.

Figure 13. Microwave tomographic picture of a hand taken in the 2.45 GHz camera depicted in Fig. 7. (Courtesy of Supelec/CNRS.)

The modulated scatterer technique provides a broad spectrum of applications, offering a valuable way to carry out electromagnetic field measurements, some of them in difficult situations for which low perturbation, rapidity, or both, are required. In addition to being less perturbing for the fields, it is easier to implement than direct measurements, leading to many new possibilities.

The technique was already proposed in 1955, but it became interesting only with the advent of computer-controlled measurements and image processing—which yield detailed field plots in almost real time. The effects produced by changes in frequency, geometry, and other parameters can then be determined very rapidly, and this can be extremely valuable for the practical design of antennas and devices.

The first applications were in the field of antennas, proving useful for validation of theoretical assumptions and also for obtaining far-field antenna patterns. Diagnostics of printed circuits followed, together with many other applications in the EMC and ISM fields—but the large potential of the technique is not yet fully exploited.

Simple setups can be implemented using standard laboratory equipment, without need for large material investments. While a simple test setup will not provide a high accuracy, it may still prove an extremely valuable tool for design, demonstrations, and educational purposes.

Higher-grade applications use scatterer arrays, with electronic switching speeding up the measurement rate, sometimes by several orders of magnitude. A complete antenna pattern can be obtained within a matter of minutes. Near-field antenna ranges based on the modulated scatterer technique are now commercially available.

A number of applications were also found in the measurement of materials, in particular to control industrial manufacturing processes where the controlling system

must make rapid decisions. The field plots obtained with the modulated scatterers are basically similar to those provided by computer simulation, and thus permit easy comparison and mutual validation. The two approaches are complementary because each technique provides some information that is useful in checking and improving the validity and accuracy of the other.

MEDICAL IMAGING WITH MICROWAVE: THERMOACOUSTIC TOMOGRAPHY

YUAN XU
LIHONG V. WANG
Texas A&M University
College Station, Texas

1. GENERAL REVIEW

Microwaves have two properties that are attractive for medical imaging applications: (1) they can penetrate deeply into biological tissues than can light waves and (2) the dielectric properties of biological tissues in the microwave frequency range are related to the tissues' physiological and pathological states. Imaging modalities that employ microwaves combine these two features to extract information about the physiological and pathological status of tissues that are deep in the body.

There are primarily two biomedical imaging modalities that utilize microwaves: thermoacoustic tomography [1] and pure microwave tomography [2]. Thermoacoustic tomography images the absorption of microwave energy in tissues, while pure microwave imaging images both the relative dielectric permittivity and the conductivity of tissues. In thermoacoustic tomography, a short-pulsed microwave is used to irradiate the tissues. When the electromagnetic radiation is absorbed in the biological tissues, the heating and subsequent expansion causes the emission of acoustic signals, which is called the *thermoacoustic effect*. In thermoacoustic tomography, the thermoacoustic signals are collected to map the distribution of radiative absorption within the tissues. In microwave tomography, tissues are irradiated by microwave pulses, and the scattered microwave signals from the tissues are collected to map the distribution of the dielectric properties of the tissues. Several two-dimensional (2D) and three-dimensional (3D) microwave tomography systems have been implemented experimentally with different numbers of antennas and different configurations, operation frequencies, and total acquisition times.

Thermoacoustic tomography combines the good imaging resolution of ultrasound with the good imaging contrast of microwave. Microwave tomography has the advantage of good imaging contrast but suffers from poor spatial resolution. On the other hand, purely ultrasonic imaging has good spatial resolution but poor contrast. Thermoacoustic tomography can bridge the gap between the two. Therefore, in this review, we will focus

primarily on thermoacoustic tomography in theoretical and experimental studies. Nevertheless, in vivo and in vitro results of both microwave tomography and thermoacoustic tomography will be presented in the applications section.

In the 1980s, several investigators employed microwave-induced thermoacoustic waves for imaging of biological tissues [3,4]; these early works, however, did not produce any tomographic or depth-resolved images. For example, in a study of the acoustic imaging of a model of a human hand using pulsed microwave irradiation [3], no tomographic reconstruction was utilized and, consequently, the produced image is a diffraction-propagated projection of the sample to the detection array. More recent progress realized tomographic imaging of biological tissues based on microwave-induced thermoacoustic waves. The microwave thermoacoustic tomography scanner reported in Ref. 5 was used to image a human breast in vivo and produced 3D maps of tissue absorption at 434 MHz with a spatial resolution of 1.5–4 mm throughout a $12.8 \times 12.8 \times 12.8$ cm cubical volume. Another research group achieved a spatial resolution of 0.5 mm in the 2D thermoacoustic tomography of phantoms [6].

The remainder of this article is composed as follows. First, we introduce the three mechanisms that are responsible for the dielectric properties of tissues over the microwave frequency range. Then we address some of the important theoretical issues surrounding thermoacoustic tomography, such as optimal microwave frequency, the effects of acoustical heterogeneity on breast thermoacoustic tomography, limited-view thermoacoustic tomography, the reconstruction algorithms, and spatial resolution. Then our experimental setups and results from applying thermoacoustic tomography to phantoms in planar and circular geometries are explained. Last, some in vivo and in vitro results of both pure microwave imaging and thermoacoustic tomography are presented.

2. MICROWAVE CONTRAST

There are primarily three mechanisms responsible for the dielectric properties of tissues over the microwave frequency range. The first one is the γ dispersion, in the gigahertz region, which is due to the dielectric relaxation of the free water in tissues. The second one, β dispersion, in the hundreds of kilohertz region, is due mainly to the polarization of cellular membranes that act as barriers to the flow of ions between intra- and extracellular media. Other contributions to the β dispersion come from the polarization of protein and other organic macromolecules. Last, the low-frequency α dispersion is associated with ionic diffusion processes at the site of the cellular membrane. In addition, tissues have finite ionic conductivities commensurate with the nature and extent of their ionic content and mobility [7]. For example, the contributions to the conductivity of barnacle muscle at 37°C from the α , β , and γ dispersions are 17, 7, and 1 mS/cm, respectively, at 1 GHz; 17, 16.5, and 6.5 mS/cm, respectively, at 2.5 GHz; and 17, 25.5, and 25.5 mS/cm, respectively, at 5 GHz [8]. Therefore, the dielectric properties of the tissues at the

microwave range are related to their ionic content and mobility, the membrane proteins, and the free water content.

3. THERMOACOUSTIC TOMOGRAPHY THEORY

In this section, some basic but important theoretical issues in thermoacoustic tomography are addressed to provide a comprehensive understanding of its technical side. The following topics are covered.

1. What is the optimal microwave frequency for a specific imaging application? Basically, two factors need to be considered here. The first one is imaging depth. Higher microwave frequency leads to more attenuation and, consequently, less imaging depth. The second factor is the contrast between different tissues or between malign and normal tissues. Usually, at higher frequencies, it is easier to distinguish different tissues. Balancing these two factors is essential in selecting the optimal microwave frequency for a specific application.
2. In a clinical environment, access to thermoacoustic signals is spatially limited. For example, in the thermoacoustic tomography of skin and breast, the thermoacoustic signals can be detected from only one side of the tissues. In these cases, do we have enough information to reconstruct the electromagnetic energy deposition in the tissues? This situation is referred to as *limited-view thermoacoustic tomography*.
3. Biological tissues are usually acoustically heterogeneous, which causes the distortion of thermoacoustic waves. Acoustic distortion has hindered the development of ultrasound tomography. Can thermoacoustic tomography overcome this obstacle? We use breast thermoacoustic tomography as an example to show that the acoustic distortion in the thermoacoustic tomography of soft tissues is not serious.
4. Other basic issues in thermoacoustic tomography, such as exact and approximate reconstruction algorithms and the point spread function of a thermoacoustic tomography system are also addressed here.

3.1. Optimal RF Frequencies for Thermoacoustic Tomography

Figure 1a shows the penetration depth of electromagnetic waves in various human tissues as a function of the frequency in the radiofrequency (RF) region, where the penetration depth is the inverse of the absorption coefficient [1]. The penetration depths of muscle and fat tissues are plotted in solid lines. At a frequency of 3 GHz, the penetration depths for fat and muscle are 9 and 1.2 cm, respectively. The penetration depths of normal and malignant human breast tissues are plotted in dashed lines [9]. At 3 GHz, the penetration depths for malignant and normal breast tissue are approximately 2.3 and 4.4 cm, respectively. Malignant breast tissue is more strongly absorbent to microwaves than the surrounding normal breast tissue. Muscle and fat tissues have very high and very low water contents, respectively; therefore, they represent the extreme microwave absorption properties. Most other soft tissues have an absorption coefficient between those of muscle and fat tissues. The wide range of values among various tissues is desirable for achieving high imaging contrast.

The dependence of the thermoacoustic signals on the electromagnetic frequency and the breast tumor location (the depth from the tissue surface) is shown in Fig. 1b [1]. If the detection system is instrument-noise-limited, the signal-to-noise ratio (SNR) of the system is different from this thermoacoustic signal by a constant factor. The SNR decreases as the tumor location is farther away because of the increasingly attenuated microwave intensity. When a tumor is located near the tissue surface, for example, at 1 cm depth, the SNR is better at higher RF frequencies. When the tumor is located more deeply, the choice of frequency for an optimal SNR is rather broad. This is because the decrease in thermoacoustic pressure that accompanies an increasing frequency is compensated for by the increasing difference of the RF absorption coefficients between the tumor and the normal breast tissues.

3.2. Limited-View Problem

Limited-view thermoacoustic tomography was investigated in Ref. 10 to determine what kind of boundary can be correctly reconstructed when some of the thermoacoustic signals are missed. A “detection region,” within which all points have sufficient detection views, was defined. It was explained analytically and shown numerically that the

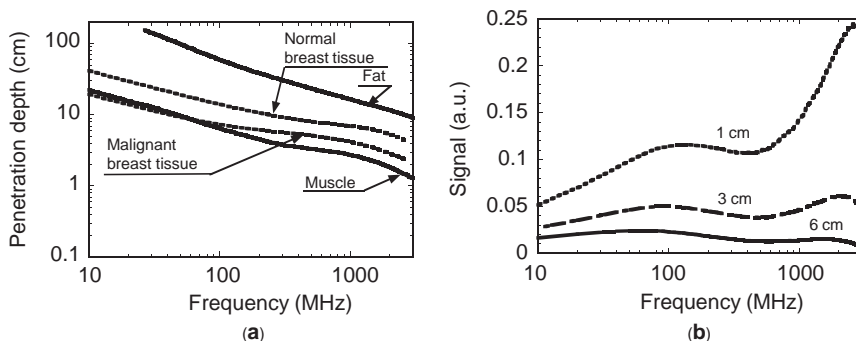

Figure 1. (a) Penetration depths of various biological tissues versus the microwave frequency; (b) a simulated piezoelectric signal in response to a thermoacoustic wave from a tissue sample containing a buried tumor versus the microwave frequency. (Reprinted with permission from Ref. 1. Copyright 2004, American Association of Physicists in Medicine.)

boundaries of any objects inside this region could be recovered stably. Outside of this region, some sharp details become blurred. One can identify in advance the parts of the boundaries that will be affected if the detection view is insufficient. In particular, a piece of the boundary of an object (i.e., interfaces between objects) can be stably reconstructed if, and only if, at least one of its two normal directions passes through a detector position. Otherwise the boundary piece cannot be reconstructed sharply no matter what reconstruction algorithms are used.

In order to support these theoretical conclusions, three types of reconstruction methods were utilized: a filtered backprojection (FBP) approximate inversion, which is shown to work well for limited-view data, a local-tomography-type reconstruction that emphasizes sharp details (e.g., boundaries of inclusions), and an iterative algebraic truncated conjugate gradient algorithm used in conjunction with FBP. Computations conducted for both numerically simulated and experimental data confirmed the theoretical predictions.

The following experimental results illustrate the abovementioned theoretical conclusions. The sample and the polar coordinate system describing the scanning orbit

in the experiment are shown in Fig. 2a. The sample consisted of a muscle cylinder of 4 mm in diameter and 5 mm in length embedded in a chunk of pork fat 1.2 cm in radius. There was a 10-mm fat layer below the muscle and another 7-mm one above it. An electromagnetic pulse was delivered to the sample from below (i.e., from behind the picture plane). Thermoacoustic data were collected around the sample over a 2π angular span with 161 steps, and a scanning radius of 71 mm. Figures 2b–2d show the reconstructed images using FBP with three sets of data. In the first of them, the data were collected along a circular detector arc of 92 degrees located at the top of the picture (Fig. 2a) and almost symmetric with respect to its vertical axis. One sees that the left and right boundaries of the muscle cylinder and of the pork chunk are blurred, because their normal lines do not touch the detector arc, while the rest of the boundary is sharp. The next figure shows a reconstruction obtained with the data collected from a 202° arc, which is the case when the whole phantom fits into the detection region. All boundaries are sharp now. Finally, the last figure shows the reconstruction with the full-view data. It can be seen that the image reconstructed from the partial-view data (Fig. 2c) has a

Figure 2. (a) Photograph of the experimental sample. (b–d) Thermoacoustic tomography reconstructions using detection arcs of 92° [from 50° to 142° in (a)], 202° (from -18° to 184°), and 360°, respectively. The blurred parts of the boundaries in (b), which are due to the limited view, agree with the theoretical predictions. In (c) all the boundaries are resolved, since the object fits into the “detection region”. (Reprinted with permission from Ref. 10. Copyright 2004, American Association of Physicists in Medicine.)

comparable quality with the image from the full-view data (Fig. 2d).

3.3. Effects of Acoustical Heterogeneity on Breast Thermoacoustic Tomography

Acoustic heterogeneities in breast thermoacoustic tomography can cause two types of wavefront distortion: amplitude distortion and phase distortion [11]. Amplitude distortion is due to refraction-induced multiple-path interference. When there is acoustic heterogeneity across a tissue interface, refraction occurs. Because of refraction, rays from a single source can reach the same receiver by different paths. The interference between these rays causes amplitude distortions. These amplitude distortions are strong in pure ultrasound tomography. However, the amplitude distortions are shown to be insignificant in thermoacoustic tomography because of the low-frequency nature of the thermoacoustic pulses [11]. The effects of phase distortions (errors in time of flight) were numerically studied. The numerical results on the spreads of the point sources and boundaries caused by phase distortions are in good agreement with the following formula

$$w(\mathbf{r}) = \int \alpha(\mathbf{r}'') dl_p \quad (1)$$

where $w(\mathbf{r})$ is the width of the point spread function at \mathbf{r} along line l_p and $\alpha(\mathbf{r}'') = 1 - v_{s0}/v_p(\mathbf{r}'')$ is the velocity deviation of $v_p(\mathbf{r}'')$, the acoustic speed at point \mathbf{r}'' , from the background speed v_{s0} .

Acoustic heterogeneity can result in blurring and artifacts. Nevertheless, it was demonstrated that the blurring of images can be compensated for by using the distribution of the acoustic velocity in reconstructions of weakly heterogeneous tissues. The effects of the errors in the acoustical velocities on this compensation were also investigated.

3.4. Reconstruction Algorithms

Reconstruction algorithms, including both exact and approximate ones, have been studied extensively in thermoacoustic tomography. It has been proved that exact reconstructions in thermoacoustic tomography are equivalent to time-reversing the pressure field across the detection surface back to the time when the thermoacoustic sources were excited. Exact reconstruction algorithms for thermoacoustic tomography have been derived for planar, cylindrical, and spherical geometries [6,12,13] using series expansion, and for an arbitrary geometry using time-reversal methods [14]. The reconstruction algorithms proposed in Refs. 12 and 13 are computationally efficient with the use of the fast Fourier transform. These formulas can also be used to evaluate the resolution of thermoacoustic tomography, as will be shown in Section 3.5, and to optimize the system design.

These exact thermoacoustic tomography reconstructions can also be implemented in a backprojection algorithm [14,15] after assuming that the distance between the objects and the detectors is much larger than the

typical acoustic wavelength

$$A(\mathbf{r}) = -\frac{1}{2\pi\eta v_{s0}^5} \oint_{\Sigma} dS_0 \frac{\mathbf{n} \cdot (\mathbf{r}_0 - \mathbf{r})}{t^2} \frac{\partial p(\mathbf{r}_0, t)}{\partial t} \Big|_{t=|\mathbf{r}_0-\mathbf{r}|/v_{s0}} \quad (2)$$

where $A(\mathbf{r})$ is the reconstructed value at \mathbf{r} , $p(\mathbf{r}_0, t)$ is the thermoacoustic signal at \mathbf{r}_0 and time t , \mathbf{n} is the outward normal to the detection surface Σ at \mathbf{r}_0 , and η is a constant. An important improvement of this backprojection algorithm over the usual backprojection (delay-and-sum) algorithms used in thermoacoustic tomography is that an orientation factor is included. Equation (2) can also be extended to derive quantitative reconstruction algorithms for limited-view thermoacoustic tomography [10].

3.5. Spatial Resolution

Spatial resolution is an important index of an imaging system. Spatial resolution in thermoacoustic tomography can be affected by various factors, such as the system bandwidth, the detector aperture, and the acoustic heterogeneity of the to-be-imaged object. The effects of acoustic heterogeneity on the resolution can be described by Eq. (1). In this subsection, we will first discuss the effects of the system bandwidth. The dependence of the spatial resolution on the system bandwidth, which is the combined bandwidth of the microwave bandwidth and the detector bandwidth, is presented in Ref. 16. Three special detection geometries, including spherical, planar, and cylindrical surface, as well as an arbitrary detection geometry, were investigated. Analytic expressions of the point spread function (PSF), as a function of the system bandwidth, were derived from rigorous reconstruction formulas. Extension of the results to an arbitrary geometry is also discussed. The analyses reveal that the PSF for an arbitrary detection geometry is space-invariant and depends only on the frequency response function of the thermoacoustic tomography system.

The effects of the finite size of the detector aperture on the system's resolution were also studied in the planar, spherical, and cylindrical detection geometries. In the planar geometry, the PSF is space-invariant and anisotropic; the lateral PSF (parallel to the detection plane) is just the profile of the detector and the axial PSF is a delta function. In the spherical geometry, the PSF is space-variant and anisotropic; the lateral PSF at \mathbf{r} (perpendicular to the radius) is just the profile of the detector scaled down by the ratio of the radius of point \mathbf{r} and the radius of the detection surface while the PSF along the radius is a delta function. In the cylindrical geometry, the PSF is space-variant and anisotropic and is a mix of the PSFs of planar and spherical geometries.

4. THERMOACOUSTIC TOMOGRAPHY EXPERIMENTS

In this section, the experimental setups and results of the thermoacoustic tomography of the phantoms are presented to demonstrate the principles and resolution capabilities of thermoacoustic tomography. Most of the thermoacoustic tomography setups are in either circular

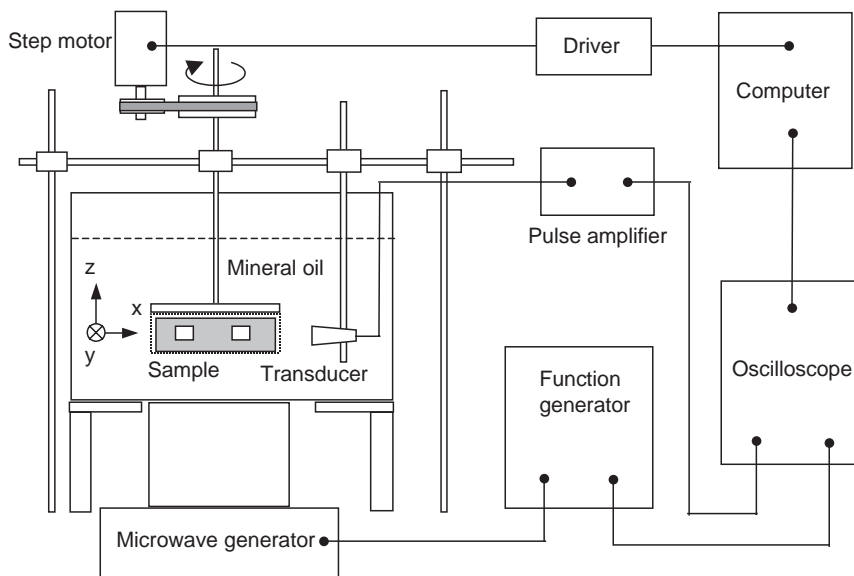

Figure 3. The experimental setup for circular thermoacoustic tomography. (Reprinted with permission from Ref. 6. Copyright 2002, IEEE.)

or planar geometry. In the circular geometry thermoacoustic tomography, the detector was scanned along a circle; while in the planar geometry thermoacoustic tomography, the detector was scanned along a line or a plane. The choice of the geometry depended mainly on the geometry of the tissues to be imaged.

4.1. Circular Geometry

Figure 3 shows the experimental setup for the circular thermoacoustic tomography [6]. The transducer was unfocused and had a central frequency of 2.25 MHz and a diameter of 6 mm. It pointed horizontally to the center of

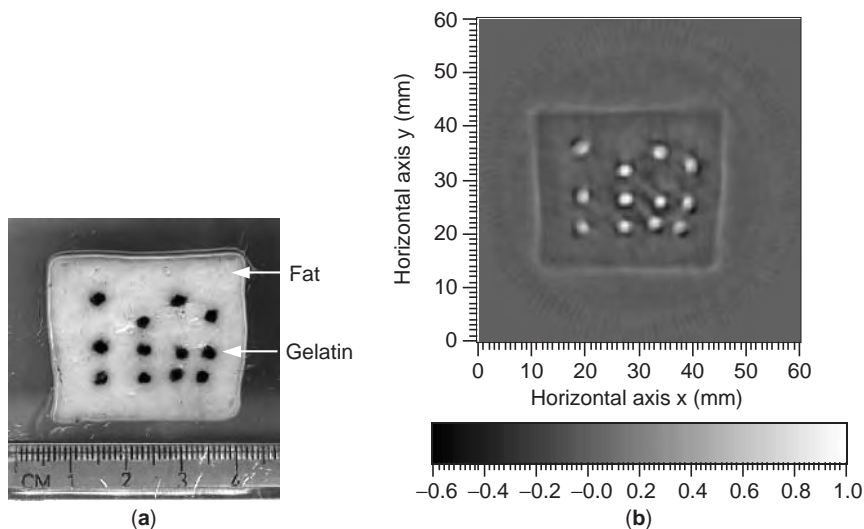

Figure 4. (a) Cross section of a tissue sample in circular thermoacoustic tomography; (b) reconstructed image; (c) comparison between a line profile (solid curve) of the reconstructed image (b) at $x = 27.45$ mm and the corresponding grayscale profile (dashed curve) of the original image (a). (Reprinted with permission from Ref. 6. Copyright 2002, IEEE.)

the rotation stage. For good coupling of the acoustic waves, both the transducer and the sample were immersed in mineral oil. The microwave pulses were transmitted from a 3-GHz microwave generator with a pulse energy of 10 mJ and a width of $0.5\ \mu\text{s}$, and then delivered to the sample from the bottom by a rectangular waveguide.

The sample shown in Fig. 4a was made of a thin piece of homogeneous pork fat tissue (5 mm thick and a maximum diameter of 4 cm) including a set of small gel cylinders (made from a solution of 5% gelatin, 0.8% salt, and a drop of dark ink to improve the photographic properties of the sample). During the experiment, the transducer rotationally scanned the sample from 0° to 360° with a stepsize of 2.25° . The detection radius was 43 mm.

The image reconstructed with the backprojection method is shown in Fig. 4b; it agrees well with the real sample. The relative locations and sizes of the gel cylinders are clearly resolved and perfectly match the original ones. Figure 4c shows the plot (solid curve) along the line at $x = 27.45\ \text{mm}$ in Fig. 4b. The reconstructed profile is in good agreement with the original profile (dashed curve), which is the corresponding grayscale profile in Fig. 4b. The half-amplitude line cuts across the reconstructed profile at points B_1 , A_1 , A_2 , and B_2 , respectively. The distances $|A_1B_1| = 1.72\ \text{mm}$ and $|A_2B_2| = 1.67\ \text{mm}$ in the image

are close to the measured real values of about 1.80 and 1.60 mm, respectively. Therefore, the width of the profile at the half-amplitude closely measures its physical size.

Figure 5 demonstrates the large penetration depth of microwave in soft tissues. The sample (Fig. 5a) is similar to the one used in Fig. 4 except that this one was much larger (the diameter of the fat is 70 mm), as shown. The reconstructed image (Fig. 5c) agrees well with the real sample (Fig. 5b).

4.2. Planar Geometry

In the planar thermoacoustic tomography, the detector was scanned over a plane or a line [12]. The experimental setup is reported in Ref. 17 and, for convenience, is only briefly described here (see also Fig. 6). The x axis points perpendicularly to the drawing plane, the y axis points to the right in the plane, and the z axis points downward along the acoustic axis. Microwave pulses were transmitted by a 9-GHz microwave generator. The pulsewidth is $0.5\ \mu\text{s}$. The imaged object shown in Fig. 7c is a cylinder of pork fat containing a thin layer of connective tissue, labeled as (7), and six yellow microstructures, labeled

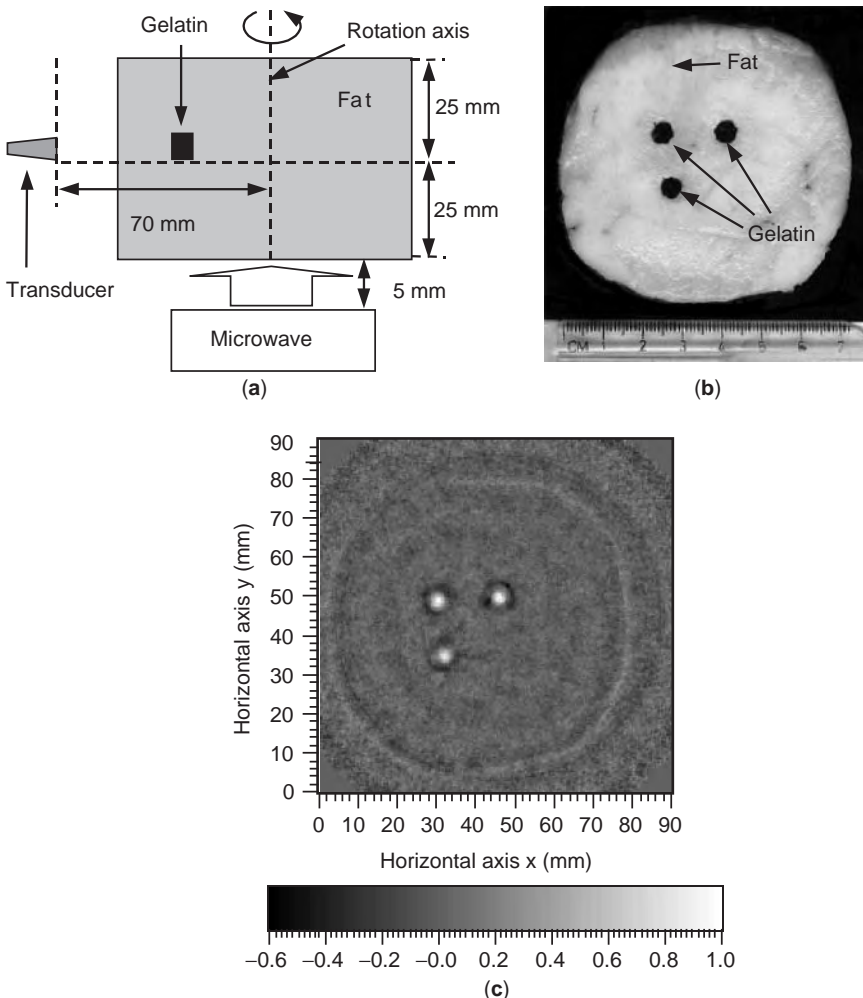

Figure 5. (a) Diagram of the sample structure and the measurement for circular thermoacoustic tomography; (b) cross-section of the tissue sample; and (c) reconstructed image. (Reprinted with permission from Ref. 6. Copyright 2002, IEEE.)

Figure 6. Experimental setup for planar thermoacoustic tomography. (Reprinted with permission from Ref. 12. Copyright 2002, IEEE.)

(1)–(6), respectively. The diameter of the cylinder fat was 14 mm and the length in the x direction 30 mm. The cylinder was immersed in mineral oil. The central frequency of the ultrasonic transducer was 2.25 MHz, the bandwidth was 1.8 MHz, and the diameter of the active element was 6 mm.

As shown in the discussion on resolution of thermoacoustic tomography in the last section, the finite size of the detector aperture can seriously blur the image. To improve the system resolution, deconvolution with respect to the finite size of the detector surface was applied to the reconstructed image [12]. In the reconstructed image before deconvolution (Fig. 7a), the connective tissue between the two parts of fat and the yellow microstructures is imaged clearly. The dimension of the image is 16.4 mm along the z direction and 19.2 mm along the y direction. However, it is obvious that the image before deconvolution is blurred along the y axis, which makes the lateral boundaries unclear and the yellow microstructures (1), (2) and (3), (4) merge into one object, respectively. The lateral resolution of the image after deconvolution (Fig. 7b) is greatly improved. The merged objects can be distinguished clearly, and the lateral boundaries of the cylinder become much clearer. The dimension of the fat cylinder in the image after deconvolution was 16.4 mm along the z direction and 16.7 mm along the y direction.

Figure 7. The reconstructed images from the experimental data in a planar thermoacoustic tomography (a) before and (b) after the deconvolution with respect to the detector surface; (c) cross section of a cylinder of fat sample containing six yellow microstructures labeled from (1) to (6) and a layer of connective tissue in the middle labeled as (7). 5. APPLICATIONS OF THERMOACOUSTIC TOMOGRAPHY AND MICROWAVE TOMOGRAPHY

The feasibility of utilizing microwave tomography for biological imaging has been demonstrated on volunteers' forearms, a canine kidney, explanted static and beating canine hearts, and breast imaging. Figure 8 shows the results of imaging experiments and anatomical slices from a canine heart [18]. Both anatomical slices demonstrate an area of left ventricle myocardium with significant infarction. A longitudinal view (through the long axis base to apex) is presented on top in Fig. 8 for ϵ' (the real part of complex dielectric permittivity ϵ), and a transversal view (through an area with significant infarction injury) is presented at the bottom of Fig. 8 for ϵ'' (the imaginary part of ϵ). Areas of the images of the heart with dielectric properties similar to the dielectric properties of infarct myocardium are plotted in crimson and red for ϵ' and ϵ'' , respectively. As can be seen, the reconstructed images reveal the shape and intracardiac anatomy. Furthermore, suspected areas of infarction (in terms of the dielectric properties) are consistent with anatomical slices. Because of the imperfection of the procedure for image reconstruction, there are areas of the image of ϵ' with dielectric properties similar to those of the infarcted area (colored in crimson). However, correlation of suspected infarct areas of the images of ϵ' with corresponding areas of the images

of ϵ'' helps determine the location of the exact area of the infarction. This is supported by the next group of images presented in Fig. 9 for $|\epsilon|$.

The response of breast cancer to chemotherapy was also measured with thermoacoustic tomography [19]. Longitudinal changes in breast architecture during primary chemotherapy produce dramatic changes in RF absorption as revealed with thermoacoustic tomography. The tumor mass appears to have decreased markedly after 7 weeks of chemotherapy treatment, as indicated by the arrows, but there is little change thereafter (Fig. 10).

6. CONCLUSIONS AND FUTURE STUDIES

Microwaves can be used in medical imaging to extract the physiological and pathological status of tissues deep in the body. Thermoacoustic tomography has a higher resolution than does microwave tomography. Some preliminary results of studies on optimal microwave frequencies, the effects of acoustical heterogeneity on breast thermoacoustic tomography, limited-view thermoacoustic tomography, reconstruction algorithms, and spatial resolution are presented. The experimental results of circular thermoacoustic tomography show a spatial resolution of about 0.5 mm. We also present some in vivo and in vitro results that

demonstrate the feasibility of clinical applications of thermoacoustic tomography and microwave tomography.

Nevertheless, there are still questions about thermoacoustic tomography that deserve further investigation. For example, it has generally been assumed that with thermoacoustic tomography, microwaves are homogeneous in the tissues under study. However, microwave attenuation and the variation of microwave within one

wavelength can result in microwave heterogeneity. The effects of microwave heterogeneity on thermoacoustic tomography are still unknown. Another challenge for thermoacoustic tomography is brain imaging. In this case, the skull may cause distortion of the thermoacoustic waves. Consequently, the capability to obtain high-quality images from distorted signals is critical for the application of thermoacoustic tomography to brain imaging.

MEI METHOD

KENNETH K. MEI
City University of Hong Kong
Hong Kong

1. INTRODUCTION

The MEI (measured equation of invariance) method was originally developed as an absorbing boundary condition to terminate FD/FE (finite-difference/finite-element) equations at the mesh boundary. Later improvements, which have brought the MEI terminating equations to the boundary of the target surface, bypassing the need for the FD/FE mesh and equations, have advanced the MEI method to become a numerical method in its own right. The objective of this article is to present the theory on which the method is based, the latest developments in MEI technology, and a guide to numerous applications of the method.

Numerical solutions of Maxwell's equations use either integral equations or differential equations. The classical solution of a radiation problem by the differential equation approach requires a radiation condition, known as the *Sommerfeld's radiation condition*, applied at infinity, that is, at a distant location from the radiating object. Numerical solutions by the differential equation approach utilize the finite-difference or finite-element equations (FD/FE) also require radiation conditions, which are applied at the mesh boundary, preferably as close to the object boundary as possible. Such boundary equations are often known as absorbing boundary conditions (ABCs). An earlier absorbing boundary condition by Mei [1] is robust but is global in nature; that is, a full matrix of field values at all the boundary nodes is required. A representative local absorbing boundary condition, which produces equations of the fields only at a few neighboring nodes, is that by Enquist and Majda [2]; however, like most local absorbing boundary conditions, it is robust only when the mesh boundary is far from the object surface. An extensive list of references to local absorbing boundary conditions may be found in the Ref. 3. Almost all local absorption boundary conditions use plane waves as models for absorption. An absorption equation can usually absorb plane waves perfectly at a few angles of arrival. The latest addition to absorbing boundary condition is the perfectly matched layer (PML) by Berenger [4], which uses a special layer of

nonisotropic material capable of absorbing plane waves arriving at any angle.

Common to all absorbing boundary equations is that the equations are all derived from an assumption of a known incident wave. The MEI method of obtaining boundary equations is based on the observation that there is symmetry between the coefficients a_i and the field values ϕ_i in a linear equation:

$$a_1\phi_1 + a_2\phi_2 + a_3\phi_3 + a_4\phi_4 = 0 \quad (1)$$

Normally, the coefficients represent the equation, which are known, and the ϕ_i values represent the solutions to be found. The symmetry of the equation tells us that if the field values were known, we could also recover the coefficients or the equation at any point. In Eq. (1), for example, since the equation equals zero, one of the coefficients can be set to unity, and thus three sets of linearly independent solutions should give a 3×3 matrix, from which the coefficients can be calculated. This suggests that if Eq. (1) were a boundary equation of a radiation problem, the absorbing boundary equation would be contained in the solutions. We shall designate each linear equation of the a_i terms by substituting a set of solutions ϕ_i in Eq. (1) as a measure. This requires $n - 1$ measures to find the coefficients of a linear equation of n unknowns.

At first glance, the insight we have come up with does not seem to be useful because the solutions are unknowns, which are unavailable to us. Actually solutions to a radiation problem of a specific geometry are not difficult to obtain. Only the solution to a specific excitation and of a specific geometry is difficult to find. The procedures and justification for MEI are presented in the following sections.

2. THE POSTULATE OF INVARIANCE

Let us limit the present discussion to two-dimensional problems of wave scattering for pedagogical purposes. Figure 1 represents scattering of a plane wave, either TE or TM, by an infinite cylinder of arbitrary shape. A solution of the scattered field can be readily obtained by the following integral

$$\phi_k = \oint_C G(\mathbf{r}/\mathbf{r}') J_k(\mathbf{r}') dc' \quad (2)$$

Figure 1. Schematics of a 2D scattering problem.

Figure 2. The six points for a boundary equation.

where $G(\mathbf{r}/\mathbf{r}')$ is the Green function of the 2D wave equation and J_k is a current we assign to the scatterer. We shall name each assigned current a “metron” and the resulting field ϕ_k , a measuring function. When $n - 1$ measuring functions are substituted into a boundary equation, we can calculate the coefficients of the boundary equations by solving an $(n - 1) \times (n - 1)$ matrix. In order for the method to work, it is necessary that the boundary equations be invariant with respect to the excitations or the incident fields. Mei [5] postulates that in order to bring the terminating boundary close to the scatterer, a terminating boundary equation should fit the following profile:

1. It must be different for different target geometry.
2. It must be different at different locations.
3. It must be invariant with respect to excitation so that the process of measure can work.

During the early development period of the MEI method, it was strictly used as a technique to terminate finite difference equations. The metrons

$$J_k(\mathbf{r}') = \cos\left\{2(k - 1)\pi \frac{l'}{L}\right\} \quad k = 1, 2, \dots \quad (3)$$

have been used, where L is the total circumferential length of the scatterer and l' is the circumferential distance from a reference. A two-dimensional scattering problem can normally be solved this way by only four layers of finite-difference equations. Each boundary equation is formulated at six adjacent nodal points on the outer two layers, as shown in Fig. 2. Figures 3 and 4 show

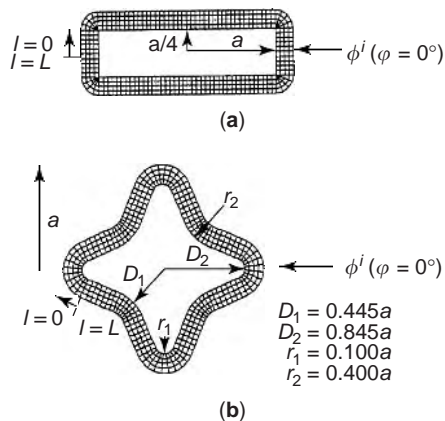

Figure 3. (a) The mesh around a rectangular cylinder; (b) the mesh around a star-shaped cylinder.

Figure 4. Induced current densities on a rectangular cylinder for $\lambda = a$ and angle of incidence of 30° as calculated by the MEI method and MoM for (a) E wave and (b) H wave.

Figure 5. Currents on a center-fed thin-strip dipole antenna ($l = 18.5w$) for $l = 1.07\lambda$ (the scale in y has been enlarged by a factor of 4).

some of the surface current densities on two-dimensional scatterers found by the finite-difference method using MEI terminations, where the results by MoM are also

presented in the same figures for comparison. In addition to 2D problems, the MEI method has also been applied to ribbon antennas (see Figs. 5 and 6) and scattering of plane waves by rectangular patches and bodies of revolution [5].

3. ACCURACY OF MEI

Shortly after the appearance of the first paper on MEI [5], several papers appeared in the literature [6–9] debating the validity of the postulates of MEI, in particular the postulate of invariance. There are also papers [10] questioning the accuracy of the MEI. The postulate of invariance of the boundary equations to excitation (or incident fields) should be the least controversial one of the three postulates, because the terminating conditions are part of the system equations. In all linear systems, including the Maxwell equations, the equations should be independent of the excitations.

In fact, all absorbing boundary conditions in the published literature are obtained with no reference to excitation. This means that the same absorbing boundary equations are used regardless of the incident fields.

Figure 6. Current on an off-center-fed thin-strip dipole antenna ($l = 18.5w$) for $l = 2.12\lambda$ (the scale on y has been enlarged by a factor of 4).

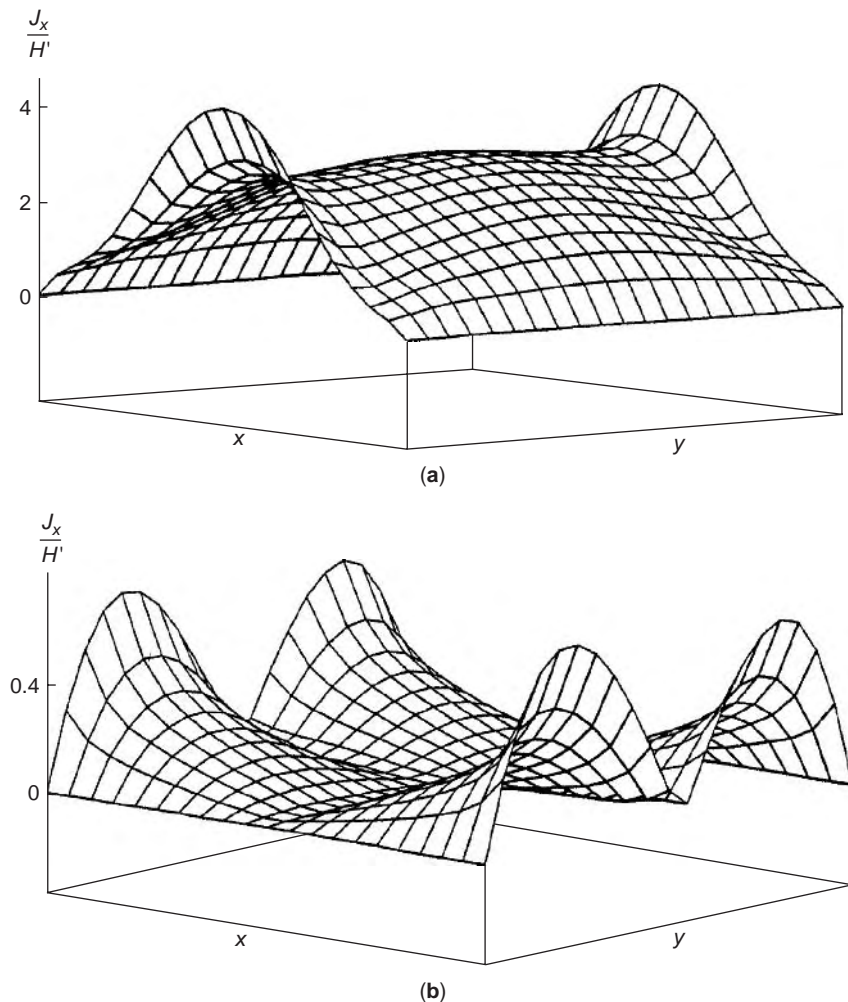

Figure 7. Current densities on a square plate when illuminated by a normally incident plane wave, with the E field polarized in the z direction, with $\lambda = a$: (a) J_x ; (b) J_y .

Mei and Liu [7] have shown that the criticism on the invariance arises from the misunderstandings, that the metrons were incident fields. And, the doubts on the accuracy arise from the misunderstanding that, the metrons were base functions. In the paper by Luo et al. [11], it is shown that the conclusions reached by Barkdoll and Lee

[10] that (1) MEI is not accurate for 3D as compared to 2D problems and (2) the distance between the target boundary and terminating boundary should be large for MEI to be accurate in 3D, are ill-founded because the authors have not properly applied the coupled finite difference equations for the body of revolution [10].

4. APPLICATIONS OF MEI

4.1. Applications to Three-Dimensional Problems

The MEI method has been applied to scattering of plane waves by flat rectangular patches [12]. In this case, Maxwell’s equations are most conveniently formulated in terms of the vector potential, which has only two components. The scattered fields are

$$\mathbf{H}^s = \nabla \times \mathbf{A} \tag{4}$$

$$\mathbf{E}^s = \frac{1}{j\omega\epsilon} \nabla \times \mathbf{H}^s \tag{5}$$

The finite-difference mesh of the vector potentials A_x and A_y are structured around the patch for four layers. The measuring functions and the metrons are given by

$$\mathbf{A}_{m,n} = \int_0^a \int_0^b G(\mathbf{r}/\mathbf{r}') \mathbf{J}_{m,n}(\mathbf{r}') ds \tag{6}$$

where G is the free-space Green function and

$$J_{x/m,n}(x,y) = \frac{\sin \frac{m\pi x}{a} \bullet \cos \frac{(n-1)\pi y}{b}}{\sqrt{y(y-b)}} \tag{7}$$

$$1 \leq m \leq M, \quad 1 \leq n \leq N$$

$$J_{y/m,n}(x,y) = \frac{\cos \frac{(m-1)\pi x}{a} \bullet \sin \frac{n\pi y}{b}}{\sqrt{x(x-a)}} \tag{8}$$

$$1 \leq m \leq M, \quad 1 \leq n \leq N$$

where a, b are the width and length of the patch, respectively; and M, N are the total numbers of nodes along the width and length, respectively.

The surface current densities on a square plate of side dimension of 1.0λ are shown in Fig. 7. The applications to microstrip lines have been studied by Prouty [13].

4.2. Applications to Large Parabolic Reflectors

Parabolic reflectors are normally studied by physical optics, which assigns the current density as twice the tangential incident magnetic field in the illuminated surface and zero in the shadow region. It is well known that current behaviors are much more complicated than that, particularly near the edges. A detailed inspection of the current density cannot be realized unless we can solve the Maxwell equations associated with a parabolic reflector accurately. Such solutions can be realized nowadays by either MoM or FD/FE methods. MoM probably would be a preferable method for such a task over the FD/FE methods, when a large reflector is considered. However, with MEI, the situation is changed, in that the number of nodes

Figure 10. Variation of the MEI coefficients of a circular cylinder with respect to frequency.

Figure 11. Current densities on a square cylinder of side dimension 256λ illuminated by 30° incidence as calculated by the MEI method as compared with those by MoM: (a) TM nodes; (b) TE nodes.

involved in the FD/FE is greatly reduced when MEI brings the mesh termination very close to the reflector surface and preserves the advantage of the sparse matrix of the FD/FE methods. The solutions of Maxwell's equations of parabolic reflectors of diameters up to 80λ have been obtained by Luo et al. [11] utilizing the MEI method. The current densities near the edge and shadow region have been presented in Fig. 8. The standing waves of the current densities are particularly pronounced for the radial

components, which are known to be the causes of high copper loss and high sidelobes.

4.3. Applications to Very Large Scatterers

When the FD/FE methods are used, the resulting matrices are very sparse. With the MEI method, which brings the mesh termination very close to the object boundary, the mesh region is also greatly reduced. So, the most time

consuming part of the computation is no longer the solution of the matrix. The task of finding the boundary equations, which involves the integrations around the target surface for the measuring functions, has become the most demanding part of the method. The integration time is proportional to N^2 , where N is the number of nodes on the object surface. When the object is very large, such as hundreds of wavelengths in dimension, the computational expense could be very large. To overcome such a predicament, one may consider the method of interpolation and extrapolation of the coefficients of MEI [14], instead of direct computation. Once the boundary equations are found for a specific mesh, it is possible to double, triple, or quadruple the density of the mesh, and obtain the boundary equations in between nodes, by interpolations of the coefficients. In effect, one can find the boundary equation at any location. Suppose that we solve a problem at a frequency f and double the mesh density to

Figure 12. Mesh and schematics of a post in a rectangular waveguide: (a) mesh around a post; (b,c) schematics of scattering by a post in a rectangular waveguide.

Figure 13. Results of MEI and those of variational principle for S_{11} of scattering inside a rectangular waveguide.

solve the problem at $2f$, and double it again to solve it at $4f$, and so on. As the boundary nodes get closer to the boundary surface as the frequency increases, the center node of the boundary equations approach normally toward the boundary. In that case, the coefficients of each boundary equation converge to their respective limits. Figure 9 shows the mesh configuration as the frequency is doubled, and Fig. 10 shows the extrapolation of the coefficients of MEI. Figure 11 shows the current densities on a rectangular cylinder of side dimension 256λ , calculated using the interpolation–extrapolation technique.

Figure 14. Boundary meshing of the scatterer for IE-MEI.

4.4. MEI and Absorbing Boundary Conditions

In an earlier paper by Ramahi et al. [15], multipole fields were used as measuring functions to find the absorbing boundary conditions for 2D scattering problems. They have termed such a boundary condition, the *numerical absorbing boundary condition* (NABC). The boundary equations, in that case, are independent of the geometry of the scatterer. They have also included MEI as part of the NABC [16]. We would like to point out here that MEI includes but is not limited to ABC. An ABC cannot account for reflections from an outer boundary; that is, it is applicable only if there is no incoming wave on the boundary surface. The MEI can still be applied when there are incoming waves on the terminating boundary. A case illustrating this point is the scattering by an inductive post in a rectangular waveguide. Figure 12 shows the FD mesh around an elliptical post inside a rectangular waveguide. The measuring functions are obtained by the integration of Eq. (2) using the Green function of the waveguide. In this case, ABC cannot be applied, but MEI is still valid. Figure 13 shows the MEI calculated S_{11} of the scattering configuration of Fig. 12 by the MEI method as compared with the same calculations by MoM.

5. ON-SURFACE MEI (OS-MEI) AND INTEGRAL EQUATION MEI (IE-MEI)

In the beginning of this article, we postulated that for a terminating boundary equation to work close to the object boundary, it should fit a profile of three characteristics. Of all terminating boundary conditions that we know of, only the MEI method offers boundary equations that fit all the characteristics of the profile. The immediate issue is how close one can move the MEI boundary toward the target surface. In the early development of the MEI, it was discovered that it was possible to have only one layer of nodal points around the target surface [12]. In that case, the nodes on the object boundary are directly connected to the terminating boundary. The number of unknowns is equal to that of MoM, but one needs to solve only a tridiagonal matrix instead of a full matrix. However, in order to bring the terminating boundary next to the target surface, one requires higher numerical accuracy, which involves double precision and singular integrals on the surface of the

object. To be on the safe side, to ensure that other researchers could easily duplicate the calculations, the earlier results were all obtained with four layers of finite-difference equations. Even with only one layer of nodes around the object surface, the method is still off-surface. One-sided finite differences are needed to find the surface current densities on the object surface, which contribute some extra errors to the calculations.

Instead of two layers of nodes, Rius et al. [17] derived the integral equation MEI (IE-MEI) utilizing the reciprocity theorem

$$\int_v (\mathbf{E}_1 \cdot \mathbf{J}_2 - \mathbf{H}_1 \cdot \mathbf{M}_2) dv = \int_v (\mathbf{E}_2 \cdot \mathbf{J}_1 - \mathbf{H}_2 \cdot \mathbf{M}_1) dv \quad (9)$$

and postulated the existence of local \mathbf{J}_2 and \mathbf{M}_2 on neighboring nodes on the surface of the object such that the right side of Eq. (9) will vanish for all testing sources \mathbf{J}_1 and \mathbf{M}_1 . For a two-dimensional problem, \mathbf{J}_2 and \mathbf{M}_2 will be on three adjacent nodes as shown in Fig. 14. For scattering by conducting cylinders, we may let $\mathbf{M}_1 = 0$, and designate appropriate metrons to find \mathbf{E}_1 and \mathbf{H}_1 to obtain the linear equations

$$\sum_{i=1}^n a_i \mathbf{H}_i^s + \sum_{i=1}^n b_i \mathbf{E}_i^s = \mathbf{0} \quad (10)$$

In Ref. 17 Rius et al. have calculated the radar scattering cross sections of an electrically large ogive as shown in Fig. 15. In a similar approach, Liu et al. [18] were able to arrive at Eq. (10) by replacing the off-surface layer of E nodes by the surface derivatives of the tangential H and named it *on-surface MEI* (OS-MEI). Hirose et al. have used the IE-MEI to solve scattering problems of impedance boundary conditions [19]. With IE-MEI, one is able to reformulate integral equations into sparse matrices, which enables us to solve large scattering problems. So, IE-MEI has been applied to solve 3D problems by Rius et al. [20] for electromagnetics and by Chowdhury et al. [21] for scalar fields.

6. CONCLUSION

It has been shown that despite some doubts expressed by some investigators of the MEI method, there have been many satisfactory applications of MEI reported by other

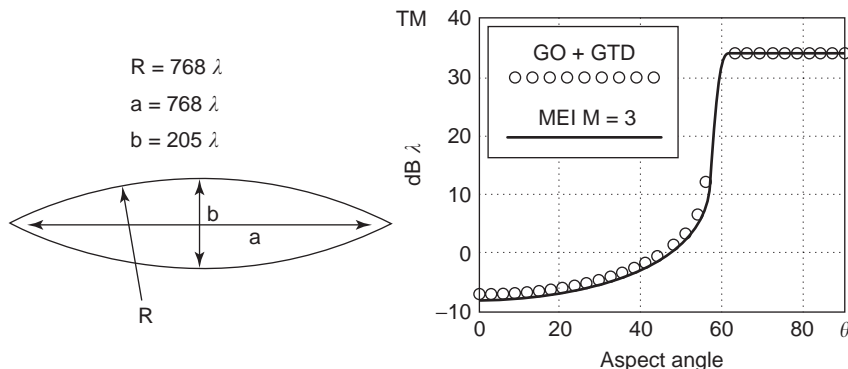

Figure 15. Radar cross section.

investigators. The most basic assumption of the MEI method is the existence of a local linear relation of the fields. Such an assumption is plausible for far fields, which is a differential relation of the fields, known as the *Sommerfeld radiation condition* in classical theory. One may question whether it can still be so assumed on the surface of the object. However, the success of IE-MEI suggests that it may be true that such local linear equations do exist on the object surface. If this were true, the on-surface Maxwell differential equations could be found. What an exciting discovery would that be! Mei has proved the existence of the differential equation of currents on thin wire structure. The readers may find the presentation in the MAXWELLIAN CIRCUITS article in this encyclopedia. Perhaps, it is not far away that someone will prove the existence of differential equations of the surface current density on conduction surfaces.

METHOD OF LINES

ALESSANDRO TOSCANO
LUCIO VEGNI
“Roma Tre” University
Rome, Italy

1. INTRODUCTION

Planar passive structures and planar transmission lines are widely used in microwave and millimeter-wave integrated circuits. Characterization and modeling of transmission lines and their discontinuities are of great importance in the development of integrated circuits. It is not economical, or in many cases not even feasible, to tune the circuits once they are fabricated. Therefore, accurate methods are needed to model the structures.

Quasistatic methods, equivalent waveguide models, and equivalent-circuit models have been used in the modeling of microstrip or slotlines, and discontinuities in the past [1,2]. A more rigorous approach, which takes into account all the physical effects including radiation and surface waves is the spectral-domain Galerkin method (SDGM) [3]. This method transforms an integral equation into a linear system of equations, where the solution (e.g., electric currents or fields) has to be computed numerically. The method is known to be efficient but is restricted, in

investigators. The most basic assumption of the MEI method is the existence of a local linear relation of the fields. Such an assumption is plausible for far fields, which is a differential relation of the fields, known as the *Sommerfeld radiation condition* in classical theory. One may question whether it can still be so assumed on the surface of the object. However, the success of IE-MEI suggests that it may be true that such local linear equations do exist on the object surface. If this were true, the on-surface Maxwell differential equations could be found. What an exciting discovery would that be! Mei has proved the existence of the differential equation of currents on thin wire structure. The readers may find the presentation in the MAXWELLIAN CIRCUITS article in this encyclopedia. Perhaps, it is not far away that someone will prove the existence of differential equations of the surface current density on conduction surfaces.

METHOD OF LINES

ALESSANDRO TOSCANO
LUCIO VEGNI

Rome, Italy

1. INTRODUCTION

Planar passive structures and planar transmission lines are widely used in microwave and millimeter-wave integrated circuits. Characterization and modeling of transmission lines and their discontinuities are of great importance in the development of integrated circuits. It is not economical, or in many cases not even feasible, to tune the circuits once they are fabricated. Therefore, accurate methods are needed to model the structures.

Quasistatic methods, equivalent waveguide models, and equivalent-circuit models have been used in the modeling of microstrip or slotlines, and discontinuities in the past [1,2]. A more rigorous approach, which takes into account all the physical effects including radiation and surface waves is the spectral-domain Galerkin method (SDGM) [3]. This method transforms an integral equation into a linear system of equations, where the solution (e.g., electric currents or fields) has to be computed numerically. The method is known to be efficient but is restricted, in

general, to well-shaped structures that involve infinitely thin conductors as ground planes. The main reason for the efficiency is that the SDGM allows significant analytical preprocessing in comparison to other numerical techniques such as the finite-difference method, finite-element methods, or the method of lines. The method of partial discretization or method of lines is a well-established technique for the analysis of different microwave structures.

The method of lines is regarded as a special finite-difference method but is more effective with respect to accuracy and computational time than is the regular finite-difference method. It basically involves discretizing a given differential equation in one or two dimensions while using an analytical solution in the remaining direction. The method of lines (MoL) has the merits of both the finite difference method and the analytical method; it does not yield spurious modes, nor does it have the problem of "relative convergence." Besides, the method of lines has the following properties that justify its use:

1. *Computational efficiency*—the semianalytical character of the formulation leads to a simple and compact algorithm, which yields accurate results with less computational effort than do other techniques.
2. *Numerical stability*—by separating discretization of space and time, it is easy to establish stability and convergence for a wide range of problems.
3. *Reduced programming effort*—by making use of the state-of-the-art well-documented and reliable ordinary differential equations (ODE) solvers, programming effort can be substantially reduced.
4. *Reduced computational time*—since only a small amount of discretization lines are necessary in the computation, there is no need to solve a large system of equations; hence computing time is small.

2. STEPS IN MoL APPLICATION

Application of MoL usually involves the following four basic steps:

1. Partitioning the solution region into lines
2. Discretization of the differential equation in one or two coordinate direction
3. Transformation to obtain decoupled ordinary differential equations
4. Introduction of the boundary conditions and solution of the equations.

2.1. Partitioning the Solution Region into Lines (Step 1)

The method of lines is particularly suitable for modeling a wide range of transmission lines and integrated structures with multiple layers [4–6]. This involves in the most general case discretizing the Helmholtz wave equation in two directions while the other direction is treated analytically. We will illustrate the method for planar integrated structures.

In this section we describe a formulation of the electromagnetic problem in an arbitrary general isotropic medium leading, besides, to the decoupling of the Maxwell's equations describing the electromagnetic field and to an equivalent-circuit representation of the layered medium.

The geometry of the problem and coordinate definitions of the structure are given in Fig. 1, where elementary current sources are shown and/or a plane wave is incident on a multilayer generalized planar structure. First, we consider the i th layer, which is not infinitely large in the planar direction (x - z plane) and the homogeneous material is characterized via the constitutive relation proper of the dielectric medium considered.

Starting from Maxwell's equations, the whole field may be obtained from the component in the \hat{z} -direction E_z and H_z . For these components the following wave equations hold

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} + k^2 \psi = 0 \quad (1)$$

where $\psi = E_z, H_z$, $k^2 = \omega^2 \mu \epsilon$ and μ and ϵ are the magnetic permeability and the electric permittivity, respectively.

The other four components can be expressed in terms of E_z and H_z as follows

$$\begin{pmatrix} \frac{\partial^2}{\partial z^2} + k^2 \end{pmatrix} \begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} \frac{\partial^2}{\partial x \partial z} & -jk\eta \frac{\partial}{\partial y} \\ \frac{\partial^2}{\partial y \partial z} & jk\eta \frac{\partial}{\partial x} \end{bmatrix} \begin{bmatrix} E_z \\ H_z \end{bmatrix} \quad (2)$$

$$\begin{pmatrix} \frac{\partial^2}{\partial z^2} + k^2 \end{pmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix} = \begin{bmatrix} j\eta \frac{\partial}{\partial y} & \frac{\partial^2}{\partial x \partial z} \\ -j\eta \frac{\partial}{\partial x} & \frac{\partial^2}{\partial y \partial z} \end{bmatrix} \begin{bmatrix} E_z \\ H_z \end{bmatrix} \quad (3)$$

where

$$\begin{cases} \eta = \sqrt{\mu_0/\epsilon} = \eta_0/\sqrt{\epsilon_r} \\ \eta_0 = \sqrt{\mu_0/\epsilon_0} \end{cases}$$

Figure 1. Geometry of the electromagnetic problem.

Figure 2. Transverse section of the generic layer of height d discretized along the \hat{x} direction (— e lines; - - - h lines).

It should be noted that the wave equation (1) and the field relations (2) and (3) are still valid also for inhomogenous isotropic media characterized by constitutive parameters $\mu = \mu_0$ and $\varepsilon = \varepsilon_0 \varepsilon_r(y)$.

Since we are considering the most general case of application of the method of line, here, for a solution of the wave equation (1) and for determination of the field components, a discretization along both the \hat{x} and the \hat{z} directions is performed. The discretization is performed using two different sets of lines: the so called e lines and h lines. The smallest separation between two e lines is s , while the smallest separation between an e and an h line is $s/2$. Different sets of boundary conditions at the two ends of the generic layer can be considered (e.g., Neumann and/or Dirichlet, periodic, absorbing boundary). In Fig. 2 we have depicted the transverse section of the generic discretized along the \hat{x} direction.

If N_x is the number of the e lines, N_x is also the number of the h lines and s is the separation between the lines. Once the transverse section of the generic layer is discretized, for the components of the electric field, we have

$$\begin{cases} E_x(x, y, z) \rightarrow \underline{E}_x(y) = [E_x^1(y), E_x^2(y), E_x^3(y) \cdots E_x^N(y)] \\ E_y(x, y, z) \rightarrow \underline{E}_y(y) = [E_y^1(y), E_y^2(y), E_y^3(y) \cdots E_y^N(y)] \\ E_z(x, y, z) \rightarrow \underline{E}_z(y) = [E_z^1(y), E_z^2(y), E_z^3(y) \cdots E_z^N(y)] \end{cases} \quad (4)$$

where, for instance, $\underline{E}_x(y)$ is the vector whose elements are the values of the \hat{x} component of the electric field sampled on the e lines. The discretization for the magnetic field is dual.

2.2. Discretization of Differential Equation in One or Two Coordinate Directions (Step 2)

The first-order derivative operators are replaced by difference operators that can be described by the Kröner products (\otimes) of the difference operators for the longitudinal ($\underline{\mathbf{d}}_z^m$) or azimuthal ($\underline{\mathbf{d}}_y^m$) line system and the unit matrices $\underline{\mathbf{I}}_x$ and $\underline{\mathbf{I}}_z$ of order $N_x \times N_x$ and $N_z \times N_z$, respectively:

$$\begin{cases} \underline{\mathbf{D}}_z^m = \underline{\mathbf{d}}_z^m \otimes \underline{\mathbf{I}}_x \\ \underline{\mathbf{D}}_x^m = \underline{\mathbf{I}}_z \otimes \underline{\mathbf{d}}_x^m \end{cases} \quad \text{with } m = e, h \quad (5)$$

The formal expression of the difference operators $\underline{\mathbf{d}}_z^m$ and $\underline{\mathbf{d}}_x^m$ depends on the boundary conditions used. In the case of Neumann and/or Dirichlet conditions they are given in Ref. 3, in the case of periodic boundary condition they are also given in Ref. 3, and for the case of absorbing boundary conditions they are given in Ref. 7.

For the second-order derivatives we directly have

$$\begin{cases} \underline{\mathbf{D}}\underline{\mathbf{D}}^m = -(\underline{\mathbf{d}}_z^m \otimes \underline{\mathbf{I}}_x) \cdot (\underline{\mathbf{d}}_z^m \otimes \underline{\mathbf{I}}_x)^t \\ = -(\underline{\mathbf{d}}_z^m \otimes \underline{\mathbf{I}}_x) \cdot (\underline{\mathbf{d}}_z^{m,t} \otimes \underline{\mathbf{I}}_x^t) = (\underline{\mathbf{d}}\underline{\mathbf{d}}_z^m \otimes \underline{\mathbf{I}}_x) \\ \underline{\mathbf{D}}\underline{\mathbf{D}}_x^m = -(\underline{\mathbf{I}}_z \otimes \underline{\mathbf{d}}_x^m) \cdot (\underline{\mathbf{I}}_z \otimes \underline{\mathbf{d}}_x^m)^t \\ = -(\underline{\mathbf{I}}_z \otimes \underline{\mathbf{d}}_x^m) \cdot (\underline{\mathbf{I}}_z^t \otimes \underline{\mathbf{d}}_x^{m,t}) = (\underline{\mathbf{I}}_z \otimes \underline{\mathbf{d}}\underline{\mathbf{d}}_x^m) \end{cases} \quad (6)$$

It can now be easily shown that the vector $\underline{\psi} = \underline{E}_z, \underline{H}_z$ satisfies the following set of coupled differential equations:

$$\frac{\partial^2 \underline{\psi}}{\partial y^2} + \underline{\mathbf{D}}\underline{\mathbf{D}}_x^{e,h} \cdot \underline{\psi} + \underline{\mathbf{D}}\underline{\mathbf{D}}_z^{e,h} \cdot \underline{\psi} + k^2 \underline{\psi} = 0 \quad (7)$$

2.3. Transformation to Obtain Decoupled Ordinary Differential Equations (Step 3)

The next step is to solve analytically the equations resulting along the y coordinate. To solve (7) analytically, we need to obtain a system of uncoupled ordinary differential equations from the coupled equation (7). To achieve this, we define the transformed vector $\underline{\psi}^*$ by letting

$$\underline{\psi} = \underline{\mathbf{T}}^{e,h} \cdot \underline{\psi}^* \quad (8)$$

and requiring

$$\begin{cases} (\underline{\mathbf{T}}^{e,h})^{-1} \cdot \underline{\mathbf{D}}\underline{\mathbf{D}}_x^{e,h} \cdot \underline{\mathbf{T}}^{e,h} = \underline{\Lambda}_x^2 \\ (\underline{\mathbf{T}}^{e,h})^{-1} \cdot \underline{\mathbf{D}}\underline{\mathbf{D}}_z^{e,h} \cdot \underline{\mathbf{T}}^{e,h} = \underline{\Lambda}_z^2 \end{cases} \quad (9)$$

where the elements of the diagonal matrices $\underline{\Lambda}_x^2, \underline{\Lambda}_z^2$ are the eigenvalues of $\underline{\mathbf{D}}\underline{\mathbf{D}}_x^{e,h}$ and $\underline{\mathbf{D}}\underline{\mathbf{D}}_z^{e,h}$, respectively.

In (8) we advanced the following position

$$\underline{\mathbf{T}}^{e,h} = \underline{\mathbf{t}}_z^{e,h} \otimes \underline{\mathbf{t}}_x^{e,h} \quad (10)$$

equaling $\underline{\mathbf{t}}_x^m$ and $\underline{\mathbf{t}}_z^m$, the eigenvector matrices belonging to second-order difference operators $\underline{\mathbf{d}}\underline{\mathbf{d}}_x^m$ and $\underline{\mathbf{d}}\underline{\mathbf{d}}_z^m$, respectively.

After some algebraic manipulations, it can be shown that, for homogeneous layers where μ and ε do not depend on y , the general solution for the k th component of the vector $\underline{\psi}^*$ can be expressed as

$$\psi_k^*(y) = A_k \cdot \cosh(k_{y,k}y) + B_k \cdot \sinh(k_{y,k}y) \quad (11)$$

where A_k and B_k are integration constants and depend on the proper boundary condition to be applied.

From the general solution (11) we can relate to each other the field solution at the interfaces in y_p and y_{p+1} of the generic p th layer as follows:

$$\begin{bmatrix} \underline{E}'_{zk}(y_{p+1}) \\ \underline{E}'_{zk}(y_p) \end{bmatrix} = \begin{bmatrix} \phi e_k^{(1,1)}(y_p, y_{p+1}) & \phi e_k^{(1,2)}(y_p, y_{p+1}) \\ \phi e_k^{(2,1)}(y_p, y_{p+1}) & \phi e_k^{(2,2)}(y_p, y_{p+1}) \end{bmatrix} \cdot \begin{bmatrix} \underline{E}^*_{zk}(y_{p+1}) \\ \underline{E}^*_{zk}(y_p) \end{bmatrix} \quad (12)$$

$$\begin{bmatrix} \underline{H}'_{zk}(y_{p+1}) \\ \underline{H}'_{zk}(y_p) \end{bmatrix} = \begin{bmatrix} \phi h_k^{(1,1)}(y_p, y_{p+1}) & \phi h_k^{(1,2)}(y_p, y_{p+1}) \\ \phi h_k^{(2,1)}(y_p, y_{p+1}) & \phi h_k^{(2,2)}(y_p, y_{p+1}) \end{bmatrix} \cdot \begin{bmatrix} \underline{H}^*_{zk}(y_{p+1}) \\ \underline{H}^*_{zk}(y_p) \end{bmatrix} \quad (13)$$

In (12) and (13) the apex prime stands for first derivative with respect the variable y and we have stated the following positions:

$$\begin{cases} \phi e_k^{(1,1)}(y_p, y_{p+1}) = -k_{y_k} \cdot \coth[(y_p - y_{p+1}) \cdot k_{y_k}] \\ \phi e_k^{(1,2)}(y_p, y_{p+1}) = k_{y_k} \cdot \operatorname{csch}[(y_p - y_{p+1}) \cdot k_{y_k}] \\ \phi e_k^{(2,1)}(y_p, y_{p+1}) = -k_{y_k} \cdot \operatorname{csch}[(y_p - y_{p+1}) \cdot k_{y_k}] \\ \phi e_k^{(2,2)}(y_p, y_{p+1}) = k_{y_k} \cdot \coth[(y_p - y_{p+1}) \cdot k_{y_k}] \end{cases} \quad (14)$$

$$\begin{cases} \phi h_k^{(1,1)}(y_p, y_{p+1}) = \frac{-k_{y_k} \cdot \coth[(y_p - y_{p+1}) \cdot k_{y_k}]}{k_{y_k}} \\ \phi h_k^{(1,2)}(y_p, y_{p+1}) = \frac{k_{y_k} \cdot \operatorname{csch}[(y_p - y_{p+1}) \cdot k_{y_k}]}{k_{y_k}} \\ \phi h_k^{(2,1)}(y_p, y_{p+1}) = \frac{-k_{y_k} \cdot \operatorname{csch}[(y_p - y_{p+1}) \cdot k_{y_k}]}{k_{y_k}} \\ \phi h_k^{(2,2)}(y_p, y_{p+1}) = \frac{k_{y_k} \cdot \coth[(y_p - y_{p+1}) \cdot k_{y_k}]}{k_{y_k}} \end{cases} \quad (15)$$

Now we derive from (12) and (13) the discretized transverse $\hat{\mathbf{x}}$ component of the electric and magnetic fields in terms of the E_z and H_z components as follows:

$$\begin{cases} \underline{E}_x(y) = \left[\underline{\mathbf{D}}_z^h \cdot \underline{\mathbf{D}}_z^e + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \cdot \left[\underline{\mathbf{D}}_z^h \cdot \underline{\mathbf{D}}_x^e \cdot \underline{\mathbf{T}}^e \cdot \underline{E}_z^*(y) + j\omega\mu \cdot \underline{\mathbf{T}}^h \cdot \underline{H}_z^*(y) \right] \\ \underline{H}_x(y) = \left[\underline{\mathbf{D}}_z^e \cdot \underline{\mathbf{D}}_z^h + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \cdot \left[\underline{\mathbf{D}}_z^e \cdot \underline{\mathbf{D}}_x^h \cdot \underline{\mathbf{T}}^h \cdot \underline{H}_z^*(y) - j\omega\epsilon \cdot \underline{\mathbf{T}}^e \cdot \underline{E}_z^*(y) \right] \end{cases} \quad (16)$$

It can now be shown that for the two interfaces A and B in y_p and y_{p+1} , respectively, of a generic layer the following

relation in matrix form holds:

$$\begin{bmatrix} \underline{\mathbf{H}}_B \\ \underline{\mathbf{H}}_A \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_{11}^{(a,b)} & \underline{\mathbf{Y}}_{12}^{(a,b)} \\ \underline{\mathbf{Y}}_{21}^{(a,b)} & \underline{\mathbf{Y}}_{22}^{(a,b)} \end{bmatrix} \cdot \begin{bmatrix} \underline{\mathbf{E}}_B \\ \underline{\mathbf{E}}_A \end{bmatrix} \quad (17)$$

where

$$\begin{cases} \underline{\mathbf{E}}_A = \begin{bmatrix} \underline{E}_x(a) \\ \underline{E}_z(a) \end{bmatrix} \\ \underline{\mathbf{E}}_B = \begin{bmatrix} \underline{E}_x(b) \\ \underline{E}_z(b) \end{bmatrix} \end{cases}, \quad \begin{cases} \underline{\mathbf{H}}_A = \begin{bmatrix} \underline{H}_x(a) \\ \underline{H}_z(a) \end{bmatrix} \\ \underline{\mathbf{H}}_B = \begin{bmatrix} \underline{H}_x(b) \\ \underline{H}_z(b) \end{bmatrix} \end{cases}$$

$$\begin{bmatrix} \underline{\mathbf{Y}}_{11}^{(a,b)} & \underline{\mathbf{Y}}_{12}^{(a,b)} \\ \underline{\mathbf{Y}}_{21}^{(a,b)} & \underline{\mathbf{Y}}_{22}^{(a,b)} \end{bmatrix} = \underline{\mathbf{B}} \cdot \underline{\mathbf{Z}} \cdot \underline{\mathbf{A}}^{-1}$$

$$\underline{\mathbf{A}} = \begin{bmatrix} \underline{\alpha} \cdot \underline{\mathbf{T}}^e & \underline{\gamma} \cdot \underline{\mathbf{T}}^h & \underline{\mathbf{0}} & \underline{\mathbf{0}} \\ \underline{\mathbf{T}}^e & \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\alpha} \cdot \underline{\mathbf{T}}^e & \underline{\gamma} \cdot \underline{\mathbf{T}}^h \\ \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\mathbf{T}}^e & \underline{\mathbf{0}} \end{bmatrix}$$

$$\underline{\mathbf{B}} = \begin{bmatrix} \underline{\beta} \cdot \underline{\mathbf{T}}^h & \underline{\delta} \cdot \underline{\mathbf{T}}^e & \underline{\mathbf{0}} & \underline{\mathbf{0}} \\ \underline{\mathbf{T}}^e & \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\beta} \cdot \underline{\mathbf{T}}^h & \underline{\delta} \cdot \underline{\mathbf{T}}^e \\ \underline{\mathbf{0}} & \underline{\mathbf{0}} & \underline{\mathbf{T}}^h & \underline{\mathbf{0}} \end{bmatrix}$$

$$\underline{\mathbf{Z}} = \begin{bmatrix} \underline{\mathbf{0}} & \underline{\phi h}^{(1,1)}(a, b) & \underline{\mathbf{0}} & \underline{\phi h}^{(1,2)}(a, b) \\ \underline{\phi e}^{(1,1)}(a, b) & \underline{\mathbf{0}} & \underline{\phi e}^{(1,2)}(a, b) & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\phi h}^{(2,1)}(a, b) & \underline{\mathbf{0}} & \underline{\phi h}^{(2,2)}(a, b) \\ \underline{\phi e}^{(2,1)}(a, b) & \underline{\mathbf{0}} & \underline{\phi e}^{(2,2)}(a, b) & \underline{\mathbf{0}} \end{bmatrix}$$

$$\begin{cases} \underline{\alpha} = \left[\underline{\mathbf{D}}_z^h \cdot \underline{\mathbf{D}}_z^e + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \cdot \underline{\mathbf{D}}_z^h \cdot \underline{\mathbf{D}}_x^e \\ \underline{\gamma} = j\omega\mu \left[\underline{\mathbf{D}}_z^h \cdot \underline{\mathbf{D}}_z^e + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \\ \underline{\beta} = \left[\underline{\mathbf{D}}_z^e \cdot \underline{\mathbf{D}}_z^h + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \cdot \underline{\mathbf{D}}_z^e \cdot \underline{\mathbf{D}}_x^h \\ \underline{\delta} = -j\omega\mu \left[\underline{\mathbf{D}}_z^e \cdot \underline{\mathbf{D}}_z^h + \omega^2 \mu \underline{\mathbf{E}} \right]^{-1} \end{cases}$$

Equation (17) gives the transfer equation for the generic layer. The transfer equation for a number of layers is obtained by multiplication of the transmission matrices proper of the single layers.

Special attention must be paid to the upper isotropic half-space. For the radiation condition, we have

$$\psi_k^*(y) = C_k \cdot e^{-k_{y_k} y} \quad (18)$$

Figure 3. Geometry of the layered structure.

In this case we can write

$$\underline{\mathbf{H}}_F = \underline{\mathbf{Y}}_t^{(c)} \bullet \underline{\mathbf{E}}_F \tag{19}$$

where

$$\underline{\mathbf{Y}}_t^{(c)} = \underline{\mathbf{B}}^{(c)} \times \underline{\mathbf{Z}}^{(c)} \times (\underline{\mathbf{A}}^{(c)})^{-1}$$

$$\underline{\mathbf{A}}^{(c)} = \begin{bmatrix} \underline{\alpha} \times \underline{\mathbf{T}}^e & \underline{\gamma} \times \underline{\mathbf{T}}^h \\ \underline{\mathbf{T}}^e & \underline{\mathbf{0}} \end{bmatrix}$$

$$\underline{\mathbf{B}}^{(c)} = \begin{bmatrix} \underline{\beta} \times \underline{\mathbf{T}}^h & \underline{\delta} \times \underline{\mathbf{T}}^e \\ \underline{\mathbf{T}}^h & \underline{\mathbf{0}} \end{bmatrix}$$

$$\underline{\mathbf{Z}}^{(c)} = \begin{bmatrix} \underline{\mathbf{0}} & \underline{\zeta e}(y_N) \\ \underline{\zeta h}(y_N) & \underline{\mathbf{0}} \end{bmatrix}$$

$\underline{\zeta e}(y_N)$ and $\underline{\zeta h}(y_N)$ are diagonal matrices whose elements are given by $\overline{y}^{-1}(1/k_{y_k})$ and $-k_{y_k}$, respectively.

The method of lines can be used to analyze homogeneous and inhomogeneous cylindrical transmission structures [8–10] and circular and elliptic waveguides [11]. The principal steps involved in applying MoL in cylindrical coordinates are the same as in Cartesian coordinates.

2.4. Introduction of Boundary Conditions and Solution of Equations (Step 4)

Here, we illustrate with the use of MoL, an analysis of the electromagnetic characteristics of planar integrated structures.

In this section we apply the theory described in the previous sections to two practical geometries. The first one is a microstrip patch antenna fed by a coplanar microstrip line as shown in Fig. 3. The second one is a layered structure with three layers in the presence of an aperture between layers 2 and 3 (Fig. 4). We give two examples in Sections 2.4.1. and 2.4.2.

Figure 4. Geometry of the layered structure.

2.4.1. Coplanar Microstrip Line. Two different regions are described by the following transmission matrices:

Region 1 ($y_a \leq y \leq y_b$):

$$\begin{bmatrix} \underline{\mathbf{H}}_B \\ \underline{\mathbf{H}}_A \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} & \underline{\mathbf{Y}}_{12}^{(y_a, y_b)} \\ \underline{\mathbf{Y}}_{21}^{(y_a, y_b)} & \underline{\mathbf{Y}}_{22}^{(y_a, y_b)} \end{bmatrix} \bullet \begin{bmatrix} \underline{\mathbf{E}}_B \\ \underline{\mathbf{E}}_A \end{bmatrix} \tag{20}$$

Region 2 ($y_b \leq y \leq \infty$):

$$\underline{\mathbf{H}}_F = \left[\underline{\mathbf{Y}}_t^{(y_b)} \right] \underline{\mathbf{E}}_F \tag{21}$$

On the ground plane we have

$$\vec{\mathbf{E}}_A = 0 \tag{22}$$

On the first in $y = y_b$ we must impose the continuity of the tangential components of the electric field. The magnetic field shows a discontinuity due to the presence of electric impressed sources ($\underline{\mathbf{J}}_{imp}$) on the feedline and of induced or scattered currents on the metallic path ($\underline{\mathbf{J}}_S$):

$$\begin{cases} \underline{\mathbf{H}}_F^{(patch)} - \underline{\mathbf{H}}_B^{(patch)} = \underline{\mathbf{J}}_S \\ \underline{\mathbf{H}}_F^{(feed)} - \underline{\mathbf{H}}_B^{(feed)} = \underline{\mathbf{J}}_{imp} \end{cases} \tag{23}$$

Moreover, on the metallic patches the tangential components of the electric field must vanish:

$$\vec{\mathbf{E}}_F \Big|_{patch} = 0 \tag{24}$$

From (20) and (22) we get

$$\vec{\mathbf{H}}_B = \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} \bullet \vec{\mathbf{E}}_B \tag{25}$$

From the first equation of (23) and from (21) and (25), we can write

$$\begin{aligned} \begin{bmatrix} \underline{\mathbf{H}}_B^{(\text{patch})} \\ \underline{\mathbf{H}}_F^{(\text{feed})} \end{bmatrix} &= \begin{bmatrix} \underline{\mathbf{H}}_F^{(\text{patch})} \\ \underline{\mathbf{H}}_B^{(\text{feed})} \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_S \\ \underline{\mathbf{J}}_{\text{imp}} \end{bmatrix} \\ &= \begin{bmatrix} \underline{\mathbf{Y}}_t^{(y_b)} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} \end{bmatrix} \times \begin{bmatrix} \underline{\mathbf{E}}_F^{(\text{patch})} \\ \underline{\mathbf{E}}_B^{(\text{feed})} \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_S \\ \underline{\mathbf{J}}_{\text{imp}} \end{bmatrix} \end{aligned} \quad (26)$$

and thus

$$\begin{aligned} \begin{bmatrix} \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} & \underline{\mathbf{Y}}_{12}^{(y_a, y_b)} \\ \underline{\mathbf{Y}}_{21}^{(y_a, y_b)} & \underline{\mathbf{Y}}_{22}^{(y_a, y_b)} \end{bmatrix} \cdot \begin{bmatrix} \underline{\mathbf{E}}_F^{(\text{patch})} \\ \underline{\mathbf{E}}_B^{(\text{feed})} \end{bmatrix} \\ = \begin{bmatrix} \underline{\mathbf{Y}}_t^{(y_c)} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} \end{bmatrix} \cdot \begin{bmatrix} \underline{\mathbf{E}}_F^{(\text{patch})} \\ \underline{\mathbf{E}}_B^{(\text{feed})} \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_S \\ \underline{\mathbf{J}}_{\text{imp}} \end{bmatrix} \end{aligned}$$

or, in a more compact form

$$\begin{aligned} (\underline{\mathbf{A}}_{11} - \underline{\mathbf{A}}_{12} \cdot \underline{\mathbf{A}}_{22}^{-1} \cdot \underline{\mathbf{A}}_{21}) \cdot \vec{\underline{\mathbf{E}}}_F + \vec{\underline{\mathbf{J}}}_S \\ = -\underline{\mathbf{A}}_{12} \cdot \underline{\mathbf{A}}_{22}^{-1} \cdot \vec{\underline{\mathbf{J}}}_{\text{imp}} \end{aligned} \quad (27)$$

with

$$\left\{ \begin{array}{l} \underline{\mathbf{A}}_{11} = \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} - \underline{\mathbf{Y}}_t^{(y_b)} \\ \underline{\mathbf{A}}_{22} = \underline{\mathbf{Y}}_{22}^{(y_a, y_b)} - \underline{\mathbf{Y}}_{11}^{(y_a, y_b)} \end{array} \right\}, \quad \left\{ \begin{array}{l} \underline{\mathbf{A}}_{12} = \underline{\mathbf{Y}}_{12}^{(y_a, y_b)} \\ \underline{\mathbf{A}}_{21} = \underline{\mathbf{Y}}_{21}^{(y_a, y_b)} \end{array} \right\}$$

It is important to note that in Eq. (27) $\underline{\mathbf{E}}_F$ has to be set to zero in the metallic regions, where only $\underline{\mathbf{J}}_S$ and $\underline{\mathbf{J}}_{\text{imp}}$ have components and $\underline{\mathbf{J}}_S$ and $\underline{\mathbf{J}}_{\text{imp}}$ must be set to zero above the dielectric interface, where, on the contrary, only $\underline{\mathbf{E}}_F$ has components.

Thanks to this property, all those columns of the matrix $\underline{\mathbf{A}}_{11} - \underline{\mathbf{A}}_{12} \cdot \underline{\mathbf{A}}_{22}^{-1} \cdot \underline{\mathbf{A}}_{21}$ that multiply for column void values of $\underline{\mathbf{E}}_F$ can be replaced by columns of zeros. Therefore, to obtain a solution both for $\underline{\mathbf{E}}_F$ and $\underline{\mathbf{J}}_S$, it suffices to operate a sort of “fusion” of the two vectors in an only one (the vector $\underline{\mathbf{X}}$), and to rewrite Eq. (27) as the following linear, matrix equation:

$$\underline{\mathbf{A}} \cdot \underline{\mathbf{X}} = \underline{\mathbf{B}} \cdot \underline{\mathbf{J}}_{\text{imp}} \quad (28)$$

It is worth remarking that if we change the location and the dimensions of the radiating patches and the impressed source, we have only to compute again the vectors $\underline{\mathbf{X}}$ and $\underline{\mathbf{J}}_{\text{imp}}$ (which is not time-consuming) and numerically solve the same linear, matrix equation. So, the MoL analysis technique presented here is found to be sufficiently versatile to handle important practical configurations such as stacked patches, patches with superstrates, without

[unlike e.g., those for the moment method (MoM)] the expense of very long computer runtimes. We should also note that the computational efficiency is high, and thanks, to the reduced system (28), a smaller number of discretization lines is necessary.

2.4.2. Layered Structure with Three Layers in Presence of an Aperture. In this case four different regions are described by the following transmission matrices:

Region 1:

$$\begin{bmatrix} \underline{\mathbf{H}}_B \\ \underline{\mathbf{H}}_A \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_1^{(1,1)} & \underline{\mathbf{Y}}_1^{(1,2)} \\ \underline{\mathbf{Y}}_1^{(2,1)} & \underline{\mathbf{Y}}_1^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_B \\ \underline{\mathbf{E}}_A \end{bmatrix} \quad (29)$$

Region 2:

$$\begin{bmatrix} \underline{\mathbf{H}}_D \\ \underline{\mathbf{H}}_C \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_2^{(1,1)} & \underline{\mathbf{Y}}_2^{(1,2)} \\ \underline{\mathbf{Y}}_2^{(2,1)} & \underline{\mathbf{Y}}_2^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_D \\ \underline{\mathbf{E}}_C \end{bmatrix} \quad (30)$$

Region 3:

$$\begin{bmatrix} \underline{\mathbf{H}}_F \\ \underline{\mathbf{H}}_E \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_3^{(1,1)} & \underline{\mathbf{Y}}_3^{(1,2)} \\ \underline{\mathbf{Y}}_3^{(2,1)} & \underline{\mathbf{Y}}_3^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_F \\ \underline{\mathbf{E}}_E \end{bmatrix} \quad (31)$$

Region 4:

$$\underline{\mathbf{H}}_G = \underline{\mathbf{Y}}_G \cdot \underline{\mathbf{E}}_G \quad (32)$$

The boundary conditions are

Interface 1:

$$\underline{\mathbf{E}}_A = 0 \quad (33)$$

Interface 2:

$$\begin{cases} \underline{\mathbf{H}}_C - \underline{\mathbf{H}}_B = \underline{\mathbf{J}}_{\text{imp}} \\ \underline{\mathbf{H}}_C = \underline{\mathbf{H}}_B \end{cases} \quad (34)$$

Interface 3:

$$\begin{cases} \underline{\mathbf{H}}_E - \underline{\mathbf{H}}_D = \underline{\mathbf{J}}_{S1} \\ \underline{\mathbf{E}}_E|_{\text{slot}} = \underline{\mathbf{E}}_D|_{\text{slot}} \\ \underline{\mathbf{E}}_E|_{\text{ground}} = 0 \end{cases} \quad (35)$$

Interface 4:

$$\begin{cases} \underline{\mathbf{H}}_G - \underline{\mathbf{H}}_F = \underline{\mathbf{J}}_{S2} \\ \underline{\mathbf{E}}_G|_{\text{slot}} = \underline{\mathbf{E}}_F|_{\text{slot}} \\ \underline{\mathbf{E}}_G|_{\text{patch}} = 0 \end{cases} \quad (36)$$

From (29) and (33) we can write

$$\underline{\mathbf{H}}_B = \underline{\mathbf{Y}}_1^{(1,1)} \cdot \underline{\mathbf{E}}_B \quad (37)$$

From (35), (36), and (31) we have

$$\begin{bmatrix} \underline{\mathbf{H}}_F \\ \underline{\mathbf{H}}_E \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{H}}_G \\ \underline{\mathbf{H}}_D \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_{S2} \\ \underline{\mathbf{J}}_{S1} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_3^{(1,1)} & \underline{\mathbf{Y}}_3^{(1,2)} \\ \underline{\mathbf{Y}}_3^{(2,1)} & \underline{\mathbf{Y}}_3^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_G \\ \underline{\mathbf{E}}_D \end{bmatrix} \quad (38)$$

and then

$$\begin{bmatrix} \underline{\mathbf{Y}}_G \cdot \underline{\mathbf{E}}_F \\ \underline{\mathbf{H}}_D \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_{S2} \\ \underline{\mathbf{J}}_{S1} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_3^{(1,1)} & \underline{\mathbf{Y}}_3^{(1,2)} \\ \underline{\mathbf{Y}}_3^{(2,1)} & \underline{\mathbf{Y}}_3^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_F \\ \underline{\mathbf{E}}_E \end{bmatrix} \quad (39)$$

From (34), (35), and (30) it follows that

$$\begin{bmatrix} \underline{\mathbf{H}}_D \\ \underline{\mathbf{H}}_C \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{H}}_E \\ \underline{\mathbf{H}}_B \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_{S1} \\ \underline{\mathbf{J}}_{imp} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_2^{(1,1)} & \underline{\mathbf{Y}}_2^{(1,2)} \\ \underline{\mathbf{Y}}_2^{(2,1)} & \underline{\mathbf{Y}}_2^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_D \\ \underline{\mathbf{E}}_C \end{bmatrix} \quad (40)$$

and then

$$\begin{bmatrix} \underline{\mathbf{H}}_E \\ \underline{\mathbf{Y}}_2^{(1,1)} \cdot \underline{\mathbf{E}}_B \end{bmatrix} + \begin{bmatrix} -\underline{\mathbf{J}}_{S1} \\ \underline{\mathbf{J}}_{imp} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{Y}}_2^{(1,1)} & \underline{\mathbf{Y}}_2^{(1,2)} \\ \underline{\mathbf{Y}}_2^{(2,1)} & \underline{\mathbf{Y}}_2^{(2,2)} \end{bmatrix} \begin{bmatrix} \underline{\mathbf{E}}_D \\ \underline{\mathbf{E}}_B \end{bmatrix} \quad (41)$$

Finally, from (39) and (41), after some algebraic manipulations, we derive the following linear system, which, when solved, gives the unknown electric field on the slot and the induced currents $\underline{\mathbf{J}}_{S1}$ and $\underline{\mathbf{J}}_{S2}$ on the metallizations at interfaces 3 and 4, respectively:

$$\begin{cases} \underline{\mathbf{P}}_1 \underline{\mathbf{E}}_F - \underline{\mathbf{P}}_2 \underline{\mathbf{E}}_E - \underline{\mathbf{J}}_{S1} = -\underline{\mathbf{P}}_3 \underline{\mathbf{J}}_{imp} \\ \underline{\mathbf{Q}}_1 \underline{\mathbf{E}}_F - \underline{\mathbf{Q}}_2 \underline{\mathbf{E}}_E - \underline{\mathbf{J}}_{S1} = 0 \end{cases} \quad (42)$$

Once we solve Eq. (42), the current distributions on the metallizations and the electric and magnetic fields can be computed in every region of the structure.

1. INTRODUCTION

A general electromagnetic problem of an object in unbounded media such as a scatterer or antenna is a complex mathematical boundary value problem, which so far has resisted exact analytical treatment, except in such special cases as circular cylinders [1], spheres [2], and spheroids [3]. In these cases the surface of the object coincides with one of the coordinate surfaces of an orthogonal coordinate system, in which the vector wave equation can be solved by the method of separation of variables. However, for an object of arbitrary shape, such an analytic solution is not feasible and an approximate or numerical solution must be obtained. The problem can, in general, be formulated using the integral equation method involving the surface field distributions or the differential equation method involving the field distribution throughout the volume. The equations describing the problem are exact and can generally be given as

$$L(f) = g \quad (1)$$

where L is an operator, f is the unknown response of the system to be determined, and g is the known source. If the solution to (1) satisfies the boundary conditions of the problem, then f is a unique solution to the problem due to the source g .

The process of solving (1) might require some approximations, and the accuracy of the solution will depend on the numerical technique and the number of samples used to describe the structure. Here we are interested in the method of moments as one of the most widely used numerical techniques. The method of moments, in general, reduces the linear operator equation (1) to a system of finite linear matrices that can be solved numerically to obtain the solution. The technique can be used in the frequency domain or the in the time domain. Here, we will consider the formulation of the problem using integral equations in the frequency domain.

The method of moment process is simple and straightforward. In electromagnetics, the physical problem is specified by Maxwell's equations and the boundary

Figure 1. Representation of numerical integration using the rectangular rule.

conditions are reduced to integral equations. The unknowns (f) are under the integral, which is the operator (L). The unknowns are expanded as a series of known basis functions and unknown constant coefficients.

The method of moment can be understood easily if we draw an analogy with the numerical integration of a function. Let

$$F(x) = \int_a^b f(x')G(x, x')dx' \quad (2)$$

where $F(x)$ is unknown and the integrand $f(x')G(x, x')$ is known. If the integration is performed numerically using the simple rectangular rule, the interval $[a, b]$ can be divided to N segments of $\Delta x'_i$. For generality, the segments are considered unequal as shown in Fig. 1. Then (2) can be approximated as

$$F(x) = \sum_{i=1}^N f(x_i)G(x, x_i)\Delta x'_i \quad (3)$$

where x_i is the middle of the segment i and $f(x_i)$ is the value of the function at x_i . Equation (2) can be considered an integral equation when $F(x)$ is known as the source or the excitation and $f(x)$ is the unknown function. Then if the unknown function can be expanded as

$$f(x') = \sum_{i=1}^N a_i b_i(x') \quad (4)$$

where the b_i values denote known functions and the a_i values represent unknown constant coefficients. Substitute (4) in the integral equation (2) we obtain

$$\int_a^b \sum_{i=1}^N a_i b_i(x')G(x, x')dx' = F(x) \quad (5)$$

Because the a_i values are constants, we can write (5) as

$$\sum_{i=1}^N a_i \int_a^b b_i(x')G(x, x')dx' = F(x) \quad (6)$$

Now we have the completely known integrand, which can be integrated analytically or numerically. To make the analogy with the numerical integral using the rectangular

rule, let

$$b_i(x') = \begin{cases} 1 & x' = x_i \\ 0 & \text{elsewhere} \end{cases} \quad (7)$$

and thus (6) becomes

$$\sum_{i=1}^N a_i G(x, x_i)\Delta x_i = F(x) \quad (8)$$

which is similar to (3), and one can see that $a_i = f(x_i)$. However, Eq. (8) is one equation in N unknowns. If we evaluate (8) at each x_i , we obtain the following system of equations:

$$\begin{aligned} a_1 G(x_1, x_1)\Delta x_1 + a_2 G(x_1, x_2)\Delta x_2 + \cdots + a_N G(x_1, x_N)\Delta x_N &= F(x_1) \\ a_1 G(x_2, x_1)\Delta x_1 + a_2 G(x_2, x_2)\Delta x_2 + \cdots + a_N G(x_2, x_N)\Delta x_N &= F(x_2) \\ &\vdots \\ a_1 G(x_N, x_1)\Delta x_1 + a_2 G(x_N, x_2)\Delta x_2 + \cdots + a_N G(x_N, x_N)\Delta x_N &= F(x_N) \end{aligned} \quad (9)$$

Equation (9) can be expressed in matrix form as

$$\begin{bmatrix} G(x_1, x_1)\Delta x_1 & G(x_1, x_2)\Delta x_2 & \cdots & G(x_1, x_N)\Delta x_N \\ G(x_2, x_1)\Delta x_1 & G(x_2, x_2)\Delta x_2 & \cdots & G(x_2, x_N)\Delta x_N \\ \vdots & \vdots & \cdots & \vdots \\ G(x_N, x_1)\Delta x_1 & G(x_N, x_2)\Delta x_2 & \cdots & G(x_N, x_N)\Delta x_N \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_N \end{bmatrix} = \begin{bmatrix} F(x_1) \\ F(x_2) \\ \vdots \\ F(x_N) \end{bmatrix} \quad (10)$$

or in a compact form as

$$[Z][I] = [V] \quad (11)$$

The Z is a square matrix, I is the unknown vector, and V is the known excitation vector. The solution of (11) will provide the unknown vector.

2. SIMPLE ELECTROMAGNETIC SCATTERING PROBLEM

To illustrate, how an electromagnetic problem can be formulated, consider an arbitrarily shaped conducting two-dimensional scatterer. A two-dimensional body is infinite in the axial direction (here considered to be the z direction) and has the same physical cross section in any

Figure 2. Original scattering problem.

plane cut, which is orthogonal to the axis (any plane cut parallel to the xy plane) as illustrated in Fig. 2. The scatterer is bounded by the surface S and surrounded by the free space, which is characterized by the permittivity and permeability of the free space (ϵ_0, μ_0). The excitation is an electromagnetic plane wave of the incident fields E^{inc} and H^{inc} . The total electric and magnetic fields in the exterior region are denoted by E_0 and H_0 , respectively. Inside the conducting object the fields are known and of zero value. The normal unit vector on the surface S is $\hat{n} = \hat{t} \times \hat{z}$ where \hat{z} and \hat{t} are the unit vectors in the direction of z and tangential to the surfaces S parallel to the xy plane. The time variation $e^{j\omega t}$ is implied and suppressed throughout.

The incoming wave in the 2D case always travels on a ray, which is orthogonal to the axis of the body. Because of this, an incoming wave of arbitrary polarization can always be written as the sum of waves, which are transverse electric (TE) and transverse magnetic (TM) to the axis of the body. A wave that is transverse magnetic has electric field components only in the z direction and a magnetic field with no z -directed components. The currents, which result from the arbitrarily polarized waves, can be obtained by summing the currents that result from the TE portion of the wave with those that result from the TM portion of the wave.

In order to use the free-space Green function in the solution of this problem, we have to have an unbounded homogeneous region. The surface equivalence principle is usually used to create an equivalent problem that converts the original problem from inhomogeneous region to a homogeneous region, but reserves the same boundary conditions of the original problem on the surface S . In the equivalent problem, the conducting object is removed and filled with the same materials of the exterior region of the original problem and forces the fields within the boundary of S to be zero and the fields outside S to be the same fields and materials of the original problem. Since the equivalent problem represents an unbounded homogeneous region, the fields must be continuous everywhere in the space, but by forcing the fields inside S to be zero, we have created discontinuity of the fields that must be compensated by inserting sources on the surface S . These sources are electric and magnetic surface currents that are proportional to the exterior tangential fields on S .

Figure 3. Surface equivalent problem.

The surface electric and magnetic currents are $\mathbf{J} = \hat{n} \times \mathbf{H}_0$ and $\mathbf{M} = -\hat{n} \times \mathbf{E}_0$. Since the surface of the original problem is a perfect conducting surface, the tangential electric fields to the surface are zero. Therefore, the equivalent surface magnetic current \mathbf{M} must be zero. Now, Fig. 3 illustrates the equivalent problem. The total fields in the exterior region are due to the equivalent electric current on the surface and the incident fields. The fields due to the equivalent electric current (E^{sc}, H^{sc}) are referred to as the *scattered fields*. It should be clear that the equivalent surface electric current is unknown and should be determined in order to compute the fields (E^{sc}, H^{sc}).

To formulate the integral equation, the boundary condition is applied on the surfaces S . The boundary condition is expressed as

$$E_{0|tan} = -\hat{n} \times (\hat{n} \times E_0) = 0 \text{ on } S \quad (12)$$

For simplicity, we consider the TM case. As mentioned above, for the TM case, only E_z exists and the magnetic field is transverse to z with no component in the z direction. Therefore, (12) can be written as

$$E_z^{sc} = -E_z^{inc} \text{ on } S \quad (13)$$

In an integral equation form, (13) can be written as

$$-j\omega\mu \int_C \mathbf{J}_z(\rho')g(\rho, \rho')d\ell = -E_z^{inc}(\rho) \text{ on } S \quad (14)$$

where C is the contour of the surface S along the tangential direction t and (ρ, ρ') are the position vectors in the xy plane that identify the field and source points, respectively. The contour integral proceeds in the direction of the tangential direction t . The function g is the Green function, which is given in terms of the Hankel function of zero order and second type as

$$g(\rho, \rho') = \frac{1}{4j} H_0^{(2)}(k_0|\rho - \rho'|) \quad (15)$$

where k_0 is the wavenumber. The plane-wave fields are given as

$$E_z^{inc} = A_0 e^{-jk_0 \hat{k} \cdot \rho} \text{ and } \mathbf{H}^{inc} = (\hat{k} \times \hat{z}) \frac{A_0}{\eta_0} e^{-jk_0 \hat{k} \cdot \rho} \quad (16)$$

where A_0 is the amplitude of the incident electric field and, $\hat{k} = -\hat{x} \cos \varphi^{\text{inc}} - \hat{y} \sin \varphi^{\text{inc}}$ is the unit vector in the direction of the plane-wave propagation, which is forming an angle φ^{inc} with the x axis. This integral equation is referred to as an *electric field integral equation* (EFIE).

To solve the surface integral equation (14), the contour of the scattering body is divided into a number of linear segments N with width ΔC . The end points of the segments lie on the actual contours of the body. The center of the segment i is located at ρ_i . The length of the zones is taken to be less than one-tenth of a wavelength. The currents are expanded in pulse basis functions multiplied by unknown coefficients as

$$\mathbf{J}_z = \sum_{i=1}^N I_i P_i \quad (17)$$

where I_i are the unknown constant current coefficients and P_i are the pulse basis functions, that defined as

$$P_i(\rho') = \begin{cases} 1 & \text{over the segment } i \\ 0 & \text{elsewhere} \end{cases} \quad (18)$$

Substitute (17) in (14). Then the point matching technique is employed to reduce the integral equations to a system of linear equations. Equation (14) reduces to a standard matrix element, which is placed in the proper location in the matrix. For each point matching j , equation (14) can be written as

$$\begin{aligned} & -\frac{\omega\mu_0}{4} \sum_{i=1}^N I_i \int_{\Delta C_i} H_0^2(k_0|\rho_j - \rho'|) d\ell \\ & = -A_0 e^{jk_0(x_j \cos \varphi^{\text{inc}} + y_j \sin \varphi^{\text{inc}})} \quad \text{on } \Delta C_j \end{aligned} \quad (19)$$

where (x_j, y_j) are the rectangular coordinates of the middle of the segment j and φ^{inc} is the angle of the incident plane wave measured from the x axis. Now, the matrix element Z_{ji} and the excitation vector element V_j can be written as

$$\begin{aligned} Z_{ji} &= -\frac{\omega\mu_0}{4} \int_{\Delta C_i} H_0^2(k_0|\rho_j - \rho'|) d\ell \quad \text{and} \\ V_j &= -A_0 e^{jk_0(x_j \cos \varphi^{\text{inc}} + y_j \sin \varphi^{\text{inc}})} \end{aligned} \quad (20)$$

In the method of moments, the diagonal elements of the matrix should always have special treatment because the integrand becomes singular at $\rho_j = \rho'$. The singular term can be subtracted and integrated analytically, or we may use the small-argument approximation for the Green function. When the argument of the Hankel function is very small, it can be approximated as

$$H_0^{(2)}(k_0\Delta\rho) \simeq 1 - j\frac{2}{\pi} \ln(1.7811k_0\Delta\rho/2) \quad (21)$$

Now the self-term ($i=j$) can be written as

$$Z_{jj} = -\frac{\omega\mu_0\Delta C_j}{4} \left[1 - j\frac{2}{\pi} \ln\left(\frac{1.781k_0\Delta C_j}{4e}\right) \right] \quad (22)$$

At this point, the MoM matrix is completely known. The solution of the matrix determines the current coefficients on the surface of the scattering body. Then these coefficients are used to obtain the near or the far scattered fields. For the far fields, far-field approximations can be considered, and the far scattered field after using the large-argument approximations of the Hankel function can be expressed as

$$E_z^{\text{sc}}(\rho, \varphi) = -\omega\mu_0 \sqrt{\frac{1}{2\pi\rho k_0}} e^{j\pi/4} e^{-jk_0\rho} \sum_{i=1}^N I_i \Delta C_i e^{jk_0\hat{\rho}\cdot\rho_i} \quad (23)$$

An important measure of the fields scattered by an object is the radar cross section (RCS). To determine the RCS, the scattering object is illuminated by a uniform plane wave. For the TM case the radar cross section σ is defined by the following equation:

$$\begin{aligned} \sigma(\phi) &= \lim_{\rho \rightarrow \infty} 2\pi\rho \frac{|E_z^{\text{sc}}(\rho, \phi)|^2}{|E_z^{\text{inc}}|^2} \\ &= \lim_{\rho \rightarrow \infty} 2\pi\rho \frac{|E_z^{\text{sc}}(\rho, \phi)|^2}{|A_0|^2} \end{aligned} \quad (24)$$

In Equation (23), $E_z^{\text{sc}}(\rho, \varphi)$ is the z component of the scattered electric field at the point (ρ, φ) .

The electric field integral equations (EFIE) suffer from the problem of internal resonance. If we are trying to solve a waveguide problem with a cross section similar to that of the scattering problem, the resulting integral equation will be exactly the same as the integral equation of the scattering problem. At the cutoff frequencies, the MoM matrix is singular and an infinite number of solutions exist for a source-free case. At these frequencies, the scattering problem doesn't provide a unique solution.

3. POSSIBLE INTEGRAL EQUATIONS

If we consider the equivalent problem in Fig. 3, another integral equation can be formulated. If we use the magnetic field integral equation in the same way that the tangential magnetic field on the surface S is discontinuous by the surface equivalent current \mathbf{J}_z , the integral equation can be written as

$$\hat{n} \times \mathbf{H}_0 = \mathbf{J} \Rightarrow H_t = J_z \quad \text{on } S \quad (25)$$

or in the form

$$J_z - H_t^{\text{sc}} = H_t^{\text{inc}} \quad \text{on } S \quad (26)$$

Equation (26) can be written in an operator form as

$$J_z - H_t(J_z) = H_t^{\text{inc}} \quad \text{on } S \quad (27)$$

which is referred to as the *magnetic field integral equation* (MFIE). The EFIE can be written as

$$-\frac{1}{\eta_0} E_z(J_z) = \frac{1}{\eta_0} E_z^{\text{inc}} \quad \text{on } S \quad (28)$$

where $H(J)$ and $E(J)$ are the magnetic field and electric field due to the surface electric current J . These operators will be defined later. The MFIE also suffer from the internal resonance problem. To avoid the internal resonance problem, the EFIE and MFIE are combined together to form the combined field integral equation (CFIE) as

$$\begin{aligned}
 J - H_t(J_z) - \frac{\alpha}{\eta_0} E_z(J) \\
 = H_t^{\text{inc}} + \frac{\alpha}{\eta_0} E_z^{\text{inc}} \text{ on } S
 \end{aligned}
 \tag{29}$$

The parameter α is a scalar combination factor less than or equal to 1. As can be seen, the EFIE is normalized to η_0 . This normalization adjusts the value level of the MoM matrix due to the EFIE part to values comparable to those of the MoM matrix element of the MFIE in order to obtain stable numerical inversion of the MM matrix. Note that all the expressions above are for the TM case of a two-dimensional infinitely extended conducting cylinder and all the expression are scalar equations. These expressions can be generalized and presented in vector form. After that, they should be reduced to scalar form, as will be described next.

4. GENERAL TWO-DIMENSIONAL PROBLEM

Consider a composite 2D object parallel to the z axis present with electric or magnetic harmonic current sources \mathbf{J} and \mathbf{M} , respectively. These current sources are of infinite extent and parallel to the z axis with harmonic variations in the z direction. Therefore, the total fields produced by these harmonic 2D sources must be harmonic in z as well in order to satisfy the boundary conditions on the objects [4]. The geometry and notations for such an object are given in Fig. 4. The whole space is divided into $N + 1$ homogeneous regions V_i , which may be either dielectric regions with permittivities ϵ_i and permeabilities μ_i , or closed conductor regions. These regions are numbered $i = 0, 1, 2, \dots, N$, where $i = 0$ corresponds to the exterior region, namely, free space. Lossy materials are

considered by allowing ϵ_i and μ_i , $i = 1, 2, \dots, N$, to be complex. Each region V_i is surrounded by a closed surface S_i and associated with an inward-directed normal unit vector \hat{n}_i . The surface interface between regions V_i and V_j is denoted as S_{ij} , $i \neq j$. Thus, S_i constitutes the set of all interface surfaces S_{ij} , where j represents all region numbers adjacent to region V_i . Note that S_{ij} is the same surface as S_{ji} ; however, the normal unit vectors \hat{n}_i and \hat{n}_j are in opposite directions to each other on the two surfaces. The concept of the equivalence principle is used to derive a surface integral equation (SIE) formulation for 2D objects with $N + 1$ homogeneous regions. The total fields in each homogeneous region are denoted by \mathbf{E}^i and \mathbf{H}^i $i = 0, 1, 2, \dots, N$ for the electric and magnetic fields, respectively. Any perfect conducting region need not be considered as a region because the fields are known to be equal to zero. In the free-space region V_0 , the total fields are denoted by $(\mathbf{E}^0, \mathbf{H}^0)$. From Maxwell's equations and the equivalence principle, one can express the fields in each region in terms of unknown electric and magnetic equivalent surface currents plus the fields due to the harmonic 2D sources present in the region.

According to the surface equivalence principle, we can break the original problem into a number of auxiliary problems that are equal to the number of the nonperfect conducting regions. To obtain the i th auxiliary problem, the boundaries of region V_i are replaced by equivalent surface currents radiating in a homogeneous medium with the constitutive parameters of region V_i using electric currents for the conductor boundaries and equivalent electric and magnetic currents for the dielectric boundaries. The electric and magnetic currents appearing on opposite sides of a dielectric interface in different auxiliary problems are taken equal in magnitude and opposite in direction to ensure the continuity of the tangential components of the fields on these boundaries, as in the original problem. In this procedure the fields produced by the equivalent currents within the region boundaries are the same as those in the original problem, while the zero field is produced outside these boundaries. The electric and magnetic surface currents along the boundaries are

$$\mathbf{J}^i = \hat{n}_i \times \mathbf{H}^i \text{ and } \mathbf{M}^i = -\hat{n}_i \times \mathbf{E}^i \text{ on } S_i \tag{30}$$

Both \mathbf{J}^i and \mathbf{M}^i have components in both the longitudinal \hat{z} and transverse \hat{t} directions

$$\begin{Bmatrix} \mathbf{J}^i \\ \mathbf{M}^i \end{Bmatrix} = \begin{Bmatrix} J_z^i \\ M_z^i \end{Bmatrix} \hat{z} + \begin{Bmatrix} J_t^i \\ M_t^i \end{Bmatrix} \hat{t} \text{ on } S_i \tag{31}$$

where \hat{n}_i is the unit normal to S_i . The currents on the surface S_i are the sum of the currents on all the boundaries S_{ij} , where $j \neq i$ and j represents the entire region numbers adjacent to the region V_i

$$\mathbf{J}^i = \sum_{vj} \mathbf{J}^{ij} \text{ on the boundaries of region } i \tag{32}$$

and similarly for \mathbf{M}^i . On the conductor boundaries the magnetic current is zero. We can now obtain the electric

Figure 4. Cross section of multiregion cylindrical object.

and magnetic fields $E^i(\rho, k_z)$ and $H^i(\rho, k_z)$ due to the electric current $J^i(\rho', k_z)$ by using

$$\mathbf{E}^i(\rho, k_z) = -j\omega A^i(\rho, k_z) - j \frac{1}{\omega \epsilon_i \mu_i} \nabla \nabla \cdot \mathbf{A}^i(\rho, k_z) \quad (33)$$

$$\mathbf{H}^i(\rho, k_z) = \frac{1}{\mu_i} \nabla \times \mathbf{A}^i(\rho, k_z) \quad (34)$$

where the vector potential \mathbf{A} is

$$\mathbf{A}^i(\rho, k_z) = \frac{\mu_i}{j4} \int_{V'} \mathbf{J}^i(\rho', k_z) H_0^{(2)}(k_\rho |\rho - \rho'|) dl' \quad (35)$$

The ∇ operator is $\nabla = \nabla_t - jk_z \hat{z}$, $\nabla_t = (\partial/\partial x)\hat{x} + (\partial/\partial y)\hat{y}$ and $k_\rho = \sqrt{k^2 - k_z^2}$. For each value of $k_z \in [-k, k]$, the far field is radiating on a cone around the z axis with cone angle $\theta = \cos^{-1}(k_z/k)$ [4]. Equations (33) and (34) can be given in an operator form $\mathbf{E}^i(\mathbf{J}^i)$ and $\mathbf{H}^i(\mathbf{J}^i)$. The vector tangential operator can be presented in terms of their operator components as

$$\mathbf{E}_{\tan}^i(\mathbf{J}^i) = [E_t^i(J_t^i) + E_z^i(J_z^i)] \hat{t} + [E_z^i(J_t^i) + E_z^i(J_z^i)] \hat{z} \quad (36)$$

$$\mathbf{H}_{\tan}^i(\mathbf{J}^i) = [H_t^i(J_t^i) + H_z^i(J_z^i)] \hat{t} + H_z^i(J_t^i) \hat{z} \quad (37)$$

After some mathematical manipulations the electric and magnetic fields due to the electric currents can be expressed in operator form. Expressions are given for $E_t^i(J_t^i)$, $E_z^i(J_t^i)$, $E_z^i(J_z^i)$, and $E_z^i(J_z^i)$, which are the components of the vector operator $\mathbf{E}_{\tan}^i(\mathbf{J}^i)$ for the tangential E field at a point ρ on S_i , and in the same fashion we get $H_t^i(J_t^i)$, $H_z^i(J_t^i)$, and $H_z^i(J_z^i)$ for the tangential H -field vector operator $\mathbf{H}_{\tan}^i(\mathbf{J}^i)$. The electric and magnetic field operators due to the electric current components are expressed as

$$E_z(J_z) = \frac{-jk_z k_\rho}{4\omega \epsilon_0} e^{jk_z z} \int_C J_z H_1^{(2)}(k_\rho \Delta \rho) (\hat{t}' \bullet \Delta \hat{\rho}) dl' \quad (38)$$

$$E_t(J_z) = \frac{-jk_\rho k_z}{4\omega \epsilon_0} e^{jk_z z} \int_C J_z H_1^{(2)}(k_\rho \Delta \rho) (\hat{t} \bullet \Delta \hat{\rho}) dl' \quad (39)$$

$$E_z(J_z) = -\frac{k_\rho^2}{4\omega \epsilon_0} e^{jk_z z} \int_C J_z H_0^{(2)}(k_\rho \Delta \rho) dl' \quad (40)$$

$$E_t(J_t) = -\frac{e^{jk_z z}}{4\omega \epsilon_0} \int_C k_z^2 J_t \{(\hat{t}' \bullet \hat{t}) H_0^{(2)}(k_\rho \Delta \rho) - \frac{k_\rho}{\Delta \rho} H_1^{(2)}(k_\rho \Delta \rho) (\hat{t}' \bullet \hat{t}) - k_\rho [k_\rho H_0^{(2)}(k_\rho \Delta \rho) - \frac{2}{\Delta \rho} H_1^{(2)}(k_\rho \Delta \rho)] (\hat{t}' \bullet \Delta \hat{\rho}) (\hat{t} \bullet \Delta \hat{\rho})\} dl' \quad (41)$$

$$H_t(J_z) = -\frac{jk_\rho}{4} e^{jk_z z} \int_C J_z H_1^{(2)}(k_\rho \Delta \rho) (\hat{n} \bullet \Delta \hat{\rho}) dl' \quad (42)$$

$$H_z(J_z) = 0 \quad (43)$$

$$H_z(J_t) = -\frac{k_\rho}{4j} e^{jk_z z} \int_C J_t H_1^{(2)}(k_\rho \Delta \rho) (\hat{n}' \bullet \Delta \hat{\rho}) dl' \quad (44)$$

$$H_t(J_t) = -\frac{k_z}{4} e^{jk_z z} \int_C J_t H_0^{(2)}(k_\rho \Delta \rho) (\hat{t} \bullet \hat{n}') dl' \quad (45)$$

where $H_1^{(2)}(\cdot)$ is the Hankel function of the first order and second type and $\Delta \rho = |\rho - \rho'|$. The hat is used to indicate the unit vectors. In Eqs. (38)–(45) the prime is used to indicate the source coordinates. The fields due to the magnetic current $\mathbf{M}^i(\rho', k_z)$ can be obtained using duality [5, Chap. 3, Sect. 3-2]. Now the boundary conditions must be enforced on each boundary on the object, which can be used as surface integral equations after substituting the proper operators as follows

$$- [E_{\tan}^i(\mathbf{J}^i) + E_{\tan}^j(\mathbf{J}^j) + E_{\tan}^i(\mathbf{M}^i) + E_{\tan}^j(\mathbf{M}^j)] = [E_{\tan}^i(\mathbf{J}^{i,inc}) + E_{\tan}^i(\mathbf{M}^{i,inc}) - E_{\tan}^j(\mathbf{J}^{j,inc}) + E_{\tan}^j(\mathbf{M}^{j,inc})] \quad (46)$$

on S_{ij}

$$- \hat{n}_i \times [H^i(\mathbf{J}^i) + H^j(\mathbf{J}^j) + H^i(\mathbf{M}^i) + H^j(\mathbf{M}^j)] = \hat{n}_i \times [H^i(\mathbf{J}^{i,inc}) + H^i(\mathbf{M}^{i,inc}) - H^j(\mathbf{J}^{j,inc}) + H^j(\mathbf{M}^{j,inc})] \quad (47)$$

on S_{ij}

if the boundary S_{ij} is a perfect conducting boundary and the region V_j is a perfect conducting region, Eqs. (46) and (47) become

$$-E_{\tan}^i(\mathbf{J}^i) - E_{\tan}^i(\mathbf{M}^i) = E_{\tan}^i(\mathbf{J}^{i,inc}) + E_{\tan}^i(\mathbf{M}^{i,inc}) \text{ on } S_{ij} \quad (48)$$

$$- \hat{n}_i \times [H^i(\mathbf{J}^i) + H^i(\mathbf{M}^i)] = \hat{n}_i \times [H^i(\mathbf{J}^{i,inc}) + H^i(\mathbf{M}^{i,inc})] \quad (49)$$

on S_{ij} (just inside V_i)

Only one of the equations (48) and (49) can be used. If Eq. (48) is used on the perfect electric conductor (PEC) with (46) and (47) on the dielectric boundary, the formulation is called E-PMCHW formulation, and if Eq. (49) is used just inside the PEC boundary with (46) and (47) on the dielectric boundary, the formulation is referred to as H-PMCHW [6]. The combined field formulation on the conductor can be obtained if Eqs. (48) and (49) are combined together and used as one equation with (46) and (47) [6]. The combined field formulation is referred to as C-PMCHW.

Following the method of moments, the object contour C is divided into N linear segments with length ΔC^ℓ , $\ell = 1, 2, \dots, N$ as in Ref. 9, and each current component is expanded into N pulse basis function p^ℓ . In equation form, the unknown currents can be expressed as

$$\mathbf{J}^i = \sum_{\ell}^N (I_z^{\ell,i} \hat{t} + I_z^{\ell,i} \hat{z}) P^\ell \text{ on all } S_{ij} \quad (50)$$

and

$$M^i = \sum_{\ell=N+1}^{N+N_d} (M_t^{\ell,i} \hat{t} + M_z^{\ell,i} \hat{z}) P^\ell \quad (51)$$

only on the dielectric boundaries

where $I_{\alpha\beta}^{(\ell,i)}$ and $M_{\alpha\beta}^{(\ell,i)}$ are the unknown electric and magnetic current coefficients, respectively. The pulse function is $P^\ell = 1$ on the subdomain ΔC^ℓ and zero elsewhere. N_d is the number of segments on the dielectric boundaries. Substituting (50) and (51) into the operators defined in (38)–(45) and then satisfying (46) to (47) at the match point (middle of the segments), the integral equations reduce to a matrix of order $2(N + N_d)$, which can be written in the form

$$\begin{bmatrix} Z_{zz}^{ij,i} + Z_{zz}^{ij,j} & Z_{zt}^{ij,i} + Z_{zt}^{ij,j} & Y_{zz}^{ij,i} + Y_{zz}^{ij,j} & Y_{zt}^{ij,i} + Y_{zt}^{ij,j} \\ Z_{tz}^{ij,i} + Z_{tz}^{ij,j} & Z_{tt}^{ij,i} + Z_{tt}^{ij,j} & Y_{tz}^{ij,i} + Y_{tz}^{ij,j} & Y_{tt}^{ij,i} + Y_{tt}^{ij,j} \\ Y_{tz}^{ij,i} + Y_{tz}^{ij,j} & Y_{tt}^{ij,i} + Y_{tt}^{ij,j} & -\frac{1}{\eta_i} Z_{tz}^{ij,i} - \frac{1}{\eta_j} Z_{tz}^{ij,j} & -\frac{1}{\eta_i} Z_{tt}^{ij,i} - \frac{1}{\eta_j} Z_{tt}^{ij,j} \\ Y_{zz}^{ij,i} + Y_{zz}^{ij,j} & Y_{zt}^{ij,i} + Y_{zt}^{ij,j} & -\frac{1}{\eta_i} Z_{zz}^{ij,i} - \frac{1}{\eta_j} Z_{zz}^{ij,j} & -\frac{1}{\eta_i} Z_{zt}^{ij,i} - \frac{1}{\eta_j} Z_{zt}^{ij,j} \end{bmatrix} \begin{bmatrix} I_z^{ij} \\ I_t^{ij} \\ M_z^{ij} \\ M_t^{ij} \end{bmatrix} = \begin{bmatrix} V_z^{ij,i,\text{inc}} - V_z^{ij,j,\text{inc}} \\ V_t^{ij,i,\text{inc}} - V_t^{ij,j,\text{inc}} \\ I_t^{ij,i,\text{inc}} - I_t^{ij,j,\text{inc}} \\ I_z^{ij,i,\text{inc}} - I_z^{ij,j,\text{inc}} \end{bmatrix} \quad (52)$$

where $Z_{\alpha\beta}^{ij,i}$ and $Y_{\alpha\beta}^{ij,i}$ denote matrix elements obtained from the operators $E_{\alpha}^{ij}(J_{\beta})$ and $H_{\alpha}^{ij}(J_{\beta})$, respectively, on the surface S_{ij} from the region i . Therefore, the first suffix of the subscript refers to the field component, and the second suffix of the subscript refers to the current component. The first pair of the superscripts refers to the surface boundary ij and the second suffix, to the region number i or j . This matrix is built assuming that all the boundaries are dielectric boundaries, but on the perfect conducting parts the columns and the rows that correspond to the magnetic currents and the magnetic field, respectively, which are in the third and fourth columns and rows, respectively, must be removed, and in the first and second columns of (52) the parts that correspond to perfect conducting regions i or j must be forced to zero.

The quantities I_t^{ij} , I_z^{ij} , M_t^{ij} , and M_z^{ij} are the unknown expansion coefficients of the electric and magnetic currents, respectively. The right-hand-side (RHS) columns are the excitation vectors, where $V_t^{ij,i}$, $V_z^{ij,i}$, $I_t^{ij,i}$, and $I_z^{ij,i}$ denote the electric and magnetic fields, respectively, on the surface S_{ij} due to all electric and magnetic sources in the region i . The matrix elements can be written as

$$Z_{zz}^{ij} = \begin{cases} -\frac{k_\rho^2}{4k_0} \int_{\Delta C^j} H_0^{(2)}(k_\rho \Delta \rho^{ij}) dt' & i \neq j \\ -\frac{k_\rho^2}{4k_0} \Delta C^j \left[1 - \frac{2j}{\pi} \left(\ln \left(\frac{\Delta C^j \gamma k_\rho}{4} \right) + 1 \right) \right] & i = j \end{cases} \quad (53)$$

$$Z_{tz}^{ij} = \begin{cases} -\frac{jk_\rho k_z}{4\omega\epsilon_0} \int_{\Delta C^j} H_1^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{t}_i \bullet \Delta \hat{\rho}^{ij}) dt' & i \neq j \\ 0 & i = j \end{cases} \quad (54)$$

$$Z_{zt}^{ij} = \begin{cases} -\frac{jk_z k_\rho}{4\omega\epsilon_0} \int_{\Delta C^j} H_1^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{t}_j \bullet \Delta \hat{\rho}^{ij}) dt' & i \neq j \\ 0 & i = j \end{cases} \quad (55)$$

$$Y_{tt}^{ij} = \begin{cases} -\frac{k_z}{4} \int_{\Delta C^j} H_0^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{t}_i \bullet \hat{n}_j) dt' & i \neq j \\ 0 & i = j \end{cases} \quad (56)$$

$$Z_{tt}^{ij} = \begin{cases} -\frac{1}{4k_0} \int_{\Delta C^j} \{k^2 (\hat{t}_j \bullet \hat{t}_i) H_0^{(2)}(k_\rho \Delta \rho^{ij}) \\ -\frac{k_\rho}{\Delta \rho^{ij}} H_1^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{t}_j \bullet \hat{t}_i) \\ -k_\rho \left[k_\rho H_0^{(2)}(k_\rho \Delta \rho^{ij}) - \frac{2}{\Delta \rho^{ij}} H_1^{(2)}(k_\rho \Delta \rho^{ij}) \right] \\ (\hat{t}_j \bullet \Delta \hat{\rho}^{ij}) (\hat{t}_i \bullet \Delta \hat{\rho}^{ij}) dt' & i \neq j \\ \times \frac{2k_\rho H_1^{(2)} \left(\frac{k_\rho \Delta C^i}{2} \right) + \frac{k_0^2 \Delta C^i}{4k_0}}{4k_0} \\ \left[1 - \frac{2j}{\pi} \ln \left(\frac{\Delta C^i \gamma k_\rho}{4} \right) - 1 \right] & i = j \end{cases} \quad (57)$$

$$Y_{zz}^{ij} = 0 \quad (58)$$

$$Y_{zt}^{ij} = \begin{cases} -\frac{k_\rho}{4j} \int_{\Delta C^j} H_1^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{n}_j \bullet \Delta \hat{\rho}^{ij}) dt' & i \neq j \\ -\frac{1}{2} & i = j \end{cases} \quad (59)$$

$$Y_{tz}^{ij} = \begin{cases} -\frac{jk_\rho}{4} \int_{\Delta C^j} H_1^{(2)}(k_\rho \Delta \rho^{ij}) (\hat{n}_i \bullet \Delta \hat{\rho}^{ij}) dt' & i \neq j \\ \frac{1}{2} & i = j \end{cases} \quad (60)$$

These integrals are performed numerically where $\Delta \rho^{ij} = |\rho^i - \rho^j|$ and ρ^j for the segment j . The excitation vector can be obtained in a manner similar to that for the matrix elements due to known electric and magnetic current sources. In the case of plane-wave incidence the excitation matrix elements are given as

$$H_t^{i,\text{inc}} = \frac{E_m}{\eta_0} \cos \theta_{\text{inc}} (E^p \sin \alpha_{\text{inc}} - E^n \cos \alpha_{\text{inc}}) \bullet \hat{t}_i e^{jk_\rho(\hat{\rho} \bullet \rho^i)} \quad (61)$$

$$H_z^{i,\text{inc}} = \frac{1}{\eta_0} \sin \theta_{\text{inc}} \sin \alpha_{\text{inc}} e^{jk_\rho(\hat{\rho} \bullet \rho^i)} \quad (62)$$

$$\mathbf{E}_z^{i,\text{inc}} = \frac{\mathbf{E}_m}{\eta_0} \sin \theta_{\text{inc}} \cos \alpha_{\text{inc}} e^{jk\rho(\hat{\rho} \cdot \hat{\rho}_i)} \quad (63)$$

$$\mathbf{E}_t^{i,\text{inc}} = \frac{\mathbf{E}_m}{\eta_0} (E^p \cos \alpha_{\text{inc}} + E^n \sin \alpha_{\text{inc}}) \bullet \hat{t} e^{jk\rho(\hat{\rho} \cdot \hat{\rho}^i)} \quad (64)$$

where the superscript i denotes the middle of segment i and α_{inc} is the angle between $\mathbf{E}^{i,\text{inc}}$ and the plane of incidence (k - z plane).

Once the MoM matrix equation is solved the far fields due to the currents on the outer surface boundary, and the current sources in the exterior region can be computed. The field will be along a cone of half-angle $\theta = \arcsin(k_z/k_0)$ around the structure [4].

5. SAMPLE RESULTS

Sample results are obtained using the formulations presented above to show the accuracy of the numerical method versus the exact solution for circular cylinder objects. Figure 5 shows the scattered field of a coated conducting cylinder with radii $ka = 2$ and $kb = 3$ and $\epsilon_r = 4$ for TM and TE polarization due to a plane wave incident by an angle of 45° from the z axis. The numerical solution is compared with the exact solution. Excellent agreement is observed.

In the preceding sections we have demonstrated the formulations of the integral equation for simple two-dimensional objects using the simplest possible basis function. This basis function is a slowly conversion function. Other basis functions can be used with better conversion rates. In the following section we will present literature review for the developments in the method of moments.

6. ADVANCED METHOD OF MOMENTS

Antennas, which usually consist of three-dimensional (3D) radiating elements (sources), can be present with two-dimensional (2D) structures (cylinders of infinite extent). Such problems can be analyzed by using a spectrum of two-dimensional solutions (S2DS), as described in Refs. 7

and 8. Generally, any antenna consisting of slots or dipoles in or in the vicinity of 2D structures of arbitrary cross-sectional shape and material combination can be analyzed by the S2DS technique.

The most significant part of an S2DS analysis is to solve repeatedly the special spectral-domain problem obtained by Fourier-transforming the sources in the z direction of the structure. This spectral-domain problem can be interpreted as a harmonic 2D spatial problem where the sources (and the resulting fields) have harmonic z variation of the form $\exp(-jk_z z)$, where $k_z = 0$ corresponds to the standard 2D problem. This general harmonic 2D problem must be solved for a large number of values of the spectral variable k_z in order to be able to inverse transform to 3D spatial domain. The radiation pattern, however, can normally be found directly without inverse transformation from the 2D harmonic solution [7].

The harmonic 2D problem is conveniently solved for each k_z by the method of moments (MoM). Plane-wave scattering from 2D composite objects [9,10] and scattering from an impedance cylinder with arbitrary cross section under oblique plane-wave incidence were analyzed, where the equivalent electric and magnetic currents were solved for by pulse expansion and point matching.

7. USE OF IMPEDANCE BOUNDARY CONDITIONS

The concept of the impedance boundary condition (IBC), which was first described by Leontovich in 1948 [11], has long been used in a variety of electromagnetic wave scattering problems. For closed bodies, it has been shown that the IBC is a valid approximation to the exact condition whenever (1) the refractive index is large compared with unity, (2) the total radii of curvature are much greater than the skin depth, (3) the body is much thicker than the skin depth, and (4) the spatial variation of the index of refraction is slow in comparison to the local wavelength [12–15]. Consequently, the IBC concept has long been utilized to solve many electromagnetic problems. Garbacz [16] investigated a special case of bistatic

Figure 5. Far scattered field from a coated conducting cylinder with radii $ka = 2$, $kb = 3$, $\epsilon_r = 4$: (a) TM; (b) TE.

scattering from a class of lossy dielectric spheres subject to the impedance boundary condition, using the classical modal solution derived from Mie's series. Using the same approach, Wait and Jackson [17] presented many computed results for the scattering by an impedance sphere assuming various surface impedances. The usefulness of the IBC in determining the scattered fields has also been demonstrated by Cassedy and Fainberg [18] for finite cylinders.

The electromagnetic scattering from bodies made of electrically dissimilar materials has also been investigated using the IBC in conjunction with the method of moments (MoM). Different geometries have been considered, such as circular and elliptical cylinders [19,20] and spheroidal bodies [21]. The introduction of dissimilar materials has opened the door for more practical uses of the IBC in antenna problems. Iskander et al. [22] used the IBC to simulate transverse corrugations in a small conical horn. A modification of the IBC concept to treat the problem of homogeneous imperfectly conducting objects, with small radii of curvature, has been described by Mitzner [23].

Different integral equation formulations have been developed to treat the problem of scattering from impedance bodies of revolution. Iskander et al. [22] employed the electric field integral equation formulation (EFIE). Later, Graglia and Uslenghi [24] examined impedance-coated bodies of revolution using the generalized MFIE formulation. In these earlier studies the problem of internal resonances had not been addressed. However, the EFIE and MFIE formulations were shown to be ill-posed and lead to ill-conditioned matrices when solved by the MoM [25–28]. The internal resonance problem has been found to be similar to the one encountered with perfectly conducting bodies, which was reported in 1978 [29] and treated by the combined field integral equation (CFIE) formulation. The problem of the internal resonances with impedance bodies of revolution was reported and treated by many investigators using CFIE. Apparently, the internal resonance problem is not the only problem associated with impedance bodies. Rusch and Pogorzelski [30] reported another problem even when applying CFIE formulation with bodies having both thin and thick parts. Accordingly, a mixed-field solution that combines different integral equations on different parts of the scatterer must be employed. They [30] recommended that the EFIE be applied on the thin parts of the scatterer in order to provide a correct solution.

The calculation of scattering from bodies composed of lossless or low loss dielectric materials and surface impedance objects using a mix of exact and impedance boundary conditions is treated with different types of integral equations by Kishk [31,32].

Some complicated structures can be modeled approximately using the concept of surface impedance, such as corrugated objects or objects coated with lossy material or thin dielectric layers, which can even be loaded with metal strips. The surface impedance model deals with the outer boundary of the structure in terms of equivalent surface impedance, which can be obtained from the expected local relation between the tangential components of the electric and magnetic fields on the outer boundary. This relation

can be found approximately at any surface point from the solution of a canonical problem, which is similar to the local geometry around this point. The equivalent surface impedance is generally anisotropic, even if the coating is isotropic, in particular at an outer surface that has two different principal curvatures. Also, structures with periodic surface discontinuities such as corrugations or strip-loaded coatings can be modeled using the anisotropic surface impedance concept, if the periods of the corrugations or strips are smaller than half the wavelength. The advantage with the surface impedance concept is that the numerical analysis of the object becomes simpler and takes less time. This is because the exact geometry of the loads needs not to be modeled to facilitate description of the problem and so that the number of unknowns can be reduced dramatically.

The impedance boundary conditions (IBCs) are a valid approximation under certain conditions [15]; more references on IBC can be found in Kishk [32]. The use of IBC can simplify the analysis of many complex electromagnetic problems. However, in other problems the use of IBC is questionable [33]. In order to widen the applicability of the IBC, generalized impedance boundary conditions (GIBCs) was proposed [34] and later improved for coated 2D structures [35] at the expense, however, of considerable analytical complications, which requires specialized expertise to work with such problems. So far, GIBC has been used only with coated metallic surfaces without corrugations. On the other hand, IBC has been used successfully to analyze corrugated horns and waveguides [22]. Anisotropic surface impedances have also been used to define soft and hard surfaces [36].

Many papers have formulated the problem of electromagnetic scattering from 2D impedance structures due to a normally incident plane wave [37–39]. However, few have considered oblique incidence [40,41]. In [40], the finite element method was used to model arbitrarily shaped objects with isotropic impedance surfaces. Gordon and Kishk [41] used the finite-difference method in the frequency domain for elliptic isotropic impedance cylinders. The problem of scattering from a two-dimensional object of arbitrary cross section and anisotropic surface impedance due to an oblique plane wave incidence has been formulated [10]. The formulation is based on the surface integral equation and solved using the method of moment with pulse basis functions and point matching. With the proper implementation of this simple expansion and testing, accurate numerical solutions are obtained. The numerical solution is verified with the exact solution of a circular cylinder [42]. Different surface integral formulations are generated and found useful in the verification of the numerical solutions for arbitrary objects.

8. FULL-WAVE ANALYSIS OF MICROWAVE CIRCUITS

In conjunction with the widespread development of wireless information networks such as cellular, personal communication services (PCS), satellite communication systems, mobile computing, and other new systems and services, monolithic microwave integrated circuits

(MMICs) have advanced significantly. The primary motivation for developing MMIC in wireless communications such as PCS is to achieve higher quality, longer battery lifetime, lower cost, and lighter terminals [43]. Dielectric resonators (DRs) with high permittivity and low temperature coefficients are smaller than waveguide or coaxial resonators, are easily fabricated, and are compatible with MMIC implementation [44,45]. Using dielectric resonators, instead of metal cavities, in a multilayered medium coupled to a microstrip line or a slot aperture eliminates the need for microstrip to cavity adapters and provides greater flexibility to realize complicated bilateral and multilayered printed circuits, thus allowing very compact, high-density circuit integration.

With the advent of the high-dielectric-constant and low-temperature-coefficient ceramic materials, DR applications of the dielectric resonator in the design of passive and active microwave circuits [46,47] have spread toward low frequencies for mobile communications such as PCS at 1.8–2 GHz. An experimental study of a dielectric resonator, of relative dielectric constant 80 and of resonant frequency ~ 1.7 GHz, coupled to a microstrip line can be found in Ref. 48. The method of moments (MoM) has been used to calculate the characteristics of an isolated dielectric resonator that is of the revolution-type body [49,50]. This model includes both dielectric loss and radiation loss. Numerical analysis of in-circuit parameters of a dielectric resonator is more challenging. A study of the DR antennas excited by a coaxial probe or slot aperture has been conducted in both theory and measurement at the University of Mississippi [51–53], where theoretical investigations have considered mainly structures consisting of body-of-revolution dielectric resonators combined with wires or slots.

The MoM full-wave analysis procedure is developed to analyze the dielectric resonator of arbitrary shape in a multilayered medium coupled to a microstrip circuit. A new mixed potential integral equation (MPIE) formulation has been developed for the analysis of electromagnetic problems involving conducting or dielectric objects of arbitrary shape embedded in a planar stratified medium [54]. In the new MPIE formulation, the dyadic kernel of the vector potential is kept in the simplest form originally developed by Sommerfeld, yet the scalar potential, which is represented by a double dot product of a dyadic kernel with a dyadic charge density, remains compatible with the original implementation. The triangular patch model, originally developed for arbitrarily shaped objects in free space [55–59], is employed in conjunction with the new MPIE formulation to model the problem of a dielectric resonator excited by microstrip circuit. The numerical procedure has been modified to handle the potential dyadic kernels and the dyadic charge density. A matched-load simulation procedure has been used to extract the network S parameters of a DR microstrip circuit. The diameters (scattering) of the Q circles have been measured to determine the coupling coefficients and the Q factors of the dielectric resonator excited by a microstrip circuit. The validity of the new MPIE formulation and the numerical procedure has been verified by comparing the S parameters obtained and the available measurement data [54].

Ceramic materials of high dielectric constant and low loss can exhibit a very high Q factor. Therefore, they have been widely used as resonators in microwave filters and oscillators. To understand the behavior of these elements and to determine the best coupling mechanism, it is necessary to determine the electromagnetic field distribution inside the cavity. The resonant frequency and the Q factor have to be computed accurately before the electromagnetic fields in the vicinity of the resonators can be obtained. It is therefore important to be able to determine the resonant frequencies and Q factors of the desired modes.

Many different approaches to the analysis of dielectric resonators have been described in the literature [60–76]. Some of these methods are based on simplifications of the geometry, such as the perfect magnetic conducting (PMC) walls method [60–62]. Dielectric waveguide methods [63], as well as their perturbation corrections and the variation improvements [64] for cylindrical resonators, have also been developed. In 1975, Van Bladel reported a rigorous asymptotic method for evaluating the modes of dielectric resonators of arbitrary shape and high permittivity [65,66]. In addition, radial and axial mode-matching methods [67] for shielded resonators as well as asymptotic expansion methods [68] have been reported. Also, general mode-matching approaches using Green's dyadic functions or transverse modes in expanding the interior and exterior fields [69] have been successful approaches for this kind of problem. Glisson, Kajfez, and James introduced the use of the method of moments for the analysis of an open dielectric resonator [70–72]. The method was applied to dielectric bodies of revolution of arbitrary cross section and is useful for any azimuthal variation. Their results indicate that their method has yielded highly accurate values of resonant frequencies and Q factors for homogeneous dielectric resonators. The finite integration method was also used for axisymmetric shielded resonators [73]. Another approach to the electromagnetic resonance of open dielectric resonators is the null-field method [74,75] developed by Wenxin Zheng and Staffan Strom. In that approach, the resonance problem is solved by searching for zeros of the determinant of the so-called Q matrix for the dielectric resonators.

A previously developed numerical method [76] based on the method of moments is used to search for the complex resonant frequency, from which the resonant frequency and radiation Q factor can be computed, of both homogeneous and inhomogeneous dielectric resonators in free space. The geometries considered here are rotationally symmetric, so the body-of-revolution (BoR) approach is employed. The equivalence principle is used, and the surface integral equations are formulated for the problem. Then the method of moments is used to reduce the integral equations to a matrix equation. The "natural" resonant frequencies are defined as the frequencies at which the determinant of the moment matrix vanishes. Also, since the rotationally symmetric structure supports independent azimuthal modes, the azimuthal variation of the unknown equivalent currents is expanded in Fourier series. This allows one to search for the zeros of the moment matrix for modes having a particular azimuthal variation.

To compute the Q factor of nonradiating cavities, lossless structure and search for the resonant frequencies are considered. Once the resonant frequency is known, the surface currents are computed, which are then used to compute field distributions inside the cavity. Then, the perturbation method is employed to compute the stored energy and dissipated power from which we compute the Q factor [77].

For the solution of the EM modeling problems involving arbitrary geometries, the mixed potential surface integral equation (MPSIE) formulation and the method of moments (MoM) solution procedure are employed [55–58]. The E-PMCHW form [78] of the MPSIE formulation is used. EM scattering and radiation have been the subject of numerous studies covering the whole spectrum ranging from LF (low-frequency) to the optical frequencies. Although analytical solution methods are available for some canonical cases, they are limited to simple geometries, for example, an object with boundaries of constant coordinates. Such solutions can be a useful tool in EM modeling for validation and comparison of more general solutions, and for the development of approximate asymptotic techniques. Very often an analytically solvable object is either completely a conductor or purely a dielectric, but not a composite. For an arbitrarily shaped conducting or dielectric object, however, there is no analytic solution, and one must resort to numerical methods.

For EM problems there numerous numerical methods have been developed and can be classified in many ways [79,80]. The variety of the electromagnetic numerical methods is due to the extremely wide frequency range and diverse classes of EM problems that are of interest, such as multilayer, periodic, and frequency-selective structures, to name just a few. Needless to say, the variety of the methods testifies to the fact that no single method works for all problems, and that each numerical method is well suited for the analysis of particular types of problems. The MoM (method of moments) [81], FEM (finite-element method) [82], and FDTD (finite-difference time domain) [83–85] techniques are the most powerful full-wave methods used in this frequency range. The surface integral equations are derived from the equivalence principle [86] and appropriate boundary conditions.

Although the first reported dielectric resonator antenna was used in a millimeter-wave array [87], most of the research has focused on individual DRA elements of various common shapes [88–90]. More extensive references on DRAs are found in Ref. 91. Unlike other classes of antennas, a DRA has a minimum of metal parts and consists mainly of dielectric materials mounted over a metal ground plane. When compared with traditional metallic antennas, DRA's are small and low cost, and they have relatively small losses, especially in the millimeter-wave region, where the conductor losses become severe. Aperture-coupled DRAs provide compatibility with MMIC fabrication as well as isolation between the feeding and radiating structures. Possible advantages of DRAs over microstrip antennas of similar size are wider bandwidth and higher power-handling capabilities. Dielectric radiators also offer the freedom to choose a mode for broadside radiation or another for endfire radiation.

DRAs can be designed for wide bandwidth, desired field patterns, and a linear or circular polarization by choosing appropriate dielectric constants of the DR elements, element shapes, and feeding structures. One of the main disadvantages of DRAs, however, is the difficulty of their analysis. Although the early work on DRAs was based on experiments and simple models of a DR element [92–94], more rigorous and accurate numerical methods have been indispensable for better design of DRAs. One example of such a demand is a more compact and wideband handset antenna used in the wireless communication, for which the DRA is a good candidate.

At the University of Mississippi, the MPSIE/MoM procedure [56–58] and BoR (body of revolution)/MoM [95] developed for the analysis of general EM modeling has been applied to the study dielectric resonator antennas [96–102]. The MPSIE/MoM formulation has been further developed by D. R. Wilton et al. to become a standard procedure for SIE/MoM and VIE (volume integral equations)/MoM, and a package of standard subroutines has been available [59]. For problems with a finite number of homogeneous dielectric regions in combination with conducting bodies, SIE/MoM may be advantageous over VIE/MoM, FEM, or FDTD because it discretizes only the surface of the problem space rather than the whole volume. The wavelength within the dielectric may be much shorter than that of the free space, and thus girding the whole computational space uniformly with the resolution set by the critical geometry within the dielectric region results in a very inefficient situation. Therefore most numerical methods reported for DRAs have used SIE/MoM methods and taken further computational advantage of BoR models [96–102], by which their applications are limited to the problems of axially symmetric shapes.

However, the SIE/MoM can be quite tedious and difficult to implement when applied to arbitrary configurations with complex geometries or inhomogeneous dielectrics. By *arbitrary configurations*, we refer to an arbitrary number of dielectric regions, arbitrary compositions of conductors and dielectrics, general excitations, and other factors as well as arbitrary shapes. Although numerous MoM codes have been developed, when the arbitrariness of the geometries modeled is considered, the number dwindles down quickly, and the codes capable of handling the more general geometries often involve years of work and are expensive to obtain. A 3D surface of arbitrary shape is most suitably modeled by using the triangular patches or RWG (Rao–Wilton–Glisson) basis functions compared with many other approaches [102–107]. EM modeling of arbitrarily shaped conductors [58] or homogeneous dielectric [108] has been accomplished using the RWG basis functions.

Arbitrarily shaped composite bodies of conductors and dielectrics have often been treated with the constraint of a multilayer environment [109–113], where the dielectric layers are assumed to be of infinite extent. EM modeling of arbitrarily shaped 3D composite objects using RWG basis functions has been also reported in the literature [113–119]. However, the arbitrariness of the configurations treated by them is more or less confined and no systematic procedure for extension of the formulation has been provided. For example, for some cases the number of

dielectric regions is limited to two, including the free space, and arbitrary shape is allowed only for conductors in presence of axially symmetric dielectric bodies [120], or only junctions consisting of up to three intersecting surfaces are allowed. Moreover the procedures employed to deal with the composite objects of conducting and dielectric objects are more involved than the standard MPIE/MoM formulation.

9. TIME-DOMAIN INTEGRAL EQUATIONS

The method of moments is also applied in the time domain for conducting and dielectric bodies. Several formulations have been used for the solution of the time-domain integral equation to calculate the electromagnetic scattering from arbitrarily shaped 3D structures. For the 3D structures the triangular basis function is used [121]. The time derivative in EFIE formulation of the magnetic vector potential is implemented by differentiating all the terms in the EFIE with respect to time; this magnetic vector potential term is approximated by second-order finite differences [122]. However, the results become oscillatory for late times, which could be eliminated by approximating the average value of the current [123]. The incident field should be differentiated, but an impulse or step function for the incident field cannot be used as an excitation. In addition, to overcome this problem, a backward finite-difference approximation for the magnetic vector potential term has been used for the explicit technique [124]. Many numerical results using the explicit method with forward/backward-difference schemes have been shown in [121,124,125]. An implicit scheme has been proposed to solve scattering problems [126–130]. The explicit method requires a very small timestep, and the computed time-domain response becomes unstable. This is due to the accumulation of numerical error, and it consumes much computation time. This can be overcome using an implicit method. In the implicit method the timestep is larger than that for the explicit case. Therefore numerical error due to the approximation of a time derivative with the use of finite difference is increased. Jung and Sarkar used a central finite-difference methodology, which is more accurate and provides stable solutions [131]. In this work, the time domain CFIE formulation is used. The EFIE and MFIE are converted into matrix equations and are solved for CFIE solution. The goal is to find that the CFIE gives a unique solution of transient scattering problems when the incident wave includes resonant frequencies of the scatterer. The solution technique developed in this work is capable of handling either an explicit or implicit scheme of the EFIE, MFIE, and CFIE.

MICROSTRIP ANTENNA ARRAYS

PETER S. HALL
The University of Birmingham
Edgbaston, Birmingham, UK

1. INTRODUCTION

Microstrip antenna arrays are formed from collections of microstrip antenna elements, which may then be interconnected and fed using microstrip transmission lines. For information on microstrip antenna elements, the reader is referred to other articles. In this article it is assumed that

Figure 1. Microstrip patch array (typical dimensions for operation at 12 GHz, patch size = 9.7×7.2 mm, patch spacing = 17 mm, substrate height = 1.59 mm, $\epsilon_r = 2.32$, feedline width = 0.5 mm at patches, 2.5 mm at input) [57].

the elements may be a microstrip patch or a section of microstrip transmission line that radiates. This article is concerned with the architectures of microstrip arrays and some specific issues that arise in their design, such as surface waves and mutual coupling.

In using microstrip for both the radiating elements and the feed network, a low-profile planar structure results. The minimum thickness will be obtained when the feed is coplanar with the radiators (Fig. 1), which is to say that the array and the feed are manufactured by the process of photolithography on one side of a copper-clad microwave substrate. Improved performance and more functionality will be obtained if multilayer structures are used. For example, dual polarization, with separate output connectors for each, can be achieved using two feed networks in a multilayer configuration. It is the combination of a low-profile and simple manufacturing process that is the main attraction of microstrip antenna arrays. This results in low cost and ease of installation, which means that they have found application in many areas, including satellites, aircraft and ground-based systems for communications, navigation, and radar.

There is a large body of literature on microstrip arrays. Much of this is gathered together in several books that have been published [1–5].

2. DESCRIPTION OF ARRAY ARCHITECTURES

Good overviews of array architectures can be found in two other texts [2, Chaps. 1, 13, 14; 3, Chap. 6]. The primary classifications of microstrip arrays are parallel or series feeding. These are now discussed and other variants are described.

2.1. Parallel- or Corporate-Fed Arrays

A parallel, or corporate, feed network consists of a microstrip transmission line that splits successively from the input to the radiating elements so that all elements are connected [6,7]. Figure 1 illustrates a microstrip patch array with four elements and a parallel feed. The feed input is on the right-hand side of the substrate and splits into

two near the center. These two lines then split into two, and the four lines are then attached to the patches. An impedance match is maintained at each splitter by the use of quarter-wavelength matching sections, although short tapered sections have also been used. In this case, the splitters produce equal amplitudes at each of their outputs. This then results in an equal-amplitude excitation of each patch. If unequal splitters are used, then some control of the amplitude distribution can be obtained to allow the sidelobes to be controlled. Similarly, in the array of Fig. 1, the lengths from the input to each of the patches are equal, resulting in an equiphase excitation and a beam that points broadside, or normal, to the array plane. If the lengths of line between each splitter and the next or the patches are unequal, then control of the array excitation phase will be obtained, either allowing the beam to be shaped or causing it to point away from broadside.

The parallel-fed array produces a single pencil-shaped beam, with beamwidths inversely proportional to the array aperture dimensions. The radiation pattern is relatively insensitive to changes in frequency, in that, provided the feed is matched throughout, the array excitation does not change. In addition, for a broadside beam, the angle at which the beam points does not vary with frequency. The input impedance and gain bandwidth are controlled primarily by the bandwidth of the radiating elements.

2.2. Series-Fed Arrays

In a series-fed array, the radiating elements are arranged in a line and connected to a transmission line that runs close by them. Figure 2 shows an example of a four-patch series-fed array. The input connector is attached to the right-hand end of the line. The amplitude distribution along the array is controlled by the splitter ratios. In the case shown in which the splitters all have the same geometry, the amplitudes will have an exponentially reducing distribution. While each patch is fed with the same proportion of the feedline power, that power reduces at each splitter.

If a matched load is placed on the left-hand end of the feedline, a traveling-wave array is formed. In this case, as the patches are equispaced, the phase change between

Figure 2. Series-fed patch array (typical dimensions same as those for Fig. 1).

elements down the array is constant. The relative element phase will then determine the beam pointing angle in the plane of the array. If the frequency is changed, then the relative phase will change and the beam angle will change. This type of array is thus called a *frequency scan array*.

If the feedline is not terminated in a matched load, then a resonant array is formed. The radiating elements should be placed a feedline wavelength apart. The array has a good input match albeit across a narrow beamwidth, and the beam points to broadside.

The beamshape of a single series-fed microstrip array is broad in the dimension across the array and narrow along the plane of the array. A pencil-shaped beam can be formed by placing many series arrays side by side. In this case, a one-dimensional corporate feed can be made coplanar with the array; or alternately, a series feed can be used to feed a set of series feeds. The cross-fed array [8] is a two-dimensional series array using equal-width feedlines that is center fed and automatically produces a tapered distribution with low sidelobes. Dual polarization can be obtained from a two-dimensional patch array [9] in which square patches are series-connected on all four sides, so that the horizontal connections produce horizontal polarization and the vertical connections, vertical polarization. The chain array structures give linear polarization and have rectangular [10] and triangular or honeycomb [11] shapes. The patches may be connected directly to the feedline to form a comblike array [12], coupled by a small airgap in the parasitically coupled patch array [13], or series-connected by a feedline connecting the centers of their sides [14].

As the feedline itself will radiate, the patches shown in Fig. 2 can be dispensed with and a meander array formed. There are many forms. Figure 3a shows a silhouette of the rampart line array [15] as an example. The function of radiation can be understood from the following description, which is based on an equivalent source model of microstrip radiation. Each of the four corners in each period radiates. The radiation has a polarization that is oriented 45° to the incoming line, as shown in Fig. 3b. If these four vectors, whose relative phase is determined by the intervening linelengths, are summed, then the total amount of

Figure 3. Rampart line series-fed microstrip array: (a) rampart line array (typical dimensions for operation at 15 GHz, linewidth = 1 mm, section length = $0.5\lambda_m$, substrate height = 0.793 mm, $\epsilon_r = 2.32$ [15]); (b) right-angle bend showing polarization of radiation (miter depth = $0.5 \times$ line width); λ_m = microstrip line wavelength.

radiation and its polarization can be determined. An array with uniform linewidth will result in an exponentially reducing amplitude distribution and a beam that is either broadside, if there is no matched load present on the line end; or a frequency-scanned beam, if there is a load. By varying the distance between the bends, longitudinal, transverse, or circular polarization can be obtained.

Many other forms of series array have been designed, including the serpent line [16,17], the rectangular loop line, [10], the Franklin line [18], and the circularly polarized chain antenna [19] (see Fig. 4). The dimensions can be determined from the Figure caption or the following. For the serpent line

$$\sin \theta = \frac{l_m}{s} \frac{\lambda_0}{\lambda_m} - \frac{\lambda_0}{2s} \tag{1}$$

where θ is the beam angle, λ_m and λ_0 are the line and free-space wavelengths, respectively; and l_m and s are as indicated in Fig. 4a. For the chain antenna

$$\sin \theta = \frac{2s + l_p + l_w - \lambda_0}{d} \tag{2}$$

where s, l_p, l_w and d are as indicated in Fig. 4d.

Figure 4. Microstrip series array: (a) serpent line [16,17], ($l = \lambda_m$); (b) rectangular loop line [10] ($d = \lambda_m, r = 0.4\lambda_m$); (c) Franklin line [18] (length along line A-B = $2\lambda_m$); (d) circularly polarized chain antenna [19] ($2l_p + l_w = 0.25\lambda_m$).

2.3. Leaky-Wave Arrays

A half-wavelength-wide microstrip line can also be made to radiate by feeding with an asymmetric step [20] to excite the first-order asymmetric mode, which then leaks to radiation down the array length. Synthesis of the radiation pattern is performed by modulating the line parameters, such as width or height, or by inserting radiating slots periodically down the length. A double-layer leaky-wave microstrip antenna has also been described [21].

2.4. Ultrawideband Arrays

Linear microstrip patch arrays can be made to operate over multioctave bandwidths using the log periodic principle [22] (Fig. 5 shows the architecture). A microstrip line is electromagnetically coupled to an array of patches whose dimensions and hence resonant frequency are scaled patch to patch by a constant factor τ , where

$$\tau = \frac{l_{m+1}}{l_m} = \frac{w_{m+1}}{w_m} = \frac{d_{m+1}}{d_m}$$

and l , w and d are the patch length, width, and spacing, respectively. The overall bandwidth is determined by the number of patches and the scale factor. For example, an array designed with $\tau = 1.05$ and 36 elements, achieved a 5:1 bandwidth and had a gain of around 10 dB and an input return loss of -10 dB over a 4–20 GHz range. Similar to the design of the log periodic dipole array, the element feeding arrangement is crucial. In the microstrip array, it is necessary to have electromagnetic coupling to prevent the formation of stopbands in the wanted frequency range due to the higher patch resonances. Reference 23 shows a log periodic array that consists of a feedline with directly connected patches. A useful, but limited, bandwidth of about 2:1 is achieved.

The array of Fig. 5 has a broadside beam. An endfire beam has also been demonstrated [24].

Figure 5. Log periodic microstrip patch array (typical dimensions for a 36-element array for operation at 4–18 GHz, smallest patch size 3.67×2.92 mm, smallest spacing = 3.67, $\tau = 1.05$, substrate height, feed = 0.793 mm, patch = 1.586 mm, $\epsilon_r = 2.32$) [22].

2.5. Multilayer Arrays

Multilayer arrays are designed to

- Reduce the perturbation to the pattern of radiation from the feed network in a coplanar form
- Allow multiple functions, such as dual polarization
- Prevent radiation from, and to protect active circuits in, active integrated antennas

Figure 6 shows an exploded diagram of a multilayer microstrip array. It can be seen that the front face contains only microstrip patch elements. The feed network is constructed in triplate stripline and located below the array substrate. The three layers are then glued together to form the integral array and feed. Zurcher [25] gives design techniques for high-efficiency multilayer arrays, by using foam-based low-permittivity dielectrics. An example in which multiple patch layers has been used to increase bandwidth is given by Legay and Shafai [26].

The connections from the ends of the feedline to the elements can be made either using vias or by aperture coupling. The via is a metallic rod or pin that is attached to the end of the feedline, at its lower point, and to a point on the patch that has the appropriate impedance, at its upper end. A clearance hole must be etched in the patch ground plane. The via can also be made using a plated through-hole. The aperture coupling is formed by having a (usually) rectangular aperture in the ground plane beneath the patch and above the feedline. Aperture coupling is now widely used as it is more reliable than a via connection. Examples of aperture-coupled arrays are given in Refs. 27 and 28.

2.6. Sequentially Fed Arrays

Multiple feeding of microstrip patch antennas has been shown to improve both the symmetry and the polarization

Figure 6. Multilayer microstrip array (patch and feed details same as those in Fig. 1).

Figure 7. Multiple feeding of microstrip patches.

purity of the radiation pattern and the input impedance bandwidth [29,30], in addition to allowing the generation of circular and multiple polarizations. Figure 7 illustrates this principle. The circular patch shown on the left is fed at two points. This patch can, in principle, be fed at a single point. However, some asymmetry of the pattern results, due to the presence of higher-order modes in the patch. Provided that the two points shown in Fig. 7 are fed with signals that are of equal amplitude and in antiphase, that is, at 0° and 180° , respectively, then a symmetric radiation pattern is formed that is linearly polarized in the horizontal direction. The symmetry results from cancellation of the higher-order modes in the patch. If two further feeds are added as shown in the central patch example, and if these are fed with independent signals having equal amplitude and in antiphase, then a dual linearly polarized patch is formed. If these four points are fed with equal amplitude and in a phase sequence of 0° , 90° , 180° , and 270° , then circular polarization with highly symmetric patterns and low cross-polarization will result. It has also been shown that the three-point-fed element shown on the right of Fig. 7, when fed with equal amplitude and a phase sequence of 0° , 120° , and 240° , will also result in symmetric patterns but with a considerably wider input return loss bandwidth.

These multiple-fed patches can be used in arrays using the feed structures described earlier. However, a very simplified feed results if the multiple feedpoints are distributed among the elements in an array. Figure 8a shows four circular patches fed by a corporate feed. As the patches are fed diagonally, each will radiate with a diagonal polarization. The top left patch will have a polarization inclined to $+45^\circ$, while the top right one will have -45° , and so on. However, the feed is arranged to provide the top left patch with a phase of 0° and the top left with a phase of 90° , shifting the top power splitter to the left by a line-length equivalent to 45° . These two patches together thus generate circular polarization. The bottom pair is likewise arranged and generates circular polarization in the same hand as the top pair. However, it can be seen that these patches are fed from the top rather than the bottom, thus providing an inversion. By offsetting the central power splitter, the two pairs are fed to reinforce. The result is a feed that produces a phase sequence of 0° , 90° , 180° , and 270° , to feed patches that have a similar rotation sequence.

Although this illustrates the general polarization principle, it is usual when generating circular polarization to use circularly polarized elements as shown in Figs. 8b and 8c. There are slight pattern asymmetries induced by the displacements of the linearly polarized patches in Fig. 8a,

Figure 8. Sequentially rotated patch arrays (typical dimensions for operation at 8 GHz, patch diameter = 12.25 mm, patch spacing = 21.4 mm, patch notch size = 2×1 mm, substrate height, feed = 1.586 mm, $\epsilon_r = 2.32$) [32,33].

which can be removed in this way. Figure 8b shows an arrangement in which pairs of patches are rotated and Fig. 8c, one in which all four elements are rotated.

Figure 9 shows the performance improvement of sequential rotation applied to an eight-element array. Figure 9a shows that the boresight 3 dB axial ratio bandwidth has been increased by several factors and Fig. 9b, that the input return loss bandwidth has also significantly increased. Further information on the effects of sequential rotation of the array radiation pattern is provided in Refs. 31 and 32.

Dual polarization arrays can also benefit from sequential rotation [33]. Figure 10 shows two examples. Figure 10a shows a 2×2 -element array of square patches where dual linear polarization is achieved by feeding orthogonal edges of the patch. As noted above, this leads to poor cross-polarization in the radiation patterns and to isolation between the input ports. By arranging each successive patch to ensure rotated feeding, the isolation is improved, and the pattern problems are balanced out. For the array shown in Fig. 10a, improvements of nearly 10 dB in the isolation are noted. Figure 10b shows how a linear array can be similarly fed; in this case rotation is applied to the two groups of four patch elements.

Figure 11 shows how sequential rotation can be applied to dual circularly polarized arrays. Feed 1 has positive feed progression, while feed 2 is negative, with appropriate feedpoint rotation to offset the phasing. In this case, cross-polarization is reduced and input match is improved; however, isolation is unchanged from a conventionally fed array.

2.7. Phased Arrays

The microstrip array can be used to create phased arrays by the addition of phase shifters [34]. In general, due to the planar nature of the microstrip, this medium is ideal for integration of active devices, and there are examples where multilayer structures incorporate the phase shifting elements on layers below the radiating elements.

Many arrays have been built on low-dielectric-constant substrates, and this can lead to low costs, although the array cost will then be dependent primarily on the active device cost and hence on array size. Alternatively, more thought has been given to the integration of both the radiating patch and the phase shifter onto a semiconducting substrate. This has the potential to allow cost reduction

Figure 9. Performance of sequentially rotated arrays (----- conventional; - · - · - sequential); (eight elements, substrate height = 4 mm, $\epsilon_r = 2.26$).

through chip mass production or production of the complete array on a single wafer, which is possible at millimetric wavelengths. However to date no high-volume chips have been manufactured that adopt this approach. One of the reasons for this is the high dielectric constant of semiconducting substrates, which cause substantial wave trapping in the form of surface waves, which lead to the scan blindness phenomenon. This aspect of phased array design is discussed later in Section 3.3.

2.8. Conformal Arrays

Microstrip is an ideal medium in which to make conformal arrays as the radiating elements are relatively thin and the substrates can be formed in a variety of shapes [35–39]. Cylindrical arrays are relatively straightforward as the substrate can be easily bent around the cylinder. Conical arrays have also been made in this way.

Synthesis of the radiation pattern of conformal arrays is more difficult, and procedures vary with the geometry. More details are given in the Section 3.1.

2.9. Multiple-Beam Arrays

Many forms of beamformer lend themselves to printed circuit production methods and can thus be easily

integrated with microstrip arrays [40]. For example, Fig. 12 shows a Butler matrix designed to give four beams from the four-element patch array to which it is connected [41]. The Butler matrix is formed from a number of interconnected hybrid couplers, which present a set of excitations to the linear array that give rise to multiple beams; that is, the amplitudes are equal and the phase difference between elements is such to produce beams spaced in the plane of the array. The array in Fig. 11 consists of four microstrip patches. In principle, each element can assume any form, including linear arrays of patches of series-fed discontinuity arrays described earlier. This allows a two-dimensional array to be formed with a fan of pencil beams. Such a set of beams is ideal when coverage of a horizontal area in front of the array is needed; a radar antenna for collision avoidance is an example where the multiple beams deployed across the highway enable target discrimination to be achieved.

The Butler matrix forms, in general, a set of orthogonal beams, in which the beam spacing and sidelobe level are predetermined to minimize the coupling between the beams. The Blass matrix gives more flexibility and permits the shaping of beams and arbitrary sidelobe level and overlap to be obtained. However, power is lost in resistive terminations on the beamformer circuit.

Both of these beamformers are circuit-based and permit integration with a microstrip array in either coplanar (Fig. 12) or multilayer (Fig. 6) format. One configuration in which a Blass-like beamformer is integrated with a patch array is shown in Fig. 13 [42]. The radiating elements are series-connected patch arrays. Beneath each patch of each series array lies a feedline, and coupling between the feedlines is through the fringing fields. Between

Figure 10. Examples of dual-polarized sequentially rotated arrays.

Figure 11. Sequential rotation for dual circularly polarized arrays.

Figure 12. Printed circuit Butler matrix and patch array.

the coupling areas in the feedline are meandered line-lengths that set the phase shifts between elements. Each feed has a different meander length, and this excites a phase difference between the series-connected patch arrays proportional to the meander lengths of the other feeds. Each feed excites the whole array. A set of beams in the plane of the feedlines is created, with as many beams as there are feedlines. Coupling between the feedlines is minimized by the cancellation of the power coupled out of each series-connected array into the other feedlines, provided, of course, that an orthogonal beam set is excited. If the set is not orthogonal, then power will be absorbed in the matched terminations on the feedlines and the reflection coefficient seen at the input to the feedlines will be affected.

A circular conformal version of this multibeam array has been developed that is capable of creating a set of beams filling the azimuth plane of the array [43].

2.10. Reflectarrays

The microstrip reflectarray concept is illustrated in Fig. 14. It results in a reflector antenna whose reflector

Figure 13. Microstrip multiple-beam array (typical dimensions for operation at 8.3 GHz with five beams, patch size = 11.8 × 5.9 mm, spacing along resonant arrays = 24.1 mm, spacing between resonant arrays = 18.75 mm, linewidths = 0.5 mm, substrate height, feed = 0.793 mm, patch = 1.586 mm, $\epsilon_r = 2.32$) [42].

Figure 14. Microstrip reflectarray.

surface is flat and hence conformal, but whose bandwidth is much narrower than that of a conventional parabolic metal reflector [44,45].

The reflectarray works on the principle that the reflection phase of each element is appropriate for the production of a uniform phase front in the mainbeam direction. As the path length from the feed to the central element is different from the path length to the outer elements, the reflection phase of each element must vary from the center to the edge of the array. This reflection phase can be controlled in a number of ways [46,47]. Figure 15a shows how the patch size can be used. Figure 15b shows patches whose phase is controlled by a section of transmission line attached to the patch.

2.11. Active and Grid Arrays

The insertion of active devices into the radiating elements of microstrip arrays gives rise to a distinct class of array antennas known as *active integrated antennas*, with performance very different from that of conventional microstrip arrays. Several books and review papers have described design techniques and performance capabilities [5,48,49].

Microstrip antennas can be integrated either with an oscillating transistor or a power amplifier to form transmitting elements or with detecting diodes, downconversion mixers, or low-noise amplifiers to form receive

Figure 15. Microstrip reflectarray techniques: (a) size modulation; (b) tab length modulation.

Figure 16. Microstrip duplex active integrated antenna array (typical dimensions for operation at 4.1 GHz, patch size = 24×24 mm, interconnecting linewidth = 1.55 mm, substrate height = 0.793 mm, $\epsilon_r = 2.32$, FET = atf26,884, FET stub width = 0.5 mm, lengths = 5, 19 mm) [50].

elements. Figure 15 shows examples of both classes. All of these can then be used to make active arrays.

Active arrays can be configured with conventional array spacing or very close spacing. Those with conventional spacing have been used to demonstrate the principles of such arrays, which include the integration of front-end functions with conventional beamforming. Close spacing has been used primarily in power combining arrays, where the motivation is to group together as many active elements as possible to create high powers.

Figure 16 shows an example of a conventionally spaced array that attempts to combine transmit and receive action with dual polarization [50]. The inclusion of active devices into antennas in general renders the resulting component nonreciprocal; that is, either transmit or receive. Most array examples are of one type or the other. In Fig. 16 a transmit power combining array is formed in the horizontal polarization by the use of two patch oscillators. The transistor and its source and gate loading lines can be seen attached to the outer edges of the two patches. Reception is in the vertical polarization where a low-noise amplifier and front end would normally be connected to the output port. The critical issue in duplex communication systems is the separation, or isolation, of the transmit and receive signals. This isolation determines the maximum transmit power and hence the range of the communication link. Isolation of around 25 dB is achieved by the use of orthogonal polarizations, and an additional 25 dB comes with sequential rotation in the receive-feed network. An 8×8 array of such elements could achieve a kilometer range. Active integrated transmit arrays also allow simple forms of beam scanning. The array of Fig. 16 can be phase-scanned if the free-running frequency of each patch oscillator is varied to form an appropriate phase front across the array. As the array is frequency-locked, each element continues to oscillate at a common frequency, while the radiated phase is determined by the difference between the (national) free-running frequency, controlled, for example, by the oscillator bias voltage, and the radiated frequency. Figure 17a shows this arrangement. Wide-angle scanning of a four-element array has been demonstrated using this technique [51].

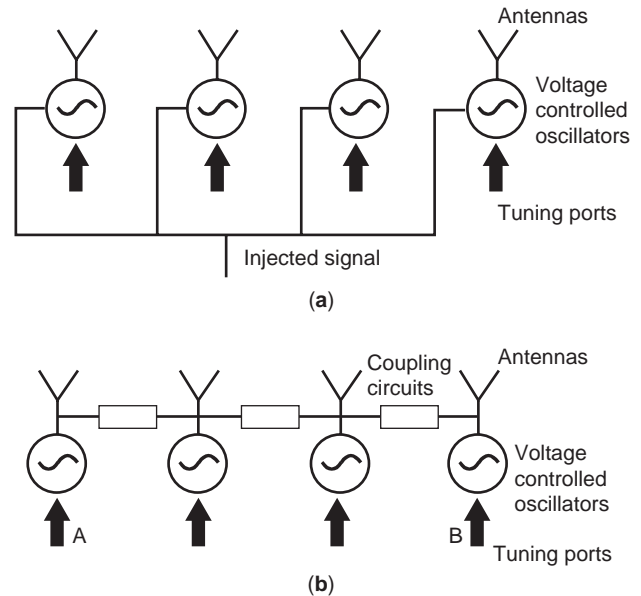

Figure 17. Active integrated antenna array configurations for beam scanning.

Figure 17b shows an arrangement of patch oscillators in which variation of the phase of the end elements gives rise to beam scanning [52]. The free-running frequencies of these elements can be controlled through their bias voltage, or by a varactor diode, through what is called the *tuning port*. All elements are locked to their neighbours through the mutual fringing fields, called *soft locking*, or through coupling circuits, called *hard locking*. A hard locking arrangement is shown. The end elements, A and B, are tuned in the opposite direction. This makes the phase of one increase while the other decreases. This phase difference is transmitted down the array and results in a linear phase front giving a well-controlled scanned beam. Scanning of two-dimensional arrays using this technique has proved harder to achieve.

Such scanning methods give rise to limitations in the maximum data rate that can be transmitted [53]. When data are applied by modulating the central element of a linear form of Fig. 17, the delays introduced by propagation of the locking signal along the array causes signal distortions. Frequency shift keying at rates of around 40 Mbps (million bits per second) have been shown to introduce significant amounts of amplitude modulation into the otherwise frequency modulation for a four-element array. Modulation of all array elements overcomes this problem, but increases the complexity of the array.

3. DESIGN ISSUES

3.1. Pattern Synthesis

Synthesis of the radiation pattern shape of microstrip linear arrays follows the fundamental methods defined for general arrays [54]. In principle, a uniform phase front is initially specified to produce a beam in the desired direction, and then beamwidth and sidelobe level are controlled by the array length and amplitude distribution.

For planar two-dimensional arrays, this technique is applied in each principal plane. For two-dimension conformal arrays, such as the cylinder or cone, such separation of the distributions in the principal planes is not possible, and more complicated synthesis procedure are necessary [35].

If the linear array is series-fed, then the synthesis procedure is modified to take account of the reducing power down the array as a proportion of it is coupled to radiation at each element [55]. While the techniques described above form the basis of synthesis, there are limits to the performance achievable. In particular, the sidelobe level is limited by manufacturing tolerances. While these have been quantified for general arrays [56], a specific study has shown that in patch arrays it is the precision with which the patch resonant frequency can be defined that sets the lower limit to sidelobe performance. Variations in the size of the patch, which affect the resonant frequency, are caused by variations in the photoetching process. The variations are the order of the thickness of the copper cladding on the substrate. These variations give rise to errors in the phase of the radiated signal, which degrade

sidelobe level. This effect is more pronounced as the frequency increases but can be made more manageable by using thinner copper cladding. The study showed that a lower sidelobe level of around 30 dB could be achieved in practice without special measures.

3.2. Feed Loss and Radiation

In large microstrip arrays, losses in the feed network limit the maximum achievable gain [57,58]. There are two sources of such loss: (1) the resistive losses in the dielectric substrate and metallic conductors give rise to loss; and (2) if a coplanar feed is used, then radiation loss can become significant, which can, in addition to limiting gain, significantly compromise the radiation pattern control.

Figure 18a shows calculated microstrip line loss for various substrates typically used in arrays and a variety of line impedances. It can be seen that line loss increases with increasing dielectric constant and impedance and reducing substrate thickness. Although typically less than 0.2 dB/line wavelength, this can be significant for arrays many wavelengths in size. Figure 18b illustrates typical radiation levels. Radiation loss from a right-angle bend is given and is seen to reduce with increasing dielectric constant and impedance and reducing substrate thickness. Again, while less than 0.5 dB per bend, a large corporate feed will have many bends, and splitters and radiation loss can be substantial.

For large microstrip arrays, these losses can become substantial. For example, for a substrate with thickness $h/\lambda = 0.06$ and $\epsilon_r = 2.32$, total losses of the order of 4 dB may occur for an array size of 16 elements and up to 10 dB for 256 elements. A similar situation occurs for $\epsilon_r = 1.06$ representing foam- or air-spaced substrates. These losses limit the array gain as shown in Fig. 19. As the array size is increased, two things happen: (1) the array gain increases because of the increasing aperture size; (2) however, for arrays of 10 wavelengths square and greater, this gain increase is offset by significant loss. Eventually this

(a)

(b)

Figure 18. Losses in microstrip arrays: (a) calculated line loss; (b) calculated radiation loss from right-angle bend (----- $\epsilon_r = 1.0$; --- $\epsilon_r = 2.32$); curves (i) $h/\lambda = 0.06$, (ii) $h/\lambda = 0.03$, (iii) $h/\lambda = 0.01$; smooth 90° bend, $\epsilon_r = 2.32$, $h/\lambda = 0.06$; bend radius, ● $\rho = 0.2\lambda_0$; + $\rho = 0.4\lambda_0$ [57].

Figure 19. Microstrip array gain (efficiency—solid line = 100%, dotted line = 50%, dotted-dashed line = 10%); ● calculated, ■ measured, feed impedance 120 Ω, Δ measured feed impedance 200 Ω; $h/\lambda = 0.06$, $\epsilon_r = 2.1$) [57].

increase in loss becomes greater than the increase in gain and a maximum of gain of around 35 dBi occurs.

Feed radiation also affects the radiation pattern. Figure 20 shows calculated radiation patterns for 16×16 patch arrays. The solid line is the envelope of sidelobe peaks from the patch radiators for a uniform amplitude and phase aperture distribution. The dotted lines show sidelobes, due to the feed radiation, that are significantly higher than those due to the patches.

3.3. Mutual Coupling

Mutual coupling between the radiating elements in arrays is a significant factor that both perturbs the aperture distribution and affects the input impedance of the elements. Figure 21 shows the mutual coupling between microstrip patch elements [59]. It is seen that a coupling in the *E* plane is stronger than in the *H* plane, and for $\epsilon_r = 2.55$ and spacing of $> 0.25\lambda_0$, as typically used in fixed-beam arrays, it is less than -20 dB.

In scanning arrays, the position is more complicated and in some cases, mutual coupling leads to undesirable

Figure 21. Mutual coupling between coaxially fed microstrip patches (---- calculated, ● measured; $W = 10.57$ cm, $L = 6.55$ cm, $d = 0.1588$ cm, $\epsilon_r = 2.55$, $f = 1.41$ GHz) [59].

blindness problems. Such effects are difficult to both measure and compute. The performance of patch elements in infinite arrays has been computed by the method of moments and Floquet mode theory and latterly by the finite-element method. Figures 22 and 23 show computed results for rectangular patches in finite arrays [60,61]. Figure 22a shows the input reflection coefficient of the center element of various size arrays or $\epsilon_r = 2.55$ substrate against scan angle. It can be seen that mutual coupling

(b)

Figure 22. Calculated performance of microstrip patches in arrays: (a) reflection coefficient magnitude versus scan angle; (b) efficiency of finite patch array versus *E*-plane scan angle ($\epsilon_r = 2.55$, substrate thickness $d = 0.04\lambda_0$, patch size $L = W = 0.3\lambda_0$, patch spacing $a = b = 0.5\lambda_0$, feed position $X = -L/2$, $Y = 0$) [61].

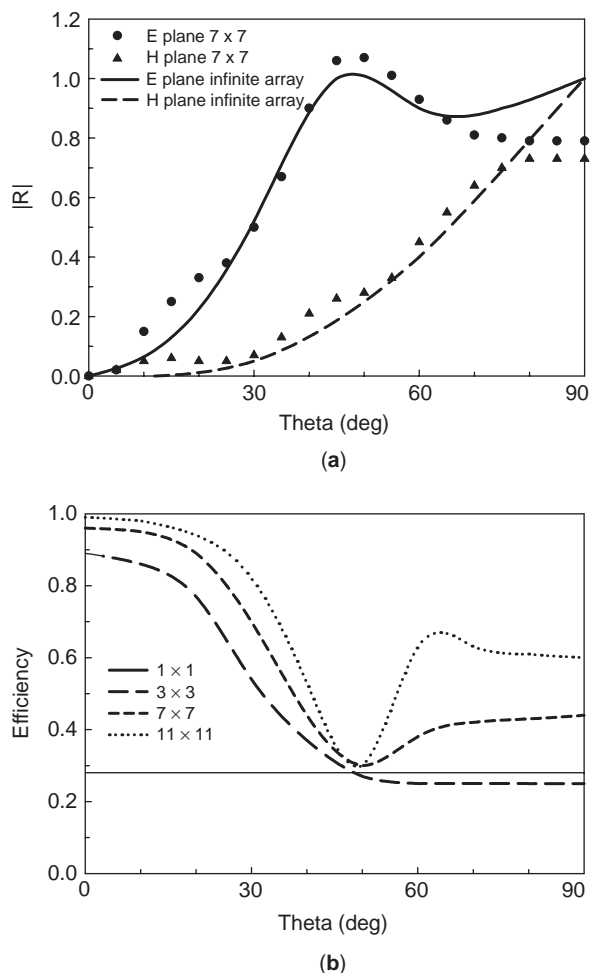

Figure 23. Calculated performance of microstrip patches in arrays: (a) reflection coefficient magnitude versus scan angle; (b) efficiency of finite patch array versus E -plane scan angle ($\epsilon_r = 12.8$, substrate thickness $d = 0.06\lambda_0$, patch size $L = 0.107\lambda_0$, $W = 0.15\lambda_0$, patch spacing $a = b = 0.5\lambda_0$, feed position $X = -L/2$, $Y = 0$) [61].

causes the reflection coefficient to increase with scan angle for both E - and H -plane scans. Results are similar to those for the infinite array case for scan angles ranging from 0° to 60° . The effect of this change in reflection coefficient is to reduce array efficiency at large scan angles, and this effect is worse for large arrays (Fig. 22b). In practice, some phased arrays incorporate circulators between the transmitter and the radiating element to absorb this reflected power. Others incorporate active matching, but this is a complicated and expensive solution.

Mutual coupling increases as the dielectric constant increases (Fig. 23). The attempts to integrate microstrip patch arrays onto semiconducting substrates led to similar computations for patch arrays on substrates with $\epsilon_r = 12.8$. While H -plane scanning performance (Fig. 23a) is similar to that on low-dielectric-constant substrates, E -plane scanning shows that the reflection coefficient becomes greater than 1.0 at scan angles near 40° . This is a classical scan blindness condition in which it is impossible to radiate power as the element is highly

mismatched. The fact that the reflection coefficient is greater than 1.0 does not violate the principle of energy conservation. The result is for one element of the array only. Other elements will have reflection coefficient less than 1.0 to achieve a power balance. At this blind angle, array efficiency is, of course, very low, as shown in Fig. 23b.

Similar computations have also been done for other types of patches, including circular patches [62], one- and two-probe-fed circular patches [63], and proximity coupled patches [64].

MICROSTRIP ANTENNAS

HOTON HOW
 Hotech, Inc.
 Belmont, Massachusetts

Microstrip circuitry consists of a metal strip or patch on a dielectric substrate backed by a metal ground plane. Microstrip antennas are finding increasing popularity owing to their advantages in size, cost, conformity to the supporting structure, low profile, and ease of fabrication. By using simple etching techniques it is possible to fabricate a wide variety of microstrip circuits including antenna arrays, feeding networks, and active devices such that preamps (preamplifiers) or distributed transmitters can be conveniently placed next to the antenna elements. In addition, diode phase shifter circuits can also be etched on the substrate to form single-board phased arrays. This article describes the microwave properties of patch antennas.

The lateral dimensions of microstrip patch antennas are large in comparison with the width of conventional microstrip lines. The main purpose of a patch antenna is to confine microwave energy within a compact region with a dimension compatible to the wavelength. Such confinement can be achieved via the resonant behavior of a finite guiding structure supporting propagation waves. As a consequence, electromagnetic energy radiates away from that part of the patch resonator that is open to free space, or the periphery of the patch antenna, in a manner similar to a slot opening cut along the side of a waveguide. In order to continuously radiate microwave energy, the patch needs to be electrically connected to a "feeder line." When the characteristic impedance of the feeder line matches the impedance of radiation waves, power is thus dumped into the confined space of the patch resonator without causing much reflection. This means that all the input microwave power delivered to the patch antenna is radiated away into free space.

At resonance electromagnetic excitations reinforce within the confined space of the patch antenna, attaining high intensity far exceeding than at the feeder-line region. Thus, radiation from the feeder line, or from a regular microstrip transmission line of the same length, is insignificant in comparison to a microstrip antenna driven at resonance. In microstrip circuitry power also radiates from open/short circuits and from discontinuities, such as corners. However, the radiated power is relatively small, since the radiation impedances there are normally very different from the characteristic impedance of the

microstrip transmission line encompassing these discontinuities.

This article introduces two calculational methods capable of quantitatively describing antenna performance. The first method, the so-called resonant cavity model, is less rigorous, but nevertheless has the advantage of being more analytical and, hence, can be applied with ease. For the cavity model perfect metal boundaries are assumed at the metal patch and at the ground-plane positions, and magnetic wall boundary conditions are assumed at the periphery, or at the sidewall position of the patch antenna. Due to fringe-field penetration, magnetic walls are located slightly beyond the boundary contour of the patch geometry. This fringe-field effect can thus be accounted for by considering the patch to fictitiously possess a boundary whose dimension extends outward by a distance consistent with the spatial extent of the fringe fields. Radiation and material imperfections are then considered as perturbations to a lossless cavity. In this manner, engineering parameters of the microstrip patch antenna, such as the resonant frequency, far-field radiation pattern, input impedance, radiation linewidth, directivity, and efficiency, are all calculable.

Although simple and straightforward, the drawback of the aforementioned analysis is that surface waves can hardly be accommodated by the cavity model, even if one is attempted in a perturbative manner. The reason for this limitation is that, unlike spatial waves, surface waves lack in closed-form expressions, and hence their existence is inconsistent with the nature of the cavity model, which requires calculations to be carried out analytically. Surface waves are identified as simple poles appearing in the integrand of a spectrum-domain analysis characteristic of the guiding structure of a microwave circuit supporting electromagnetic wave propagation along the lateral directions. Analogous to spatial radiation waves, while the asymptotic behaviors of surface waves can be readily deduced in analytic forms in the far-field zone, surface waves can hardly be accessed analytically in the near field, since the decomposition of currents into multipole expansions adopted by a conventional spatial-wave analysis is not available, rendering the failure for cavity-mode analysis. For this reason, the cavity model is considered inappropriate for a microstrip structure involving a thick substrate, or if the dielectric constant of the substrate is large, because it is known that under these conditions excitation of surface waves is significant.

The second calculational method concerns the Green function analysis. In general a Green function is defined as the solution of a (linear) differential/integral equation resulting from a (delta-function-like) point source satisfying the imposed (homogeneous) boundary conditions. Thus, under an arbitrary source excitation, the solution of the equation can be composed of a superposition of the Green functions, still satisfying the boundary conditions of the structure. In the presence of a point (dipole) current source in association with the geometry of a stratified structure consisting of dielectric/magnetic layers, the excited electromagnetic field is termed the *Green function dyad*, due to the vectorial nature of the source field and the observer field. The construction of dyadic Green

functions of a microstrip circuit is straightforward, and this article emphasizes its physical meanings and interpretations, as appearing in the original work by Sommerfeld [1].

Sommerfeld solved for the first time the Green functions associated with a horizontal point dipole and a vertical point dipole in the presence of a semiinfinite conductor half-space, our planet Earth [1]. Radiowaves are therefore radiated into free space either directly from the point dipole source or indirectly from the image dipole source induced by the (imperfect) ground plane, the Earth surface. They are called *spatial* (radiation) *waves*, because they exhibit a $1/r$ spatial dependence, where r denotes the distance from the original/image source point to the observer point. In addition, Sommerfeld also showed a second kind of radiation field that is tied to the air–Earth interface exhibiting a $1/\sqrt{\rho}$ dependence, where ρ denotes the 2D distance between the source point projected on the Earth surface to the observer point located also on the Earth surface [1]. These are called *surface waves* because they decay exponentially when departing away from the air–Earth interface. This article explains how the spatial-wave and the surface-wave solutions arrive in association with a (horizontal) point dipole source in the presence of a layered dielectric/magnetic structure.

By using the dyadic Green functions, one can then formulate the general field solution in a stratified structure excited by (external) current sources in terms of an integral equation, which is subsequently solved by applying the numerical (Galerkin) method. The external current sources are expressed in the form of surface conductor inhomogeneities appearing at the microstrip patch location. This article outlines procedures to calculate the engineering parameters of a microstrip antenna of an arbitrary geometry, and it illustrates calculational results on circular microstrip antennas, showing plots in radiation frequencies, bandwidths, far-field patterns, input impedances, effects in feeder-line positions, and interference between antennas. The dyadic Green functions involving anisotropic/gyromagnetic materials are introduced in Section 3, where the transfer matrix technique is explained. A transfer matrix translates the tangential components of the electromagnetic field over one layer of a stratified structure satisfying the boundary conditions therein. More recent developments on printed circuit antennas are reviewed in Section 4, including the important broadband techniques employing stacked parasitic elements to achieve high gain and low cross-polarization level. Fractal antennas involving a patch geometry exhibiting a fractional dimension are introduced in Section 5. More sophisticated treatments on microstrip antennas may be found in Ref. 2.

1. CAVITY MODEL

1.1. Introduction

A microstrip patch antenna is a narrowband device, and the bandwidth covers typically about 5% of the center radiation frequency. When the bandwidth Δf can be related

to the quality factor Q of a resonator, then

$$Q = 2\pi f \left(\frac{\text{maximum stored energy}}{\text{averaged power dissipation}} \right) = \frac{f}{\Delta f} \quad (1)$$

which implies that power dissipation is not significant and the circuit of a microstrip patch antenna can be approximated as a low-loss cavity resonator. This suggests that the performance of a microstrip patch antenna can be analyzed using a perturbation method; that is, the zeroth-order solution of the antenna is described in terms of the eigenmodes, or normal modes, of a lossless cavity. Losses are then added to the analysis as first-order perturbations, including conductor loss, dielectric loss, and radiation loss. Magnetic loss can also be included if ferrites are used as the substrate material.

Dissimilar to radiation loss, surface-wave loss can hardly be treated as perturbations in the cavity model. Radiation and surface waves represent leaky waves from the antenna; the former leaks directly from air and the latter, from the guided structure of the air–substrate interface. Surface waves lack analytic expressions and are not compatible with the closed-form representation of cavity modes. Surface-wave modes are identified as being associated with simple poles appearing in the integrand of a spectrum-domain analysis characteristic of the guiding structure of surface discontinuities in the circuit geometry. Surface-wave modes are readily included with a full-wave analysis, as discussed in the following section, introducing Green’s function formulation.

In contrast, the cavity model is easy to apply, allowing engineering parameters of a microstrip patch antenna to be calculated analytically, including bandwidth, input impedance, radiation efficiency, and near-field/far-field radiation patterns. Furthermore, the physical meaning of normal modes is evident in the cavity model. For example, the left/right-hand polarized radiations from a microstrip ferrite patch antenna can be readily calculated by using the cavity model. However, the cavity model will provide satisfactory calculations only if surface-wave loss is insignificant. Surface-wave loss is not important for a thin substrate exhibiting low dielectric constant, but not for a thick substrate with high dielectric constant. Also, the cavity model fails to describe the coupling effects between microstrip circuits placed close to each other. For these complex situations a full-wave analysis is needed, and the cavity model is too simple to be applicable. The full-wave analysis involving the use of dyadic Green’s functions is discussed in Section 2.

1.2. Resonant Frequency

Let a metal patch be deposited on top of a dielectric substrate backed by a ground plane. The patch geometry considered in this section is either rectangular or circular. Only dielectric substrates are considered in this section. Formulation of cavity normal modes for patch antennas fabricated on ferrite substrates can be found in Ref. 3. In the cavity model one assumes a lossless substrate in which the cavity is formed that is bounded by either electric or magnetic walls. The metal surfaces of the microstrip patch

Figure 1. Feeding the rectangular patch antenna by a microstrip line. The resonant cavity is located directly under the patch bound by a magnetic wall shown shaded in the figure.

and the ground plane are approximated as perfect conductors, or electric walls, and the peripheral surface surrounding the antenna cavity directly under the patch boundary is a magnetic wall. This is illustrated in Fig. 1, in which a rectangular microstrip patch antenna is modeled as a resonator cavity with its periphery shown shaded as a magnetic wall. An electric wall is defined so that the tangential component of the electric field vanishes at the wall surface, and a magnetic wall is defined so that the tangential component of the magnetic field vanishes at the wall surface. Thus, a normal metal surface approaches an electrical wall if the value of conductivity goes to infinity. A magnetic wall imposes fictitious boundary conditions that insulate the inside of the cavity from the outside, allowing no electromagnetic energy to exchange across it.

The active volume of the cavity is slightly exceeds that implied by the physical dimension of the patch geometry, since fringe fields are excited at the periphery of the antenna. Therefore, the effective volume of the cavity consists of both regions directly under the patch pattern and its surrounding containing the fringe field. It is shown in Fig. 2 that the effective radius of the cavity is larger than that of the metal patch of the microstrip antenna. Thus,

Figure 2. Feeding the circular patch antenna by a coaxial line. Because of the fringe-field effect, the effective radius of the resonator is larger than the resonator’s physical value.

the resonant length along the side of a rectangular patch antenna, denoted as $L' = L + 2\Delta$, is larger than the physical length L and the effective increment in length due to the fringe-field effect is 2Δ with [4]

$$\frac{\Delta}{d} = 0.412 \left(\frac{\epsilon_{\text{eff}} + 0.300}{\epsilon_{\text{eff}} - 0.258} \right) \left(\frac{L/d + 0.262}{L/d + 0.813} \right) \quad (2)$$

where d is the thickness of the substrate, ϵ_{eff} denotes the effective dielectric constant of the patch cavity given by [5]

$$\epsilon_{\text{eff}} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + \frac{10d}{L} \right)^{-1/2} \quad (3)$$

and ϵ_r is the dielectric constant of the substrate material. The rationale behind Eq. (3) is that, depending on the ratio of d/L , electromagnetic fields can extend into air directly above the metal patch, and so $\epsilon_{\text{eff}} < \epsilon_r$, and $\epsilon_{\text{eff}} \approx \epsilon_r$ if $d/L \ll 1$. The resonant frequency of the cavity resonator is therefore

$$f_n = \frac{cn}{2L'\sqrt{\epsilon_{\text{eff}}}} \quad (4)$$

where c denotes the speed of light in vacuum and n the order of the resonant mode ($n = 1$ for the fundamental mode).

On the basis of the same fringe-field consideration, we expect that for a circular patch antenna the effective resonant radius of the cavity, denoted as $R' = R + \Delta$, is larger than the physical radius of the metal patch, denoted as R , and [6]

$$\Delta = \frac{d}{\pi} \left[\ln \left(\frac{\pi R}{2d} \right) + 1.7726 \right] \quad (5)$$

as shown in Fig. 2. A similar expression for ϵ_{eff} , or Eq. (3), is expected for a circular microstrip cavity. However, such an expression is lacking in the present literature. We therefore use ϵ_r as ϵ_{eff} , bearing in mind that this approximation is true only if $R \gg d$. The resonant frequency of the cavity is therefore

$$f_{mn} = \frac{cX'_{mn}}{2\pi R'\sqrt{\epsilon_r}} \quad (6)$$

where X'_{mn} denotes the n th zero of the derivative of the Bessel function $J_m(x)$ of order m .

We note that the expressions given above for resonant frequencies for rectangular and circular microstrip patch antennas [Eqs. (4) and (6)] are derived from the cavity model assuming that standing modes are excited within the cavity. At high frequencies this quasistatic picture is no longer valid and surface waves of high orders are excited propagating away from the cavity region guided by the microstrip structure. As such, magneticwall boundary conditions are no longer adequate at the periphery of the antenna cavity. For these situations we must resort to a rigorous full-wave analysis to suitably address the leaky feature of the cavity generating surface waves, for example, by using the dyadic Green functions to be described in Section 2. To simplify notations in the following, we will

use ϵ_r for ϵ_{eff} and L and R for L' and R' , respectively, with the difference understood.

1.3. Normal Modes and Feeder-Line Excitations

The normal modes excited in a microstrip resonator cavity are normally TE waves exhibiting no nodal points along the z axis, the direction perpendicular to the substrate surface. Thus, the normal-mode solutions show no z dependence, and the electromagnetic components can be uniquely derived from E_z satisfying the following Helmholtz equation

$$(\nabla_t^2 + k_{mn}^2)E_z = 0 \quad (7)$$

where ∇_t denotes the transverse part of the del operator (with respect to the z axis), k_{mn} is given by

$$k_{mn} = \omega_{mn} \sqrt{\mu_0 \epsilon_0 \epsilon_r} \quad (8)$$

ω_{mn} is the angular frequency, and $\{m, n\}$ refers to the index of the normal mode. The boundary condition imposed on E_z is that the derivative of E_z along the normal direction of the boundary vanishes at the magnetic wall. Once E_z is solved from Eq. (7), the corresponding \mathbf{H} field is

$$\mathbf{H}_t = (j\omega\mu_0)^{-1} \mathbf{e}_z \times \nabla_t E_z \quad (9)$$

where \mathbf{e}_z denotes the unit vector along the z axis.

Let the rectangular patch be located at $0 \leq x \leq L$, and $0 \leq y \leq W$ (see Fig. 1). The normal modes are therefore

$$E_z^{mn}(x, y) = \cos \frac{m\pi x}{L} \cos \frac{n\pi y}{W} \quad (10)$$

with the corresponding modal wavenumber

$$k_{mn} = \left[\left(\frac{m\pi}{L} \right)^2 + \left(\frac{n\pi}{W} \right)^2 \right]^{1/2} \quad (11)$$

For a circular cavity of radius R the normal modes are (see Fig. 2)

$$E_z^{mn}(\rho, \phi) = J_m(k_{mn}\rho) \exp(jm\phi) \quad (12)$$

and the modal wavenumber is determined by the zeroing condition of the derivative of Bessel functions of order m

$$J'_m(k_{mn}R) = 0 \quad (13)$$

and (ρ, ϕ, z) denotes the cylindrical coordinate.

Let us consider the patch antenna be excited by either a microstrip line at the edge of the patch (Fig. 1) or by a coaxial feeder directly under the patch (Fig. 2). The angular frequency of the external driving field is $\omega = 2\pi f$. We expect that the cavity will be driven to attain the highest intensity when the excitation frequency approaches the normal-mode frequencies [Eq. (8)]. This phenomenon is generally known as the *forced oscillation* of a resonator, and it occurs commonly in many branches of physics.

Thus, at resonance, the cavity is driven by the external field undergoing the forced oscillation giving rise to a maximum efficiency in radiation. We first consider the excitation of the cavity by a microstrip feeder line. The boundary conditions for the cavity are that electric walls are located at metal boundaries and magnetic walls at the periphery not adjacent to the microstrip feeder line. At the input port of the feeder line adjacent to the cavity periphery we define a window where we assume that the excitation currents are uniformly distributed, inducing a uniform magnetic field there:

$$\mathbf{H} = \mathbf{n} \times \mathbf{e}_z h_0 \quad (14)$$

here \mathbf{n} denotes the unit vector pointing outward along the normal direction of the window and h_0 is a constant specifying the amplitude of the excitation current. The excitation field following Eqs. (7) and (9) can be uniquely solved subject to the boundary condition of Eq. (14).

For a rectangular patch depicted in Fig. 1, let the microstrip feeder be connected to the patch at the location defined by $a \leq x \leq b$, and $y = 0$. The excitation field is therefore

$$E_z(x, y) = jk\zeta h_0 \sum_{m=0}^{\infty} A_m \cos \frac{m\pi x}{L} \cos \beta_m(W - y) \quad (15)$$

$$H_x(x, y) = h_0 \sum_{m=0}^{\infty} A_m \beta_m \cos \frac{m\pi x}{L} \sin \beta_m(W - y) \quad (16)$$

$$H_y(x, y) = -h_0 \sum_{m=0}^{\infty} A_m \frac{m\pi}{L} \sin \frac{m\pi x}{L} \cos \beta_m(W - y) \quad (17)$$

where

$$\beta_m = \sqrt{k^2 - \left(\frac{m\pi}{L} \right)^2} \quad (18)$$

$$k = \omega \sqrt{\mu_0 \epsilon_0 \epsilon_r} \quad \zeta = \sqrt{\frac{\mu_0}{\epsilon_0 \epsilon_r}} \quad (19)$$

$$A_m = \frac{4}{m\pi} \frac{\sin \frac{m\pi(b-a)}{2L} \cos \frac{m\pi(b+a)}{2L}}{\beta_m \sin \beta_m W}, \quad (m \neq 0) \quad (20)$$

$$A_0 = \frac{b-a}{Lk \sin kW} \quad (21)$$

Note that when $\omega = \omega_{mn}$, then $A_m = \infty$, indicating that when the frequency of the external driving field equals one of the normal-mode frequencies, only that normal mode is excited in the cavity responsible for radiation. This statement is valid only if the cavity is lossless. However, when losses are included with the patch resonator, other normal modes can also be excited at resonance, but with much smaller amplitudes.

For a circular patch we consider the microstrip feeder line to be located at $-\alpha \leq \phi \leq \alpha$, and $\rho = R$. The excitation

field can then be written as

$$E_z(\rho, \phi) = j\zeta h_0 \sum_{n=0}^{\infty} C_n J_n(k\rho) \cos(n\phi) \quad (22)$$

$$H_\rho(\rho, \phi) = \frac{h_0}{k\rho} \sum_{n=1}^{\infty} C_n n J_n(k\rho) \sin(n\phi) \quad (23)$$

$$H_\phi(\rho, \phi) = h_0 \sum_{n=0}^{\infty} C_n J'_n(k\rho) \cos(n\phi) \quad (24)$$

$$C_n = \frac{2 \sin n\alpha}{n\pi J'_n(kR)}, \quad (n \neq 0) \quad (25)$$

where

$$C_0 = \frac{\alpha}{\pi J'_0(kR)} \quad (26)$$

and ζ and k are as given in Eq. (19). Again, from Eqs. (25) and (26) it is seen that the coefficient of C_n goes to infinity if the driving field frequency approaches the normal-mode frequencies, which are specified by Eq. (13), resulting in forced oscillation of a lossless cavity resonator.

Let us consider the excitation of the patch antenna by a coaxial line inserted directly under the patch. We assume that this line shows an inner filament of zero diameter ending in a point charge at the surface of the patch (see Fig. 2). The excitation current density is therefore

$$\mathbf{J}_e(x, y) = I_0 \delta(x - x_0) \delta(y - y_0) \mathbf{e}_z \quad (27)$$

for a rectangular patch

$$\mathbf{J}_e(\rho, \phi) = \frac{I_0 \delta(\rho - \rho_0) \delta(\phi - \phi_0)}{\rho \mathbf{e}_z} \quad \text{for a circular patch} \quad (28)$$

In the presence of a driving current, Eq. (7) is modified to include an inhomogeneous term, the source, on the right hand side:

$$(\nabla_t^2 + k_{mn}^2) E_z = j\omega\mu_0 \mathbf{J}_e \cdot \mathbf{e}_z \quad (29)$$

The boundary conditions are the same as before, leading to the normal-mode solutions, namely, electric walls at metal boundaries and magnetic walls at the periphery of the resonator cavity. Thus, Eq. (29) can be solved in terms of the normal-mode solutions:

$$E_z(x, y) = j\omega\mu_0 \sum_{m,n} \frac{E_z^{mn}(x, y)}{k^2 - k_{mn}^2} \times \frac{\int_0^L dx' \int_0^W dy' J_e(x', y') E_z^{mn}(x', y')^*}{\int_0^L dx' \int_0^W dy' |E_z^{mn}(x', y')|^2} \quad (30)$$

$$E_z(\rho, \phi) = j\omega\mu_0 \sum_{m,n} \frac{E_z^{mn}(\rho, \phi)}{k^2 - k_{mn}^2} \times \frac{\int_0^R d\rho' \int_0^{2\pi} \rho' d\phi' J_e(\rho', \phi') E_z^{mn}(\rho', \phi')^*}{\int_0^R d\rho' \int_0^{2\pi} \rho' d\phi' |E_z^{mn}(\rho', \phi')|^2} \quad (31)$$

These two equations apply for a rectangular patch and a circular patch, respectively, and the normal-mode solutions, $E_z^{mn}(x, y)$ and $E_z^{mn}(\rho, \phi)$, are as given in Eqs. (10) and

(12). We note that Eqs. (30) and (31) imply that when k approaches k_{mn} , the normal-mode $\{m, n\}$ acquires an infinite amplitude, as implied by a lossless cavity. The corresponding magnetic field can be derived using Eq. (9).

Thus, for the rectangular patch, we have

$$E_z(x, y) = \frac{4j\omega\mu_0 I_0}{LW} \sum_{m,n=1}^{\infty} \frac{\cos(m\pi x_0/L) \cos(m\pi x/L) \cos(n\pi y_0/W) \cos(n\pi y/W)}{k^2 - k_{mn}^2} \quad (32)$$

$$H_x(x, y) = \frac{4I_0}{LW} \sum_{m,n=1}^{\infty} \frac{n\pi}{W} \times \frac{\cos(m\pi x_0/L) \cos(m\pi x/L) \cos(n\pi y_0/W) \sin(n\pi y/W)}{k^2 - k_{mn}^2} \quad (33)$$

$$H_y(x, y) = \frac{-4I_0}{LW} \sum_{m,n=1}^{\infty} \frac{m\pi}{L} \times \frac{\cos(m\pi x_0/L) \sin(m\pi x/L) \cos(n\pi y_0/W) \cos(n\pi y/W)}{k^2 - k_{mn}^2} \quad (34)$$

For the circular patch, we have

$$E_z(\rho, \phi) = \frac{j\omega\mu_0 I_0}{\pi} \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} \frac{(2 - \delta_{m0}) k_{mn}^2}{k^2 - k_{mn}^2} \times \frac{J_m(k_{mn}\rho) J_m(k_{mn}\rho_0) \cos[m(\phi - \phi_0)]}{(k_{mn}^2 R^2 - m^2) [J_m(k_{mn}^2 R^2)]^2} \quad (35)$$

$$H_\rho(\rho, \phi) = \frac{-I_0}{\pi\rho} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{m(2 - \delta_{m0}) k_{mn}^2}{k^2 - k_{mn}^2} \times \frac{J_m(k_{mn}\rho) J_m(k_{mn}\rho_0) \sin[m(\phi - \phi_0)]}{(k_{mn}^2 R^2 - m^2) [J_m(k_{mn}^2 R^2)]^2} \quad (36)$$

$$H_\phi(\rho, \phi) = \frac{I_0}{\pi} \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} \frac{(2 - \delta_{m0}) k_{mn}^3}{k^2 - k_{mn}^2} \times \frac{J'_m(k_{mn}\rho) J_m(k_{mn}\rho_0) \cos[m(\phi - \phi_0)]}{(k_{mn}^2 R^2 - m^2) [J_m(k_{mn}^2 R^2)]^2} \quad (37)$$

where δ_{ij} denotes the Kröner delta function and $\delta_{m0} = 1$ if $m = 0$, and $\delta_{m0} = 0$, otherwise.

In Eqs. (32)–(34) and (35)–(37) the k_{mn} values are as given by Eqs. (11) and (13), respectively, and ζ and k are as defined in Eq. (19). Once the excitation fields are known [Eqs. (16, 17, 18, 22, 23, 24, 32, 33, 34, 35, 36, 37)], losses of various kinds, and hence the quality factor Q of the patch cavity can be calculated as discussed below.

1.4. Input Impedance

Having solved the electromagnetic fields inside a lossless cavity, we can relax the assumption of perfect electric and magnetic walls and allow electromagnetic waves to extend

beyond the wall boundaries. This results in ohmic loss and radiation (surface-wave) loss. Dielectric loss and magnetic loss occur in the interior of the patch cavity, which can be accounted for by assuming a lossy medium possessing a complex permittivity and a complex permeability, respectively. We consider first the radiation loss.

The Kirchhoff–Huygens principle, which is a vector analog of Green’s theorem, states that the electromagnetic field inside a closed volume V can be derived by the volume charge and current distributions inside V and the surface charges and currents distributed on the enclosing surface of V , denoted as S . The effective electric surface current density \mathbf{K}_e magnetic surface current density \mathbf{K}_m and electric surface charge density Σ are respectively [7]

$$\mathbf{K}_e = -\mathbf{n} \times \mathbf{H}, \mathbf{K}_m = \mathbf{n} \times \mathbf{E}, \Sigma = -\varepsilon \mathbf{n} \cdot \mathbf{E} \quad (38)$$

where \mathbf{n} denotes the unit outward vector normal to S and ε is the permittivity. Thus, if we consider the outside volume of the patch antenna cavity as the volume V , we conclude that the effective magnetic current density appearing on the magnetic wall is

$$\mathbf{K}_m = -2\mathbf{n} \times \mathbf{e}_z E_z \quad (39)$$

where \mathbf{n} denotes the unit outward vector normal to the magnetic wall whose sign changes as comparing to Eq. (38), and the factor of 2 in Eq. (39) accounts for the presence of the ground plane, \mathbf{K}_e and Σ do not show up on a magnetic wall.

The radiation field arising from the magnetic current density \mathbf{K}_m can be derived by using the same formula describing the electric current density \mathbf{K}_e but converted from the duality rule [7]. The duality rule states that the electromagnetic theory remains valid if one changes all the electric quantities into the corresponding magnetic quantities and the magnetic quantities into the negative of the corresponding electric quantities. Thus, the vector potential associated with \mathbf{K}_m can be expressed as [8]

$$\begin{aligned} \mathbf{A}_m(\mathbf{r}) &= \frac{\varepsilon_0 d}{4\pi} \oint_{C_m} d\ell' \frac{\mathbf{K}_m(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} e^{-jk_0|\mathbf{r} - \mathbf{r}'|} \\ &\approx \frac{\varepsilon_0 d}{4\pi} \frac{\exp(-jk_0 r)}{r} \oint_{C_m} d\ell' \mathbf{t}' E_z(\mathbf{r}') \exp(jk_0 \mathbf{e}_r \cdot \mathbf{r}') \end{aligned} \quad (40)$$

where d denotes the thickness of the substrate, C_m is the contour of the magnetic wall, \mathbf{t} is the unit vector along the contour C_m in the counterclockwise sense, \mathbf{e}_r is the unit vector pointing toward the observation point \mathbf{r} , and

$$k_0 = \omega(\mu_0 \varepsilon_0)^{1/2} \quad (41)$$

is the wavenumber in air. In Eq. (40) we denote “primed” symbols as referring to the source point, and have assumed $|\mathbf{r} - \mathbf{r}'| \gg d$.

In the far-field zone we have

$$\mathbf{H}(\mathbf{r}) = -j\omega \mathbf{A}_m(\mathbf{r}) \quad (42)$$

$$\mathbf{E}(\mathbf{r}) = -\zeta_0 \mathbf{e}_r \times \mathbf{H}(\mathbf{r}) \quad (43)$$

where

$$\zeta_0 = \left(\frac{\mu_0}{\varepsilon_0} \right)^{1/2} \quad (44)$$

is the wave impedance in air ($= 377 \Omega$). We derive, therefore

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &\approx \frac{j\varepsilon_0 k_0 d}{4\pi} \frac{\exp(-jk_0 \mathbf{r})}{\mathbf{r}} \\ &\times \oint_{C_m} d\ell' (-\mathbf{t}' \cdot \mathbf{e}_\phi \mathbf{e}_\theta + \mathbf{t}' \cdot \mathbf{e}_\theta \mathbf{e}_\phi) E_z(\mathbf{r}') \exp(jk_0 \mathbf{e}_r \cdot \mathbf{r}') \end{aligned} \quad (45)$$

where \mathbf{e}_θ and \mathbf{e}_ϕ denote the unit vectors along the θ and ϕ directions at the observation point \mathbf{r} . By using Eq. (45) the far-field differential-power radiation from a circular patch antenna fed by a microstrip line [Eq. (22)] is, for example

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &\approx \frac{\alpha \zeta_0 h_0 k_0 d}{\pi} \frac{R \exp(-jk_0 \mathbf{r})}{\mathbf{r}} \\ &\times \sum_{m=-\infty}^{\infty} j^{-m} \frac{J_m(kR)}{J'_m(kR)} \frac{\sin m\alpha}{m\alpha} \mathbf{e}^{-jm\phi} \\ &\cdot \left[\mathbf{e}_\theta J'_m(k_0 R \sin \theta) + j \mathbf{e}_\phi \cos \theta \frac{m J_m(k_0 R \sin \theta)}{k_0 R \sin \theta} \right] \end{aligned} \quad (46)$$

where it is understood that the ratio of $\sin m\alpha$ to $m\alpha$ is 1 when $m = 0$. Expressions of $\mathbf{E}(\mathbf{r})$ for the other rectangular patch geometry under both the microstrip and the coaxial-line feeder excitation configurations, or for the same circular patch geometry under the coaxial-line feeder excitation configuration, can be derived in a similar manner, but their explicit expressions are not given here.

The far-field differential-power radiation pattern can be calculated by using the following equation:

$$\frac{dP_r}{d\Omega} = \lim_{r \rightarrow \infty} \frac{r^2 |\mathbf{E}|^2}{2\zeta_0} \quad (47)$$

The total radiation power is then

$$P_r = \int_0^\pi \sin \theta d\theta \int_0^{2\pi} d\phi \frac{dP_r}{d\Omega} \quad (48)$$

Conductor loss and dielectric loss can also be derived from the zeroth-order normal-mode solutions of the cavity [7]. The conductor loss is given by

$$P_c = R_s \iint_{S_c} |\mathbf{H}|^2 ds \quad (49)$$

where S_c denotes the patch surface and R_s is the surface resistance

$$R_s = \sqrt{\frac{\omega \mu_0}{2\sigma}} \quad (50)$$

and σ is the conductivity of metal. The dielectric loss is given by

$$P_d = \frac{\omega \epsilon_r \epsilon_0 \tan \delta}{2} \iiint_{V_c} |E_z|^2 dv \quad (51)$$

where V_c denotes the volume of the cavity and $\tan \delta$ is the dielectric loss tangent.

The antenna efficiency or radiation efficiency is defined as the ratio of the radiated power to the input power

$$e = \frac{P_r}{P_r + P_c + P_d} \times 100\% \quad (52)$$

The total stored electric energy is

$$W_e = \frac{\epsilon_r \epsilon_0}{4} \iiint_{V_c} |E_z|^2 dv = \frac{P_d}{2\omega \tan \delta} \quad (53)$$

At resonance, because the stored magnetic energy W_m equals the stored electric energy W_e , we have thus the total stored electromagnetic energy

$$W_T = W_n + W_m = \frac{P_d}{\omega \tan \delta} \quad (54)$$

The Q factor of the cavity is, from the definition of Eq. (1)

$$Q = \frac{W_T}{P_T + P_c + P_d} \quad (55)$$

From which the VSWR bandwidth can be calculated. We define S_{\max} to be the maximum value of VSWR that can be tolerated in the radiation band. We then have [9]

$$\text{VSWR bandwidth (\%)} = \frac{100(S_{\max} - 1)}{Q\sqrt{S_{\max}}} \quad (56)$$

Typically, $S_{\max} = 2$.

The input susceptance of the antenna B can be calculated for a lossless patch cavity, which is thus a zeroth-order quantity. In contrast, the input conductance G must be calculated from the total loss of the cavity, which represents a first-order quantity. Thus

$$jB = \frac{-I}{V} \quad (57)$$

$$G = \frac{P_r + P_c + P_d}{|V|^2} \quad (58)$$

where I and V are the averaged input current and voltage at the input feeder position. For coaxial feeder with excitation current given by Eqs. (27) and (28), assuming a thin inner filament shown in Fig. 2, the current I is known and the voltage V can be calculated from E_z evaluated at the input position multiplied by the thickness of the substrate d . We have therefore

$$B^{-1} = \frac{4d\omega\mu_0}{LW} \sum_{m,n=1}^{\infty} \frac{\cos^2(m\pi x_0/L) \cos^2(n\pi y_0/W)}{k^2 - k_{mn}^2} \quad (59)$$

$$B^{-1} = \frac{d\omega\mu_0}{\pi} \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} \frac{(2 - \delta_{m0})k_{mn}^2}{k^2 - k_{mn}^2} \times \frac{[J_m(k_{mn}\rho_0)]^2}{(k_{mn}^2 R^2 - m^2)[J_m(k_{mn}^2 R^2)]^2} \quad (60)$$

for rectangular and circular patch antennas, respectively. When excited by a microstrip feeder the input voltage is obtained by averaging E_z over the width of the feeder-line window joining the cavity multiplied by the thickness of the substrate d as dictated by Faraday's law. The input current can be derived by applying Ampère's law at the feeder-line window, and the result is h_0 times the transverse length of the window, specifically, $h_0(b-a)$ for the rectangular antenna, and $h_0(2\alpha R)$ for the circular antenna. We have therefore

$$B^{-1} = \frac{\zeta d}{L} \left[\text{ctn } kW + \sum_{m=1}^{\infty} \frac{8}{(m\pi)^2} \frac{L^2}{(b-a)^2} \frac{k}{\beta_m} \times \text{ctn } \beta_m W \left(\sin \frac{m\pi(b-a)}{2L} \cos \frac{m\pi(b+a)}{2L} \right)^2 \right] \quad (61)$$

$$B^{-1} = \frac{\zeta d}{2\pi R} \left(\frac{J_0(kR)}{J'_0(kR)} + \sum_{n=1}^{\infty} \frac{2 \sin^2 n\alpha J_n(kR)}{n^2 \alpha^2 J'_n(kR)} \right) \quad (62)$$

for rectangular and circular patch antennas, respectively. Here k_{mn} in Eq. (60) is as given by Eq. (13) and β_m in Eq. (61) is as given by Eq. (18).

From Eqs. (59)–(62) we note that when excited at the normal-mode frequencies, the input susceptance $B = 0$, and hence $B^{-1} = \infty$. These points are called *antiresonance points* when referred to in a Smith chart plot (e.g., see Fig. 4 in Section 2.3). In contrast, the resonant points are defined to be purely resistive so that at resonance the input resistance of the antenna is intended to match the

Figure 3. Integration contours for Sommerfeld integrals illustrating contribution from spatial-wave and surface-wave excitations.

feeder-line impedance, thereby resulting in zero reflection. Therefore, $B^{-1} = 0$ at resonance. The resonance frequency occurs slightly above the antiresonance frequency, which requires participation of normal modes of all orders, although one normal mode responsible for antiresonance is excited with the largest amplitude. Thus, by definition, at resonance the capacitive part of the stored energy equals the inductive part, rendering the overall input reactance to be zero. In calculating the susceptance, or the stored electromagnetic energy of the cavity, we should also include the capacitive contribution from the near-field excitation. However, this contribution has already been accounted for as the increment in the effective resonance length of the antenna cavity [Eqs. (2) and (5)]. The input impedance is

$$Z = (G + jB)^{-1} \quad (63)$$

We note that, in reality, at antiresonance B is finite because of the presence of losses occurring at the antenna patch cavity.

One severe drawback of the cavity model is that it is not able to address the surface-wave loss. James and Henderson [10] estimated that surface-wave excitation is not important if $d/\lambda_0 < 0.09$ for $\epsilon_r = 2.3$ and $d/\lambda_0 < 0.03$ for $\epsilon_r = 10$, where λ_0 is the free-space wavelength. The criterion given by Wood [11] is more quantitative: $d/\lambda_0 < 0.07$ for $\epsilon_r = 2.3$, and $d/\lambda_0 < 0.0023$ for $\epsilon_r = 10$, if the antenna is to launch no more than 25% of the total radiated power as surface waves. Work by Fonseca and Giarola showed that the size of the patch is also a parameter [12], as will be discussed in more detail in the next section. When ferrite material is used as the substrate, magnetic loss can be estimated using a formula similar to Eq. (51):

$$P_m = \frac{\omega\mu''}{2} \iint_{V_c} \int |\mathbf{H}|^2 dv \quad (64)$$

where μ'' denotes the imaginary part of the permeability. In concluding this section we note that the cavity model depicts a semiempirical picture where the parameters have been adjusted to fit experiments, for example, the effective dielectric constant ϵ_{eff} [Eq. (3)], and the increment in the resonant length of the patch Δ [Eqs. (2) and (5)]. Nevertheless, the calculated radiation pattern and input impedance compared very well with measurements [13].

2. DYADIC GREEN FUNCTION

2.1. Introduction

As we have mentioned in Section 1, the open structure of a microstrip patch antenna can be rigorously accounted for only in a full-wave analysis resorting to numerical solutions. Maxwell equations can be explicitly solved numerically in either the frequency or time domain using the generic 3D finite-element and finite-difference methods [14]. However, it is more informative to use the dyadic Green functions, since the electromagnetic fields generated by a point dipole current source has already been solved “analytically” in the same microstrip geometry, which is termed the *dyadic Green function*. The electromagnetic

fields excited by a patch antenna can then be composed as superposition of the point dipole solutions in the context of a conventional Green’s function method. The numerical technique comes in only when Galerkin method is called for to solve the resultant integral equations relating the unknown current variables to the local electric fields distributed across the metal patch boundaries.

The physical meaning of Green’s function is clear, and surface waves are treated with equal importance as spatial waves in the Green’s function formulation. Furthermore, the Green function solution usually requires 2D calculations, as in contrast to the generic 3D computational methods. This is true when the metal thickness compares much smaller than the thickness of the substrate, as is usually the case. Material losses can be readily included with the Green function if complex permittivity and permeability values are used. It turns out that efficient CAD tools can be constructed using the dyadic Green’s function solutions, which calculate engineering parameters of a microstrip antenna, including radiation frequency, far-field pattern, efficiency, and input impedance, and analyze the crosstalk problem inherent in common microstrip circuitries.

To illustrate the physics in the application of a Green function, we have decided not to regenerate many mathematical formulas in this section. Instead, we concentrate on Sommerfeld’s approach to Green function analysis [1], since it lends itself to more physical understanding of the problem. We wish to introduce the methodology leading to the formulation of the dyadic Green function for a general stratified structure, consisting of finite number of dielectric and magnetic layers as constituents. We assume this layered structure is infinite in both horizontal and vertical directions, although it is possible to include finite substrate and radiation space by employing periodic boundary conditions, for example. Also, we assume the current distribution is two-dimensional, resulting in 2D analysis of the Galerkin elements. The finite conductivity of the ground plane can be accounted for by invoking complex permittivity of the conductor layer [1]. Computational results are cited mainly from Ref. 15. Background material can be found in Ref. 16.

2.2. Point Dipole Solutions

We start by introducing the vector potential \mathbf{A} , and scalar potential V , in electrodynamics subject to a Lorentz gauge [17], which has been implicitly used by Sommerfeld [1]:

$$\mathbf{H} = \frac{1}{\mu_0} \nabla \times \mathbf{A} \quad (65)$$

$$\mathbf{E} = -j\omega\mathbf{A} - \nabla V \quad (66)$$

$$\nabla \cdot \mathbf{A} + j\omega\mu_0\epsilon V = 0 \quad (67)$$

This results in uncoupled equations for \mathbf{A} and V as follows

$$(\nabla^2 + k^2)\mathbf{A} = -\mu_0\mathbf{J} \quad (68)$$

$$(\nabla^2 + k^2)V = \frac{-1}{\epsilon_0} \rho \quad (69)$$

where \mathbf{J} and ρ are the current and charge densities, respectively, and normally $\rho=0$ (oscillating charges can hardly be realized physically). We note that Eq. (68) does not specify \mathbf{A} uniquely for a finite volume under consideration [17]. However, this gauge freedom is almost fixed for a system of infinite volume, since the only source-free radiation for the entire space is the incoming waves from infinity, which can be readily checked out and excluded from the solution of \mathbf{A} by performing proper gauge transformation. From Eq. (67) the scalar potential V is obtained from the divergence of \mathbf{A} , and hence only the vector potential \mathbf{A} needs to be solved.

We are now solving the vector potential, $\mathbf{A}(x, y, z)$ [Eq. (68)], induced by a point dipole current source, $\mathbf{J}_0(x, y, z)$, in the background of a dielectric/magnetic-layered structure. A point dipole is also called a Hertzian dipole, which can be approximated by a dipole antenna whose arms are much smaller than the wavelength of radiation [1]. Assume the point dipole to be located at $(0, 0, z_0)$. The current density associated with the point dipole is therefore

$$\mathbf{J}_0(x, y, z) = \mathbf{I}_0 d\ell \cdot \delta(x)\delta(y)\delta(z - z_0) \quad (70)$$

where $\mathbf{I}_0 d\ell$ (= finite) denotes the strength of the dipole. Without loss of generality, we assume that \mathbf{I}_0 is along the x direction. From Eq. (68) we know that A_x is nonzero, corresponding to the radiation field directly from the horizontal dipole. This is the field arising from the point dipole of Eq. (70) in empty space. However, in the presence of the layered structure, A_z is also nonzero, due to oblique reflection of A_x from the layer interfaces, corresponding to the radiation field from a vertical dipole in the absence of the stratified structure. Finally, A_y is identically zero as implied by the symmetry of the problem.

We require the tangential components of \mathbf{E} and \mathbf{H} to be continuous across the layer interfaces, and these boundary conditions need to be expressed in terms \mathbf{A} satisfying Eqs. (65) and (66). According to Sommerfeld [1], these boundary conditions can be deduced by integrating Eqs. (65) and (66) with respect to the transverse coordinates x and y , and the constants of integration are justified as zeros by letting x and y go to infinity. For example, suppose that one boundary condition requires the derivative of the function $f(x, y, z)$ with respect to x to be continuous across an interface. If $f(x, y, z)$ vanishes as x goes to infinity, either decreasing exponentially to zero as for a decaying wave or averaging to zero as for an oscillating wave, we can then integrate this boundary condition with respect to x to conclude that the function $f(x, y, z)$ itself must be continuous across the interface. As such, the boundary conditions imposed on the vector potential $\mathbf{A} = A_x \mathbf{e}_x + A_z \mathbf{e}_z$ as derived by Sommerfeld are the continuity conditions on the following four quantities [1],

$$\varepsilon\mu A_x, \quad \varepsilon\mu \left(\frac{\partial A_x}{\partial z} \right), \quad \varepsilon\mu A_z, \quad \frac{\partial A_x}{\partial x} + \frac{\partial A_z}{\partial z} \quad (71)$$

There are therefore four boundary conditions at each layer interface.

Recognizing the fact that the layered structure is homogeneous in the transverse directions, say, x and y , it implies that the Helmholtz equation, Eq. (68), can be conveniently solved in the transverse Fourier spectral domain. For a given transverse spectral vector, $\mathbf{k}_t = [k_x, k_y]$, we denote the corresponding spectral-domain vector potential components as $\tilde{A}_x(k_x, k_y, z)$ and $\tilde{A}_z(k_x, k_y, z)$, which relate to $A_x(x, y, z)$ and $A_z(x, y, z)$ via double Fourier integrals, respectively. For each layer, which does not contain the dipole source, we solve the Helmholtz equation, Eq. (68), to obtain the following solutions

$$\tilde{A}_x(k_x, k_y, z) = a \exp(+\gamma z) + b \exp(-\gamma z) \quad (72)$$

$$\tilde{A}_z(k_x, k_y, z) = c \exp(+\gamma z) + d \exp(-\gamma z) \quad (73)$$

where a, b, c, d are four unknowns to be determined by the boundary conditions and γ is given by

$$\gamma^2 = k_x^2 + k_y^2 - \varepsilon\mu\omega^2 \quad (74)$$

where ε and μ are respectively the permittivity and permeability of the layer under consideration. For the uppermost layer $a=0=c$, and for the lowermost layer $b=0=d$, as required by the boundary conditions at $z = \pm\infty$. For the layer that contains the dipole source, we integrate Eq. (68) from $z=z_0^-$ to $z=z_0^+$ and note that the double Fourier transform of the function $\delta(x)\delta(y)$ is $(2\pi)^{-1}$; we then derive the following discontinuity requirement on $\partial\tilde{A}_x(k_x, k_y, z)/\partial z$ on both sides of the plane $z=z_0$:

$$\frac{\partial\tilde{A}_x(k_x, k_y, z^-)}{\partial z} - \frac{\partial\tilde{A}_x(k_x, k_y, z^+)}{\partial z} = \frac{-I_0 d\ell}{2\pi} \quad (75)$$

We therefore insert a fictitious interface at $z=z_0$ assuming different a, b, c, d values for the two subregions above and below this interface [Eqs. (72) and (73)]; γ is the same across the fictitious interface [Eq. (74)]. Thus, the boundary conditions imposed on this fictitious interface are the same as before except that the requirement on the continuity of the quantity $\varepsilon\mu(\partial A_x/\partial z)$ is now being replaced by Eq. (75). If the z_0 plane occurs at one layer interface of the stratified structure, no fictitious interface is needed; we need only to replace the continuity requirement on $\varepsilon\mu(\partial A_x/\partial z)$ by Eq. (75) where γ differs across the interface.

Thus, we arrive at $4N$ unknowns with $4N$ boundary conditions for N interfaces, including the fictitious one, if there is one. We replace in the boundary conditions [Eq. (71)] the operator $\partial/\partial x$ by $-jk_x$, and $\partial/\partial z$ by $\pm\gamma$, whichever is applicable according to Eqs. (72) and (73). The $4N$ boundary conditions converts into algebraic equations, and hence the $4N$ unknowns can be solved. The amplitudes of these unknowns are all proportional to the dipole strength $I_0 d\ell$, which can be conveniently chosen to be 1, as defined by the Green function. The vector potentials $A_x(x, y, z)$ and $A_z(x, y, z)$ can then be solved from $\tilde{A}_x(k_x, k_y, z)$ and $\tilde{A}_z(k_x, k_y, z)$ by applying the inverse two-dimensional Fourier transforms. The electric and magnetic fields can finally be obtained by using Eqs. (65)–(67).

Material imperfection results in losses of various kinds whose effects can be analytically modeled by letting the permittivity and permeability be complex numbers. The dielectric loss is described by a loss tangent, $\tan \delta$, and the permittivity takes the form of $\epsilon_0 \epsilon_r (1 - j \tan \delta)$, where ϵ_r denotes the dielectric constant. For a partially magnetized magnetic substrate the permeability is $\mu_0(\mu' + j\mu'')$, and μ' and μ'' are the real and imaginary parts of the relative permeability [3]. For a metal conductor the permittivity contains both the displacement current and the conduction current, and hence the permittivity is modified as $\epsilon_0 - j\sigma/\omega$ where σ denotes the conductivity. This is the permittivity that was explicitly considered by Sommerfeld [1] solving the electromagnetic fields generated by a Hertzian dipole in response to Earth's surface.

If perfect metal is used as the ground plane, the electromagnetic field will not penetrate into it. Therefore, the boundary condition on the metal surface is that the tangential components of the electric field vanish, and it implies

$$A_x = 0, \quad \frac{\partial A_x}{\partial x} + \frac{\partial A_z}{\partial z} = 0 \quad (76)$$

Thus, we have $4N - 2$ unknowns and $4N - 2$ boundary conditions for a layered structure possessing a perfect metal ground plane.

Actually, the interface boundary conditions [Eq. (71)] specify the reflection and transmission of electromagnetic waves from one layer to another, and \tilde{A}_x is proportional to the magnetic field component and \tilde{A}_z is proportional to the electric field component. Oblique-angle reflection and transmission can be readily expressed by using Snell's law [18] and hence the coefficients of \tilde{A}_x and \tilde{A}_z [Eqs. (72) and (73)] are determined for each layer with relation to its preceding and succeeding layers. Thus, circumventing the need to solve the boundary conditions explicitly [Eq. (71)], all the a, b, c, d coefficients for the layers are correlated to each other and only four unknowns remain, corresponding to those at the outermost layers (top and bottom), which can then be solved by using the boundary conditions at the fictitious interface imposed by the point dipole [Eq. (75)]. Suppose the last layer is a perfect metal. For this case the a, b, c, d coefficients of the layer adjacent to the metal surface satisfy the following relationships

$$b = -a, \quad d = c \quad (77)$$

which are recognized as the total reflection condition. Equation (77) can also be derived from Eq. (76).

For completeness we list below the transverse spectral-domain vector potential induced by a horizontal point dipole located on top of a dielectric substrate backed by a perfect metal ground plane:

$$\tilde{A}_x(k_x, k_y, z) = \frac{\mu_0}{2\pi} \exp\left(\frac{-\gamma_0 z}{D_{TE}}\right)$$

$$\tilde{A}_z(k_x, k_y, z) = \frac{\mu_0}{2\pi} (\epsilon_r - 1) j k_x \exp(-\gamma_0 z) / (D_{TE} D_{TM}) \quad (78)$$

for $z > 0$

$$\tilde{A}_x(k_x, k_y, z) = \frac{\mu_0}{2\pi} \sinh \frac{\gamma(z+d)}{D_{TE} \sinh \gamma d}$$

$$\tilde{A}_z(k_x, k_y, z) = \frac{\mu_0}{2\pi} (\epsilon_r - 1) j k_x \cosh \frac{\gamma(z+d)}{D_{TE} D_{TM} \cosh \gamma d} \quad (79)$$

for $0z > -h$

and D_{TE} and D_{TM} are given by

$$D_{TE} = \gamma_0 + \gamma \coth \gamma d \quad (80)$$

$$D_{TM} = \epsilon_r \gamma_0 + \gamma \tanh \gamma d \quad (81)$$

Here the dipole is located at the plane $z = 0$, the dielectric substrate is of a thickness d and permittivity ϵ_r , and γ_0 and γ are given by Eq. (74) with the zero subscript (0) referring to air. The zeros of Eqs. (80) and (81) correspond to surface-wave TE and TM modes, respectively. While there exists at least one TM surface mode, it is not always the case that TE surface modes will be excited. The threshold for TE mode excitation is

$$k_0 d (\epsilon_r - 1)^{1/2} < \frac{\pi}{2}$$

or

$$f < \frac{75}{d \sqrt{\epsilon_r - 1}} \quad (82)$$

where f is expressed in unit of GHz, and d in unit of mm. Surface-wave modes will be further discussed in the following section.

2.3. Sommerfeld Integrals

Within each layer the dipole field solutions are obtained by performing inverse Fourier transform of $\tilde{A}_x(k_x, k_y, z)$ and $\tilde{A}_z(k_x, k_y, z)$ over the two-dimensional k_x - k_y plane, or, equivalently, k_ρ - k_ϕ plane. Here (k_ρ, k_ϕ) denotes the polar coordinate and (k_x, k_y) the Cartesian coordinate. For a layered structure consisting of isotropic materials, \tilde{A}_x and \tilde{A}_z can be expressed as the following functionals

$$\tilde{A}_x(k_x, k_y, z) = f(k_\rho, z) \quad (83)$$

and

$$\tilde{A}_z(k_x, k_y, z) = k_x g(k_\rho, z) = \cos k_\phi k_\rho g(k_\rho, z) \quad (84)$$

as can be checked from the boundary condition of Eq. (71). In other words, \tilde{A}_x is an even function of k_x and \tilde{A}_z is an odd function of k_x , as implied by the symmetry of the problem. Therefore, after integration over k_ϕ , we obtain

$$A_x(\rho, \phi, z) = \int_0^\infty J_0(k_\rho \rho) k_\rho f(k_\rho, z) dk_\rho \quad (85)$$

$$A_z(\rho, \phi, z) = j \cos \phi \int_0^\infty J_1(k_\rho \rho) k_\rho^2 g(k_\rho, z) dk_\rho \quad (86)$$

Although Eqs. (85) and (86) can be numerically integrated, as will be discussed below, it is informative to discuss the physical meanings implied by these integrals. Equations

(85) and (86) are called *Sommerfeld-type integrals* whose significance was first addressed by Sommerfeld [1]. Sommerfeld noticed that the seemingly real integration starting at the fixed point $k_\rho = 0$ can be converted into a complex k_ρ integration over a path W , which closes at infinity (see Fig. 3)

$$A_x(\rho, \phi, z) = \frac{1}{2} \int_W H_0^{(2)}(k_\rho \rho) k_\rho f(k_\rho, z) dk_\rho \quad (87)$$

$$A_z(\rho, \phi, z) = \frac{j \cos \phi}{2} \int_W H_1^{(2)}(k_\rho \rho) k_\rho^2 g(k_\rho, z) dk_\rho \quad (88)$$

where $H_0^{(2)}$ and $H_1^{(2)}$ are Hankel functions of the second kind of orders 0 and 1, respectively. In Fig. 3, the contour W is detoured slightly in the complex k_ρ plane not to run into branchcuts and poles such that the integrands remain finite and single-valued. In Fig. 3 we illustrate the case that the layered structure involves only two layer substances, the air, denoted by subscript 0 (zero), and a dielectric layer, denoted by subscript 1 (one). For example, the respective permittivities for air and the dielectric layer are denoted as ϵ_0 and ϵ_1 (the permeability of the dielectric layer is assumed to be the same as that of air, μ_0). In Fig. 3, k_0 and k_1 are the branch points given by

$$k_0 = (\epsilon_0 \mu_0)^{1/2}, \quad k_1 = (\epsilon_1 \mu_0)^{1/2} \quad (89)$$

and p is the smallest zero assumed by the function D_{TM} [Eq. (81)]. It is understood that more branchpoints, and hence more branchcuts, will appear in Fig. 3 if more layers are presented in the layered structure. Also, more simple poles will appear if D_{TE} and D_{TM} of Eqs. (80) and (81) admit more zeros. In Fig. 3 the branchpoint at $k_\rho = 0$ results from the Hankel functions $H_0^{(2)}$ [Eq. (87)]. However, for Eq. (88) this branchpoint, and hence its associated branchcut, is replaced by a simple pole due to the different singular behavior of $H_1^{(2)}$ at the origin.

According to Sommerfeld, the contour W shown in Fig. 3 can be analytically deformed into three components or more surrounding the respective branchcuts and simple pole, denoted as Q_0 , Q_1 , and P . Sommerfeld showed that [1] contour integrals of Q_0 and Q_1 give rise to spatial-wave radiation and for a large (spherical) distance r , they exhibit the following asymptotic dependence:

$$Q_0(Q_1) \propto \frac{\exp(-jk_0 r)}{r} \quad (90)$$

Actually, Q_0 gives rise to the free-space dipole radiation, and Q_1 is the radiation wave diffracted by the dielectric layer (or from the image dipole induced by that layer) [1]. Assuming that the air-dielectric interface is located at $z = 0$, then, for $z > 0$, contribution from contour P has the following asymptotic expressions:

$$P \propto H_0^{(2)}(p\rho) \exp[-\sqrt{p^2 - k_0^2} z], \quad \text{for } A_x, \quad [\text{Eq. (86)}] \quad (91)$$

$$P \propto \cos \phi H_1^{(2)}(p\rho) \exp[-\sqrt{p^2 - k_0^2} z], \quad \text{for } A_z, \quad [\text{Eq. (87)}] \quad (92)$$

These are surface waves tied to the interface and decrease in a rate proportional to $1/\sqrt{\rho}$ in the lateral directions, in contrast to the spatial-wave radiation, which exhibits a $1/r$ dependence [Eq. (90)].

The significance of Fig. 3 is that through Sommerfeld's interpretations [1], spatial and surface waves have been treated on an equal basis that for a given point dipole source in a layered structure the far-field solutions can be expressed explicitly by using Eq. (90) and Eqs. (91), (92), respectively, to show radiations either propagating away semispherically in free space, or guiding away concentrically on the surface of the layered structure. By using Sommerfeld's formulation, it is now possible to include a surface-wave analysis with the resonator cavity model discussed in Section 1, and the far-field surface wave radiation pattern and the total surface wave loss from the cavity can be calculated by using the perturbation theory in a manner similar to that for the spatial radiation waves. Specifically, when the zeroth-order solution is known for an isolated cavity, the far-field solution for surface waves can be expressed as the first-order perturbation by using Eq. (40) with the spatial dependence $\exp(-jk_0 r)/r$ for A_z by $H_0^{(2)}(p\rho) \exp[-\sqrt{p^2 - k_0^2} z]$, and for A_x by $\cos \phi H_1^{(2)}(p\rho) \exp[-\sqrt{p^2 - k_0^2} z]$ [see Eqs. (90)–(92)]. However, research in this direction is lacking in the current literature. Having discussed the analytic features of Sommerfeld-type integrals, in the following we discuss how Sommerfeld-type integrals are evaluated numerically.

In the presence of material losses, the branchpoints and simple pole(s) associated with spatial and surface waves, respectively, acquire imaginary components, which are then pushed off from the real axis toward the lower half of the complex k_ρ plane. As such, numerical integration of Eqs. (65) and (66) can be properly carried out. However, care needs to be taken in order to avoid large truncation errors. Integration of k_ρ along the real positive axis can be distinguished in three regions

$$\text{Region 1: } 0 < k_\rho < k_0$$

$$\text{Region 2: } k_0 < k_\rho < k_c$$

$$\text{Region 3: } k_c < k_\rho < \infty$$

where k_c denotes a cutoff wavenumber to be discussed below. In region 1 the integrands are well behaved. However, at the resonant frequencies of a metal patch dictated by the cavity model both the numerator and denominator of the integrand vanish, although their ratio remains finite. We call these geometric resonant points *quasisingularities* [15]. Near these quasisingular points the numerator and denominator need to be expanded in Taylor series on which their common zeros cancel out.

All the surface poles are contained in region 2, and conventionally, the upper bound of region 2, k_c , is defined to be 10 times the real part of the largest surface pole occurring at the integrand. In region 2 the integrand behaves wildly in the vicinity of a surface pole. When coming across a surface pole, the integrand transits from positive infinity to negative infinity, resulting in sharp cancellation during numerical integration. To circumvent this difficulty,

we expand the integrand in Laurent series in the vicinity of a surface pole $k_\rho = p$, and the quasisingular terms (with negative exponents) are then evaluated analytically (remember p is now a complex number). Equivalently, the singular part of integration is obtained via residual calculations. After subtracting the singular part from the integrand, the integrand becomes regular, which can then be numerically integrated in region 2.

In region 3 we are involved with integration of Bessel functions at infinity, which oscillate indefinitely as infinity is approached without exhibiting a strict period. This renders the conventional extrapolation scheme inaccurate. To perform integration in this region we consider asymptotic expansion of Bessel functions:

$$\begin{aligned}
 J_m(x) = & \sqrt{\frac{2}{\pi x}} \left[\cos\left(x - \frac{m\pi}{2} + \frac{\pi}{4}\right) \sum_{k=0}^{\infty} \frac{(-1)^k}{2^{2k}} \right. \\
 & \times \frac{\Gamma\left(m + 2k + \frac{1}{2}\right)}{(2k)! \Gamma\left(m - 2k + \frac{1}{2}\right)} x^{2k} - \sin\left(x - \frac{m\pi}{2} + \frac{\pi}{4}\right) \\
 & \left. \times \sum_{k=0}^{\infty} \frac{(-1)^k}{2^{2k+1}} \frac{\Gamma\left(m + 2k + \frac{3}{2}\right)}{(2k+1)! \Gamma\left(m - 2k - \frac{1}{2}\right)} x^{2k+1} \right] \quad (93)
 \end{aligned}$$

where the Γ terms denote gamma functions. As such, integrands are written in series containing terms of the form

$$\int_{k_c}^{\infty} \frac{A_p \sin(xx + \beta)}{x^p} dx \quad (94)$$

which can be readily evaluated by exploiting sine and cosine integrals and their derivatives if p is a positive integer, or error functions and their derivatives if p is a positive half-integer larger than 1 [15].

Having discussed the Green functions due to a point dipole source in a layered structure, we mention how these Green functions are modified in the presence of material losses. For a lossy material one may use complex permittivity $\varepsilon_0 \varepsilon_r (1 - j \tan \delta)$ and complex permeability $\mu_0 (\mu' + j \mu'')$ to describe its lossy characteristics, where ε_r denotes the dielectric constant, $\tan \delta$ represents the loss tangent, and μ' and μ'' are the real and imaginary parts of the relative permeability [3]. So far we have considered perfect metal boundary conditions on bounding a layered structure at the outermost surface [Eq. (77)]. For imperfect metal boundaries, for example, our Earth's surface, one may include the layer explicitly in the formulation, but using a complex permittivity $\varepsilon_0 - j\sigma/\omega$, where σ denotes the conductivity [1]. Alternatively, one can apply Snell law to specify the relationships between the a, b, c, d , coefficients resulting from reflections of incoming waves from the surface of an imperfect metal, in a manner similar to that deriving Eq. (77). Or, if the conductivity is large, say, a good metal such as copper, and the skin depth in penetration compares much smaller than the wavelength, one can even apply the perturbation theory. Thus, one first derives the Green's functions of the layered structure assuming

perfect metal boundaries followed by first-order modification that the metal boundary is withdrawn a distance δ into the interior of the imperfect metal bulk with the recessed volume to be filled by air [19]. Here δ_c denotes the (complex) skin depth

$$\delta_c = (1 + j) \sqrt{2/\omega \mu_0 \sigma} \quad (95)$$

This procedure is parallel to Wheeler's incremental impedance [20,21], since it is recognized that the definition of a Green's function is a transimpedance. To be explicit, in the presence of a good conductor ground plane Eq. (80) is modified to include its first-order Taylor expansion in d , or Wheeler's incremental impedance, and the result is [19]

$$D_{\text{TE}} = \gamma_0 + \gamma \coth \gamma d + \delta_c (1 - \tanh \gamma d) / (1 + \tanh \gamma d) \quad (96)$$

and D_{TM} is invariant under the first-order consideration. The construction of Green functions for a layered structure containing gyromagnetic materials will be discussed in Section 4.

2.4. Numerical Solutions

The dyadic Green function, $\underline{\mathbf{G}}(\mathbf{r}, \mathbf{r}')$, is defined as the electric field at location \mathbf{r} produced by a unit point dipole located at \mathbf{r}' . We are solving the current distribution over a microstrip metal patch of negligible thickness deposited on a layered structure backed by a ground plane. Therefore, \mathbf{r} and \mathbf{r}' are both located at the same metal patch (or located at different but mutually coupled metal patches), and essentially we are solving a two-dimensional problem with the third dimension, the z direction, being absorbed into the Green function. This results in the following integral equation

$$\mathbf{t}_e \left[\int_S \underline{\mathbf{G}}(\boldsymbol{\rho}, \boldsymbol{\rho}') \cdot \mathbf{J}(\boldsymbol{\rho}') d^2 \boldsymbol{\rho}' + R_s \mathbf{J}(\boldsymbol{\rho}) \right] = \mathbf{E}_e(\boldsymbol{\rho}) \quad (97)$$

where S denotes the metal patch with surface impedance $R_s = (1 + j) \sqrt{\omega \mu_0} / 2\sigma$. The first term in Eq. (97) is the electric field induced by the background layered structure, and the second term relates to ohm's current (induction and conduction), and \mathbf{E}_e is the electric field generated by external currents. Of special concern, in Eq. (97) \mathbf{t}_e results from integration along the z axis, and hence it defines the effective thickness of the metal patch, to be either the skin depth thickness, $\delta = (2/\mu_0 \omega \sigma)^{1/2}$, or the physical thickness of the metal patch t , whichever is smaller. For a perfect metal patch $\mathbf{t}_e = 0$. Thus, \mathbf{t}_e represents the singular behavior of the current distribution exhibiting a delta-function-like profile in the thickness direction. However, we expect that \mathbf{t}_e will not enter the final expressions when evaluating engineering parameters of the antenna, as is the case shown in Eqs. (98), (100), (101), and (105) below. In Eq. (97) we have used $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ as the two-dimensional position vectors on the metal patch for which the z dependence is understood.

We denote $\{\mathbf{J}_{mn}(\boldsymbol{\rho})\}$ as a set of a complete orthonormal vector basis for currents on the metal patch. We define here $\{\mathbf{J}_{mn}(\boldsymbol{\rho})\}$ to be the regular part of the surface current density and the singular part has been factored out in

Eq. (99) as t_e^{-1} , characterizing, again, the delta-function-like distribution of surface current along the z direction. Thus, the dimension of \mathbf{J}_{mn} is amperes/meter. We apply the Galerkin's method to convert the integral equation [Eq. (97)], into the following matrix form

$$\sum_{m',n'} [B_{mnm'n'}][a_{m'n'}] = [b_{mn}], \quad (98)$$

where $[a_{mn}]$ are the unknown coefficients to be solved expressed in terms of the current basis $\{\mathbf{J}_{mn}(\rho)\}$:

$$\mathbf{J}(\rho) = t_e^{-1} \sum_{mn} a_{mn} \mathbf{J}_{mn}(\rho) \quad (99)$$

$[B_{mnm'n'}]$ are the matrix element derived from Eq. (97)

$$B_{mnm'n'} = \int_S d^2\rho \int_S d^2\rho' \mathbf{J}_{mn}^*(\rho) \cdot [\underline{\mathbf{G}}(\rho, \rho') + R_s \underline{\mathbf{I}}] \cdot \mathbf{J}_{m'n'}(\rho') \quad (100)$$

where $\underline{\mathbf{I}}$ denotes the identity dyad. The inhomogeneous term of Eq. (98), $[b_{mn}]$, is associated with current driving given by

$$b_{mn} = \int_S d^2\rho \mathbf{J}_{mn}^*(\rho) \cdot \mathbf{E}_e(\rho) = t_e^{-1} \int_V d^3\mathbf{r} \mathbf{E}_{mn}(\mathbf{r}) \cdot \mathbf{J}_e(\mathbf{r})^* \\ = \int_V d^3\mathbf{r} \int_S d^2\rho' \mathbf{J}_{mn}(\rho') \cdot \underline{\mathbf{G}}(\mathbf{r}, \rho') \cdot \mathbf{J}_e(\mathbf{r})^* \quad (101)$$

where \mathbf{E}_{mn} is the electric field generated by \mathbf{J}_{mn} , \mathbf{J}_e is the driving current density, and integration is over the whole volume, V . In Eq. (101) the reciprocity theorem has been used, which states that the response of a system to a source is unchanged if source and observer are interchanged [22]. The unit drive current density may be specified as

$$\mathbf{J}_e(\rho, z) = \underline{\mathbf{e}}_z \delta(x - x_0) \delta(y - y_0) [S(z) - S(z - d)] / 2 \\ \text{for rectangular patch} \\ = \underline{\mathbf{e}}_z \delta(\rho - \rho_0) \delta(\phi - \phi_0) [S(z) - S(z - d)] / (2\rho) \\ \text{for circular patch} \\ \mathbf{J}_e(\rho, z) = \underline{\mathbf{e}}_z [S(x - a) - S(x - b)] \delta(y) [S(z) \\ - S(z - d)] / [4(a + b)] \text{ for rectangular patch} \\ = \underline{\mathbf{e}}_z \delta(\rho - R) [S(\phi + \alpha) - S(\phi - \alpha)] [S(z) \\ - S(z - d)] / (8\alpha\rho) \text{ for circular patch} \quad (103)$$

These last two equations denote coaxial and microstrip feeders, respectively. We note that the current densities given in Eq. (103) are Huygens currents resulting from the external current fed at the microstrip input port [Eq. (38)]. By using Huygens principle the two feeder configurations, coax line and microstrip line, are cast in similar expres-

sions [Eqs. (102) and (103)] [23]. In Eqs. (102) and (103) $S(x)$ denotes the step function and

$$S(x) = 0 \quad \text{if } x < 0 \\ = 0.5 \quad \text{if } x = 0 \\ = 1 \quad \text{if } x > 0 \quad (104)$$

The input impedance is therefore, assuming unit excitation current

$$Z_{\text{in}} = -t_e \int_S d^2\rho \mathbf{E}_e^*(\rho) \cdot \mathbf{J}(\rho) \\ = - \sum_{m,n,m',n'} [b_{mn}]^* [B_{mnm'n'}]^{-1} [b_{m'n'}] \quad (105)$$

The radiation field associated with a point (Hertzian) dipole located at the air-dielectric interface of a microstrip structure is [16]

$$E_\theta = -j \frac{Z_0}{\lambda_0} \cos \phi g_\theta(\theta) \frac{e^{ik_0 r}}{r}, \quad (106)$$

$$E_\phi = j \frac{Z_0}{\lambda_0} \sin \phi g_\phi(\theta) \frac{e^{ik_0 r}}{r}$$

where

$$g_\theta(\theta) = \frac{T \cos \theta}{T - j \epsilon_r \cos \theta \cot(Tk_0 d)} \quad (107)$$

$$g_\phi(\theta) = \frac{\cos \theta}{\cos \theta - jT \cot(Tk_0 d)} \quad (108)$$

and

$$T = \sqrt{\epsilon_r - \sin^2 \theta} \quad (109)$$

The radiation pattern for a given patch current distribution $\mathbf{J}(\rho)$ [Eq. (106)] is therefore

$$\mathbf{E}^{\text{rad}}(\mathbf{r}) \\ = -j \frac{\zeta_0}{\lambda_0} \frac{\mathbf{e}^{-jk_0 r}}{r} \left[\int d^2\rho e^{i\mathbf{k} \cdot \rho} \mathbf{J}(\rho) \right] \cdot [g_\theta(\theta) \mathbf{e}_\theta \\ \times \mathbf{e}_z \mathbf{e}_\theta + g_\phi(\theta) \mathbf{e}_\phi \mathbf{e}_\phi] \quad (110)$$

where $\zeta_0 = (\mu_0/\epsilon_0)^{1/2}$ and $k_0 = 2\pi/\lambda_0 = \omega(\epsilon_0\mu_0)^{1/2}$ are, respectively, impedance and wavenumber in air.

Before performing numerical calculations, we must first determine which current basis is best suited for a given microstrip patch geometry implementing numerical calculations. For example, for a given microstrip of width expanded by interval $[-1, 1]$ one may use the triangular functions, Chebyshev polynomials, Legendre polynomials, and so on, as the functional basis to expand currents, but which one would provide the most advantages? The answer relies on the physical restriction imposed on current flow on a microstrip patch; the current basis needs to show zero (longitudinal) components when crossing the boundary of the patch; that is, the currents are not allow

to flow over metal boundaries. Under this restriction the freedom in choosing a current basis is largely fixed, which leads to the functional set of current potentials [24].

The simplest approach is to define a set of current potential $\{\psi_{mn}(\rho)\}$ satisfying the 2D Helmholtz equation

$$(\nabla_t^2 + k_{mn}^2)\psi_{mn}(\rho) = 0 \quad (111)$$

from which the current basis $\{\mathbf{J}_{mn}(\rho)\}$ is derived as

$$\mathbf{J}_{mn}(\rho) = \nabla_t \psi_{mn}(\rho) \quad (112)$$

The boundary condition imposed on $\{\mathbf{J}_{mn}(\rho)\}$ is that the current is not allowed to flow across the metal patch boundary, or, at the patch boundary

$$\mathbf{n} \cdot \mathbf{J}_{mn} = 0 \quad (113)$$

where \mathbf{n} denotes the unit outward normal at the metal patch boundary:

$$\mathbf{n} \cdot \nabla_t \psi_{mn} = 0 \text{ at patch boundary} \quad (114)$$

This equation determines the eigenvalues k_{mn} denoted in Eq. (111), and the current basis specified by Eq. (112) form a complete basis for vector fields on the metal patch.

Other advantages follow by deriving the current basis from current potentials:

1. The current potentials are intrinsic functions of the patch, so that the modal numbers $\{n,m\}$ reflect its symmetry. For example, for a rectangular microstrip antenna loaded with isotropic material the symmetry of the patch dictates currents with opposite parities do not couple. For a circular microstrip antenna loaded with isotropic materials currents with different angular modal numbers (monopole, dipole, quadrupole, etc.) do not couple. This results in largely reduced matrix size in Galerkin elements demanding numerical evaluation, thereby saving calculational efforts considerably.
2. Due to Green's theorem, in calculating a Galerkin element, most integrations required by (2D) Fourier and (2D) inverse Fourier transforms, for example [Eqs. (85) and (86)], can be performed analytically, leaving behind only onefold, or at most twofold, integrals that finally resort to numerical methods. This also saves calculational efforts.
3. By using current potentials Galerkin elements expressed by Eq. (100) reduce to scalar function multiplications rather than the originally proposed inner products between tensor and vector fields, thereby simplifying calculations.

On the basis of current potentials, we have solved the coupling problems between circular microstrip patch antennas, as introduced as follows.

For a rectangular patch located at $0 \leq x \leq L$, $0 \leq y \leq W$, the current potentials are

$$\psi_{mn}(x,y) = \frac{4}{LW} \cos \frac{m\pi x}{L} \cos \frac{n\pi y}{W}, \quad m, n = 1, 2, 3, \dots \quad (115)$$

Figure 4. Input impedance loci of the antenna observed by Lo et al. The solid line is from calculation, and small circles represent measurements from Lo et al. [13].

and for a circular patch located at $0 \leq \rho \leq R$, they are

$$\psi_{mn}(\rho, \phi) = \left[\sqrt{\pi} \beta_{mn} R \left(1 - \frac{m^2}{\beta_{mn}^2 R^2} \right)^{1/2} J_m(\beta_{mn} R) \right]^{-1} \times J_m(\beta_{mn} \rho) \exp(jm\phi) \quad (116)$$

and β_{mn} denotes the root of the derivative of Bessel function, $J'_m(x)$:

$$J'_m(\beta_{mn} R) = 0 \quad (117)$$

In the following we present some calculational results for circular microstrip patch antennas [15]. For rectangular patch antennas, see Ref. 25. The first calculation applies to the published data of a circular antenna characterized by the following parameters [13]: $R = 6.75$ cm, $d = 0.1588$ cm, $\epsilon_r = 2.62$, and $\tan \delta = 0.001$. The

Figure 5. Radiation profile of the antenna observed by Lo et al. [13] in the $\phi = 0^\circ$ plane.

Figure 6. Radiation profile of the antenna observed by Lo et al. [13] in the $\phi = 90^\circ$ plane.

calculated resonance frequency of the fundamental mode is 0.7936 GHz [15], which compares exactly to the measured value of 0.794 GHz [13]. This is contrasted to the cavity model calculation presented in Section 1, which predicts a resonant frequency of 0.805 GHz [13]. The calculated input impedance of the antenna is shown in Ref. 15, which compares nicely with measurements shown as small circles in Fig. 4 [13]. Figures 5 and 6 show the calculated radiation pattern of the antenna in the $\phi = 0^\circ$ and $\phi = 90^\circ$ planes, respectively. We note that only the co-polarized radiations are generated from the fundamental mode excitation; the cross-polarized field cancels out for the two $m = 1$ and $m = -1$ modes at the fundamental resonant frequency.

The second patch antenna geometry considered is a microstrip disk of radius $R = 1$ cm, which is fed by either a coaxial or a microstrip line [15]. The substrate has dielectric constant, $\epsilon_r = 2.2$, loss tangent $\tan \delta = 0.001$, whose thickness d is subject to vary. Figures 7–9, assuming $\alpha = 0.2$ rad, show the calculated resonant frequency, input impedance, and radiation linewidth of the fundamental mode as a function of the substrate thickness, respectively.

Figure 7. Calculated radiation frequency as a function of substrate thickness (fed by microstrip line).

Figure 8. Calculated radiation resistance as a function of substrate thickness (fed by microstrip line).

In Fig. 7 the calculated resonant frequency of the antenna decreases monotonically with the substrate thickness d , indicating the effective dimension of the patch resonator increases with d , as expected for a leaky cavity. Figure 8 shows that the input impedance of the antenna is relatively a constant, unless d becomes very small, say, smaller than 0.05 cm. In Fig. 9 we see that the radiation bandwidth increases with d , and hence the Q factor of the antenna resonator decreases with d . This finding is consistent with that revealed from Fig. 7 exhibiting the leaky feature of the antenna patch cavity.

Figure 10 shows the calculated input impedance loci of the above circular antenna of substrate thickness $d = 0.1$ cm fed by a coaxial line located at $(\rho_0, 0)$. In Fig. 10 the parameter r_e is defined as $r_e = \rho_0/R$, and $r_e = 1.0, 0.8, 0.6,$ and 0.416 . For each feeder location the two resonant

Figure 9. Calculated radiation linewidth as a function of substrate thickness (fed by microstrip line).

Figure 10. Input impedance loci of the antenna for several coaxial feeder positions.

frequencies shown in Fig. 10 are the resonance frequencies of the probe inductance in parallel with the detuned patch resonator forming a parallel-resonant circuit, and the resonance frequency of the probe inductance in series with the detuned patch resonator forming a series-resonant circuit. The field distribution of the patch at both frequencies shows very little difference, and the patch is operated at the same resonance mode, yet more or less detuned from its resonance frequency, which occurs between these two frequencies. It is seen in Fig. 10 that these resonant frequencies appear only if $0.416 \leq r_e \leq 1$.

Figure 11. Calculated radiation frequency as a function of coaxial feeder position.

Figure 12. Calculated radiation resistance as a function of coaxial feeder position.

For $r_e \leq 0.416$ no patch resonance can be possibly excited. Figure 11 shows the calculated radiation frequency as a function of r_e , or ρ_0 . It is seen in Fig. 11 that radiation frequency remains roughly constant for $0.6 \leq r_e \leq 1$, which increases rapidly when r_e is further reduced. Figure 12 shows the calculated input resistance as a function of r_e , or ρ_0 . From Fig. 12 we see that the input impedance decreases with r_e , or ρ_0 , and hence it is possible to design 50 Ω input resistance of the antenna by feeding the antenna at $r_e = 0.442$ (or $r_e = 0.488$ for 75 Ω input impedance).

Finally, we consider the interaction between two identical circular microstrip patch antennas excited by microstrip feeders at equal amplitude and phase. Let the antennas be deployed in parallel exhibiting the same parameters considered before: $R = 1$ cm, $d = 0.1$ cm, $\epsilon_r = 2.2$, and the feeder lines possess 50 Ω resistance (width 0.312 cm). The separation between the antennas is designated as R_{12} measured between their respective centers. Figure 13 shows the calculated and measured input impedance for the coupled case, $R_{12} = 2$ cm (the patches are touching each other), and the uncoupled case, $R_{12} = 5$ cm (the patches are separated by 3 cm at their edges). Measurements were performed with respect to patch antennas fabricated using RT/duroid 5880 material (Rogers Co., Chandler, AZ). The measured resonant frequencies were 5.514 and 5.561 GHz for the coupled and uncoupled cases, respectively, which compare almost exactly to their calculated values of 5.5137 and 5.5642 GHz. The resonant frequencies of the patches and their input impedances have also been calculated as a function of the patch separation, R_{12} . These are shown in Figs. 14 and 15, respectively, with measurements shown as solid squares. From Fig. 14 it is seen that the resonant frequency changes most rapidly when R_{12} is small, say, when $2 \leq R_{12} \leq 3$ cm. Further increase in R_{12} does not significantly change the resonance frequency. However, the input impedance does show long-range interference between two patch antennas. As shown

Figure 13. Calculated and measured input impedance loci of two coupled patch antennas.

in Fig. 15, the input impedance is still increasing when the two antennas are separated by 5 cm, although the rate of increase has slowed when compared with its initial rate at $R_{12} = 2$ cm.

We conclude that the leaky feature of an antenna cavity can be well characterized by using a full-wave analysis outlined in Section 2. Among many numerical methods, the dyadic Green function approach might prove to be the simplest one to apply, not only because the analysis is two-dimensional but also because the evaluation of the scalar Galerkin elements involves only one-fold Sommerfeld-type integrals. Surface-wave generation is significant for a thick dielectric substrate with large dielectric constant.

Figure 14. Calculated and measured resonant frequencies of two coupled patch antennas as a function of their separation distance.

Figure 15. Calculated and measured input impedances at resonant of two coupled patch antennas as a function of their separation distance.

The coupling between microstrip elements is of long-range nature, although the radiation frequency of a patch is less influenced by its neighboring antenna elements.

3. ANISOTROPIC/GYROMAGNETIC LAYER

In Sections 1 and 2 we considered microstrip patch antennas fabricated on isotropic materials. Anisotropic substrates, due to either the process in material preparation or crystalline asymmetry, have been included in the fabrication of microwave integrated circuits (MICs). Also, electromagnetic wave propagation in a fully saturated ferrite substrate is anisotropic, called the *gyromagnetic effect*. For the former case the dielectric properties of the substrate can be described in terms of a permittivity tensor of rank 2, and for the latter case Polder permeability tensor results under the small-signal approximations [26]. While many authors have applied numerical calculations to microwave circuitries containing anisotropic substrates [27–31], in this section we consider wave propagation in a gyromagnetic substrate [32]. Specifically, we consider the electromagnetic wave propagation involving the microstrip geometry where the metal circuit is fabricated on top of a ferrite substrate for which the bias magnetic field is applied along an arbitrary direction that is not necessarily the symmetry axis. In order to minimize magnetic loss, the ferrite substrate needs to be fully saturated so that an external DC magnetic field is applied aligning magnetic domains achieving the single-domain configuration, thereby eliminating domain wall motion to be otherwise induced accompanying electromagnetic wave propagation [33]. This external magnetic bias field can be supplied by material anisotropy as occurring to a hexaferrite substrate considered in Ref. 32.

In contrast to the permittivity tensor, Polder tensor elements are highly frequency-dependent and exhibit the resonance response in frequency and in the bias magnetic

field [33]. For example, when ferrimagnetic resonance (FMR) is encountered, the effective permeability changes from a large positive number to a large negative number together with a nonzero imaginary part accounting for magnetic loss [26]. Magnetic loss at resonance is parametrized as FMR linewidth whose occurrence arises from magnetic relaxation processes accompanying the precessional motion of spins at resonance [33]. Most useful magnetic microwave devices are designed to operate near FMR so that the rapid change in magnetic permeability is exploited, either to obtain frequency tuning capability or to remove the degeneracy in electromagnetic modes, thereby inducing nonreciprocity in wave propagation [33]. For example, ferrite phase shifters [34], resonators [35], and filters [26] are operational according to the first principle [33] and circulators and isolators, according to the second [36].

Before solving the AC problem on wave propagation involving a ferrite substrate, one is required to first solve the DC problem to calculate the demagnetizing field arising from the finite dimensions of the ferrite geometry [33]. In a cubic ferrite sample material anisotropy is seldom important, since it is small in comparison to the external bias field. In a hexaferrite substrate the internal anisotropy field can be as large as 50 kOe, and hence it can no longer be neglected [37]. Actually, hexaferrites are purposely introduced with a microwave circuit to alleviate, or even eliminate [38], the external bias-field requirement at high frequencies. In a hexaferrite material magnetic anisotropy appears in the form of an easy axis or an easy plane. For an M-type hexaferrite the c axis is an easy axis, and the magnetization vector prefers to be aligned along the c axis so as to lower its free energy [33]. For a Y-type hexaferrite the ab plane is an easy plane, and the magnetization vector is energetically favorable to stay on the ab plane [38]. The total effective field inside a ferrite substrate can be calculated from the system Lagrangian, including magnetic anisotropy, FMR linewidth, exchange coupling, demagnetization, and magnetostriction [33].

In Section 2 we have considered the Green functions of a layered structure containing isotropic materials that were constructed using the vector potentials as introduced by Sommerfeld [1]. In this section we consider the Green function construction by using the plane-wave solutions for which the substrate/superstrate may contain anisotropic layers. While plane-wave solutions are trivial within an isotropic dielectric layer, plane-wave solutions for an unbounded ferrite bulk magnetized along an arbitrary direction are also available [26], whose properties can be found in Ref. 32. For a given frequency there are four independent electromagnetic modes in a substrate material that are all degenerate if the substrate shows isotropy for wave propagation. However, for an anisotropy substrate, say, a ferrite fully biased by a magnetic field (or, a gyromagnetic material), wave propagation for these four modes becomes nondegenerate, assuming different effective permeability values for different modes, resulting in different propagation speeds and polarizations. Similar to the isotropic case, the directions of electric field, magnetic induction, and wave propagation for each mode excited in an anisotropic substrate are mutually perpendicular to

each other, as dictated by Maxwell equations. For a gyromagnetic substrate, the magnetic field is no longer aligned with magnetic induction, although it is still required to be perpendicular to the direction of the electric field [32].

One may apply the transfer-matrix technique to construct the Green functions of a layered structure. A transfer matrix is formulated in the transverse spectrum domain, which translates the surface impedance, which is itself a 2×2 matrix, from one layer interface to another, assuming the tangential components of the electromagnetic fields to be continuous across the interfaces in the absence of circuit (conductor) inhomogeneities. The transfer matrices for a given layer can be constructed in terms of the four electromagnetic modes, or the plane-wave solutions in the spectral domain, in a manner similar to the a, b, c, d coefficients introduced by Eqs. (72) and (73) (except that the γ values differ for the four modes in an anisotropic layer). The *surface impedance matrix* is defined as the ratio of the tangential electric field to the tangential magnetic field at a given layer interface, and hence it is a 2×2 matrix. The outermost layers are either air or a metal surface of finite conductivity, giving rise to the (imperfect) open-circuited or short-circuited boundaries for the layered structure, respectively. The surface impedance matrices for the outmost two layers can thus be obtained, in a manner similar to that used to obtain Eq. (77). Via the transfer matrices defined for the layers, these two outermost surface impedance matrices are translated sequentially onto an interface containing a point source responsible for the Green function definition (a Green function is defined to be the response excited by the point source). After applying Ampère law the Green functions evaluated at this interface position can thus be obtained [32]. To be explicit, assuming the point source is located at the origin, the Green functions, or the Green dyads, are defined by

$$\begin{aligned} \underline{\mathbf{e}}_t(x, y) &= \frac{1}{4\pi^2} \int_{-\infty}^{\infty} dk_x \int_{-\infty}^{\infty} dk_y \int_{-\infty}^{\infty} dx' \int_{-\infty}^{\infty} dy' \exp[ik_x(x - x')] \\ &\quad \times \exp[ik_y(y - y')] \underline{\mathbf{G}}(k_x, k_y) \underline{\mathbf{j}}(x', y') \end{aligned} \quad (118)$$

and after applying Ampère law at the interface $z = 0$ the Green functions are obtained as

$$\begin{aligned} \underline{\mathbf{G}}(k_x, k_y) &= \{ \underline{\mathbf{Z}}(0^+; k_x, k_y) \}^{-1} \\ &\quad - \{ \underline{\mathbf{Z}}(0^-; k_x, k_y) \}^{-1} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \end{aligned} \quad (119)$$

Here $\underline{\mathbf{j}}(x', y')$ denotes current density, $\underline{\mathbf{e}}_t(x, y)$ tangential electric field, and (k_x, k_y) the transverse spectral vector. In Eq. (119) $\underline{\mathbf{Z}}(0^+)$ denotes the impedance matrix that is transferred from the topmost layer, and $\underline{\mathbf{Z}}(0^-)$ from the bottommost layer, and $\underline{\mathbf{Z}}(0^+)$, $\underline{\mathbf{Z}}(0^-)$, and $\underline{\mathbf{G}}$ are all 2×2 matrices. Thus, once the Green function is known [Eq. (119)], the microstrip circuit involving a layered structure

Figure 16. Calculated current profile for the longitudinal and the transverse components across the strip width of a microstrip line fabricated on top of a hexaferrite.

containing anisotropic materials can be solved in a manner identical to that shown in Section 2.

As we have just mentioned, wave propagation is anisotropic in an anisotropic medium, and in performing numerical calculations Galerkin elements need to be all evaluated in general, since symmetry of the system ceases to apply. This is illustrated in Fig. 16, where the induced current profiles along the width direction of a microstrip line fabricated on a hexaferrite substrate no longer show left–right symmetry, due to the gyromagnetic nature of a hexaferrite material [32]. In Fig. 16 the substrate was a single-crystal Y-type hexaferrite of composition $\text{Ba}_2\text{MgZnFe}_{12}\text{O}_{22}$, and the easy plane coincides with the substrate surfaces, the xy plane. The hexaferrite substrate was characterized by the following parameters: saturation magnetization $4\pi M_S = 2.86$ kG, anisotropy field $H_A = 7.94$ kOe, dielectric constant $\epsilon_f = 18$, dielectric loss tangent, $\tan \delta_f = 0.01$, and FMR linewidth $\Delta H = 100$ Oe. The width of the fabricated microstrip line was $w = 0.0051$ in. and length $\ell = 0.0157$ in. and the thickness of the hexaferrite substrate was $d = 0.010$ in. More calculations and measurements on this fabricated microstrip line can be found in Ref. 32.

4. FRACTAL ANTENNAS

Traditional approaches to the analysis and design of antenna systems are based on Euclidean geometry. More recently, however, there has been a considerable amount of interest in developing new types of antennas that employ fractal rather than Euclidean geometries. This new and rapidly growing field is referred to as *fractal antenna engineering*, and this topic is briefly introduced in this section.

A *fractal* is a recursive object that has a fractional dimension showing shape similarity in scale; that is, a fractal preserves its shape when viewed in different scales.

Many objects, including antennas, can be designed using the recursive nature of a fractal. The term *fractal*, which means broken or irregular fragments, was originally coined by Mandelbrot [39] to describe a family of complex shapes that possess an inherent self-similarity in their geometric structure. Since the pioneering work of Mandelbrot and others, a wide variety of applications for fractals have been found in many branches of science and engineering. One such area is fractal electrodynamics, in which fractal geometry is combined with electromagnetic theory for the purpose of investigating a new class of radiation, propagation, and scattering problems. One of the most promising areas of fractal electrodynamics is in its application to antenna theory and design.

In an Euclidean geometry, broadband and frequency-independent antennas were developed and analyzed in the early 1960s, and some convoluted shapes were developed whose performance indicated the dependence of the antenna radiation properties on its physical size relative to wavelength. Spirals and logperiodic structures are some examples of successful developments giving rise to frequency-independent radiations. Fractals might join some of those designs because of their self-scaling properties. Actually, fractal antennas have been shown to provide two advantages: to generate multiband radiations and to perform beamforming capabilities. As such, the current fractal antenna engineering is applied in two areas, and the fractal pattern is either used by an isolated antenna radiator or included as elements in an antenna array (a multipole configuration). As described in Section 1, since the radiation frequency is inversely proportional to the linear dimension of a radiator, a fractal antenna can thus emit multiband radiation [40]. Furthermore, a fractal antenna can also be viewed as arrays of arrays, and hence it possesses beamforming capability, if designed and operated properly [41]. It is these novel properties that make fractal antennas very attractive, allowing phased arrays to be fabricated with conformity and reduced sizes, resulting in convenience and flexibility.

Concerning these particular issues, Puente-Baliarda et al. described [40] the behavior of the first fractal multiband antenna—the Sierpinski monopole. Such a monopole displayed similar behavior at several bands in terms of both input return loss and radiation patterns. Some steps further in the field of multiband fractal antennas were reported by Cohen [43], who also discussed other interesting features regarding small and frequency-independent fractal antennas. In [40] the behavior of both the Sierpinski monopole and dipole have been investigated, and their performance has been compared with a conventional triangular (bowtie) antenna.

Figure 17 shows the original Sierpinski triangular pattern. The Sierpinski pattern is named after the Polish mathematician Sierpinski, who described some of the main properties of this fractal shape in 1916 [42]. The original pattern is constructed by subtracting a central inverted triangle from a main triangle shape (see Fig. 17). After the subtraction, three equal triangles remain on the structure, each one half the size of the original one. One can iterate this same subtraction procedure on the remaining triangles, and if the iteration is carried out an

Figure 17. Fractal Sierpinski pattern.

infinite number of times, the ideal fraction Sierpinski pattern is obtained. In such an ideal structure, each of its three main parts is exactly equal to the whole object, but scaled by a factor of 2, and so are each of the three triangles that compose any of those parts. Because of these particular similarity properties, shared with many other fractal shapes, it is said that the Sierpinski pattern is a self-similar structure.

In Fig. 17 the Sierpinski pattern is shown with six levels in iterations, and the smallest scale is a single triangle shown shaded in Fig. 17. Sierpinski triangles constitutes the simplest geometry for a 2D fractal. In the monopole configuration, the feeder is located at the top vertex of the big (main) triangle. In this antenna geometry, if one neglects the contribution of the central holes to the antenna performance and admits that the current flowing from the feeder should concentrate over a region that is comparable in size to the wavelength, a behavior similar to six-scaled

Figure 18. A quadrupole fractal.

bowtie antennas (each one operating at its resonant frequency) could be expected. The scale factor among the six iterations is $\Delta = 2$; therefore, one should look for similarities at frequencies also spaced by a factor of 2. A Sierpinski dipole or quadrupole can be formed by joining two or four Sierpinski monopoles at the vertex points, respectively, showing improved frequency independency with reduced beamwidth in radiation. A Sierpinski quadrupole is shown in Fig. 18, which has been used as the company logo by Hotech, Inc. In conclusion, the most important features of a fractal array include the frequency-independent multiband characteristics, schemes for realizing low-sidelobe designs, systematic approach to thinning, and the ability to develop rapid beamforming algorithm, and fractal antennas are still active under current research and development.

5. RECENT DEVELOPMENTS

5.1. Wideband Techniques

A microstrip patch antenna is inherently narrowband, stemming from the cavity model, where an electromagnetic resonator confining energy locally in space with little dissipation is necessarily a high- Q , and hence narrowband, device. For a high- Q resonator the generation of surface waves is insignificant. For a thin substrate this condition amounts to $d/\lambda_0 < 0.07$ for $\epsilon_r = 2.3$ and $d/\lambda_0 < 0.023$ for $\epsilon_r = 10$, as stated at the end of Section 1 [10,11]. For a microstrip antenna fabricated on a thin substrate, the impedance bandwidth is typically 1–3%. This is contrasted with the bandwidth of 16% of a half-wave dipole with a radius:length ratio equal to 0.01, and 70% of a medium-length helix operating in the axial mode.

A number of techniques have been proposed to increase the bandwidth of a microstrip patch antenna. These techniques are generally classified into three categories: (1) a straightforward approach based on the use of a thick substrate whose dielectric constant is small, (2) an approach where a matching network is designed to enhance the bandwidth [44], and (3) a method using parasitically coupled elements in a variety of ways to produce closely spaced multiple resonances of the antenna [45,46].

By using a thick substrate whose dielectric constant is considerably different from that of air, surface waves will be generated and inevitably reduce the radiation efficiency and introduce interference between array elements. To resolve this problem, air cavities or holes may be introduced with the substrate to effectively reduce the dielectric constant of the patch. For example, Gauthier et al. [47] machined closely spaced holes in a Duroid substrate underneath a microstrip patch to lower the effective dielectric constant of the antenna. Using the micromachining technique, Zheng et al. measured a 12.8% impedance bandwidth on cavity-backed microstrip patch antennas fabricated on silicon wafers [48].

The bandwidth of the antenna is determined primarily by the rate of transition that the imaginary part of the impedance changes sign at resonance, as discussed at the end of Section 1. Thus, it is possible to introduce a cancellation mechanism on the input inductance so as to

smooth the impedance variation. For example, the inductance associated with the long wire lead of the coaxial probe will limit the bandwidth to $<10\%$ for a thick substrate. By etching a small circular slot around the probe on the patch, capacitance is thereby introduced, canceling the probe inductance to produce a bandwidth of 16% [49]. More recently, with the use of a U-shaped slot, a substantial increase in bandwidth (32%) has been demonstrated [50]. Alternatively, an L-shaped probe-wire has been shown to result a bandwidth of 28% [51].

The third method to achieving broadband operation is to couple the microstrip patch antenna parasitically with other dielectric resonators characterized by approximately the same resonant frequency of the patch. For an isolated patch the resonant frequency is determined by its lateral dimension. However, in the presence of fringe fields at the patch periphery the boundary of the antenna is neither sharply nor rigidly defined, leading to a slightly larger effective dimension of the patch, as described by Eqs. (2) and (5) for rectangular and circular microstrip patches, respectively. Thus, in contrast to a metal cavity, patch antennas have soft boundaries, which in turn give rise to finite bandwidth in radiation; the softer the boundary, the wider the bandwidth. For this reason a patch antenna fabricated on a thick substrate will show a wide bandwidth. Similarly, when coupled together many soft-boundary microstrip resonators/patches, the overall radiation bandwidth is consequently enlarged.

The disadvantage of using a thick substrate is that, besides its cost, surface waves may be generated in the substrate so as to reduce the antenna feeding efficiency. This disadvantage can be overcome by using multiple electromagnetically (EM) coupled patches. EM-coupled patches can be deployed either side-by-side (laterally coupled geometry) or layer-by-layer (vertically coupled geometry). For laterally coupled patches the antenna size will increase considerably, ultimately restricting its usage from large-array applications [52].

The two-layer EM coupled patch antenna consisting of a driven (feeder) patch in the bottom and a parasitic (radiating) patch on the top has been investigated by several authors. For circular [53], equitriangular [54], and rectangular [55] patches, experimental results have shown an enhanced gain and impedance bandwidth with low cross-polarization levels as compared to the conventional single-layer microstrip antenna. Actually, as analogous to Yagi antenna, the gain of a stacked antenna can be increased to above 20 dB at any scan angle if the thickness of the substrate and multiple superstrate layers is chosen properly [56]. Therefore, using stacked parasitic elements in microstrip arrays could improve the overall array performance, offering a higher gain and broader bandwidth, meeting with the same array design criteria of a conventional single-layer microstrip array but with fewer array elements.

5.2. Size Reduction

Microstrip antennas have a number of advantages over conventional antennas, namely, small size, light weight, low production cost, and natural conformal. However, for

many applications, for example, handheld mobile communication systems, half-wave microstrip antennas etched on a low-cost dielectric substrate are still too large to be accommodated on the portable phone. A well-known approach to reduce the size of a half-wave patch to a quarter-wave is to introduce an electrically short-circuiting wall at one of the radiating edges. Hiraswa and Haneishi [57] has shown that the length of the patch can be made sufficiently shorter than a quarter-wave by replacing the short-circuiting wall with a short-circuiting pin at the corner of the patch. Wang and Lin have shown that by replacing the short-circuiting pin with a chip resistor of low resistance, the antenna size can be further reduced in addition to an increase in bandwidth [58].

The other approach to reduce antenna size is to use a meandered geometry of the patch antenna [57]. By meandering the patch, the effective electrical length is greater than the physical length. Consequently, the resonant frequency of the meandered antenna can be much lower than that of a conventional design using the same physical length [59].

Finally, we note that it is not only possible to achieve high gain for printed circuit antennas, it is also feasible to shape the radiation pattern in some prescribed manner. Some very interesting phenomena, such as radiation into the horizon, radiation pattern monodirectionality, and azimuth-dependent radiation, have been found possible [60]. Furthermore, laterally coupled patches can serve as adaptive array antennas, because the phase of radiation from a parasitic element can be adjusted via a varactor diode inserted at some feeding position [61]. The important feature of an adaptive array antenna is that it can provide beamsteering as required by many communication and traffic control systems [62].

1. INTRODUCTION

The microstrip patch antenna offers many attractive features, including low profile, light weight, conformal structure, and inexpensive fabrication costs. The major drawback of this antenna is narrow bandwidth in its basic form. This article collects different approaches for bandwidth enhancement of linearly polarized microstrip antennas from conventional means to present-day methods, with emphasis on advanced techniques proposed by the authors (Section 2), particularly on the L-probe coupling technique. However, due to limited spacing, the

development of wideband elliptically polarized microstrip antennas will not be covered here. Interested readers can refer to some of the more recent designs reported in the literature [1–4].

The article also highlights wideband techniques for designing dual-polarized patch antennas (Section 3) and electrically small patch antennas (Section 4). In Section 3, the popular aperture coupling method for a dual-polarized patch antenna is described first. Emphasis is then placed on the wideband L-probe-coupled dual-polarized patch antenna. A technique for improving the isolation between the input ports is also presented in that section. Section 4 focuses on miniature patch antennas, including patches with shorting (short-circuiting) pins or shorting walls. Several wideband methods such as the use of stacked geometry, and the L-probe feed, are examined.

The wideband antennas discussed in Sections 3 and 4 are essential in today's wireless communication systems. For instance, the polarization diversity technique is found useful in cellular systems, and therefore most of the base station antennas require a $\pm 45^\circ$ dual-polarized feature as well as broadband characteristic. Modern mobile devices are getting smaller and smaller in size. Thus the dimensions of the antennas inside these devices have to be reduced accordingly. With the novel wideband techniques discussed, both dual-polarized patch antennas and miniature patch antennas can be operated with wide-bandwidth performance, which will be particularly useful in future high-speed wireless communications. The advanced wideband techniques proposed by the authors can also be applied to the design of dual-band and circular-polarized patch antennas.

2. LINEARLY POLARIZED WIDEBAND MICROSTRIP PATCH ANTENNAS

According to *The New IEEE Standard Dictionary of Electrical and Electronics Terms* [5], the bandwidth of an antenna is defined as “the range of frequencies within which its performance, in respect to some characteristics, conforms to a specified standard.” This characteristic can be selected as the input impedance or radiation pattern. For the former, which is more sensitive to frequency, a common standard is that the voltage standing-wave ratio VSWR, or simply SWR, should be less than a certain value, usually 1.5 ($|\Gamma(f)| = 0.2$) or 2 ($|\Gamma(f)| = \frac{1}{3}$), where Γ is the reflection coefficient. Equivalently, the return loss $S_{11}(f)$ should be less than -14 or -10 dB, respectively. Moreover, we usually express the impedance bandwidth in terms of percentage (BW), which is calculated by

$$BW = \frac{2(f_U - f_L)}{f_U + f_L} \times 100\%$$

where f_U and f_L are respectively the upper and lower cutoff frequencies of the operating bandwidth. Key methods developed to solve the inherently narrow bandwidth issue of linearly polarized microstrip patch antennas are discussed below.

Figure 1. Proximity-coupled patch antenna. (From Pozar and Kaufman [10], reprinted with permission from IEEE.)

2.1. Utilization of Electrically Thick Substrate with Low Permittivity

The patch antenna works like a lossy dielectric-loaded cavity resonator bounded by two electric and four magnetic walls. Assuming that the only loss is due to radiation, we have the antenna quality factor $Q = 2\pi f_r U / P_{rad}$, where U is the total stored energy trapped inside the cavity between the patch and the ground plane at the resonant frequency f_r . P_{rad} is the total radiated power at f_r . This quality factor is similar to that of a parallel-resonant circuit having lumped circuit elements and can also be determined from the input resistance $R(f)$ and input reactance $X(f)$ at a frequency close to f_r . It is understood that a lower value of Q will result in a wider bandwidth. For a patch antenna employing a thin substrate, a higher value of Q [6] and a narrower bandwidth will be obtained. The quality factor can be lowered by simply increasing the substrate thickness; however, the surface wave introduced will

deteriorate the overall performance, including the bandwidth. Fortunately, a substrate with lower value of permittivity $\epsilon = \epsilon_r \epsilon_0$ can minimize the surface-wave power. It is known that the foam or air substrate has the lowest value of relative permittivity ϵ_r close to unity. Thus a patch antenna with electrically thick substrate could exhibit a wide bandwidth [7]. Examples are described in Refs. 8 and 9. In Ref. 8, the bandwidth of a patch antenna over a large ground plane with an air substrate thickness $0.14\text{--}0.27 \lambda_0$ was shown to be about 40% ($VSWR \leq 2$). In Ref. 9, a similar concept was implemented. The effective substrate thickness was increased by the use of a W-shaped ground plane. A 12% ($VSWR \leq 1.5$) bandwidth was reported.

2.2. Bandwidth Improvement by Related Impedance Matching in Different Feeding Mechanisms

2.2.1. Proximity or Electromagnetic Coupling. The proximity coupling technique for patch antennas was proposed by Pozar and Kaufman in 1987 [10]. Energy is electromagnetically coupled from the feedline through a substrate to the radiating element such as a patch [10] or a printed dipole [11]. It has the merit of being less sensitive to fabrication errors. For the proximity-coupled patch as described in Ref. 10 and shown in Fig. 1, there is a relatively small open-circuited tuning stub connected in parallel with the feedline, which provides related matching to the feedpoint; hence the bandwidth can be increased to 13% ($VSWR \leq 2$).

Another proximity-coupled patch with wider bandwidth was proposed in 1998 [12]. The geometry is shown in Fig. 2. Instead of adding a tuning stub, the feedline is

Figure 2. Geometry of proximity-coupled U-slot patch antenna. (From Mak et al. [12], reprinted with permission from IEEE.)

Figure 3. Variation of VSWR of the proximity-coupled patch antenna. (From Mak et al. [12], reprinted with permission from IEE.)

terminated by a Π -shaped stub, which is underneath the radiating patch. The patch is etched with a U-shaped slot, the function of which will be elaborated later. A bandwidth of 20% ($VSWR \leq 2$) and a gain of 7.5 dBi were achieved for this single-layer patch antenna. Figures 3 and 4 show the measured VSWR and gain of this antenna. Figure 5 shows the radiation patterns at 4.3 GHz. The antenna has a broadside radiation pattern with beamwidth of about 60° in both E plane and H plane. The cross-polar level is below -15 dB. This single-element antenna has been modified and employed for the design of wideband antenna array with excellent performance [13,14].

2.2.2. Aperture Coupling Method. The aperture coupling method was proposed 1985 by Pozar again [15]. The basic geometry is shown in Fig. 6. The microstrip feedline and the patch are located on different sides of the ground plane. Energy from the microstrip feedline is electromagnetically coupled to the patch through an aperture on the ground plane. The coupling aperture can be of different shapes, sizes, and locations with respect to the patch for different coupling characteristics [16,17]. An advantage of this feeding method is that the feedline is isolated from the radiating element by the ground plane. Thus radiation from the feedline in the broadside direction is insignificant. Also this method do not have the probe inductance problem arising in the coaxial probe feed case.

Figure 4. Gain of the proximity-coupled U-slot patch antenna. (From Mak et al. [12], reprinted with permission from IEE.)

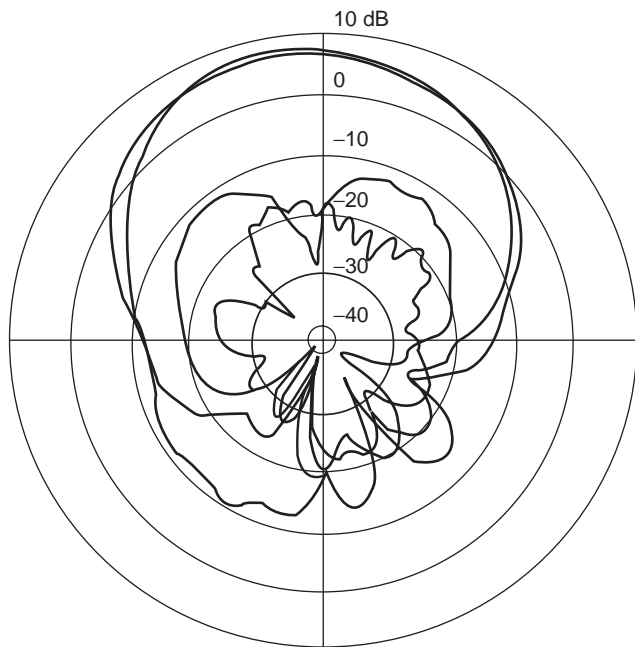

Figure 5. Radiation pattern at 4.3 GHz. (From Mak et al. [12], reprinted with permission from IEE.)

Disadvantages are comparative complexity in fabrication and relatively high level of backlobe radiation.

From Ref. 15, the bandwidth obtained was only 14%. There are two simple ways for tuning the antenna: the aperture shape and size and the stub length. So it is possible to obtain a better bandwidth if appropriate matching is achieved. One example was presented in 2002 [18], with the patch excited by an H-shaped aperture. An impedance bandwidth of 56.2% ($VSWR \leq 2$) and a 3 dB gain bandwidth of 24% were achieved.

2.2.3. Microstrip-Line Edge Feed and Coaxial Probe Feed. The microstrip-line edge feed and the coaxial probe feed are fundamental feeding methods for microstrip patch antennas, since they are the most direct way to transfer energy from the feedline to the patch and vice versa. Some methods have been proposed in the literature to improve the matching condition and the bandwidth as well. In Ref. 19, a patch is excited by a coupled linefeed. It was reported that the bandwidth can be increased by a

factor of > 2.5 as compared to the conventional edge feed method.

In using the coaxial probe feed, there are even more methods available to improve the matching condition of the single-patch configuration such as introducing a slot on the patch, adding a capacitor patch, or using the L-shaped probe. These techniques will be discussed in the following sections.

2.3. Bandwidth Widening Technique Using Parasitic Elements

The original geometry of a microstrip patch antenna consists of only one patch radiator, which is driven by the appropriate feeding techniques. The bandwidth of such a configuration can be very narrow. A significant improvement in bandwidth can be achieved by adding one or more parasitic patches next to or stacked above the

Figure 12. Wideband rectangular U-slot patch antenna. (From Lee et al. [47], reprinted with permission from IEE.)

Parameters	W	L	F	Ws	Ls	a	b	c	h	Bandwidth (VSWR ≤ 2)
Unit/mm	35.5	26	15	12	19.5	2.2	4.3	2.1	5	32.4%

driven patch. The parasitic elements can be of slightly different dimensions and are excited by electromagnetic coupling from the driven patch. By adding parasitic patches, the bandwidth can be improved because there are one or more resonant frequencies introduced by the parasitic patches. If these resonant frequencies are close to the original resonant frequency of the driven patch, they could combine together to yield a wider bandwidth. Obviously, the major drawback of using parasitic elements is the enlargement in volume of the antenna.

2.3.1. Coplanar Structure. In the coplanar geometry, the parasitic patches are placed on the same layer and adjacent to the driven patch as shown in Fig. 7. The coaxial probe feed [20–22] or the aperture-coupled feed [23] can be chosen to excite the driven patch. When using the coaxial probe feed method, 15% bandwidth (VSWR ≤ 2) can be yielded when two parasitic patches are placed next to the nonradiating edge of the driven patch [21]. In addition, if we add four parasitic patches gap-coupled to the four edges of the driven patch, around 25% bandwidth

(VSWR ≤ 2) can be obtained [21]. As for using the aperture-coupled feed, 23% bandwidth (VSWR ≤ 2) was achieved [23] when two parasitic elements were gap-coupled to the nonradiating edges of the fed patch.

2.3.2. Stacked Structure. In the stacked geometry, the parasitic patches are suspended above the driven patch and thus are placed in another upper layer with respect to the driven patch as shown in Fig. 8. Again, both coaxial probe feed [24,25] and aperture-coupled feed [26–31] methods for the driven patch are commonly used. Newer feed methods for the driven patch have been proposed: the co-planar waveguide feed (CPW) [32,33] and the L-shaped strip feed [34]. In using the coaxial probe feed method, more than 25% bandwidth (VSWR ≤ 2) can be achieved [25]. If the aperture-coupled feed is employed, around 40% bandwidth (VSWR ≤ 2) was obtained [28,29].

2.4. Wideband Patch Antenna with Probe Inductance Cancellation

As mentioned in Section 2.1, employing electrically thick substrate could increase the impedance bandwidth by about 20% (VSWR ≤ 2) [7] when the substrate thickness is around 0.15λ₀. However, in the probe feed case, the bandwidth is limited to about 10% (VSWR ≤ 2) because of

Figure 13. Measured and FDTD-simulated VSWR of rectangular U-slot patch antenna. (From Lee et al. [47], reprinted with permission from IEE.)

Figure 14. Examples of U-slot equivalent patches [52–54].

Figure 15. Basic geometry of L-shaped probe-fed patch antenna. (From Luk et al. [55], reprinted with permission from IEE.)

the larger probe inductance [35,36] introduced by the longer probe required. This undesired inductance results in antenna mismatch. Moreover, the unwanted radiation from the longer probe is a major source of high cross-polarization in the H plane and also causes an unsymmetric copolarization in the E plane. Thus a shorter probe and a thicker substrate are desired in designing wideband patch antennas. In one method, employing a W-shaped ground plane [9] to increase the (effective) substrate thickness without lengthening the feeding probe, a bandwidth of 15% (VSWR ≤ 1.5) can be achieved. Apart from retaining a short feeding probe, there are other effective methods to compensate the unwanted probe inductance in wideband patch antenna design.

Figure 16. VSWR and gain of L-shaped probe-fed rectangular patch antenna. (From Luk et al. [55], reprinted with permission from IEE.)

2.4.1. Capacitive Coupling Patch Antenna. In the design of capacitively coupled patch antenna, a small patch, which is connected to the feeding probe, is introduced between the ground plane and the radiating patch as shown in Fig. 9 [37–39]. The structure is somewhat similar to the probe-fed stacked-patch antenna, but the small patch together with the radiating patch works as a capacitor that is used to cancel out the unwanted probe inductance within the antenna structure itself. Thus a simpler matching network can be used at the back of the ground plane. About 5% impedance bandwidth (VSWR ≤ 2) was reported [37].

2.4.2. Coaxial Probe-Fed Slotted Patch. Without using an additional capacitor patch between the ground and the radiating patch, the unwanted probe inductance can be canceled out by introducing appropriate slots, surrounding the feedpoint, on the patch [40]. The method can retain the advantage of a single-patch configuration. Not long ago, the authors introduced different-shaped slots on the patch, including an arc-shaped slot and a U-shaped slot, for wideband operation [41,42]. The latter case with U-shaped slot has received much attention in the literature [12,13,43–51]. Many similar designs have also been proposed such as the E-shaped patch [52,53], and the back-to-back L-shaped slotted patch [54].

2.4.2.1. Circular Patch with an Arc-Shaped Slot. In a procedure reported in 1997 [41], an arc-shaped slot was cut inside the circular patch as shown in Fig. 10. It is found that the offset feed ($r > 0$) will give a better bandwidth (VSWR ≤ 2) of 14% than the 11% of the center feed case ($r = 0$). Figure 11 shows the measured VSWR response.

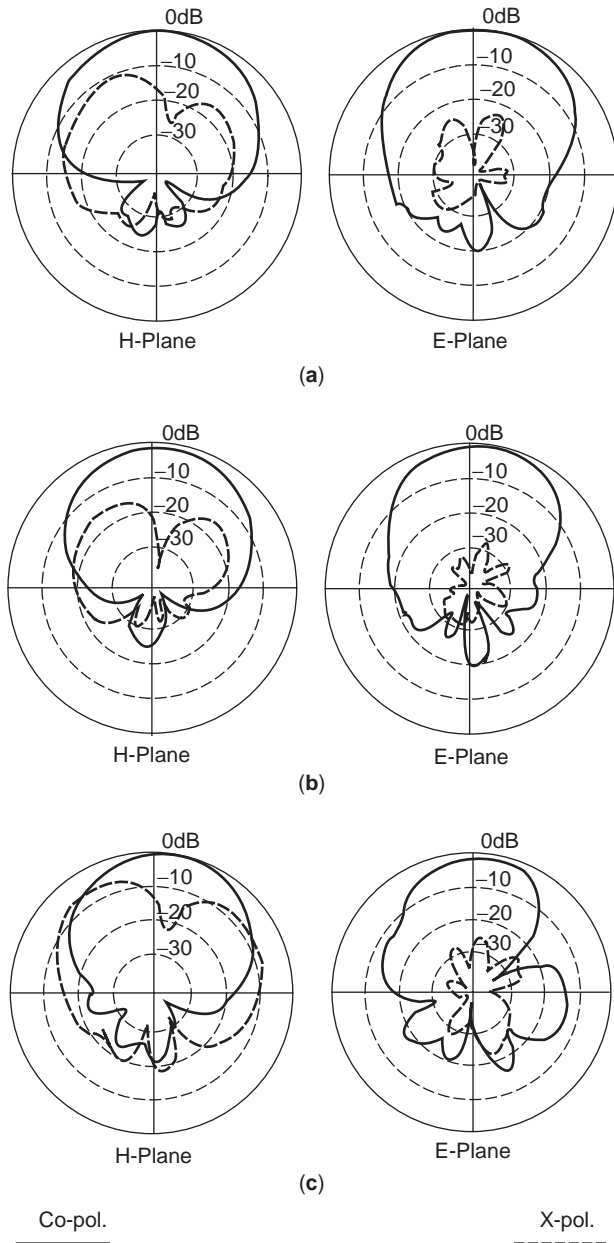

Figure 17. Far-field radiation patterns of L-shaped probe-fed patch antenna: (a) 4 GHz; (b) 4.53 GHz; (c) 5.34 GHz. (From Mak et al. [56], © 2000 IEEE.)

2.4.2.2. Rectangular Patch with a U-Shaped Slot. The design was first proposed in 1995 by Huynh and Lee [42]. An impedance bandwidth of around 30% ($VSWR \leq 2$) can be easily obtained [47]. A typical example is described below with the basic geometry shown in Fig. 12. Note that the thickness is around $0.08 \lambda_0$. Figure 13 shows the measured and simulated [finite-difference time-domain (FDTD)] results of VSWR of this wideband antenna.

The arc-shaped or U-shaped slot, surrounding the feed-point, on the patch provides a capacitive component in the input impedance of the antenna, compensating the strong inductive component from the long feeding probe. Therefore, appropriate matching can be obtained for wideband performance. Apart from the broadband characteristics,

the U-slotted patch preserves the single-patch low-profile feature in comparison to the geometry with parasitic patches. The thickness of such a wideband single-patch antenna is only $\leq 0.08 \lambda_0$. Due to such an attractive feature, many U-slot equivalent patch antennas have been designed for bandwidth enhancement. For examples, an E-shaped patch [52,53] and the back-to-back L-shaped slotted patch [54] were proposed, as shown in Fig. 14. Similar wide bandwidths of around 30% were reported.

2.5. Wideband Patch Antenna with L-Shaped or T-Shaped Probe

It is believed that using slightly thicker substrate with low permittivity for patch antenna design is the most effective way to achieve wideband operation, at the same time retaining the attractive original low-profile characteristic. Of course, the probe-fed U-slotted patch can easily achieve such merit of wideband and low-profile structure. However, the fabrication process is not so convenient, and the fine-tuning process of the U-shaped slot is not an easy task. Such problems may increase the fabrication cost and time.

2.5.1. L-Probe-Coupled Patch Antenna. More recently, a novel L-probe coupling technique was invented, and awarded patents from the People's Republic of China and the United States. This design, first proposed in 1998 [55], preserves the original advantages of patch antennas with an improvement in impedance bandwidth without increasing the fabrication difficulties since no slot is needed on the patch and no soldering process is required. Many investigations have been undertaken on L-shaped probe coupling [49,50,56–66], including the circular polarization design and the dual-band design.

The basic geometry of the L-probe-coupled patch antenna is shown in Fig. 15. This is a single-layer patch antenna with a rectangular patch of width $W_x = 30$ mm ($0.45 \lambda_0$) and length $W_y = 25$ mm ($0.375 \lambda_0$). Note that the operating center frequency is $f_0 \approx 4.5$ GHz. The copper-made L-shaped probe is constructed by simply bending a straight copper wire of radius $R = 0.5$ mm ($0.0075 \lambda_0$) into an L shape. When this L-shaped probe is then connected to the inner conductor of a 50- Ω launcher without touching the patch, as shown in Fig. 15, it becomes an effective coupling probe for the radiating patch. The L-shaped probe has a vertical arm length $L_v = 10.5$ mm ($0.1575 \lambda_0$) and a horizontal arm length $L_h = 5.5$ mm ($0.0825 \lambda_0$), which are exciting the fundamental TM_{01} mode of the rectangular patch. A supporting foam layer ($\epsilon_r \approx 1$) is employed with thickness $H = 6.6$ mm ($0.099 \lambda_0$), which is about one-tenth of the operating wavelength. Moreover, from the top view, the distance between the lower edge of the patch and the horizontal arm of the L-shaped probe is $S \approx 2$ mm. The values of these parameters are chosen after a series of extensive appraisals, from $H \approx 3.3$ mm ($0.05 \lambda_0$) to $H \approx 16$ mm ($0.25 \lambda_0$) and are believed to provide an optimum performance of bandwidth and gain.

Both the measured VSWR and gain (copolarization gain at $\theta = 0^\circ$ and cross-polarization gain at $\theta \approx 45^\circ$ in

the *H* plane) are shown in Fig. 16, where θ is the azimuth angle. A wide bandwidth of up to 36% ($VSWR \leq 2$) with 7.5 dBi gain is obtained. The cross-polarization level in the *H* plane is slightly higher at the two ends of the band of

operation, and about 15 dB down from the copolarization level is attained at the center region of the band of operation. The far-field radiation patterns measured at 4, 4.53, and 5.34 GHz are shown in Fig. 17. It can be observed that

Parameters	W_x	W_y	H	T_h	T_v	h	Bandwidth (VSWR ≤ 2)

Figure 20. VSWR and gain of T-probe coupled patch antenna. (From Mak et al. [67], reprinted with permission from IEE.)

the copolarization patterns are stable across the band of operation, with the mainbeam toward the broadside direction.

Apart from the rectangular patch coupled by the L-shaped probe as described, circular and triangular patches are also investigated [57,58], which are also able to show the wideband characteristic. It is believed that the L-shaped probe coupling technique is also suitable for other common patch shapes such as elliptical patch, semidisk, and circular ring, as well as the bowtie patch and the notched patch for different requirements. The wideband performance of the L-probe-coupled patch antenna is achieved by two basic insights: (1) the use of an electrically thick substrate ($\approx 0.1\lambda$) [7], which provides a lower Q factor, thus potentially giving a wider bandwidth; and (2) probe inductance compensation [37–42], where, from the transmission-line perspective, the vertical arm between the patch and the ground forms an open circuit stub of length less than a quarter-wavelength; thus a capacitive reactance is provided. This is similar in concept to the capacitive coupled patch antenna [37–39]. Moreover, it is necessary to note that the total length of the L-shaped probe is less than a quarter-wavelength (i.e., $L_v +$

$L_h < 0.25\lambda$), thus maintaining the patch as the only radiating element. Experiments also show that the L probe itself without the patch does not act as an efficient radiator across the operation band.

In the process of finding an optimum configuration, it is found that the bandwidth generally increases with the value of H , the separation between the patch and ground. However, an optimum gain is obtained when H is around 0.1λ . Furthermore, the gain is highly sensitive to the value of H . Measurements also show that the gain is usually higher when part of the L probe is not under the patch, as shown in Fig. 15, than when the whole L probe is completely covered by the patch [56]. It is essential to mention that when varying the value of H , it is necessary to slightly alter the other parameters such as L_v , L_h , and S simultaneously in order to obtain a wideband performance again.

It has been shown that the L-shaped probe is effective for exciting linearly polarized patch antennas. For elliptical polarized patch antenna designs, some studies have been performed on the use of the L-probe coupling method [63–65]. For dual-band operation, an L-probe-coupled patch antenna operating at GSM/PCS band has also been investigated [59]. As for combining the L-probe coupling method with other bandwidth enhancement techniques, there are L-probe-coupled U-slotted patch antennas [49,50], together with a parasitic patch [60], or with a short-circuiting post [61].

2.5.2. Extensions of the L-Probe Coupling Technique.

Further development based on the original L-shaped probe design was made in order to provide more alternative coupling methods that maintain the fundamental features and enhance the flexibility of the design. One of these is an L-shaped strip coupling method [34]; the concept of the L-shaped probe is extended to accommodate a microstrip feedline without the process of drilling the substrate and soldering the L-shaped probe to the feedline. The use of a microstrip feedline can allow the array design using low-loss microwave substrates and inexpensive PCB substrates. The second design is based on the T-shaped probe coupling [67], which allows the vertical arm to point in a direction orthogonal to both arms of the original L-shaped probe. The feeding probe appears as a letter “T” when examined from the side view. Details of the two feeding techniques are discussed below.

Figure 21. Far-pol radiation patterns of the two-T-probe-coupled patch antenna. (From Mak et al. [67], reprinted with permission from IEE.)

2.5.2.1. L-Strip-Coupled Patch Antenna.

A single-layer patch antenna coupled by an L-shaped strip is shown in Fig. 18. A rectangular patch, with $W \times L = 30 \times 25$ mm, is designed to operate at $f_0 = 4.5$ GHz. The air substrate has a thickness of $H = 8.3$ mm. A $50\text{-}\Omega$ microstrip feedline is etched on a microwave substrate ($\epsilon_r = 2.33$) of thickness $h = 1.6$ mm, which is located symmetrically with respect to the patch. A stepped feedline, referred to as an “L-shaped strip,” is introduced at the end of the $50\text{-}\Omega$ microstrip feedline. The width of the L-shaped strip is chosen to be the same as that of the feedline. Moreover, referring to Fig. 18b, the vertical and horizontal portions of this L-shaped strip, with dimensions $a = 5$ mm and $b = 10$ mm,

Figure 22. Configuration of a dual-polarized stacked-patch antenna with aperture-coupled feed. (From Edimo et al. [70], reprinted with permission from IEEE.)

respectively, excite the TM_{01} mode of the patch by electromagnetic coupling. Note that the horizontal portion of the L-shaped strip is supported by a foam material ($\epsilon_r \approx 1$) while the vertical portion is located under the patch at an inset distance $S = 1$ mm from the edge of the patch. The VSWR and gain (copolarization gain and cross-polarization gain) are measured. A wide bandwidth of up to 49% ($VSWR \leq 2$) and 7 dBi gain are achieved, details can be found in Ref. 34.

2.5.2.2. T-Shaped Probe-Coupled Patch Antenna. The second feeding method derived from the idea of the L-shaped probe is the T-shaped probe [67]. A single patch coupled by two identical T-shaped probes is discussed in this section. The geometry is shown in Fig. 19. The objective here is to improve the radiation performance by cancellation of unwanted probe radiation [68], caused by the vertical arm when using only one probe, without reducing the achievable bandwidth.

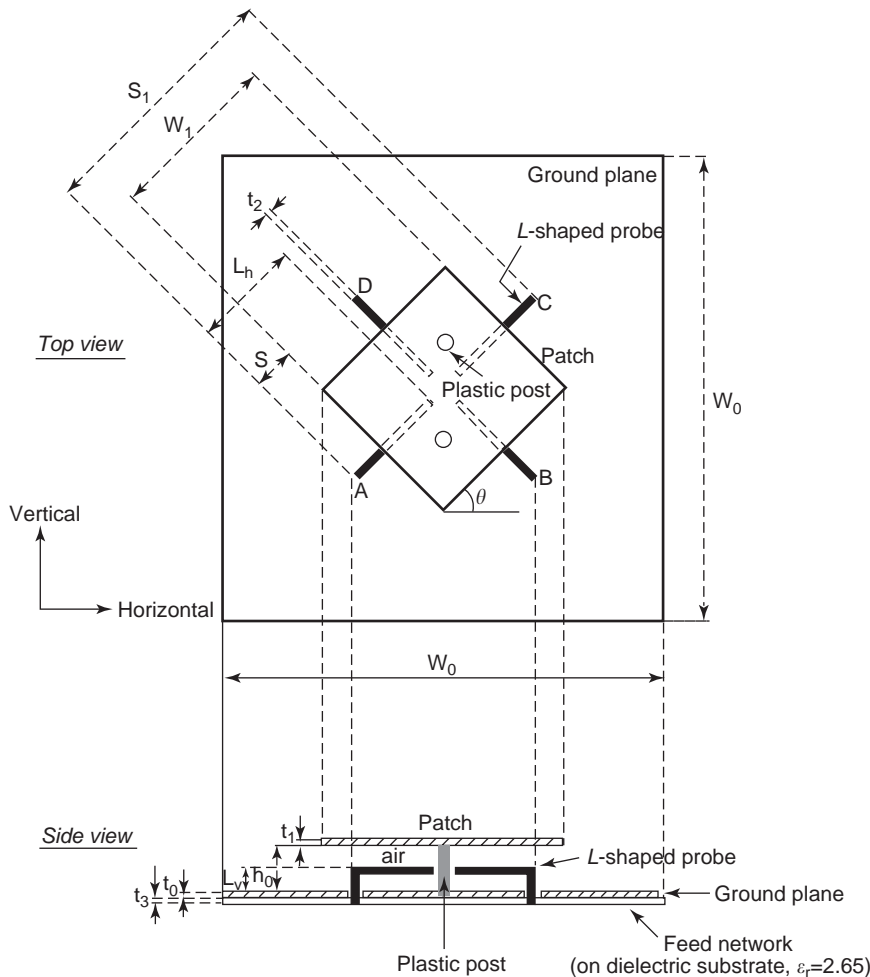

Figure 23. Geometry of a dual-polarized antenna with a dual feed. (From Wong et al. [71], © 2004 IEEE.)

(Unit: mm, $t_0=2$, $t_1=2$, $t_2=2$, $t_3=1.5$, $h_0=17$, $L_v=9$, $W_0=180$, $W_1=62$, $L_h=38$, $S=15$, $S_1=92$, $\theta=45^\circ$)

Figure 24. Outlook of feed network. (From Wong et al. [71], © 2004 IEEE.)

In Fig. 19, a microstrip feedline, with a quarter-wavelength transformer designed to operate at 4.5 GHz, is etched onto a dielectric substrate of thickness $h = 1.6$ mm and $\epsilon_r = 2.33$. Two identical T-shaped probes, $T_v = 5.6$ mm and $T_h = 9$ mm, are connected to the feedline below the ground plane and separated by $\lambda_g/2$, where λ_g is the guide wavelength at 4.5 GHz. A rectangular patch of dimensions 30×25 mm is located at a height of $H = 6.6$ mm. Also, the position of the patch is such that the two T-shaped probes are inset the same distance S from the patch edges and are symmetric with respect to the y axis, as shown in the top view. In addition, because of the $\lambda_g/2$ separation, the two T-shaped probes simultaneously excite the same TM_{01} mode of the patch.

Figure 20 shows the variations of VSWR with frequency, the broadside copolarization gain and the cross-polarization gain in the H plane with $\theta \approx 45^\circ$, together with that using one single T probe [67]. It is seen from the figure that both antennas have impedance bandwidth ($VSWR \leq 2$) of around 40%. Also both antennas have copolarization gain greater than 6.5 dBi across most of their bands of operation, and the patch with a single T probe has an average gain of 7 dBi. Most importantly, by using two T probes to excite a single patch, the cross-polarization in the H plane is significantly suppressed and is

Figure 25. Isolation of dual-polarized L-probe-fed patch antenna with and without dual feed. (From Wong et al. [71], © 2004 IEEE.)

Figure 26. Measured SWR against frequency for dual-polarized L-probe-fed patch antenna with dual feed. (From Wong et al. [71], © 2004 IEEE.)

20 dB or more below the copolarization gain between 4.2 and 5.15 GHz.

The far-field radiation patterns at 4.5 GHz are shown in Fig. 21. It can be observed that the copolarization patterns in the H plane are symmetric about the broadside direction and have low backlobe radiation. Also, the cross-polarization patterns in the E plane are well below -25 dB. Moreover, with the use of the additional out-of-phase T-shaped probe, the dent in the E plane (when using a single T) disappears and the E -plane copolarized pattern becomes more symmetric. The H -plane cross-polarized pattern has also been effectively suppressed to less than -20 dB in all directions.

3. DUAL-POLARIZED WIDEBAND PATCH ANTENNA

3.1. Dual-Polarized Aperture-Coupled Stacked-Patch Antenna

A dual-polarized aperture-coupled stacked-patch antenna is shown in Fig. 22. Two square stacked patches are fed by two crossed and stacked microstrip lines through two crossed and nonresonate slots in the ground plane. A thin substrate is placed between the microstrip lines to enhance the port decoupling. The use of the stacked-patch design is to obtain a wideband operation [69]. By applying two orthogonal crossed slots located beneath the center of the patch, symmetric far-field copolarization patterns are achieved and high isolation can be obtained [70]. This structure of dual-polarized patch antenna yields about 30% impedance bandwidth (for $VSWR \leq 2$) and around 28 dB isolation across the operating bandwidth.

3.2. A Dual-Polarized L-Probe-Coupled Patch Antenna

A square patch antenna can be excited with $\pm 45^\circ$ polarizations by using only two orthogonal L-shaped probes. However, this antenna has poor input port isolation due to strong coupling between the two vertical arms of the L probes. To tackle this problem, a dual-feed concept is introduced here to improve the isolation.

A modified dual-polarized patch antenna coupled by two pair of L-shaped probes is shown in Fig. 23. The

Figure 27. Measured far-field patterns at 1.8 GHz: (a) port 1; (b) port 2. (From Wong et al. [71], © 2004 IEEE.)

antenna employs a pair of L probes to excite one polarization, say, $+45^\circ$ polarization. Then, another pair excites the -45° polarization. The operating center frequency is $f_0 \approx 1.8$ GHz. The patch, which is made of aluminum with dimensions of $W_1 = 62$ mm ($0.37\lambda_0$) \times $W_1 = 62$ mm ($0.37\lambda_0$) \times $t_1 = 2$ mm ($0.012\lambda_0$), is supported by two plastic posts and is placed $h_0 = 17$ mm ($0.1\lambda_0$) above the ground plane.

Four copper L-shaped probe feeds with radius of 1 mm are located below the patch and are connected to a feed network. Each probe is designed to have an input impedance of $50\ \Omega$. The horizontal and vertical lengths of each probe are $L_h = 38$ mm ($0.22\lambda_0$) and $L_v = 9$ mm ($0.05\lambda_0$), respectively. As shown in the figure, the four L-shaped probes are located at points A , B , C , and D with $AB = BC = CD =$

Figure 28. Configuration of a dual-polarized patch antenna array with surrounding metallic walls. (From Wong et al. [71], © 2004 IEEE.)

(Unit: mm, $t_0=2$, $t_1=2$, $t_3=1.5$, $h_0=22$, $h_1=9$, $h_2=30$, $W_0=180$, $W_2=300$, $S_3=133$)

DA. Probes A and C are excited with 180° phase difference, while probes B and D are also excited with antiphase. Probes A and C are used to excite the $+45^\circ$ polarization, while probes B and D are for the -45° polarization. Figure 24 shows the outlook of feed network that has a dielectric substrate of $\epsilon_r = 2.65$.

3.2.1. Experimental Results. Figure 25 shows measured results of S_{21} for both antennas with or without the dual-feed. It is observed that across the GSM1800 operating bandwidth from 1.71 to 1.88 GHz, the S_{21} of the antenna without the dual feed is about -19 dB and the corresponding value of the antenna with the dual feed is less than -30 dB. The 10 dB improvement is contributed by the dual feed suppression technique. The VSWR of the antenna with the dual feed (Fig. 26) is less than 2 in the frequency range from 1.56 to 1.99 GHz, and an impedance bandwidth of 23.8% is obtained. The VSWR is less than 1.5 from 1.66 to 1.94 GHz, and a 15% impedance bandwidth is obtained that is wide enough to cover the GSM1800 bandwidth.

The measured far-field patterns at 1.8 GHz for the antenna with dual feed are shown in Fig. 27. The 3 dB beamwidths are 61° and 62° in the vertical and horizontal planes, respectively, for the $+45^\circ$ polarization. The corresponding values for the -45° polarization are 62°

and 60° . The backlobe levels for both $+45^\circ$ and -45° polarizations are about -15 dB, which may be quite high. This is due to the use of a relatively smaller ground plane (180×180 mm) in the measurement. The antenna has the average gain of 8.5 dBi.

3.3. Dual-Polarized L-Probe Antenna Array

A basic element of a dual-polarized L-probe patch antenna has been presented in Section 3.2. Although the single element can have good self-isolation, in the array environment, the existence of coupling between array elements results in poor input port isolation. To solve this problem, we [71] also introduced techniques to enhance input ports isolation by reducing coupling between elements. To enhance the isolation of a dual-polarized patch antenna array, one solution is to use metallic walls surrounding each element [71]. The function of the walls is to act as a barrier, which avoids coupling between different elements. The configuration of a dual-polarized patch antenna array with surrounding metallic walls is shown in Fig. 28. The separation between two elements is 133 mm ($0.8\lambda_0$). For each element, a square aluminum patch with thickness of 1 mm and lengths of 58 mm is coupled by four identical L-shaped probes located at each corner of the patch. The patch is supported by plastic posts and placed 22 mm above the ground plane. Each probe with radius of 1 mm, vertical

Figure 29. VSWR of antenna array with metallic walls surrounding elements. (From Wong et al. [71], © 2004 IEEE.)

length of 9 mm, and horizontal length of 38 mm is placed 13 mm below the patch. Each probe is designed to have a characteristic input impedance of $50\ \Omega$. Metallic walls with thickness of 2 mm surround the patch and act as an open-ended cavity with dimensions of $120 \times 120 \times 30$ mm. The size of ground plane is 180×300 mm. All L-shaped probes are connected to the feed network, and placed underneath the ground plane. Ports 1 and 2 are the input ports of the $+45^\circ$ and -45° polarizations, respectively.

3.3.1. Results. Measured results of S_{11} , S_{12} , and S_{22} for the antenna array are shown in Figs. 29 and 30. As seen in Fig. 29, the impedance bandwidth is 23.8% from 1.50 to 1.93 GHz, for $\text{VSWR} \leq 2$, and is 12% from 1.66 to 1.89 GHz for $\text{VSWR} \leq 1.5$. Across the frequency range from 1.71 to 1.88 GHz, the value of S_{12} is less than -30 dB as shown in Fig. 30. This indicates that the vertical metallic walls are able to reduce the coupling between different elements. The measured far-field patterns for the center frequency of 1.8 GHz are shown in Fig. 31. The 3 dB beamwidths are 31° and 64° in the vertical and horizontal planes, respectively,

for the -45° polarization. The corresponding values for the $+45^\circ$ polarization are 30° and 65° . The backlobe levels for both $+45^\circ$ and -45° polarizations are about -25 dB. The performance of this antenna array is suitable for using as base station antennas in mobile communication systems.

3.4. Dual-Polarized Patch Antenna with Hybrid Feeding Mechanism

A hybrid feeding mechanism for dual-polarized patch antennas have been proposed [72,73]. They combine an aperture coupling feed [15–17] and a capacitive coupling feed [37–39] to enhance the isolation between input ports. One of these hybrid dual-polarized patch antennas [72] is discussed here. The geometry of the antenna is shown in Fig. 32. The square patch, separated from the ground plane by a thick foam substrate, is fed by two perpendicular strip-lines etched on the feed layer, one through a small circular hole and the other through a near-resonance aperture formed in the upper ground plane. These two lines have

Figure 30. Isolation of antenna array with metallic walls surrounding elements. (From Wong et al. [71], © 2004 IEEE.)

Figure 31. Measured far-field patterns at 1.8 GHz: (a) port 1; (b) port 2. (From Wong et al. [71], © 2004 IEEE.)

characteristic impedance $Z_c = 50 \Omega$. At port 1, an L-shaped probe is connected at the end of the line via the small circular hole to cancel the inductance introduced by the thick substrate. At port 2, an open-ended stub is needed to tune out the large inductive reactance delivered to the feedline by the aperture.

3.4.1. Measured Results. Figure 33 shows the measured VSWR and input port isolation of the antenna. It is ob-

served that, for $VSWR \leq 1.5$, the frequency range is 1.68–2.06 GHz, or $BW = 20.5\%$ for port 1 and 1.59–2.03 GHz, $BW = 24.9\%$ for port 2, respectively. Over the bandwidth, input port isolation is below -25 dB. The radiation patterns at 1.8 GHz for the two ports are shown in Fig. 34. The 3 dB beamwidths for the L-probe coupling case (port 1) are 70° and 71° in the E and H planes, respectively. The corresponding values for the aperture-fed case (port 2) are 60° and 72° , respectively. The measured gain at each of the

(Unit: mm, $H1 = 10$, $Lh = 34$, $Lv = 12$, $La = 48$, $Wa = 1$, $Ls = 10$, $d1 = 30$, $H2 = 1.6$, $H3 = 18$, $PL = PW = 59.5$, $d2 = 8$)

Figure 32. Antenna geometry. (From Guo et al. [72], © 2002 IEEE.)

two ports is greater than 6.0 dBi over the bandwidth. It can be observed that the level of backradiation is high, which is due to a relatively small ground plane used in the measurement and can be reduced through the use of a larger ground plane. The techniques described in Refs. 74 and 75 are also the efficient ways to reduce backradiation. The stripline feed structure can reduce backradiation considerably. On the other hand, backradiation from the aperture is trapped between the upper and lower metallic planes, resulting in the appearance of higher modes, which enhances the cross-polarization components. It is seen in Fig. 34 that the cross-polarization is quite high. The cross-polarization and efficiency can be improved with the use of shorting pins between the two ground planes

[76]. The high cross-polarization can also be overcome in the array design using a balanced feed mechanism [77].

4. MINIATURE WIDEBAND PATCH ANTENNAS

Extensive studies have been dedicated to size reduction techniques of microstrip patch antennas [78–81]. Several techniques have been proposed to reduce the size of the conventional half-wave patch. One approach involves the use of expensive high-dielectric-constant materials [82]. Other approaches are to use either a shorting (short-circuiting) wall [83,84] or a shorting pin [78–81,85–87] or various methods to increase the current pathlength flowing on the patch [88]. However, a narrow bandwidth of less than 6% ($VSWR \leq 2$) is achieved on these designs. In this section, we will summarize several designs of the miniature patch antenna with bandwidth enhancement. Bandwidth enhancements of small patch antennas with more than 10% ($VSWR \leq 2$) impedance bandwidth have been reported in a number of papers. The designs can be divided into two major categories, one based on the quarter-wave patch (shorting wall) structure and the other one based on the shorting pin structure.

4.1. Wideband Patch Antennas Design Based on Quarter-Wave Patch Structure

We know that placing a short circuit at the zero electric field line of a half-wave rectangular patch can reduce the size of the patch since half of the patch can be removed. The narrow bandwidth of only about 6% ($VSWR \leq 2$) is achieved on this quarter-wave patch antenna.

Figure 33. Measured reflection and coupling coefficients. (From Guo et al. [72], © 2002 IEEE.)

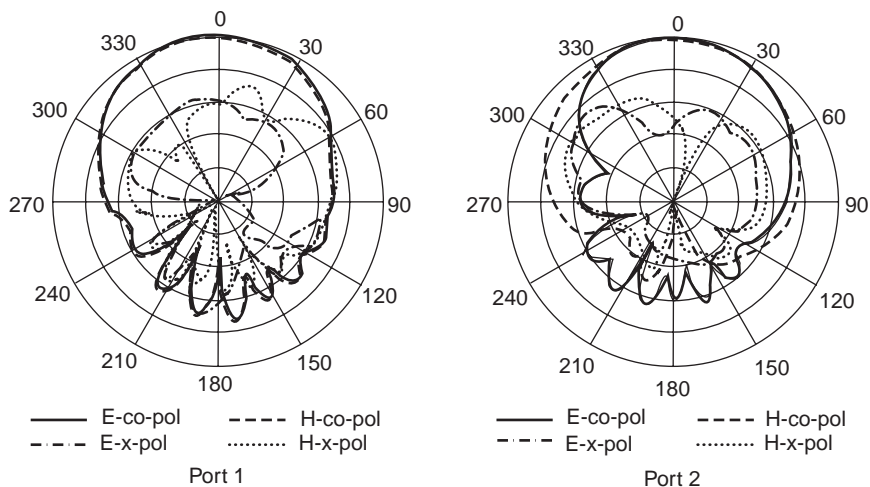

Figure 34. Measured patterns for ports 1 and 2 at 1.8 GHz, 10 dB/div. (From Guo et al. [72], © 2002 IEEE.)

4.1.1. Quarter-Wave Patch with Short-Circuiting Pin.

Figure 35 shows the conventional quarter-wave patch antenna and the quarter-wave patch antenna with shorting pin. By applying a shorting pin, as much as 20.7% bandwidth is achieved on the quarter-wave patch antenna [89]. The patch size is 30 mm (L) \times 20 mm (W), with one of the longer edge short-circuited to the ground via a short-circuiting wall. The feed position is $d_f = 5.5$ mm away from the shorting wall, and the feed radius is $r_f = 0.5$ mm. The shorting pin of radius $r_s = 0.5$ mm is placed $d_s = 11$ mm away from the open edge.

Figure 36 shows the VSWR of the quarter-wave patch antenna with shorting pin for different substrate thickness. The substrate thickness (h) varies from 3 mm ($0.375\lambda_0$) to 9 mm ($0.837\lambda_0$). The resonant frequency decreases when the substrate thickness increases. The bandwidth varies from 9% when $h = 3$ mm ($0.375\lambda_0$) at 3.76 GHz to 20.7% when $h = 9$ mm ($0.837\lambda_0$) at 2.79 GHz, where the feed location has varied in order to obtain the widest bandwidth. Table 1 summarizes the feedprobe location d_f , shorting pin location d_s , feedprobe radius r_f , and shorting pin radius r_s .

Figure 37 shows the measured radiation pattern when $h = 9$ mm. It is observed that the shorting wall leads to asymmetric radiation pattern and causes the $\phi = 0^\circ$ plane copolarized radiation pattern (E_θ) tilting away from the broadside direction, which is similar to the quarter-wave patch antenna. Also, the radiation of the shorting wall and

the shorting pin cause the cross-polarized field (E_ϕ) in the $\phi = 90^\circ$ plane to increase, and this becomes greater when the substrate thickness h is increased. This antenna achieves a gain of more than 3 dBi when the substrate thickness varies from $h = 3$ to 9 mm. Table 1 summarizes the performance of the antenna with different substrate thicknesses.

4.1.2. Shorted Two-Layer Patch Antennas.

The design of this type of antennas is based on the two-layer patch antenna. A shorting wall is placed at the line of symmetry of this two-layer patch antenna as shown in Fig. 38a. Figures 38b–38d show different configurations of the short-circuited two-layer patch antennas. The differences among the three antennas are the upper patch shape and the width of the shorting wall. The impedance bandwidth achieves more than 8% ($VSWR \leq 2$) in all designs [90–92].

The projection dimensions of the antenna are, width $W = 17.5$ mm and length $L = 17.5$ mm. The substrate between the upper patch and the lower patch has a thickness of $h_1 = 2$ mm. The antennas are excited in the TM_{10} mode by a coaxial feed, where the feed position is 13.5 mm away from the radiating edge. The lower patch is held by a foam substrate of thickness $h_2 = 6$ mm. The area of the shorted two-layer patch antenna has been reduced by 92% when compared with the conventional rectangular patch. The bandwidth has been enhanced to 8.3%. In cases with higher resonant frequency, the bandwidth can attain 11%.

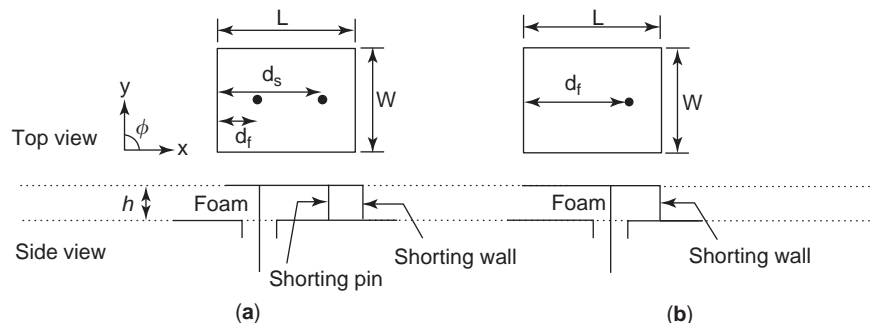

Figure 35. Geometry of quarter-wave patch antenna with short-circuiting pin. (From Mok et al. [89], reprinted with permission from IEE.)

Figure 36. VSWR of quarter-wave patch antenna with short-circuiting pin. (From Mok et al. [89], reprinted with permission from IEE.) (This figure is available in full color at [http://www.mrw.interscience.wiley.com/erfme.](http://www.mrw.interscience.wiley.com/erfme))

Figure 39 shows the radiation pattern of the shorted two-layer patch antenna. Again, a relatively high cross-polarization level is measured as a result of the radiation of the coaxial feed. It is also observed that the shorting wall leads to the asymmetric radiation pattern. As the size has been greatly reduced, the average gain obtained is only 1.5 dBi for the configuration shown in Fig. 38d.

4.1.3. Other Structures with Shorting Walls

4.1.3.1. L-Probe Feed. The L-shaped probe coupling technique [55] has been demonstrated to enhance the bandwidth of the traditional patch antennas in Section 2.5. Here, the bandwidth is enhanced by applying the L-probe coupling techniques incorporated with the quarter-wave patch antenna [93], as shown in Fig. 40.

The patch is excited in the TM_{01} mode by the L-probe fed. The patch size has length $L=0.17\lambda_0$, width $W=0.46\lambda_0$, and height $H=0.1\lambda_0$. Figure 41 shows the impedance bandwidth and gain, where the impedance bandwidth achieves as much as 39% ($VSWR \leq 2$) with an average gain of 7 dBi. The radiation pattern is stable across the passband and is radiated in the broadside direction with a beam squint of $\sim 15^\circ$ due to the asymmetric structure of the antenna.

4.1.3.2. Capacitive Coupling. This is another feeding method introduced to enhance the bandwidth of regular patch antenna, as discussed in Section 2.4.1, and also for the miniature patch antenna. A circular disk is connected to the coaxial probe, which acts as a capacitor patch to

compensate the inductance introduced from the feeding probe [94]. The structure is shown in Fig. 42.

The capacitance from the capacitor patch and the inductance from the coaxial probe are in resonance near the patch resonance. As shown in Fig. 43, there are two resonances: one from the series resonance by the feed mechanism and the other one from the patch. Once the resonances are close to each other, a bandwidth of 35% ($VSWR \leq 2$) is achieved. The average gain obtained is 4 dBi across the passband. The cross polarization level is as high as the copolar value.

4.1.3.3. Stacked Patch. In the stacked-patch techniques (Section 2.3.2), where the parasitic patch has a close resonance to the driven patch, the bandwidth is enhanced because the two resonators have two closely packed resonant frequencies. Several designs have been reported on the bandwidth enhancement of the quarter-wave patch antenna using stacked structure [95–97]. Figures 44a and 44b show two different configurations. The structure shown in Fig. 44a consists of a driven lower patch with a parasitic element placed horizontally on top of it, and a common shorting wall is connected to both patches [95,96]. The driven patch is larger than the parasitic patch. Figure 44b shows another configuration with a tilted parasitic patch where the shorted edge is common to the shorted edge of the driven patch [97].

Table 1. Parameter Study of the Quarter-Wave Patch Antenna with Short-Circuiting Pin

h (mm)	d_f (mm)	d_s (mm)	f_0 (GHz)	Bandwidth (%)	Maximum Gain (dBi)
3	5	8	3.75	9.1	3.4
4	3	10	3.88	12.4	3.5
5	2	14	3.6	17.2	3.3
6	3	16	3.49	19.2	3.7
7	3	18	3.17	20.2	4
8	5	20	2.95	20.7	3
9	3	22	2.79	20	3.6

Figure 39. Radiation pattern of short-circuited two-layer patch antennas. (From Chair et al. [91], reprinted with permission from IEE.)

Figure 45 shows the VSWR of the quarter-wave patch antenna shown in Fig. 44a. Two resonances come from two stacked resonators. A maximum of 30% of impedance bandwidth is obtained when the antenna thickness is $0.082\lambda_0$. Table 2 summarizes the relationship between the antenna thickness and the impedance bandwidth.

In the second design, based on the stacked-patch structure, the upper patch is tilted by 13.6° and the impedance

bandwidth enhances to 44% ($VSWR \leq 2$). Both radiation patterns are stable across the passband with a shift of 45° in the *E*-plane copolarized field. This is due mainly to the asymmetric structure of the quarter-wave patch antenna. The cross-polarization levels in the *H*-plane are quite high, which is typical of the behavior of the quarter-wave patch antenna. Figure 46 shows the radiation pattern of the titled upper patch antenna.

4.2. Wideband Patch Antenna Design Based on the Short-Circuiting Pin Structure

The use of a shorting pin to adjust the resonant frequency of a patch antenna is well known [98]. As the design is similar, but not identical, to the PIFA (planar inverted-F antenna) design, it was shown that the size of the traditional patch antenna can be reduced by adding a shorting pin near the feed location [81]. The size reduces by more than 80%; however, narrow impedance bandwidth is its drawback, and only 1.2% is achieved. With the use of a thicker substrate, around 0.06λ , the bandwidth can be improved to 6% [99].

4.2.1. Multiple Shorting Pins

4.2.1.1. Single-Layer Patch. In Ref. 99, by using more shorting pins, the bandwidth of the antenna can be increased. Figures 47a and 47b show the antennas structure with two and three shorting pins, respectively. The shape of the patch can be either circular or rectangular.

The bandwidth ($VSWR \leq 2$) with 7.9% and 9.4% is achieved when two and three shorting pins are used as shown in Figs. 47a and 47b, respectively. Unlike the single

Figure 45. VSWR of stacked quarter-wave patch antenna. (From Zaid et al. [96], © 1999 IEEE.)

shorting pin, the multiple shorting pins should be positioned further apart. However, the tradeoff is the increase in patch size. Since the number of the shorting pins increases, the performance of the antenna tends toward a quarter-wave antenna behavior. The *H*-plane cross-polarization level is still relative high because the presence of the shorting pins.

4.2.2. Slot-Loaded Patch

4.2.2.1. U-Shaped Slot. Lee [42] proposed a U-shaped slot on the patch to enhance the bandwidth of the traditional probe feed patch, as discussed in Section 2.4.2.2. In Ref. 100, a design combining the U shaped slot and the shorting pin that can reduce the size and enhance the bandwidth of the antenna is presented. The structure is shown in Fig. 48.

This patch antenna can achieve an impedance bandwidth to 30% ($VSWR \leq 2$) with substrate thickness of $0.084\lambda_0$. The size of the proposed antenna is only 21% of the original half-wave patch antenna. As the size of this antenna has been greatly reduced, the average gain is

around 2 dBi. Figure 49 shows the radiation pattern of the antenna. The radiation pattern is stable across the band, whereas the strongest radiation has tilted 52° away from the broadside direction. The high cross-polarization level in the H -plane is obtained due to the radiation of the shorting pin and coaxial feed.

4.2.2.2. Rectangular Notch. Figure 50 shows the shorted rectangular shaped slot semidisk microstrip antenna [101]. The antenna is designed be used in the IMT2000 (1885–2200 MHz), DECT (1880–1900 MHz), and Bluetooth wireless communication (2400–2483.5 MHz) systems.

With an appropriate rectangular slot size and locations of the shorting pins, the impedance bandwidth achieves 32.4% ($VSWR \leq 2$), which covers the frequency range from 1.86 to 2.58 GHz. The size reduction is due mainly to the shorting pin, which acts as an inductive loading. Enhancement of the electric fields by the thin rectangular slot can further reduce the size of the antenna. With the thin rectangular slot, the shorted semidisk patch antenna excites dual-frequency resonance. Therefore, a broad bandwidth is obtained by optimizing the size of the rectangular slot in order to merge the two resonances closely packed. Figure 51 shows the return loss and input impedance of the antenna. The thickness of the antenna is about $0.07\lambda_1$, and the size is less than $0.35\lambda_1$, where λ_1 is the wavelength at the lowest frequency (1.86 GHz).

5. CONCLUDING REMARKS

This article begins with the introduction of several common bandwidth-widening methods for microstrip antennas. Features of each method are discussed with

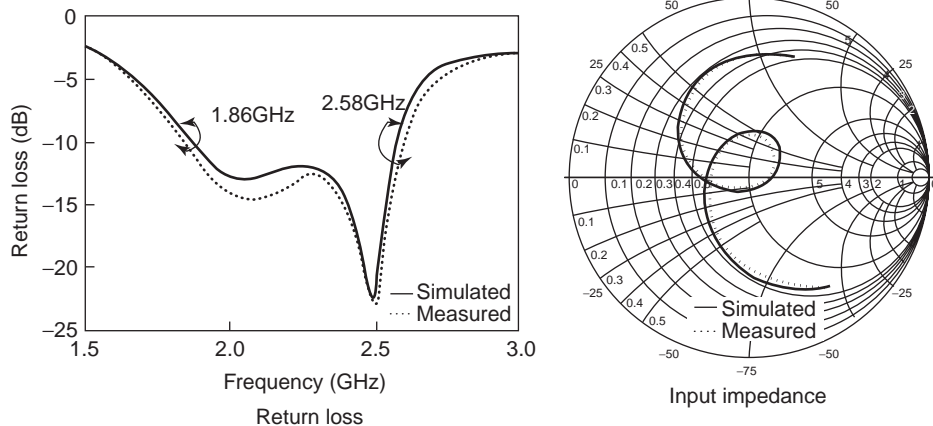

Figure 51. Return loss and input impedance of short-circuited notch patch. (From Wang et al. [101], © 2002 John Wiley & Sons, Inc.)

related illustrations and references. One of the basic means of increasing bandwidth is to employ electrically thick substrate with low dielectric constant, but the problem associated with increasing the substrate thickness is the increased reactance associated with the longer probe feed required. This limits the achievable bandwidth of microstrip antennas to only a few percent. Several wideband techniques designed by the authors are then discussed, including the advanced technique of employing the L-probe coupling technique. The article proceeds to discuss the wideband performance on two popular antenna designs: the wideband dual-polarized patch antennas designs and the wideband miniature patch antennas designs. Throughout the article, experimental results are presented and referenced.

MICROSTRIP ANTENNAS, COMPACT

KIN-LU WONG
National Sun Yat-Sen
University
Kaohsiung, Taiwan

1. INTRODUCTION

Microstrip antennas are usually formed by printing a conducting patch on a grounded dielectric substrate, and show the attractive features of lightweight, low profile, easy fabrication, and conformability to mounting hosts [1]. In order to meet the miniaturization requirement of mobile communication equipment [2], researchers have devoted much attention to compact microstrip antennas. Many related compact designs with broadband, dual-frequency, dual-polarized, circularly polarized, and gain-enhanced operations have been reported since the late 1990s [3]. This article addresses these innovative designs for compact microstrip antennas.

In Section 2, promising design techniques for reducing the size of microstrip antennas at a fixed operating frequency are introduced. These techniques include the uses of a high-permittivity substrate, a short-circuited patch, a slotted or meandered patch, a slotted or meandered slotted ground plane, and chip capacitor loading. Some reported compact microstrip antenna designs are described and discussed in this section. Section 3 discusses compact broadband microstrip antenna designs. The design techniques for achieving broadband operation with reduced antenna size are described. The related design techniques include the use of a short-circuited patch with a thick air-layer substrate, stacked shorted patches, chip resistor loading, and slot loading in the radiating patch or ground plane. Some interesting designs are presented.

Sections 4 and 5 present the designs of compact dual-frequency and dual-polarized microstrip antennas, respectively. Compact microstrip antennas with dual-frequency operation have attracted much attention recently (as of 2004), and many related designs have been available in

the open literature. The advances in compact circularly polarized (CP) microstrip antennas are considered in Section 6. A variety of design examples of the compact CP microstrip antennas are presented. The designs for achieving gain-enhanced compact microstrip antennas are included in Section 7. Some design examples are demonstrated. Finally, in Section 8, concluding remarks are made, and some future studies of compact microstrip antennas are addressed.

2. DESIGN TECHNIQUES FOR COMPACT MICROSTRIP ANTENNAS

2.1. Use of a High-Permittivity Substrate

In general, microstrip antennas are a half-wavelength structure and are operated at the fundamental resonant mode of TM_{01} or TM_{10} , with a resonant frequency given by (valid for a rectangular microstrip antenna with a thin microwave substrate)

$$f_0 \cong \frac{c}{2L\sqrt{\epsilon_r}} \quad (1)$$

where c is the speed of light, L is the patch length of a rectangular microstrip antenna, and ϵ_r is the relative permittivity of the grounded microwave substrate. From (1), it is known that the radiating patch of the microstrip antenna has a resonant length approximately proportional to $1/\sqrt{\epsilon_r}$, and the use of a microwave substrate with a larger permittivity thus can result in a smaller physical antenna length required at a fixed operating frequency. For comparison, taking two microstrip antenna designs with substrates of different relative permittivities of 3 and 27 as an example, the required length of the microstrip patch of the latter design will be only about one-third of that of the former one, as predicted from (1); that is, the required patch size of the latter design is only about 10% that of the former one. This result suggests that an antenna size reduction as large as about 90% can be obtained, if the design with $\epsilon_r = 27$ is used instead of the case with $\epsilon_r = 3$ for a fixed operating frequency.

2.2. Use of a Short-Circuited Patch

Figure 1 shows the geometry of a short-circuited rectangular microstrip antenna with a short-circuiting (shorting) pin. For the case that the short-circuiting pin is absent, the rectangular microstrip antenna is usually operated as a half-wavelength antenna, and the fundamental resonant frequency is given in (1). When there is a short-circuiting (SC) pin placed at $x = L/2$, $y = 0$ (center of the patch edge) and the feed position is chosen from the centerline (x axis), the first resonant frequency occurs at about $0.38f_0$ [4] (When there is more than one SC pin at the edge or a SC wall is used, the first resonant frequency occurs close to or at about $0.5f_0$. In this case, the short-circuited microstrip antenna is operated as a quarter-wavelength antenna.). This behavior suggests that the SC-pin-loaded rectangular microstrip antenna is operated with a resonant length less than one quarter-wavelength, and a greater reduced antenna size than the case with a SC wall can be obtained.

Figure 1. Geometry of a compact microstrip antenna with short-circuiting-pin loading.

With the SC-pin-loading technique, the antenna size reduction is due mainly to the shifting of the null voltage point at the center of the rectangular patch (excited at TM_{01} mode) and the circular patch (operated at TM_{11} mode) to their respective patch edges, which causes the short-circuited patches to resonate at a much lower frequency. Thus, at a given operating frequency, the required patch dimensions can be significantly reduced, and the reduction in the patch size is limited by the distance between the null voltage point in the patch and the patch edge. For this reason, compared to the case of SC-pin-loaded rectangular and circular patches, it is expected that an equilateral triangular microstrip patch excited at its fundamental mode (TM_{10} mode), where the null voltage point is at two-thirds of the distance from the triangle tip to the bottom edge of the triangle, will have a much larger reduction in the resonant frequency, when applying the SC-pin-loading technique. For comparison with the prediction, a compact triangular microstrip antenna with a SC pin loaded at the triangle tip was constructed and tested [5]. In this study, it is found that, for operating at about the same frequency, the side length of the compact (short-circuited) triangular microstrip antenna is only about 25% that of the conventional (regular-size) triangular microstrip antenna. This means a reduction of about 75% of the linear dimension of the antenna, or the size of the compact antenna is only about 7% of that of the conventional microstrip antenna. This reduction in antenna size is greater than those reported for the compact rectangular and circular microstrip antennas using the same technique.

2.3. Use of a Slotted or Meandered Patch

Compact operation of microstrip antennas can be obtained by embedding slots in the radiating patch or inserting slits at the boundary of the radiating patch. In this case, the effective surface current path in the radiating patch can be greatly lengthened or meandered, thereby leading to a large decrease in the antenna's fundamental resonant frequency. Figure 2 shows some slotted or meandered patches suitable for the design of compact microstrip antennas. In Fig. 2a, the embedded slot is a cross-slot, whose two

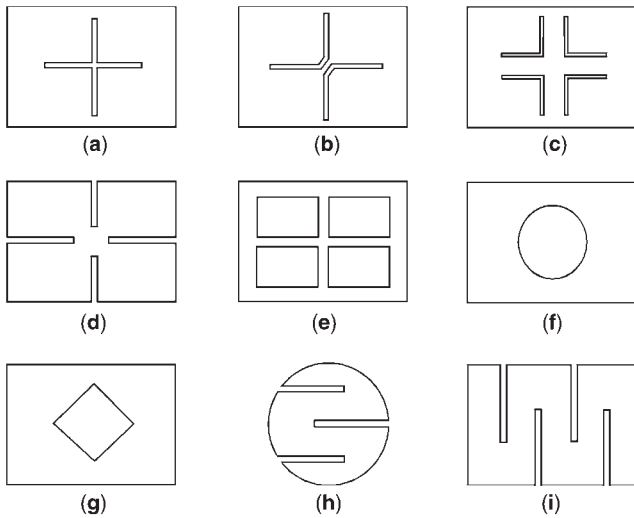

Figure 2. Some reported slotted or meandered patches suitable for the design of compact microstrip antennas.

orthogonal arms can be of unequal or equal lengths. This kind of slotted patch causes meandering of the patch surface current path in two orthogonal directions and is suitable for achieving compact circularly polarized radiation [6,7] or compact dual-frequency operation with orthogonal polarizations [8]. Similarly, the designs with a pair of bent slots [9] (Fig. 2b), a group of four bent slots [10] (Fig. 2c), four 90°-spaced inserted slits [11] (Fig. 2d), a perforated square patch or a square-ring patch with a cross-strip [12] (Fig. 2e), a circular slot [13] (Fig. 2f), a square slot [14] (Fig. 2g), and a group of meandering slits at the boundary of a circular patch [15] (Fig. 2h) or at the nonradiating edges of a rectangular patch [16] (Fig. 2i) have been successfully applied to achieve compact circularly polarized or compact dual-frequency microstrip antennas.

2.4. Use of a Slotted or Meandered Ground Plane

The technique shown in Section 2.3 for lengthening the excited patch surface current path to lower the antenna's fundamental resonant frequency can also be applied to the antenna's ground plane [17]. Figures 3a and 3b show, respectively, the geometries of compact microstrip antennas with a meandered ground plane and a slotted ground plane. The design in Fig. 3a is intended for achieving linearly polarized radiation for a compact microstrip antenna, while that in Fig. 3b can be used to generate dual linearly polarized waves for compact dual-polarized operation. In addition to a large decrease in the antenna's fundamental resonant frequency obtained, similar to the behavior described in Section 2.3, the impedance bandwidths of the compact microstrip antennas shown in Fig. 3 are all greater than that of the regular-size microstrip antenna. This behavior is due largely to the slots embedded in the antenna's ground plane, which effectively lowers the quality factor of the antenna. Moreover, an increase in the radiation efficiency of the antenna has also been obtained, and an enhanced antenna gain has been measured. From the results obtained in Ref. 17, for the case of using an FR4 substrate, the measured impedance bandwidth of the

Figure 3. Geometries of compact microstrip antennas with (a) a meandered ground plane and (b) a slotted ground plane.

design shown in Fig. 3a is about 1.85 times that (3.7 vs. 2.0%) of a corresponding conventional (regular-size) microstrip antenna without embedded slots in the antenna's ground plane, and a gain enhancement of 1.6 dBi (4.6 vs. 3.0 dBi) is also obtained. However, a larger front-to-back ratio (F/B) was also measured. From the measured results, the backward radiation is increased by about 7 dBi, compared to the conventional microstrip antenna. This increase in the backward radiation is contributed by the embedded slots in the ground plane and the decreased ground-plane size in wavelength.

2.5. Use of a Chip Capacitor Loading Technique

With the use of one or more chip capacitors loaded into the microstrip antenna (see Fig. 4), compact microstrip antennas can be obtained [18,19]. For the construction of this kind of chip capacitor-loaded microstrip antenna, a via hole at a suitable position is first drilled through the substrate. Then, a chip capacitor of suitable capacitance is loaded into the via hole, with its two ends connected to the radiating patch and the ground plane. It has been reported that a large frequency reduction of about 65% can be obtained using the chip capacitor loading technique [19]. Moreover, with the large frequency reduction obtained, the radiated power from the antenna is almost the same. This suggests that no significant change in the antenna

Figure 4. Geometry of a compact microstrip antenna with chip capacitor loading.

gain of such a compact microstrip antenna compared to a conventional microstrip antenna at a fixed operating frequency is expected.

3. COMPACT BROADBAND MICROSTRIP ANTENNAS

With the size reduction at a fixed operating frequency, the impedance bandwidth of a microstrip antenna is usually decreased. To obtain an enhanced impedance bandwidth, one can simply increase the antenna's dielectric substrate thickness to compensate the decreased electrical thickness of the substrate due to the lowered operating frequency or apply the compact broadband design techniques of using chip resistor loading, a short-circuited patch with a thick air-layer substrate, stacked short-circuited patches, and slot loading. These compact broadband design techniques are described in this section.

3.1. Use of a Chip Resistor Loading Technique

Figures 5a and 5b show two promising designs of chip-resistor-loaded microstrip antennas. Two different feed mechanisms using a probe feed and an inset microstrip-line feed have been implemented and analyzed [20]. This kind of microstrip antenna design is achieved by replacing the short-circuiting pin in a short-circuited microstrip antenna, as seen in Fig. 1, with a chip resistor of low resistance (generally $1\ \Omega$). In this case, with the same antenna parameters, the antenna size reduction obtained can be even greater for a design using SC-pin loading described in Section 2.2. Moreover, the obtained impedance bandwidth can be increased by a factor of six compared to a design using shorting-pin loading. For the case of using an FR4 substrate of thickness 1.6 mm and relative permittivity 4.4, the impedance bandwidth can reach 10% in the L-band operation [20]. However, as a result of the introduced ohmic loss of the chip resistor loading, the antenna gain is decreased, and is estimated to be about 2 dBi, compared to a shorted patch antenna with a SC pin.

3.2. Use of a Short-Circuited Patch with a Thick Air-Layer Substrate

Broadband short-circuited microstrip antennas fed by using a probe feed, a capacitively coupled feed [21] or an

Figure 5. Geometries of chip-resistor-loaded microstrip antennas with (a) a probe feed and (b) an inset microstrip-line feed.

L-probe feed [22] have been reported. Figure 6 shows typical geometries of this kind of short-circuited microstrip antenna. The design shown in Fig. 6a uses a simple probe feed with a long probe pin, which may introduce a large inductance to the input impedance of the antenna, thus resulting in poor impedance matching for frequencies

Figure 6. Geometries of short-circuited microstrip antennas with a thick air-layer substrate fed using (a) a probe feed, (b) a capacitively coupled feed, and (c) an L-probe or L-strip feed.

across the desired operating band. To solve the problem, the designs shown in Figs. 6b and 6c can be applied.

The design shown in Fig. 6b uses a capacitively coupled feed, which usually consists of either a circular or a rectangular metal plate to capacitively couple the electromagnetic energy from the source to the short-circuited radiating patch. By further incorporating a capacitive load to this short-circuited (SC) patch, it has been demonstrated that the overall length of the SC microstrip antenna with an air-layer substrate can be reduced from a quarter-wavelength to less than one-eighth wavelength [21]. Such a design with a volume of $20 \times 8 \times 4 \text{ mm}^3$ has been constructed, and an impedance bandwidth of 178 MHz centered at 1.8 GHz has been obtained, which meets the bandwidth requirement of the DCS (Digital Communication System) cellular communication system.

For the geometry shown in Fig. 6c, the capacitive coupling of the electromagnetic energy from the source to the SC patch is achieved by using an L probe or an L strip. It has been reported that, with the use of a foam substrate of thickness about $0.1\lambda_0$ (where λ_0 is the free-space wavelength of the center operating frequency), an impedance bandwidth of 39% can be obtained for an L-probe-fed SC microstrip antenna [22]. In this design, the L probe incorporated with the SC patch introduces a capacitance compensating some of the large inductance introduced by the long probe pin in the thick foam substrate, which makes it possible for achieving good impedance matching over a wide frequency range. However, a beam squint of about $15\text{--}60^\circ$ in the E -plane radiation pattern obtained has also been observed, which is probably attributed to the asymmetric current distribution of the shorted patch, due to the presence of the SC wall and the L probe.

3.3. Use of Stacked Short-Circuited Patches

The impedance bandwidth of a microstrip antenna is in general proportional to the antenna volume measured in wavelengths. However, by using two stacked short-circuited (SC) patches and making both patches radiate as equally as possible and have a radiation quality factor as low as possible, one can obtain enhanced impedance bandwidth for a fixed antenna volume [23]. Figure 7 shows two typical geometries of stacked SC microstrip antennas for broadband operation. In Fig. 7a, the two stacked SC patches have different short-circuiting (SC) walls. By selecting a proper distance between the two offset SC walls, one can achieve a wide impedance bandwidth for the antenna. For the geometry shown in Fig. 7b, a common SC wall is used for the two stacked SC patches. In this case, impedance matching is achieved mainly by selecting a proper feed position and a proper distance between the two SC patches. It should also be noted that, for the two geometries shown in Fig. 7, the upper SC patch can be considered to be a parasitic element coupled to the lower shorted patch, the driven element. In the design, the two SC patches are usually selected to have approximately the same, but unequal, dimensions. The substrates between the two SC patches and between the lower SC patch and the ground plane can be with air, foam or dielectric materials. Also, a partial SC wall or a SC pin can be used in

Figure 7. Geometries of stacked short-circuited microstrip antennas with (a) offset short-circuiting walls and (b) a common short-circuiting wall.

place of the offset SC walls or the common SC wall shown in Fig. 7.

3.4. Use of a Slot-Loading Technique

By embedding suitable slots in the radiating patch of a microstrip antenna, enhanced bandwidth with a reduced antenna size can be obtained [24]. A typical design with a slotted equilateral-triangular patch is shown in Fig. 8. It is found that, by embedding a pair of branchlike slots of proper dimensions, the first two broadside radiation modes of TM_{10} and TM_{20} of the equilateral-triangular microstrip antenna can be perturbed such that their resonant frequencies are both lowered and close to each other to form a wide-impedance bandwidth. In this design, the obtained impedance bandwidth is usually about equal to or less than 2.0 times that of a corresponding conventional microstrip antenna.

Figure 8. Geometry of a slotted equilateral triangular patch for the design of compact broadband microstrip antenna.

4. COMPACT DUAL-FREQUENCY MICROSTRIP ANTENNAS

Dual-frequency operation has been an important subject in microstrip antenna designs [25], and many such designs are known. To achieve dual-frequency operation for reduced-size or compact microstrip antennas, many promising designs have been reported [3]. Some typical compact dual-frequency designs are presented in this section. The two operating frequencies can have the same polarization planes [4,26–30] or orthogonal polarization planes [8,9]. In Section 4.1, two kinds of compact dual-frequency design techniques of using slot loading and SC-pin loading for the case with same polarization planes are introduced. In Section 4.2, the designs of compact dual-frequency microstrip antennas with orthogonal polarization planes are described.

4.1. With Same Polarization Planes

The design using a slot-loading technique is first described. Figures 9a and 9b show the promising geometries

Figure 9. Geometries of (a) a slot-loaded, meandered rectangular microstrip antenna and (b) a slot-loaded, bowtie microstrip antenna for compact dual-frequency operation with same polarization planes.

of a slot-loaded, meandered rectangular microstrip antenna [26] and a slot-loaded, bowtie microstrip antenna [27] for compact dual-frequency operation with same polarization planes. In the design shown in Fig. 9a, the radiation characteristics of the antenna operated in the TM_{10} and TM_{30} modes are similar and have the same polarization planes. These two modes can be excited with good impedance matching using a single probe feed, and owing to the meandering of the rectangular patch with slits inserted at the patch's nonradiating edges, the resonant frequencies f_{10} and f_{30} of the two operating modes can be significantly lowered, with the radiation characteristics slightly affected. This indicates that a large antenna size reduction can be obtained by using the present design compared to the slot-loaded patch without slits for fixed dual-frequency operation.

Based on its compactness in antenna size for a fixed operating frequency and the fact that its radiation characteristics are similar to those of a regular-size rectangular microstrip antenna, the bowtie microstrip antenna is also a good candidate for achieving compact dual-frequency operation. A typical design obtained by using a slot-loading technique is shown in Fig. 9b. In this design, a pair of narrow slots is embedded close to the radiating edges of the bowtie patch. The bowtie patch has a flare angle of α and a patch width of W . The linear dimension of the bowtie patch in the resonant direction is fixed to be L . A pair of narrow slots having dimensions of $1\text{ mm} \times l$ are embedded in the bowtie patch and placed close to the radiating edges at a distance of 1 mm . A single probe feed is located along the centerline of the bowtie patch. It is found that both the TM_{10} and TM_{30} modes are strongly perturbed, and that their respective resonant frequencies decrease with increasing flare angle of the bowtie patch. In addition, there exists a feed position for good impedance matching of the two operating frequencies. In addition to the compact dual-frequency operation obtained, the two operating frequencies have the same polarization planes, and good cross-polarization radiation is observed, especially for the E -plane radiation [27].

In Fig. 10, the geometries of short-circuited microstrip antennas for compact dual-frequency operation with same polarization planes are presented. These designs are achieved by applying the SC-pin loading technique [4,28–30]. By incorporating a SC pin in the centerline of a rectangular microstrip patch and exciting the patch through a suitable feed position also chosen from the centerline (see Fig. 10a), a good matching condition for both the first two resonant frequencies of the microstrip antenna can be obtained, which makes possible the dual-frequency operation of such a compact microstrip antenna through a single coax feed. The obtained frequency ratios between the two operating frequencies have been reported to be about 2.0–3.2 [4]. For the case of using a circular microstrip antenna (Fig. 10b), the frequency ratio obtained for the compact dual-frequency operation is about 2.55–3.83 [28], while that for a triangular microstrip antenna is about 2.5–4.9 [29]. As for the case of using a bowtie microstrip antenna (see Fig. 10d), it is possible to obtain a frequency ratio of about 5.0 [30].

Figure 10. Geometries of short-circuited microstrip antennas for compact dual-frequency operation with same polarization planes.

4.2. With Orthogonal Polarization Planes

In this section, rectangular microstrip antennas with promising embedded slots or inserted slits for achieving compact dual-frequency operation with orthogonal polarization planes [8,9] are described. Figure 11 shows four promising designs of this kind of compact dual-frequency microstrip antenna. In the design shown in Fig. 11a, the embedded slot is a cross-slot of equal arm lengths. It is found that, by increasing the cross-slot length, both the antenna's first two excited resonant frequencies (f_{10} and f_{01}) can be lowered with the frequency ratio almost unchanged. Note that the frequency ratio obtained is close to the aspect ratio of the rectangular patch. It has also been found that the reduction in the two excited resonant frequencies results in a patch size reduction of about 23% for a given dual-frequency design [8].

With the loading of a pair of bent slots, compact dual-frequency operation for a rectangular microstrip antenna has been reported [9]. Figure 10b shows the antenna geometry studied. It has been determined that, for fixed dual-frequency operation, the required patch size is only about 68% that of the design using a simple patch without bent slots. This corresponds to a 32% patch size reduction. The measured radiation patterns of the two operating frequencies were also measured. Although the excited patch surface current paths are significantly altered to lower the desired resonant frequencies, no special distortion of the radiation patterns is observed and the cross-polarization radiation is at an acceptable level.

Figure 10c shows the design of using four inserted slits at the patch edges of a rectangular patch [3]. The four inserted slits are of the same length. When the slit length increases, the resonant frequencies of the first two resonant modes are lowered, similar to the cases with a cross-slot (Fig. 11a) or a pair of bent slots (Fig. 11b).

Experimental results have shown that, for fixed dual-frequency operation, the patch size of the present design can be reduced to 56% of that using a simple patch without inserted slits [3]. With the use of four T-shaped slots (Fig. 11d), a patch size reduction of about 38% has been obtained [3].

5. COMPACT DUAL-POLARIZED MICROSTRIP ANTENNAS

This section describes the dual linearly polarized operation of a compact square microstrip antenna with a slotted radiating patch. It is demonstrated that such a slotted microstrip antenna with a group of four symmetric bent slots can perform excellent dual-polarized radiation [31], while the antenna size is significantly reduced for operation at a fixed frequency. Figure 12 shows the geometries of two possible designs. In Fig. 12a, the design is with bent slots parallel to the patch's central lines (denoted design A), while the design in Fig. 12b is with bent slots parallel to the patch's diagonals (design B). The square patch has a side length of L , and the four bent slots are of the same dimensions and have a narrow width of 1 mm. The two arms of each bent slot have the same length ℓ , and are perpendicular to each other. The feed arrangement in design A excites 0° (\hat{x} -directed) and 90° (\hat{y} -directed) linearly polarized waves, while the feed arrangement in design B radiates $\pm 45^\circ$ slanted linearly polarized waves.

For design A, experimental results [31] indicate that the resonant frequency is lowered by about 25% compared to that of a simple square patch without bent slots. This lowering in the resonant frequency corresponds to an antenna size reduction of about 44%. Furthermore, the antenna shows an input isolation (S_{21}) of less than -39.2 dB across the obtained impedance bandwidth, which is better than that (-31.9 dB) of a simple square patch. This

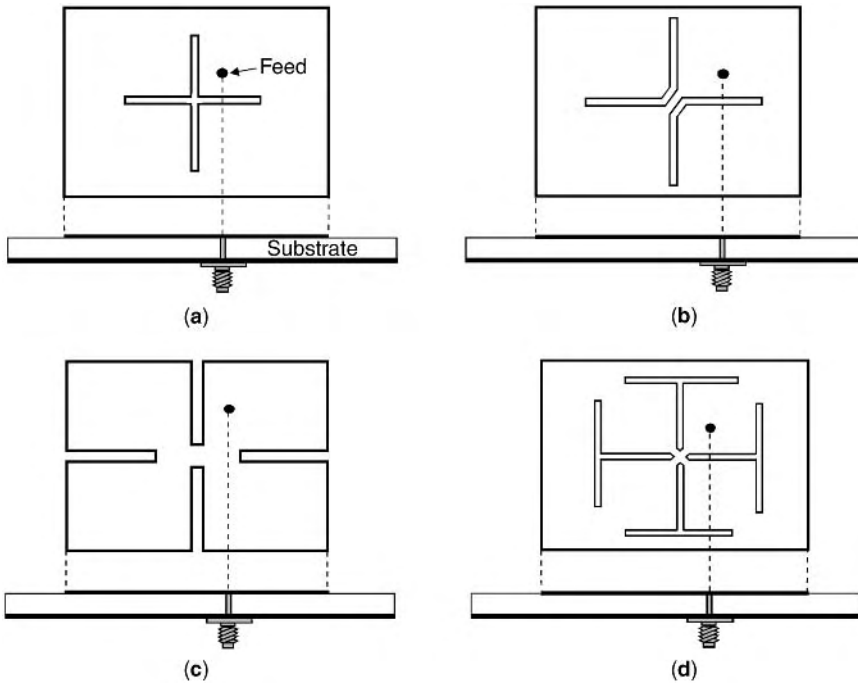

Figure 11. Geometries of slotted rectangular microstrip antennas for compact dual-frequency microstrip antennas with orthogonal polarization planes.

behavior suggests that improved input isolation can be obtained while resonant frequencies are significantly lowered for achieving compact operation.

For design B, an experimental study was also conducted. The side lengths of the square patch and microwave substrate used were the same as those in the study of design A. A reduction of about 16% compared to that of a simple square patch has been obtained [31]. This lowering in the resonant frequency corresponds to about 30% reduction in patch size for design B compared to the design with a simple square patch for fixed dual-polarized operation.

6. COMPACT CIRCULARLY POLARIZED MICROSTRIP ANTENNAS

Various CP designs with a compact patch size at a fixed operating frequency have been reported [3]. Figure 13 shows some reported patches suitable for the design of compact circularly polarized microstrip antennas. In Fig. 13a, the design is with a cross-slot of unequal arm lengths [32]. By incorporating a probe feed at 45° to the two arms of the cross-slot as shown in the figure, it has been found that CP radiation can be obtained at frequencies much lower than the fundamental resonant frequency of the antenna without a cross-slot. That is, for a fixed operating frequency, the antenna can perform CP radiation with a smaller antenna size than can a regular-size microstrip antenna without a cross-slot.

Figure 13b shows a square patch with four inserted slits for compact CP operation. Two pairs of the slits are cut in the centerlines of the square patch. Each pair of slits has equal lengths, but the total lengths of the two pairs of slits are unequal, which can split the resonant mode of interest into two orthogonal near-degenerate modes for CP radiation [11]. By embedding a group of four bent slots in a

corner-truncated square microstrip patch, a single-feed, compact circularly polarized microstrip antenna can easily be obtained. Figure 13c shows the geometry of the microstrip patch studied. The two arms of each bent slot are aligned parallel to the centerlines of the square patch. By increasing the arm length of the bent slots, the fundamental resonant frequency of the slotted square patch is significantly decreased. By further truncating a suitable size of the patch corners, the antenna can perform CP operation. Results show that, for a given CP operating frequency, the antenna can have a patch size reduction of more than 50% compared to the conventional CP design using a corner-truncated square patch without slots [10].

The method of producing single-feed CP operation of a square microstrip antenna by truncating a pair of patch corners used in Fig. 13c can also be applied to a modified square microstrip patch with four inserted slits of equal lengths to achieve compact CP operation with relaxed manufacturing tolerances. The geometry of such a microstrip patch is shown in Fig. 13d. The compactness of the proposed CP design is achieved because of the inserted slits at the patch corners of the square patch. These inserted slits result in meandering of the excited fundamental-mode patch surface current path, which effectively lowers the resonant frequency of the modified square patch, similar to the design using four inserted slits of different lengths at the boundary of a square patch (see Fig. 13b). Instead of using different slit lengths for CP excitation, which usually requires a very small slit length difference for the case of a large patch size reduction, the present design uses the perturbation of truncating a pair of patch corners, with the inserted slits to be of equal lengths. Experimental results show that the required size of the truncated corners for CP operation increases with increasing reduction in patch size [33]. This behavior gives the present design a relaxed manufacturing tolerance for

Figure 12. Geometries of compact dual-polarized square microstrip antennas: (a) design with bent slots in parallel with the patch's central lines (design A); (b) design with bent slots in parallel with the patch's diagonals (design B).

achieving a compact circularly polarized microstrip antenna.

Compact CP operation of the circular microstrip antenna with a cross-slot of equal arm lengths in the patch center and a pair of peripheral cuts at opposite sides of the patch boundary has been proposed and experimentally studied [6]. Figure 13e shows the geometry of the microstrip patch studied. Experimental results show that the present compact CP antenna has a center frequency about 10.4% lower than that of a corresponding regular-size antenna. This lowering of the center frequency corresponds to a patch size reduction of about 20% by using the present compact design in place of the regular-size design at a fixed operating frequency.

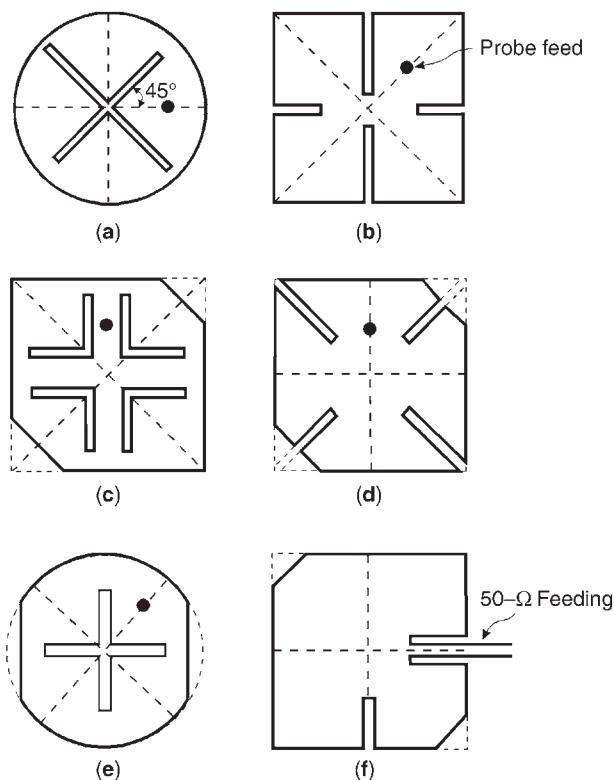

Figure 13. Some reported patches suitable for the design of compact circularly polarized microstrip antennas.

The CP design for exciting a circularly polarized microstrip antenna using a 50-Ω inset microstrip-line feed has been reported [34]. The proposed design is shown in Fig. 13f. In this design, a narrow slit is inserted at the patch edge. Because of the combined effects of the inset microstrip line and the inserted slit, two orthogonal near-degenerate modes for CP radiation can easily be excited. Also, the excited patch surface currents are meandered in the present design, and the CP operating frequency obtained is greatly lowered; thus, compact CP radiation can be achieved for the present design.

7. COMPACT MICROSTRIP ANTENNAS WITH ENHANCED GAIN

Most compact microstrip antenna designs show decreased antenna gain owing to the antenna size reduction. To overcome this disadvantage and obtain an enhanced antenna gain, several designs for gain-enhanced compact microstrip antennas with the loading of a high-permittivity dielectric superstrate have been demonstrated [35–37]. Figure 14 shows two promising designs of gain-enhanced compact broadband microstrip antenna. In Fig. 14a, a gain-enhanced compact broadband rectangular microstrip antenna is shown [35]. It has been demonstrated that, by adding a high-permittivity superstrate layer, the antenna gain of a chip-resistor-loaded microstrip antenna can be increased to about the same level of a conventional microstrip antenna. The radiating patch has

Figure 14. Geometries of gain-enhanced (a) compact broadband microstrip antenna and (b) compact circularly polarized microstrip antenna.

a 1-Ω chip resistor loaded at one of the patch edges. For operating at 1.84 GHz, a microwave substrate of $\epsilon_r = 3.0$ and $h_1 = 1.524$ mm is covered with a high-permittivity ceramic superstrate of $\epsilon_r = 79$ and $h_2 = 3.05$ mm. The superstrate thickness is determined by trying various thicknesses to optimize the enhanced gain with acceptable radiation patterns. Conventional and chip-resistor-loaded rectangular microstrip antennas were fabricated and measured for comparison. It is found that, at the fixed frequency $f = 1.84$ GHz, the patch size of the resistor and superstrate-loaded microstrip antenna can be reduced to 6.05% times that of a conventional microstrip antenna. The measured input impedance bandwidths (10 dB return-loss bandwidth) are 19.6 MHz (1.07%) for the conventional antenna, 145.6 MHz (7.91%) for the resistor-loaded antenna, and 120 MHz (6.52%) for the proposed resistor and superstrate-loaded antenna. The maximum relative received power for the proposed antenna is -46.9 dBm; that is, the proposed antenna has a net power increment of 10.4 dB compared with the resistor-loaded antenna (-57.3 dBm), and about 1.3 dB lower than that (-45.6 dBm) of the conventional antenna (Detailed results of the gain and radiation patterns can be found in Ref. 35.). A gain-enhanced compact microstrip antenna is thus achieved.

The design of a high-gain, compact microstrip antenna with CP radiation has been reported [36]. The small size of the microstrip antenna results from both the high-permit-

tivity superstrate loading and slits cut in the patch. In addition, the antenna gain is enhanced by choosing the superstrate thickness to be about one-quarter wavelength in the superstrate layer. A typical design of 30% lower antenna size (projection area) and 5.2 dB higher antenna gain compared to the conventional CP design has been obtained. Figure 14b shows the proposed compact circularly polarized microstrip antenna with an enhanced gain. The two pairs of unequal slits l_x and l_y ($l_x > l_y$) are cut in the patch to split the fundamental resonant mode into two orthogonal near-degenerate modes for CP operation. The case with $l_x > l_y$ and feed position shown in the figure is for right-hand CP operation. When the superstrates of various thicknesses are loaded onto the microstrip antenna, its resonant frequency is decreased, and the required slit lengths and 50-Ω feed position need to be readjusted to achieve good CP operation. High-permittivity ($\epsilon_{r2} = 79$) ceramic superstrates of various thicknesses were loaded onto a compact circularly polarized microstrip antenna. When no slits and superstrate are present, a square patch with dimensions 26.2×26.2 mm² has a fundamental resonant frequency of 2697 MHz. For antennas with various superstrate loadings, the slit length l_y is fixed and l_x is adjusted to achieve CP operation. For good impedance matching, the feed position is slightly varied along the patch diagonal. The results show that the microstrip antenna has a maximum relative received power when the superstrate thickness is about one-quarter of the wavelength of the wave propagating in the superstrate layer. Compared to a conventional CP design using a nearly square patch without slits and superstrate loading at the same operating frequency (2272 MHz), the proposed antenna has a 30% smaller patch size and a 5.21 dB greater antenna gain [36]. In addition, the results show that the CP bandwidth determined from 3-dB axial ratio is about 32 MHz or 1.4%, which is larger than that obtained for a conventional CP design.

8. CONCLUDING REMARKS

A variety of compact microstrip antennas with broadband, dual-frequency, dual-polarized, circularly polarized, and gain-enhanced operations have been presented. These compact microstrip antennas are attractive for applications in present-day wireless communication systems, in which portable communication products are becoming smaller and smaller. However, in order to be more competitive and attractive in practical applications, the reduction in the construction cost of compact microstrip antennas is yet an important topic for intensive studies.

To reduce the construction cost, it is most effective to use an inexpensive substrate such as the FR4 substrate for compact microstrip antennas. However, the FR4 substrate has a high loss, especially for higher operating frequencies, which usually leads to some degradation in antenna performance. Thus, some new dielectric materials with low cost and low loss for the substrate of compact microstrip antennas should be developed. Such substrate materials can make possible high-performance, low-cost compact microstrip antennas, which are very attractive for practical applications.

Another important topic for further studies is the ground-plane effects on compact microstrip antennas. Traditionally, compact or even regular-size microstrip antennas that have been studied are usually with the condition that the ground plane is symmetrically centered below the microstrip patch. However, for practical applications, the antenna may be required to be mounted on arbitrary positions on the ground plane of a wireless communication device, for example, along the edge of the ground plane of the system circuit board. In this condition, the effects of the ground plane on the performance of the compact microstrip antenna cannot be ignored. This is because the ground plane is an integral part of the compact microstrip antenna, and thus will greatly affect the impedance and radiation characteristics of the antenna. However, related studies on this issue are relatively scanty, and more efforts should be taken in this field of compact microstrip antenna designs.

1. THE BASIC MICROSTRIP STRUCTURE

The general geometry of microstrip is shown in Fig. 1. Fundamentals and design equations for its manufacture are discussed in the article, where the basic advantages are also described in comparison with other types of MIC and MMIC transmission lines. The most important dimensional parameters are the microstrip width w and the height h (equal to the thickness of the substrate). Also of main importance is the relative permittivity of the substrate ϵ_r . In RF and microwave applications the thickness t of the metallic, top conducting strip is generally of much lesser importance and may quite often be neglected. However microstrip lines on chip and on MCMs are relatively thick as a result of the need to keep resistance down while still achieving a high wiring density by keeping the width down. We shall consistently refer to the xyz coordinate system as shown in Fig. 1.

Some of the particularly useful characteristics of microstrip include the following:

1. DC as well as AC signals may be transmitted.
2. Active devices, diodes, and transistors may readily be incorporated (shunt connections are also quite easily made).
3. In-circuit characterization of devices is straightforward to implement.
4. Line wavelength is reduced considerably (typically by one-third) from its free-space value, because of the substrate fields. Hence distributed component dimensions are relatively small.
5. The structure is quite rugged and can withstand moderately high voltages and power levels.

Most of the material presented here has been developed from Edwards and Steer [1].

Figure 1. The general geometry of a microstrip line, including choice of coordinates.

2. QUASI-TEM MODE AND EFFECTIVE MICROSTRIP PERMITTIVITY

It is clear from Fig. 1 that microstrip involves an abrupt dielectric interface between the substrate and the air above it. Any transmission line that is filled with a uniform dielectric can support a single, well-defined mode of propagation, at least over a specified range of frequencies (TEM for coaxial lines, TE for waveguides, etc.).

Transmission lines that do not have such a uniform dielectric filling cannot support a single mode of propagation, and microstrip falls within this category. Although this is true, the bulk of the energy is transmitted along microstrip with a field distribution that quite closely resembles TEM; it is usually referred to as “quasi-TEM.” The detailed field distribution is quite complicated, but the main transverse electric field can be visualized as shown in Fig. 2.

Gupta et al. [2] have used Maxwell’s equations to convincingly demonstrate the necessity for longitudinal components of electric and magnetic fields. This is clearly inconsistent with a pure TEM or a TE propagating mode.

Representative views of the magnetic and electric field distributions are given in Fig. 3. (These are not precisely determined field contours, and they must be regarded only as diagrammatic illustrations of the situation.) The longitudinal components can be clearly seen, and these become increasingly significant as the frequency is raised.

From either of these diagrams, note the abrupt change in direction of the electric field line as it passes through the air–substrate interface. These fields have been analysed by a number of workers using various static techniques. We shall not study any of these techniques in detail here, but the results are powerful and significant for the circuit designer wishing to use microstrip. There are two reasons for this:

1. For the majority of microstrip lines suitable for MICs, the statically derived results are quite accurate where the frequency is below a few gigahertz.
2. At higher frequencies, up to the limits for the useful operation of microstrip, these “static” results can still be used in conjunction with frequency-dependent functions in closed formulas. This is developed in some detail later.

The earliest work concerning microstrip is generally accepted as that reported by Grieg and Engelmann [3]. Many other workers investigated basic characteristics of microstrip [4,5], but the major fundamental work on important and closely related parallel-strip transmission

Figure 2. Transverse cross section of microstrip, showing electric field only.

Figure 3. Three-dimensional views of approximate magnetic (a) and electric fields (partial view) (b) surrounding a shielded microstrip line. For simplicity here, only the electric field in the air is shown in (b).

lines was due to Wheeler [6]. This led to analysis and synthesis on the static TEM basis.

3. STATIC TEM PARAMETERS

The microstrip synthesis problem consists of finding the values of width w and length l corresponding to the characteristic impedance Z_0 , and electrical length θ (in degrees or radians) defined at the network design stage.

Initially a suitable substrate, of thickness h and relative permittivity ϵ_r , will have to be chosen. A wide range of substrates is available, suited to various types of

applications. Alumina is popular in many instances although LTCC (low-temperature cofired ceramic) tape is becoming increasingly important. Microstrip circuits are also designed on-chip (on-die) for MMICs and RFICs and then it is the relative permittivity and thickness of the semiconductor chip that form the starting data. A good example in this respect is semiinsulating GaAs. The choice of substrate, particularly “passive” substrates such as alumina, also depends on certain frequency limitations. The synthesis actually yields the normalized width-to-height ratio w/h initially, as well as an important quantity called the *effective microstrip permittivity* ϵ_{eff} . This quantity is unique to mixed-dielectric transmission-line systems and provides a useful link between various wavelengths, impedances, and propagating velocities. We shall shortly define the static TEM effective microstrip permittivity (ϵ_{eff}) precisely.

3.1. The Characteristic Impedance Z_0

For any TEM-type transmission line the characteristic impedance at high frequencies may be expressed in any one of three alternate forms:

$$Z_0 = \sqrt{\frac{L}{C}} \tag{1}$$

$$Z_0 = v_p L \tag{2}$$

$$Z_0 = \frac{1}{v_p C} \tag{3}$$

Note that both (2) and also (3) involve the phase velocity v_p of the wave traveling along the line. It is also recalled that this phase velocity is given by

$$v_p = \frac{1}{\sqrt{LC}} \tag{4}$$

When the substrate of the microstrip line is (effectively) removed, we have an air-filled line along which the wave will travel at c , the velocity of light in free space ($c = 2.99793 \times 10^8$ m/s). The characteristic impedance of this air-filled “microstrip” Z_{01} , is given by

$$Z_{01} = \sqrt{\frac{L}{C_1}} \tag{5}$$

where L remains unaltered by the change in dielectric constant and C_1 is the capacitance per unit length for this structure. Alternatively

$$Z_{01} = cL \tag{6}$$

$$Z_{01} = \frac{1}{cC_1} \tag{7}$$

Combining Equations (1), (6) and (7) yields the following very significant result:

$$Z_0 = \frac{1}{c\sqrt{CC_1}} \tag{8}$$

This means that we have the required characteristic impedance only if we can evaluate the capacitances per unit

length of the structure, with and without the presence of the dielectric substrate. One way in which this has been achieved will be outlined shortly.

3.2. The Effective Microstrip Permittivity ϵ_{eff}

For the air-spaced microstrip line, the propagation velocity is given by

$$c = \frac{1}{\sqrt{LC_1}} \tag{9}$$

and, dividing Eq. (9) by Eq. (4) and squaring, we obtain

$$\frac{C}{C_1} = \left(\frac{c}{v_p}\right)^2 \tag{10}$$

The capacitance ratio $C = C_1$ is termed the *effective microstrip permittivity* ϵ_{eff} , an important microstrip parameter. From (10), ϵ_{eff} is given by

$$\epsilon_{\text{eff}} = \left(\frac{c}{v_p}\right)^2 \tag{11}$$

Although this result has been derived on a static basis here, it is fundamentally important for microstrip and will be used again shortly, when v_p is taken to be frequency-dependent.

A useful relationship between Z_0 , Z_{01} , and ϵ_{eff} can be obtained by combining Eqs. (3), (7), (10), and (11). The result is

$$Z_0 = \frac{Z_{01}}{\sqrt{\epsilon_{\text{eff}}}} \tag{12}$$

that is

$$Z_{01} = Z_0 \sqrt{\epsilon_{\text{eff}}} \tag{13}$$

This expression is useful in several respects during microstrip circuit design procedures.

Upper and lower bounds can readily be found for ϵ_{eff} , in the static low-frequency limit, by considering the effects of very wide and very narrow lines as indicated in Fig. 4. For the very wide lines nearly all of the electric field is confined to the substrate dielectric, the structure resembles a parallel-plate capacitor, and therefore, at this extreme

$$\epsilon_{\text{eff}} \rightarrow \epsilon_r \tag{14}$$

In the case of very narrow lines the field is almost equally shared by the air ($\epsilon_r = 1$) and the substrate so

Figure 4. Microstrip lines: (a) extremely wide ($w \gg h$); (b) extremely narrow ($w \ll h$) lines.

that, at this extreme

$$\epsilon_{\text{eff}} \approx \frac{1}{2}(\epsilon_r + 1) \tag{15}$$

The range of ϵ_{eff} is therefore

$$\frac{1}{2}(\epsilon_r + 1) \leq \epsilon_{\text{eff}} \leq \epsilon_r \tag{16}$$

It may be convenient to express the effective microstrip permittivity as follows

$$\epsilon_{\text{eff}} = 1 + q(\epsilon_r - 1) \tag{17}$$

where the new quantity, the filling factor q , has the bounds

$$\frac{1}{2} \leq q \leq 1 \tag{18}$$

Wheeler [6,7] has evaluated this filling factor in detail.

3.3. Synthesis: The Width-to-Height Ratio w/h

The width-to-height ratio (w/h) is a strong function of Z_0 and of the substrate permittivity ϵ_r . Wheeler's results [7] are particularly useful in this respect, although it has been found that some modifications are necessary for high accuracy (within 1%) to be achieved [8]. Closed formulas for w/h are available [1].

3.4. Microstrip Wavelength and Physical Length

For any propagating wave, the velocity is given by the appropriate frequency-wavelength product. In free space we have $c = f\lambda_0$ and in microstrip the velocity is $v_p = f\lambda_g$. Substituting these products into (11), we obtain

$$\epsilon_{\text{eff}} = \left(\frac{\lambda_0}{\lambda_g}\right)^2 \tag{19}$$

or

$$\lambda_g = \frac{\lambda_0}{\sqrt{\epsilon_{\text{eff}}}} \tag{20}$$

where λ_0 is the free-space wavelength and λ_g is the wavelength of the dominant mode in the microstrip. More conveniently in practical design, where the frequency is given in gigahertz and denoted by F , the wavelength can be expressed directly in millimetres as follows:

$$\lambda_g = \frac{300}{F\sqrt{\epsilon_{\text{eff}}}} \text{ mm} \tag{21}$$

The physical length l of a microstrip line to yield a specified electrical length θ (in degrees) is easily determined. We begin with the well-known expression for the electrical length of a section of any transmission line of this physical length, as a function of the phase coefficient (in radians),

$$\beta l = \theta \tag{22}$$

and hence

$$\frac{2\pi l}{\lambda_g} = \theta \tag{23}$$

With θ in degrees this gives

$$l = \frac{\theta \lambda_g}{360} \tag{24}$$

Thus, with λ_g evaluated using (21), we can simply find l .

An important aspect to mention at this juncture is that all the way through we are specifically discussing open microstrip, whereas in practice the circuits will be shielded to some extent. Such shielding generally attracts more electric field into the airspace, above the substrate, and therefore a greater proportion of this field exists in air with relative permittivity 1. The effective permittivity is thereby decreased and the microstrip wavelength increases with the square root relationship (see equations above). So microstrip design lengths also increase. The closer the shielding gets to the microstrip lines, the greater this effect becomes.

4. DISPERSION AND ITS EFFECTS ON DESIGN

As we have seen in Section 3.2 above, because the electric and magnetic fields are in more than one medium (a non-homogeneous transmission line), as for the microstrip line shown in Fig. 1, the effective microstrip permittivity ϵ_{eff} is used. The characteristics of the nonhomogenous line are then more or less the same as for the same structure with a uniform dielectric of permittivity ϵ_{eff} .

Permittivity ϵ_{eff} changes with frequency as the proportion of energy stored in the different regions changes. This effect, called *dispersion*, causes a pulse to spread out as the different frequency components of the pulse travel at different speeds. Another way of looking at this situation is to observe that the phase coefficient is a nonlinear function of the phase (propagation) velocity. As a direct consequence, the microstrip wavelength λ_g is now a nonlinear function of frequency. Therefore, we must account for the dispersion effect if we are to design accurately at microwave frequencies.

Because of its importance in microstrip circuit design, over the years many researchers have analyzed and measured the basic microstrip structure and published dispersion results. Although intensive numerical analyses have been employed in several instances, using substantial computer power, currently much more convenient and useful closed-formulas are available that predict dispersion. All aim at determining the effective microstrip permittivity—but now as a nonlinear function of frequency $\epsilon_{\text{eff}}(f)$.

At DC there can be no dispersion, and all the static TEM expressions already given can be directly used. Theoretically, as the frequency approaches infinity (well into

sub-millimeter-wave region and beyond), $\epsilon_{\text{eff}}(f)$ approaches ϵ_r . This situation can be summarized as follows:

1. $\epsilon_{\text{eff}}(f)$ always increases with frequency.
2. $\epsilon_{\text{eff}}(f)(f \rightarrow 0) \Rightarrow \epsilon_{\text{eff}}$ (calculated using static TEM analysis)
3. $\epsilon_{\text{eff}}(f)(f \rightarrow \infty) \Rightarrow \epsilon_r$.

In addition to these three basic features, it is also noted that $\epsilon_{\text{eff}}(f)$ is asymptotic at both limits, and the fourth feature concerns phase velocity $v_p(f)$. This suffers inflection at some frequency close to the cutoff frequency f_c of the TE_1 surface wave. Therefore this fourth feature is $\partial^2 v_p / \partial f^2 = 0$ when $f = f_c$.

Several earlier researchers utilized all or most of these features to develop closed-form expressions for predicting microstrip dispersion. However, more recent work has resulted in more accurate formulas, notably from Kirschning and Jansen [9]. The approach adopted by these workers begins with a function used by most investigators in this area, as follows

$$\epsilon_{\text{eff}}(f) = \epsilon_r - \frac{\epsilon_r - \epsilon_{\text{eff}}}{1 + P(f)} \tag{25}$$

and the form of the denominator frequency function is

$$P(f) = P_1 P_2 \{ (0.1844 + P_3 P_4) 10 f h \}^{1.5763} \tag{26}$$

where

$$\left. \begin{aligned} P_1 &= 0.27488 + \left\{ \frac{0.6315 + 0.525}{(1 + 0.157 fh)^{20}} \right\} \frac{w}{h} \\ &\quad - 0.065683 \exp - \frac{8.7513w}{h} \\ P_2 &= 0.33622 \{ 1 - \exp(-0.03442 \epsilon_r) \} \\ P_3 &= 0.0363 \exp \left(- \frac{4.6w}{h} \right) \left[1 - \exp \left\{ - \left(\frac{fh}{3.87} \right)^{4.97} \right\} \right] \\ P_4 &= 1 + 2.751 \left[1 - \exp \left\{ - \left(\frac{\epsilon_r}{15.916} \right)^8 \right\} \right] \end{aligned} \right\} \tag{27}$$

These workers used computer-based matching in conjunction with the available hybrid-mode results (derived from full electromagnetic numerical computations) to force the correct asymptotic behavior of the function $P(f)$. An accuracy of better than 0.6% is claimed for all frequencies up to 60 GHz (although a full check appears to have been conducted up to only 30 GHz). The validity ranges are very wide:

$$\begin{aligned} 1 &\leq \epsilon_r \leq 20 \\ 0.1 &\leq \frac{w}{h} \leq 100 \\ 0 &\leq \frac{h}{\lambda_0} \leq 0.13 \end{aligned}$$

There are further formulations enabling the effects of dispersion in microstrip to be calculated at frequencies through millimeter waves. Although the last word has almost certainly not yet been stated in the literature on this subject, the position has been reached where reported accuracies are within 1% (of measurements and independent theoretical results over a wide range). Having said this, it must be recognized that care is always required in selecting an appropriate accurate dispersion expression.

5. OPERATING FREQUENCY LIMITATIONS FOR MICROSTRIP

As the signal frequency applied to an MIC (or an MMIC) is steadily increased, some characteristic frequency may be reached at which undesirable effects occur. Two possible spurious effects restrict the desirable operating frequencies: (1) the lowest-order TM mode and (2) the lowest-order transverse microstrip resonance. In practice, one of these modes will be experienced at some frequency lower than the other and will thus set the frequency limitation.

5.1. The TM-Mode Frequency Limitation

Vendelin [10] has indicated that the most significant modal limitations in microstrip are associated with strong coupling between the quasi-TEM mode and the lowest-order TM mode. In the cited paper Vendelin gives the main relationships quoted here (although the original analysis is due to Collin in Ref. 6 of Vendelin's paper).

We start with the substrate viewed as a dielectric slab, having the coordinate notation shown in Fig. 5. This slab is a fair approximation for the situation with narrow microstrip lines.

The analysis involves setting eigenvalues for air and substrate and solving these either graphically or using the computer. We will not pursue this analysis here, but the final result is given by Eq. (23) for the maximum "safe" frequency under these conditions:

$$f_{\text{TEM}1} = \frac{c \tan^{-1}(\epsilon_r)}{\sqrt{2\pi h} \sqrt{\epsilon_r - 1}} \quad (28)$$

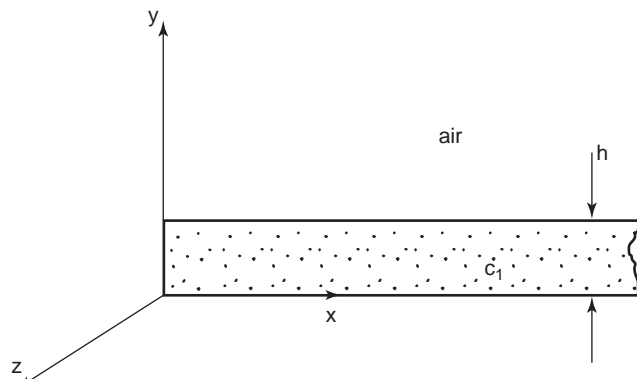

Figure 5. An (isotropic) substrate viewed as a dielectric slab, showing the nomenclature.

This is the frequency applying to strong coupling between the basic microstrip quasi-TEM mode and the TM mode.

In the important case of relatively narrow microstrip lines, where the relative permittivity is around 10 or greater, Eq. (28) tends toward

$$f_{\text{TEM}1} = \frac{106}{h\sqrt{\epsilon_r - 1}} \quad (29)$$

Using this equation, with thickness h directly substituted in millimeters, the frequency comes out directly in gigahertz.

The maximum restriction on usable substrate thickness is then easily obtained as

$$h = \frac{0.354\lambda_0}{\sqrt{\epsilon_r - 1}} \quad (30)$$

Care should be exercised in the use of these expressions, as Eq. (28) is more general and applicable to all types of substrates. Operating frequencies should be kept well below this maximum frequency. It is also recommended that substrates should be as thin as possible because Eq. (28) show that this makes the TM mode onset high. However, it should also be noted that thinner substrates result in lower Q factors, notably at lower frequencies.

5.2. The Lowest-Order Transverse Resonance in Microstrip

For a sufficiently wide microstrip line, a transverse resonant mode can exist that can also couple strongly to the quasi-TEM microstrip mode. At the cutoff frequency for this transverse resonant mode, the equivalent circuit is a resonant transmission line of length $(w + 2d)$, where d accounts for the microstrip side-fringing capacitance: $d = 0.2h$. In this situation a half-wavelength must be supported by the length $(w + 2d)$, stretching across the width of the microstrip. Setting down the simple equation for this transverse resonance and converting to the resonant frequency, we obtain

$$f_{\text{CT}} = \frac{c}{\sqrt{\epsilon_r}(2w + 0.8h)} \quad (31)$$

This is the maximum operating frequency under this limitation and it applies especially to relatively wide microstrips.

Vendelin [10] has indicated that slots, introduced into the metal strip, can suppress the transverse resonant mode. However, this may not always be practicable (e.g., when short stubs are involved), and it should be checked by calculating from Eq. (31), whether the transverse resonance might be excited. Sometimes a change in the circuit configuration will enable the offending wide lines to be avoided altogether.

In practice it is essential to check whether either the Eq. (28) or Eq. (31) frequency limitation will apply to every section of microstrip in a first-cut circuit design. The design must then be altered accordingly such that the operating frequencies remain below the set conditions as defined above.

5.3. Power Losses and Related Effects

Four separate mechanisms can be identified for power losses and parasitic effects associated with microstrip lines:

1. Conductor losses
2. Dissipation in the dielectric of the substrate
3. Radiation losses
4. Surface-wave propagation

The first two items are dissipative effects, whereas radiation loss and surface-wave propagation are essentially parasitic phenomena.

5.3.1. Conductor Losses. These losses occur as a result of the current conduction effects in the metal of the microstrip line and depend on several parameters associated with the microstrip and are probably best embodied in the expressions originally due to Hammerstad and Bekkadal [11]. The basic expression given by these workers is

$$\alpha_c = 0.072 \frac{\sqrt{f}}{wZ_0} \lambda_g \text{ dB/microstrip wavelength} \quad (32)$$

where the frequency f is in gigahertz and Z_0 is in ohms.

In practice, Eq. (32) yields somewhat low results, and surface roughness must be considered. Hammerstad and Bekkadal [11] gave the following curve-fitted formula to accommodate this problem:

$$\alpha'_c = \alpha_c \left[1 + \frac{2}{\pi} \tan^{-1} \left\{ 1.4 \left(\frac{\Delta}{\delta_s} \right)^2 \right\} \right] \quad (33)$$

where

Δ = RMS surface roughness

$\delta_s = 1/(R_s\sigma)$, the skin depth at the appropriate operating frequency, in which

R_s = surface resistance

σ = the conductivity of the metal

In order to observe the typical magnitudes involved, consider a copper microstrip, where the skin depth at a few gigahertz is $1 \mu\text{m}$. Also, assume the RMS surface roughness to be of similar magnitude, namely, $1 \mu\text{m}$ (this is fairly typical of rutile and some other hard substrates).

Equation (33) then shows that the attenuation coefficient becomes

$$\alpha'_c \approx 1.6\alpha_c \quad (34)$$

That is to say, the loss is approximately 60% increased when surface roughness is taken into account. The increase will be still greater for alumina and other substrates where the roughness can exceed $10 \mu\text{m}$.

5.3.2. Dielectric Loss. This type of loss has also been analyzed by several groups of workers, including again

Hammerstad and Bekkadal [11] and also Gupta et al. [12], who derived the following expression for the dielectric attenuation coefficient, α_d , per unit length

$$\alpha_d = 27.3 \frac{\epsilon_r(\epsilon_{\text{eff}} - 1) \tan \delta}{\sqrt{\epsilon_{\text{eff}}}(\epsilon_r - 1)\lambda_0} \text{ dB/unit length} \quad (35)$$

where $\tan \delta$ is the loss tangent for the substrate material and the microstrip wavelength λ_g given by

$$\lambda_g = \frac{\lambda_0}{\sqrt{\epsilon_{\text{eff}}}} \quad (36)$$

Equation (35) can also be written

$$\alpha_d = 27.3 \frac{\epsilon_r(\epsilon_{\text{eff}} - 1) \tan \delta}{\epsilon_{\text{eff}}(\epsilon_r - 1)} \text{ dB/microstrip wavelength} \quad (37)$$

which is the expression given by Hammerstad and Bekkadal [11].

For microstrip lines on alumina, $\epsilon_{\text{eff}} \rightarrow \epsilon_r$, at least very approximately, and the attenuation coefficient is, roughly, $\alpha_d = 27 \tan \delta$. In most cases $\tan \delta \sim 10^{-3}$ (or less) and therefore $\alpha_d \sim 0.027$ dB/microstrip wavelength. This is a factor of ≥ 5 smaller than the conductor loss that was calculated earlier. Conductor losses greatly exceed dielectric losses for most microstrip lines on alumina or sapphire substrates. However, where plastic substrates are used, this will by no means always be the case, and (especially) silicon or gallium arsenide substrates result in much larger dielectric losses (~ 0.04 dB/mm; i.e., 0.4 dB/microstrip wavelength at 10 GHz for silicon).

5.3.3. Loss Due to Radiation. This type of loss also represents a significant microstrip effect—again increasing as frequency rises. Microstrip is an asymmetric transmission line structure and is often used in unshielded or poorly shielded circuits where any radiation is either free to propagate away or to induce currents in the shielding. Further power loss is the net result.

In particular, discontinuities such as abruptly open-circuit microstrip (i.e., “open” ends), steps, and bends will all radiate to a certain extent. Such discontinuities form essential features of a microwave integrated circuit and radiation cannot therefore be avoided altogether. Efforts must be made to reduce such radiation and its undesirable effects. In circuits such as filters and amplifiers, this radiation is an acknowledged nuisance.

Both radiation and surface-wave propagation may be represented as a shunt admittance at the end of an open-circuit microstrip stub or at the plane location associated with some other abrupt discontinuity. This equivalent admittance is given by the following expression:

$$Y = G_r + G_s + jB \quad (38)$$

James and Henderson [13] show that, at frequencies where the surface wave is highly trapped in the substrate and with *thin substrates and narrow lines relative to the*

free-space wavelength, the radiation conductance G_r is approximated by

$$G_r Z_0 \approx \frac{4\pi h w_{\text{eff}}}{3\lambda_0^2 \sqrt{\epsilon_{\text{eff}}}} \quad (39)$$

in which w_{eff} is an effective microstrip width defined by the following expression:

$$w_{\text{eff}} = \frac{376.7h}{Z_0 \sqrt{\epsilon_{\text{eff}}}} \quad (40)$$

The remaining terms in Eq. (38), G_s and B , represent conductance due to surface-wave propagation and susceptance arising from the many field influences around the discontinuity.

Various techniques may be adopted to reduce radiation:

1. Metallic shielding or “screening”
2. Introduction of a small specimen of lossy (i.e., absorbent) material near any radiative discontinuity
3. Utilization of compact, planar inherently enclosed circuits (e.g., spurline filters or hairpin resonators)
4. Reduction of the current densities flowing in the outer edges of any metal sections so as to concentrate currents toward the center of the microstrip
5. Possibly shaping of the discontinuity in some way to reduce the radiative efficiency

5.3.4. Surface-Wave-Induced Loss. Surface waves also emanate from microstrip, and their undesirable effects have to be accounted for. Surface-wave propagation may be reduced by technique 2 listed above or by cutting slots into the substrate surface just in front of an open circuit. However, this is an expensive process and is usually unrealizable in MMICs. Parasitic coupling, where adjacent circuitry couples energy from nearby sources, is an undesirable consequence of surface-wave propagation. It is often necessary to minimize parasitic coupling (i.e., increase the isolation), and this requires attention to the following attributes:

1. Use relatively high permittivity substrates. Then ϵ_{eff} is relatively large (e.g., alumina is better than plastic, which should be anticipated on physical grounds).
2. Use fairly thin substrates (make the *free-space wavelength/thickness ratio* as large as possible).
3. Employ high-impedance (Z_0) stubs, for example, wherever this is feasible.

6. DISCONTINUITIES IN MICROSTRIP

All microstrip circuits must be designed with discontinuities fully accounted for. Several forms of discontinuity emerge from circuit requirements:

1. Foreshortened open circuits
2. Series coupling gaps

3. Short circuits through to the ground plane
4. Right-angled corners or “bends” (unmitered and mitered)
5. Step width changes
6. Transverse slit
7. T junction
8. Cross-junctions

An example of a microwave transistor amplifier layout is shown in Fig. 6, and at least three of the discontinuities can be readily identified. Some of these are numbered on the diagram, in accordance with the list above. Many other circuits, such as filters, mixers, and oscillators, involve several discontinuities. All technologies, whether hybrid MIC or MMIC, inherently involve such transmission discontinuities.

The various discontinuities are accommodated in the design process by approaches including extra line extensions and shifting the reference planes. In all cases the effects are strictly frequency-dependent, but in practice this results in only third-order adjustments at the most, so “quasi-TEM” (often DC) calculations are usually sufficient to quite accurately account for the effects of discontinuities. We will restrict the presentation here mainly to three types of discontinuity: the foreshortened open circuit, the right-angled bend, and the T junction.

With the *foreshortened open circuit*, the most common method of accommodating this is by supposing the line to be effectively longer than it is physically. We term this the *equivalent end-effect length*, and an empirical expression has been developed by Hammerstad and Bekkadal [11].

$$l_{\text{eo}} = 0.412h \left(\frac{\epsilon_{\text{eff}} + 0.3}{\epsilon_{\text{eff}} - 0.258} \right) \left(\frac{w/h + 0.262}{w/h + 0.813} \right) \quad (41)$$

It appears that, over a wide range of materials and microstrip width-to-height ratios, this expression can often give errors of $\geq 5\%$. In practice, however, this level of error

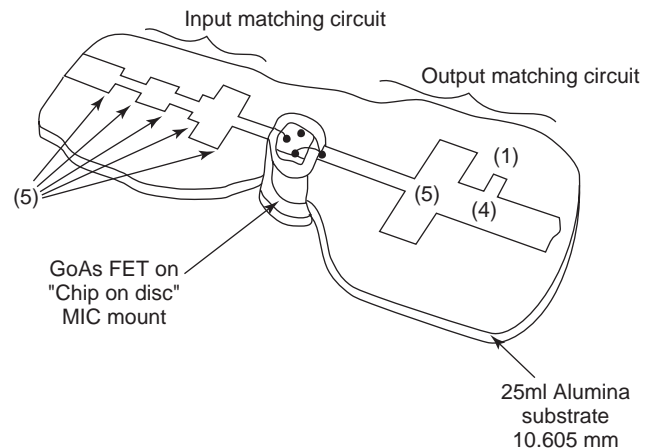

Figure 6. Layout of a simple, single-ended, hybrid MIC microwave amplifier using a GaAsFET device and showing several discontinuities in the microstrip lines (DC bias filters are not shown here).

almost always results in an acceptably small error in the overall microstrip-line design. For example, consider a microstrip line physically 3 mm in length and assume that the end-effect length extension calculates to 0.14 mm using Eq. (41). If this 0.14 mm is actually 6% high in error, then the corrected end-effect length will be just over 0.13 mm, giving a total effective length of 3.13 mm instead of 3.14 mm. The overall error is therefore about 0.3% and this is well within most acceptable design limits.

Series gaps represent a variation on the foreshortened open circuit, and the effective length extensions may be deduced by modifying Eq. (41). In general, because of the increased electric fields across such gaps compared to the foreshortened open circuit, the end-effect equivalent length extensions are somewhat greater. Series gaps are sometimes used in compact bandpass filters.

The *right-angled bend* (“corner”) is the second major form of microstrip discontinuity that we are considering here. Because the outer tip of the simple right-angled bend presents such a known and severe discontinuity (radiation and reflection), we shall restrict our attention to the *mitered right-angled bend*. Several techniques have been investigated for the compensation of microstrip bends, greatly reducing the effect of the capacitance and hence improving the VSWR and reducing the radiation. In particular, Anders and Arndt [14] have reported a moment method to calculate the appropriate capacitances and inductances for both curved and mitered bends.

Their results indicate that, at least up to a frequency of ~ 10 GHz, a mitered bend produces a performance as good as, or better than, that of curved bends. This applies to a wide range of bend angles, from 30° up to 120° . At least 70% mitering is recommended for an acute-angled bend of 120° , that is, one that acutely bends back on itself. Guidance for the design of such mitered bends, but for an angle of 90° , is also available for the structure shown in Fig. 7.

The equivalent circuit shown in Fig. 7b is for the region between planes P and P' , and the curves of Fig. 7c relate to measured results [15]. Although these curves apply to the specific instance defined, the considerable reduction of susceptance B (and therefore also capacitance C) would be expected in widely different substrates and structures. As can be seen, the equivalent linelength parameter l_c increases with enhanced mitering. Because of this and the substantial line narrowing in the center of the bend, the degree of miter is generally restricted to around the value calculated from the following expression:

$$1 - \frac{b}{\sqrt{2}w} \approx 0.6 \quad (42)$$

With this restriction the “extent of chamfer or miter parameter b ” becomes $b \approx 0.57w$, which means, for example, that the miter on a line that is 0.5 mm wide should optimally amount to $b \approx 0.28$ mm. It is instructive to observe that, whether unmitered or mitered, the effect of the discontinuity is that of a lowpass filter.

T junctions in microstrip are important in many circuits, notably amplifier-matching networks and stub-based filters. The basic, uncompensated, T junction and its equivalent circuit are shown in Fig. 8.

Figure 7. Mitered, right-angled bend together with its equivalent circuit and parameter variations (as a function of the amount of miter): (a) structure and nomenclature; (b) equivalent circuit; (c) parameter trends. (Reproduced by permission of the Institution of Electronic and Radio Engineers from Easter et al. [15].)

The immediate discontinuity effects, in the vicinity of the junction itself, are somewhat similar to those associated with the right-angled bend, represented as series inductance and shunt capacitance in the equivalent circuit. Note that the branchline of width w_2 (feeding out to what is termed a “secondary load” in Fig. 8a) is represented as a line coupled via an equivalent transformer of transformation ratio n in Fig. 8b.

Although rarely implemented (somewhat surprisingly), *compensated T junctions* are of considerable potential interest. One simple way to at least compensate the capacitance of a T junction is to introduce a slit across the width of the main through microstrip line, opposite the branch arm. Kompa [17] has shown further that a comparatively wide “slot” ($b \sim w_2$) in this position, specifically, a wide slit, strongly affects the transmission of higher-order modes in the mainline and leads to enhanced skirt sensitivity of filters composed of stubs with such modified T junctions. To the best of the present writers’ knowledge, this kind of approach has not yet been developed further, and more investigation could prove very fruitful.

Dydyk [18] has described a T-junction compensation technique that appears to work well in the case of a branch line microstrip coupler circuit. Dydyk’s aim was to modify the microstrip lines in the vicinity of the junction in order to compensate for reference plane shifts, at least over a specified range of frequencies. The analysis of such a junction can exclude any discussion of radiation loss with little error in circuit performance results, up to a frequency of

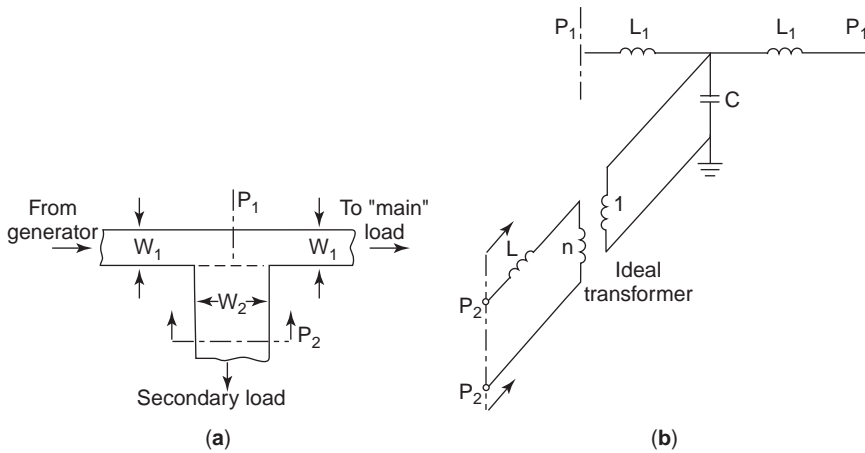

Figure 8. The T junction in microstrip: (a) structure and nomenclature; (b) equivalent circuit. (Copy right 1973 IEEE. Reprinted, with permission, from Silvester and Benedek [16]).

17 GHz at least. The compensated T junction takes on the form shown in Fig. 9.

A microstrip branch line coupler designed using these principles yielded the following performance over the frequency band 16–18 GHz:

- Insertion loss: 3.5–4.0 dB over the entire band
- Isolation: >20 dB over the entire band
- Return loss: 10 dB (at 17.5 GHz), otherwise 10 to –25 dB

The very “flat,” almost frequency-independent, insertion loss and isolation are attributed to the compensated junction design. Dydyk also describes an SPDT switch designed according to these principles.

7. PARALLEL-COUPLED MICROSTRIPS AND BANDPASS FILTERS

The arrangement shown in Fig. 10 illustrates the transverse cross-section basic structure under consideration here.

It will be assumed that both microstrip lines have the same widths, which is nearly always the case in practical applications. Some work has also been carried out on multiple arrays of such parallel, edge-coupled lines, but we can usefully restrict the considerations to just two lines in

Figure 9. A compensated form of T junction. (Reproduced by permission of MicroWaves from Dydyk [18]).

this treatment. There are two general areas of application for these structures:

1. *Directional couplers*—for use in a variety of circuits including balanced mixers, balanced amplifiers, phase shifters, attenuators, modulators, discriminators, and measurement bridges
2. *Filters, delay lines, and matching networks*—often using arrays of parallel-coupled microstrips as resonant elements

In the first instance (1), a prescribed amount of the incident power is required to be coupled out of the system. Thus, for example, a “–3-dB coupler” is one in which half of the power input is coupled from one microstrip line into another and then on to separate circuitry. In practice, however, this simple structure is inadequate for such applications and special couplers are realized. This topic is outside the scope of the present discussion. Microstrip filters application (2) employing the parallel-coupled structure are usually of the bandpass or bandstop type. An outline example of a design approach employing resonators coupled in this manner is given later here.

For each half-cycle of the RF wave, the two coupled lines will have precisely opposite voltage polarities. In one half-cycle the opposing lines will be similarly polarized (e.g., equally positive), while in another half-cycle the lines will be oppositely polarized (i.e., one positive and one negative). In the first instance we term the situation even-mode; in the second instance, odd-mode. Each parameter associated with each polarisation has an extra

Figure 10. A pair of parallel, edge-coupled microstrip lines.

Figure 11. Field distributions resulting from (a) even-mode and (b) odd-mode excitation of parallel-coupled microstrip lines.

subscript attributed; “e” for even-mode and “o” for odd-mode.

The even- and odd-mode characteristic impedances ($Z_{0,e}$ and $Z_{0,o}$) are major design parameters for any parallel-coupled transmission-line configuration—whatever its application. These impedances are obtained at an early circuit/system design stage and are functions of the degree of coupling (C) and the single-line terminating characteristic impedance (Z_0). The relationships between $Z_{0,e}$ and $Z_{0,o}$ and the physical dimensions of the coupled structure (including the substrate permittivity) are therefore of prime significance to the designer. As with single microstrip lines, in this coupled situation as well we can determine $Z_{0,e}$ and $Z_{0,o}$ from known physical dimensions, which amounts to analysis. Alternatively, with greater difficulty, we may synthesize the physical structure from starting values of the impedances. Both of these procedures are useful in practice.

The electric (E) and magnetic (H) fields associated with each mode are indicated in Figs. 11.

In the design of filters or matching networks using parallel-coupled lines, we usually begin with either insertion loss as a function of frequency or VSWR requirements over some band. In either event we still arrive at desired values of $Z_{0,e}$ and $Z_{0,o}$ followed by a final synthesis aimed at the physical realization of the circuit. Input information required includes

Figure 13. General top-view appearance of a practical parallel-coupled microstrip BPF.

- Bandwidth (B) and center frequency (f_0)
- In-band and attenuation-band insertion loss (both dB—for filters)
- Terminating characteristic impedance Z_0 (usually 50 Ω)
- Permittivity and thickness of the substrate

From this information the designer must ultimately determine the widths of the microstrip lines, the separation between them, the length of the coupled region, and hence ultimately the physical lengths of the microstrips.

For the present purposes we will not expound on the precise details of parallel-coupled microstrip design (this is covered in detail in Ref. 1). It should, however, be mentioned that dispersion is present in this structure, and this affects the even and odd modes differently. The single microstrip models covered in Section 1 can be modified to suit the parallel-coupled case.

With microstrip couplers, maximum coupling is obtained between physically parallel microstrips when the length of the coupled region is $\lambda_g/4$, or some odd multiple thereof. To achieve resonance, each resonator element has to be $\lambda_g/2$ in length, or many multiple thereof. Therefore the microstrip circuit must have the general layout shown in Fig. 12 where $l_1, \dots, l_4 \approx \lambda_g/4$.

We will assume, for the moment, that this fairly straightforward cascade of parallel-coupled (or edge-coupled) microstrip resonators can be designed on a basis of all-parallel resonator networks together with intervening circuits known as inverters.

Figure 12. General microstrip configuration for a seven-section, parallel-coupled bandpass filter (BPF).

The four main design steps are outlined as follows:

1. Determine the one-type resonator network, to realize the specification, from the original prototype;
2. From the network parameters, evaluate the even- and odd-ordered characteristic impedances $Z_{0,e}$ and $Z_{0,o}$ applicable to the parallel-coupled microstrip (this is not discussed in detail here, but see ref. 1).
3. Relate the values of $Z_{0,e}$ and $Z_{0,o}$ to microstrip widths and separations (w,s) (detailed microstrip design).
4. Calculate the entire resonator length $2l'$, slightly less than $\lambda_g/2$ because of the semiopen end effects (see Section 6), and therefore of the coupled section length l' , which is slightly less than $\lambda_g/4$ for the end effect reason again (Fig. 12).

Here λ_g is the midband and average microstrip wavelength. Allowance must be made for the semi-open-circuit microstrip end effects that exist for all elements in this circuit.

In practice, most microstrip or related planar BPFs have their topologies rotated for spatial convenience (on chip or substrate) as shown in Fig. 13.

All the dense black features are microstrip lines, and Fig. 13 is not to scale since it is only meant to provide the concept of the layout.

Communications

1. TRANSVERSE ELECTROMAGNETIC TRANSMISSION LINES

One of the most familiar waveguiding structures is the conventional transmission line such as the two-wire line and the coaxial line. The fundamental mode of propagation on a transmission line is essentially a *transverse electromagnetic (TEM) wave*, which owns neither electric nor magnetic field in the direction of propagation [1].

An ideal lossless uniform TEM transmission line can be represented by a lumped circuit and consists of series inductance L and shunt capacitance C , all defined per unit length of the line, as shown in Fig. 1. The inductance L is proportional to the permeability μ of the surrounding medium, and the capacitance C proportional to the permittivity ϵ of the medium. Their values depend on the transverse geometry of the transmission line, and are determined from the electrostatic analysis [1] of the cross-section of the structure that solves a two-dimensional Laplace equation in the medium surrounding the conductors of the transmission line.

The voltage and current waves, expressed by $V = V_0 e^{\pm j\beta z}$ and $I = I_0 e^{\pm j\beta z}$, along the transmission line are solutions of the *telegraphists' or transmission-line equations* [1]

$$\frac{d^2 V}{dz^2} + \omega^2 L C V = 0 \quad (1)$$

$$\frac{d^2 I}{dz^2} + \omega^2 L C I = 0 \quad (2)$$

Figure 1. Lumped-circuit representation of an ideal TEM transmission line. L is the series inductance, C the shunt capacitance; both are defined per unit length of the line.

where $\omega = 2\pi f$ (frequency) is the radian frequency and β is the phase constant.

TEM transmission lines are characterized by line parameters such as phase constant, characteristic impedance, and attenuation constant. Formulas for line parameters of an ideal lossless transmission line are given in what follows [1,2]:

Phase constant

$$\beta = \omega\sqrt{LC} = \omega\sqrt{\mu\epsilon} = \omega/v \tag{3}$$

Characteristic impedance

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{vC} \tag{4}$$

Voltage and current along line

$$V(z) = V_0 e^{j\beta z} [1 + \Gamma(z)] \tag{5}$$

$$I(z) = \frac{V_0}{Z_0} e^{j\beta z} [1 - \Gamma(z)] \tag{6}$$

Input impedance

$$Z(z) = Z_0 \frac{Z_L \cos \beta z + jZ_0 \sin \beta z}{Z_0 \cos \beta z + jZ_L \sin \beta z} \tag{7}$$

In these expressions, v is the velocity of TEM waves in the dielectric of line, v_0 is the amplitude of the incident voltage, z_L is the value of the load impedance, and z is the distance along the line from the load end.

2. STRIPLINES

A stripline, also referred to as a *triplate line*, consists of a conducting strip lying between, and parallel to, two wide conducting ground planes, as shown in Fig. 2. The region between the strip and the planes is filled with a uniform dielectric. Stripline is one of the most commonly used transmission lines for passive *microwave integrated circuits* (MICs). The fundamental mode in a stripline is a TEM mode, and its field distribution is illustrated in Fig. 3.

The line parameters of a stripline can be obtained completely by electrostatic analysis such as the conformal mapping technique [1,3]. An approximate expression for the characteristic impedance of a stripline with zero-thickness strip is given by [2,3]

$$Z_0 = \frac{30\pi}{\sqrt{\epsilon_r}} \frac{K'(k)}{K(k)} \tag{8}$$

where ϵ_r is the relative permittivity of the dielectric filled in the stripline, $k = \tanh(\pi w/2h)$, K represents a complete

elliptic function of the first kind, and K' is its complementary function. The velocity of the TEM mode in a stripline is $v = 1/\sqrt{\mu_0\epsilon_0\epsilon_r}$. Both the wave velocity and characteristic impedance are independent of frequency.

An accurate but simple approximate expression for $K(k)/K'(k)$ is given by

$$\frac{K(k)}{K'(k)} = \begin{cases} \frac{\pi}{\ln[2(1 + \sqrt{k})/(1 - \sqrt{k})]} & \text{for } 0 \leq k \leq 0.707 \\ \frac{1}{\pi} \ln[2(1 + \sqrt{k})/(1 - \sqrt{k})] & \text{for } 0.707 \leq k \leq 1 \end{cases} \tag{9}$$

An approximate expression for the attenuation constant arising from the conductor surface resistance, $R_s = \sqrt{\omega\mu_0/2\sigma}$, is given by (1)

$$\alpha_c = \frac{R_s}{h\eta} \left[\frac{\pi w/h + \ln(4h/\pi t)}{\ln 2 + \pi w/2h} \right] \text{ Nps/m} \tag{10}$$

where $\eta = \sqrt{\mu_0/\epsilon_0\epsilon_r} = \eta_0/\sqrt{\epsilon_r}$, $\eta_0 = 120\pi$ is the wave impedance in free space and t is the thickness of the strip. Equation (10) is valid for $w > 2h$ and $t < h/10$.

The attenuation constant from lossy dielectric medium with $\epsilon = \epsilon' - j\epsilon''$ is expressed by

$$\begin{aligned} \alpha_d &= \text{Re}(j\omega\sqrt{\mu_0\epsilon}) = \text{Re}(j\omega\sqrt{\mu_0(\epsilon' - j\epsilon'')}) \\ &\approx \frac{\omega\sqrt{\mu_0\epsilon'}\epsilon''}{2\epsilon'} = \frac{\omega\sqrt{\mu_0\epsilon'}}{2} \tan \delta \text{ Nps/m} \end{aligned} \tag{11}$$

where $\tan \delta$ is the dielectric loss tangent.

Figure 2. Geometry of a stripline. The strip conductor is sandwiched between two wide parallel conducting ground planes. The region between the strip and the ground planes is filled with a uniform dielectric.

Figure 3. Electromagnetic field distribution in a stripline. The fundamental TEM mode is considered. The electric field goes from the conductor strip to the grounded planes. The magnetic field surrounds the conductor strip.

In addition to the dominant TEM mode, higher-order *transverse electric (TE) modes* and *transverse magnetic (TM) modes* can also propagate in a stripline. A TE mode owns magnetic field but no electric field in the direction of propagation. A TM mode contains electric field but no magnetic field in the direction of propagation. The cutoff frequency of the lowest order TE mode is [2]

$$f_c = \frac{15}{h\sqrt{\epsilon_r}} \frac{1}{w/h + \pi/4} \quad (12)$$

where f_c is given in gigahertz and w and h are in centimeters.

More detailed and accurate formulas for the stripline parameters, such as the characteristic impedance, and the attenuation constant, can be found in Ref. 2.

3. MICROSTRIP LINES

3.1. General Descriptions

3.1.1. Microstrip Geometry and Advantages. A microstrip line [4] is a type of open planar transmission line that consists of a dielectric substrate medium with a ground plane on the lower side and a conducting strip on the upper side. The geometry of a microstrip line is shown in Fig. 4. The substrate provides mechanical rigidity and permits the accurate positioning of the circuitry. The transmission-line characteristic parameters, like the

Figure 4. Geometry of a microstrip line. The conducting strip is placed above a dielectric substrate, which is supported on its bottom by a conducting plate.

phase constant and characteristic impedance, can be determined from the substrate permittivity (ϵ_r) and the geometrical dimensions (strip width w and thickness t , substrate thickness h) in the transverse plane. For this reason, various types of microstrip circuits can be fabricated conveniently with high precisions by employing the simple photolithographic and photoetching techniques. Use of these techniques at microwave and millimeter-wave frequencies has led to the development of hybrid and monolithic microwave integrated circuits (MICs) [5–11].

Microstrip line is now one of the most widely used transmission lines for MICs. Active devices (diodes and transistors), lumped circuit elements (capacitors, resistors, inductors), dielectric resonators, and antennas can be easily incorporated into the circuit. Compared with the traditional bulky and heavy metallic waveguides and coaxial lines, the planar microstrip structures are small-size, lightweight, easy for mass production, and inexpensive.

3.1.2. Dielectric Substrate. The properties of the dielectric substrate material affect the overall performance of the microstrip structures. Different substrate materials possess characteristics that may make them better suited for a given application. For instance, higher-dielectric-constant materials are preferred in order to achieve a very compact microwave circuit, while lower-dielectric-constant materials are required for antenna structures to ensure efficient radiation.

In general, the substrate material parameters, permittivity ϵ and permeability μ , should be homogeneous (independent of position), isotropic (independent of wave propagation direction), and should have low dispersion. The loss tangent should be small to reduce energy dissipation. Furthermore, these parameters should have very small variation with temperature to ensure circuit stability. The substrate thermal conductivity should be high enough to ensure efficient removal of heat from power transistors, attenuators, and loads in high-power applications. In high-power applications, a high breakdown voltage is also desirable. The thermal expansion coefficient of the material should be similar to that of the deposited conductors and housing to withstand temperature fluctuations and improve reliability. The material must allow drilling, cutting, machining, and etching for easy workability and lower production costs. Also important is a good surface finish to ensure good conductor adhesion and reduce conductor loss.

A wide variety of dielectric substrates are now commercially available. Characteristics, including mechanical and thermal as well as electronic facets, of a number of representative substrate materials, such as alumina, fused quartz, silicon, gallium arsenide, synthetic, and composite materials, are compared in Refs. 6–12.

Although the microstrip line appeared first in 1952 [4], the rapid increase of the use of microstrip circuits was seen during the 1960s when high permittivity and low-loss dielectric substrates became available. At the same time, microwave semiconductor devices appeared, and miniature lumped elements (capacitors, resistors, inductors)

became available for implantation on planar circuits. Coupled with steady advances in photolithographic technology, the combination of microstrips, lumped elements, and semiconductors led to the advent of microwave integrated circuits (MICs) [5–11].

3.1.3. Field Configuration and Analysis Methods. The microstrip line is an inhomogeneous transmission line, involving an abrupt dielectric interface between the substrate and the air above it. The electromagnetic fields extend over inhomogeneous regions, partly in the dielectric substrate, and partly in the air, as shown in Fig. 5. Waves propagating along the line cannot be purely TEM, TE, or TM modes, but *hybrid modes* containing both electric and magnetic fields in the transverse and longitudinal directions of propagation [6]. This may cause some complication in microstrip analysis and design. However, in many practical situations, the dominant mode of a microstrip line resembles closely a TEM mode. Therefore, it is usually referred to as quasi-TEM mode.

The microstrip line has been analyzed by numerous workers using various analytical and numerical techniques. As with many other transmission lines, the analysis methods for a microstrip line are aimed at determining the characteristic impedance and propagation constant (phase velocity and attenuation constant). The various methods of microstrip line analysis can be divided into two main groups [6–10]. In the first group, which comprises *quasistatic methods*, the nature of the mode of propagation is considered to be pure TEM and the microstrip characteristics are calculated from the electrostatic capacitance of the structure. The quasistatic methods commonly used include the conformal transformation method [13], the variational method [14,15], the finite-difference method, and the integral equation method [6–10]. It is found that this quasistatic analysis is adequate for designing circuits at lower frequencies where the strip width and the substrate thickness are much smaller than the wavelength in the dielectric material.

The methods in the second group are *full-wave approaches*, which take into account the hybrid nature of the mode of propagation. They include the integral equation method [16], the spectral-domain method [17], and the finite-difference time-domain (FDTD) method [6–10,17]. The full-wave analysis methods are more rigorous and

Figure 5. Electromagnetic field distribution in a microstrip line. The fundamental quasi-TEM mode is considered. The electromagnetic fields extend over inhomogeneous regions, partly in the dielectric substrate, and partly in the air.

can predict frequency-dependent variation of the microstrip characteristics. However, they are analytically complex, and usually require large computer memories and long computation time, which may become prohibitive when optimization process is demanded in the design of circuits.

3.1.4. High-Frequency Problems and Quasi-TEM Wave Results. Microstrip lines have been extensively used for MICs at frequencies ranging from hundreds of megahertz to tens of gigahertz. At high frequencies, particularly into the millimeter wavelength ranges, conductor ohmic and dielectric losses increase greatly. Surface waves of the dielectric substrate and higher-order modes excited at discontinuities start to propagate or to radiate [6–10]. The conductor and dielectric losses and radiation reduce the amplitude of a signal propagating along the line and may cause spurious coupling between neighbouring parts of a circuit. The simultaneous propagation of several modes, with different velocities, produces a distortion of the signal. The fabrication tolerances become very difficult to meet. These factors prohibit the extensive use of microstrip lines at high frequencies.

For the majority of microstrip lines suitable for MICs, the statically derived results are quite accurate when the frequency is below a few gigahertz. At higher frequencies, up to the limits for the useful operation of microstrip lines, these static results can still be used in conjunction with some quasiempirical functions in closed formulas to find the variations of microstrip characteristics with frequency. Therefore, results by the static techniques are powerful and significant in the design of microstrip circuits.

3.1.5. Quasi-TEM Wave Parameters. Under the quasi-TEM wave approximation, an ideal microstrip line can be represented by the lumped circuit for the TEM transmission line shown in Fig. 1. The characteristic impedance is expressed by

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{vC} \quad (13)$$

When the substrate of the microstrip line is replaced by air, we have an air-filled line along which the wave will travel at c , the velocity of light in free space. The characteristic impedance of this air-filled line, defined as Z_a , is given by

$$Z_a = \sqrt{\frac{L}{C_a}} = \frac{1}{c \cdot C_a} \quad (14)$$

Combining Eqs. (13) and (14), we get

$$Z_0 = \frac{1}{c\sqrt{C \cdot C_a}} \quad (15)$$

Phase constant

$$\beta = \frac{\omega}{v} = \omega\sqrt{LC} = \frac{\omega}{c} \sqrt{\frac{C}{C_a}} = \beta_0 \sqrt{\frac{C}{C_a}} \quad (16)$$

here β_0 is the wavenumber in free space. The normalized phase constant is written as

$$\frac{\beta}{\beta_0} = \frac{c}{v} = \frac{\lambda_0}{\lambda_g} = \sqrt{\frac{C}{C_a}} \quad (17)$$

here λ_0 and λ_g are the wavelengths in free space and along the microstrip line, respectively. Equations (15) and (17) indicate that the characteristic impedance and phase constant of a microstrip line can be obtained if we can evaluate the capacitance per unit length of the line, with and without the presence of the dielectric substrate.

The *effective permittivity* ε_e is defined as the capacitance ratio

$$\varepsilon_e = \frac{C}{C_a} \quad (18)$$

From Eq. (17) we immediately get

$$\varepsilon_e = \left(\frac{c}{v}\right)^2 \quad (19)$$

$$\beta = \sqrt{\varepsilon_e} \cdot \beta_0 \quad (20)$$

The effective permittivity has a physical meaning that the original inhomogeneous microstrip line is replaced by an equivalent homogeneous line with conductors having exactly the same geometry (w, h, t) , surrounded by a single homogeneous dielectric of effective permittivity ε_e .

From Eqs. (17) and (18), we also have the formula

$$\lambda_g = \frac{\lambda_0}{\sqrt{\varepsilon_e}} \quad (21)$$

3.1.6. Formulas for Quasi-TEM Wave Parameters. As stated previously, closed formulas are of significant importance in the design of microstrip-line circuits. Various workers have reported formulas for microstrip calculations [6–10]. These formulas may be classified into two types, one for the analysis purpose, and the other for the synthesis purpose. When the geometric and material parameters (w, h, t, ε_r) are known, we use the analysis formulas to evaluate the line's electrical characteristics ε_e , Z_0 , and λ_g . Conversely, when Z_0 and ε_r are given and we want to specify the width–height ratio w/h of the microstrip line, we employ the synthesis formulas.

3.1.7. Analysis Formulas (w/h and ε_r Given). Very accurate formulas derived by Hammerstad and Jensen [18] are provided below:

Effective permittivity ε_e .

$$\varepsilon_e = \frac{\varepsilon_r + 1}{2} + \frac{\varepsilon_r - 1}{2} \left(1 + 10 \frac{h}{w}\right)^{-a(w/h) \cdot b(\varepsilon_r)} \quad (22)$$

with

$$a\left(\frac{w}{h}\right) = 1 + \frac{1}{49} \ln \left\{ \frac{(w/h)^4 + [w/(52h)]^2}{(w/h)^4 + 0.432} \right\} \quad (23)$$

$$+ \frac{1}{18.7} \ln \left[1 + \left(\frac{w}{18.1h}\right)^3 \right]$$

$$b(\varepsilon_r) = 0.564 \left(\frac{\varepsilon_r - 0.9}{\varepsilon_r + 3}\right)^{0.053} \quad (24)$$

Characteristic impedance Z_0 .

$$Z_0 = \frac{\eta_0}{2\pi\sqrt{\varepsilon_e}} \cdot \ln \left[F_1 \left(\frac{w}{h}\right) \frac{h}{w} + \sqrt{1 + \left(\frac{2h}{w}\right)^2} \right] \quad (25)$$

with

$$F_1\left(\frac{w}{h}\right) = 6 + (2\pi - 6) \exp \left[-\left(30.666 \frac{h}{w}\right)^{0.7528} \right] \quad (26)$$

where $\eta_0 = 120\pi$ is the wave impedance in free space. The accuracy of these expressions is better than 0.01% for $w/h \leq 1$ and 0.03% for $w/h \leq 1000$.

3.1.8. Synthesis Formulas (Z_0 and ε_r Given) [7]. For narrow strips (when $Z_0 > (44 - 2\varepsilon_r) \Omega$)

$$\frac{w}{h} = \left(\frac{\exp(A)}{8} - \frac{1}{4 \exp(A)}\right)^{-1} \quad (27)$$

where

$$A = \frac{Z_0 \sqrt{2(\varepsilon_r + 1)}}{119.9} + \frac{1}{2} \left(\frac{\varepsilon_r - 1}{\varepsilon_r + 1}\right) \left(\ln \frac{\pi}{2} + \frac{1}{\varepsilon_r} \ln \frac{4}{\pi}\right)$$

For wide strips (when $Z_0 < (44 - 2\varepsilon_r) \Omega$)

$$\frac{w}{h} = \frac{2}{\pi} [(B - 1) - \ln(2B - 1)] \quad (28)$$

$$+ \frac{\varepsilon_r - 1}{\pi \varepsilon_r} \left[\ln(B - 1) + 0.293 - \frac{0.517}{\varepsilon_r} \right]$$

where

$$B = \frac{59.95\pi^2}{Z_0 \sqrt{\varepsilon_r}}$$

3.1.9. Strip Thickness Correction. In correcting the results above, ε_e and Z_0 given by Eqs. (22) and (25), for non-zero strip thickness t , a corrected strip width w_e/h is defined as follows [18]:

$$\frac{w_e}{h} = \frac{w}{h} + \frac{1}{2\pi} \frac{t}{h} \left[1 + \frac{1}{\cosh(\sqrt{\varepsilon_r - 1})} \right] \quad (29)$$

$$\cdot \ln \left[1 + \frac{4h \exp(1)}{t \coth^2(\sqrt{6.517}w/h)} \right]$$

With this corrected strip width, the effect of strip thickness on ε_e and Z_0 of microstrip lines can be included in the

Eqs. (22) and (25). We have therefore

$$\epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + 10 \frac{h}{w_e}\right)^{-a(w_e/h) \cdot b(\epsilon_r)} \tag{30}$$

$$Z_0 = \frac{\eta_0}{2\pi\sqrt{\epsilon_e}} \cdot \ln \left[F_1 \left(\frac{w_e}{h} \right) \frac{h}{w_e} + \sqrt{1 + \left(\frac{2h}{w_e} \right)^2} \right] \tag{31}$$

where $\eta_0 = 120\pi$ is the wave impedance in free space. In these expressions, the functions $a(w_e/h)$, $b(\epsilon_r)$, and $F_1(w_e/h)$ are defined in Eqs. (23), (24), and (26), respectively, with the normalized strip width w/h replaced by the corrected normalized strip width w_e/h . It is observed that the effect of the strip thickness on ϵ_e and Z_0 is insignificant for small values of t/h . However, the effect of strip thickness is significant on conductor loss in the microstrip line.

3.1.10. Effect of Dispersion. The effect of frequency (dispersion) on ϵ_e and Z_0 has been described in a number of publications. The accurate expressions in Ref. 18 for $Z_0(f)$ and in Ref. 19 for $\epsilon_e(f)$ are

$$Z_0(f) = Z_0 \cdot \frac{\epsilon_e(f) - 1}{\epsilon_e - 1} \cdot \sqrt{\frac{\epsilon_e}{\epsilon_e(f)}} \tag{32}$$

$$\epsilon_e(f) = \epsilon_r - \frac{\epsilon_r - \epsilon_e}{1 + (f/f_{50})^m} \tag{33}$$

where

$$f_{50} = \frac{f_{k,TM_0}}{0.75 + [0.75 - (0.332/\epsilon_r^{1.73})]w/h}$$

$$f_{k,TM_0} = \frac{c \cdot \tan^{-1} \left(\epsilon_r \sqrt{\frac{\epsilon_e - 1}{\epsilon_r - \epsilon_e}} \right)}{2\pi h \sqrt{\epsilon_r - \epsilon_e}}$$

$$m = m_0 m_c$$

$$m_0 = 1 + \frac{1}{1 + \sqrt{w/h}} + 0.32 \left(\frac{1}{1 + \sqrt{w/h}} \right)^3$$

$$m_c = \begin{cases} 1 + \frac{1.4}{1 + w/h} \left[0.15 - 0.235 \exp \left(-\frac{0.45f}{f_{50}} \right) \right] & \text{for } w/h \leq 0.7 \\ 1 & \text{for } w/h > 0.7 \end{cases}$$

where Z_0 and ϵ_e are the quasi-TEM wave values obtained earlier, and c is the velocity of light in free space.

3.1.11. Effect of Enclosure. Most microstrip circuit applications require a metallic enclosure for hermetic sealing, mechanical strength, electromagnetic shielding, mounting connectors, and ease of handling. Because the fringing electromagnetic fields are prematurely terminated on the enclosure walls, both the top cover and side walls tend to lower impedance and effective dielectric constant.

Equations for evaluating the effect of the topcover and sidewalls on Z_0 and ϵ_e are provided in Refs. 6 and 7.

When the topcover and sidewalls are placed in close vicinity of the microstrip line, the line parameters may vary significantly. It is recommended to leave at least 10 times the substrate thickness between the circuit and the cover [11].

A metal box is actually a microwave cavity, which resonates at some particular frequencies corresponding to its resonant modes. The size of the box should be chosen in such a way that the signal frequency does not coincide with the resonant frequencies. When this cannot be done, the resonant modes can be damped by placing absorbing materials at carefully selected locations.

3.1.12. Attenuation. The attenuation constant of a transmission line is usually defined as

$$\alpha \approx \frac{P_{\text{loss}}}{2P(z)} = \frac{\text{power loss per unit length}}{2(\text{power transmitted})} \tag{34}$$
