The reader might wonder how a thin substrate consisting of this periodic array of vias can be modeled by the same equations that describe a medium of infinitely long rods. The answer lies in the terminating metal plates of the capacitive FSS layer. The current in the via rod continues onto the FSS metal plates and spreads radially out within the unit cell all the way to the end of the periodic cell. Thus the upper metal plates act as a ground plane mirroring the lower ground plane and thus creating, by virtue of the theory of images, effectively infinite rods. That this mechanism is crucial to the proper functioning of AMCs has been proved by electrically disconnecting the via rods from the FSS layer. In that case the AMC's TM surface suppression properties quickly vanish as the separation between the vias exceeds the height of the vias.

The transverse permittivity of the rodded medium is obtained by simply invoking the Clausius–Mosotti formula for a two-dimensional array of infinite metallic cylinders. The effective property is due to the transverse polarization of the rods and is simply given by

$$\epsilon_{xx2} = \epsilon_{yy2} = \epsilon_D \left(\frac{1 + \alpha}{1 - \alpha} \right) \quad (9)$$

The transverse permeability can be deduced from the following argument. A TEM wave traveling along the rods (z direction) must experience ϵ_{xx} and μ_{yy} (or ϵ_{yy} and μ_{xx}) and yet must have a phase velocity equal to that of the background dielectric:

$$v_{\text{phase}} = \frac{c}{(\epsilon_D \mu_D)^{1/2}} \quad (10)$$

It follows that for this rodded medium

$$\mu_{xx} = \mu_{yy} = \frac{\epsilon_D}{\epsilon_{xx}} \mu_D \quad (11)$$

Finally, the z -directed permeability of the rodded layer is deduced by recognizing that a PEC rod excludes the magnetic field from its interior, thus reducing the cell permeability and creating an effective unit cell that is diamagnetic:

$$\mu_{zz} = (1 - \alpha) \mu_D \quad (12)$$

2.2. Effective Medium Model for the FSS

Next we must consider the FSS layer. For the single-layered ‘‘Cohn square’’ structure that makes up the FSS layer of the original Sievenpiper embodiment of an AMC (Fig. 1), the effective permittivity in the x and y directions comes from the edge-to-edge capacitance induced whenever there is a planar component of the electric field. For both TM waves (magnetic field perpendicular to the plane

of incidence) and TE waves (electric field perpendicular to the plane of incidence), there is such a planar electric field, and so it is expected that both cases experience an effective transverse (x - y) permittivity. However, the only case where the magnetic field is affected by the (assumed extremely thin) metal squares of the FSS is when it has a component perpendicular to the plane (the TE case). The eddy currents induced on the squares repel the magnetic field and allow it to flow only through the gaps between the squares. Thus it is expected that the TE case will exhibit a normal permeability that is depressed below the value of free space. These effective constitutive properties can be derived rigorously from the classic case of the periodic strip surface as a shunt obstacle in the transmission line of free space.

First, for the following derivations we will need to define the TE and TM impedances and propagation constants for uniaxial anisotropic media where the x - and y -axis properties are equal and the z (normal to the plane) properties are different. These expressions are [5,6]

$$Z_n^{\text{TM}} = \frac{k_{zn}^{\text{TM}}}{\omega \epsilon_0 \epsilon_{xn}} \quad Z_n^{\text{TE}} = \frac{\omega \mu_0 \mu_{xn}}{k_{zn}^{\text{TE}}} \quad (13)$$

$$k_{zn}^{\text{TM}} = k_0 \sqrt{\mu_{yn} \epsilon_{xn} - \left(\frac{k_x}{k_0}\right)^2 \frac{\epsilon_{xn}}{\epsilon_{zn}}} \quad (14)$$

$$k_{zn}^{\text{TE}} = k_0 \sqrt{\mu_{xn} \epsilon_{yn} - \left(\frac{k_x}{k_0}\right)^2 \frac{\mu_{xn}}{\mu_{zn}}}$$

2.2.1. The TM Case. When a wave with its E field in the x - z plane and H field in the y direction is incident at an angle θ as shown in Fig. 6 on a Cohn square FSS in free space, its total tangential E field on the metal squares goes to zero. It follows that for narrow gaps between the squares, the total E field in the x direction in that plane also tends to zero in the gaps aligned with the x direction. To first order the only relevant field is the one concentrated in the gaps aligned with the y axis, implying that the behavior of the Cohn square FSS [7] must be the same as that from a plane of parallel infinite strips aligned with the y axis. The solution for this latter case is well known [8].

According to Ref. 8 considering the plane of the strips a shunt obstacle, the input admittance for arbitrary angles

of incidence is

$$Y_{\text{in}} = Y_0 \cdot \left[1 + j \cdot \frac{4d}{\lambda_0 \cos \theta} \cdot \ln \left(\csc \frac{\pi b'}{2d} \right) \right] \quad (15)$$

Realizing that k_{z0} is just $2\pi/\lambda_0 \cos \theta$, we have

$$Y_{\text{in}} = Y_0 \left[1 + j \frac{2d}{\pi} k_{z0} \ln \left(\csc \frac{\pi b'}{2d} \right) \right] \quad (16)$$

where Y_0 is the admittance of free space, d the periodic unit length, k_{z0} the propagation constant of the incident plane wave in the z direction corresponding to a free-space propagation constant $k_0 = \omega/c$, and b' the gap between the strips.

If, however, the FSS layer were modeled as a material layer of thickness t_1 with uniaxial anisotropic properties, the input admittance could also be obtained using the transmission-line equation where the load is the free space behind the FSS and the transmission line is the FSS layer

$$Y_{\text{in}} = Y_0 \frac{\cos k_{z1} t_1 + j \left(\frac{k_{z0}/\omega \epsilon_0}{k_{z1}/\omega \epsilon_0 \epsilon_x} \right) \sin k_{z1} t_1}{\cos k_{z1} t_1 + j \left(\frac{k_{z1}/\omega \epsilon_0 \epsilon_x}{k_{z0}/\omega \epsilon_0} \right) \sin k_{z1} t_1} \quad (17)$$

where k_{z1} is the z -directed propagation constant in the FSS equivalent material layer, given by

$$\left(\frac{k_{z1}}{k_0} \right)^2 = \mu_y \epsilon_x - \left(\frac{k_x}{k_0} \right)^2 \frac{\epsilon_x}{\epsilon_z} \quad (18)$$

where ϵ_x , ϵ_z and μ_y are the relevant constituent parameters of the material tensor for TM incidence and k_x is the propagation constant in the x direction of the waves in all the layers. Under the assumption that t_1 is small and that the permittivity of the FSS layer in the z direction and the permeability in the y direction are 1 (since the ideal FSS is infinitely thin), Eq. (17) reduces to

$$Y_{\text{in}} = Y_0 \frac{1 + j \frac{k_{z0}/\omega \epsilon_0}{k_{z1}/\omega \epsilon_0 \epsilon_x} k_{z1} t_1}{1 + j \frac{k_{z1}/\omega \epsilon_0 \epsilon_x}{k_{z0}/\omega \epsilon_0} k_{z1} t_1} = Y_0 \frac{1 + j \epsilon_x k_{z0} t_1}{1 + j \frac{(k_{z1})^2 t_1}{\epsilon_x k_{z0}}} \quad (19a)$$

Figure 6. Incidence of a plane TM wave onto the Cohn square FSS can be approximated with the problem of the scattering from a strip array.

and since $kz_1^2 = k0^2 \epsilon_x (1 - (kx/k0)^2) = k0^2 \epsilon_x (kz_0/k0)^2$, it follows that $kz_1^2/kz_0 = kz_0 \epsilon_x$ and, again assuming $kz_0 t_1$ very small compared to 1, Eq. (19a) becomes

$$Y_{\text{in}} = Y_0 \frac{1 + j \epsilon_x k_{z0} t_1}{1 + j k_{z0} t_1} \approx Y_0 [1 + j \epsilon_x k_{z0} t_1] \quad (19b)$$

Comparing Eq. (19b) to Eq. (16), we conclude that the FSS layer has an effective x -directed relative permittivity equivalent to a pure shunt capacitance that is angle-independent, given by

$$\epsilon_x = \frac{2d}{\pi t_1} \ln \left(\csc \frac{\pi b'}{2d} \right) \quad (20a)$$

Since the FSS layer is not floating in space but supported by a dielectric substrate, the result of Eq. (20) is increased in practice by the average relative permittivity ϵ_{avg} of the dielectric materials surrounding the FSS and the final result for the transverse effective relative permittivity is

$$\epsilon_{xx} = \frac{2d}{\pi t_1} \ln \left(\csc \frac{\pi b'}{2d} \right) \epsilon_{\text{avg}} \quad (20b)$$

For thin gaps the logarithm term simplifies to $\ln(2d/\pi b')$. It should be noted that this result is simply the statement $\epsilon_1 = C_{\text{FSS}}/t_1$, where C_{FSS} is the capacitance in farads per square of the FSS sheet.

2.2.2. The TE Case. The TE case is analyzed following a parallel procedure. The z -directed propagation constant in the uniaxial medium for TE is given by

$$\left(\frac{k_{z1}}{k_0} \right)^2 = \epsilon_y \mu_x - \left(\frac{k_x}{k_0} \right)^2 \frac{\mu_x}{\mu_z} \quad (21)$$

Knowing that t_1 is small, the input impedance for the material layer model is given by Eq. (22), while the TE incidence result from Ref. 8 for the FSS as a shunt obstacle is still given by Eq. (16):

$$Y_{\text{in}} = Y_0 \frac{1 + j \frac{k_{z1}/\omega \mu_0 \mu_x}{k_{z0}/\omega \mu_0} k_{z1} t_1}{1 + j \frac{k_{z0}/\omega \mu_0}{k_{z1}/\omega \mu_0 \mu_x} k_{z1} t_1} \quad (22)$$

$$= Y_0 \frac{1 + j \left(\frac{k_{z1}}{k_{z0}} \right)^2 \frac{k_{z0} t_1}{\mu_x}}{1 + j k_{z0} \mu_x t_1}$$

But we know that μ_x is approximately 1 and that $k_z = k_0 \cos \theta$, so that

$$Y_{\text{in}} \approx Y_0 \left(1 + j \left(\frac{k_{z1}}{k_0} \right)^2 \frac{k_{z0} t_1}{\cos^2 \theta \mu_x} \right) \quad (23)$$

Finally, using Eq. (21), and $k_x = k_0 \sin \theta$, we have

$$Y_{\text{in}} = Y_0 \left[1 + j \frac{k_{z0} t_1}{\cos^2 \theta} \left(\epsilon_y - \sin^2 \theta \frac{1}{\mu_z} \right) \right] \quad (24)$$

In order for Eq. (24) to be equivalent to Eq. (16), the θ -dependent terms must vanish. This can happen only if ϵ_y is the inverse of μ_z :

$$\epsilon_{yy} = \frac{1}{\mu_{z \text{ strips}}} = \frac{2d}{\pi t_1} \ln \left(\csc \frac{\pi b'}{2d} \right) \quad (25)$$

This relation shows us that the normal permeability of the strip layer is the inverse of the transverse permittivity because to the extent that the structure concentrates the in-plane E field, to the same extent that it squeezes the normal H field. In other words if we were to consider a TEM wave guided along the strips of the strip medium, it would have to travel at the speed of light, yet its concentration of electric field is equivalent to an increased permittivity. Therefore the squeezing of the H field must be equivalent to a depressed (diamagnetic) permeability exactly the inverse of the increased permittivity. The depression of the normal permeability is therefore a geometric effect proportional to the ratio of gap area to blocking metal area. (Note that if we were to ignore the effective normal permeability of the FSS, we would be forced to model the FSS as an angle-dependent shunt capacitance.)

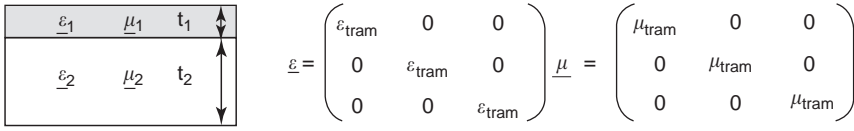

Therefore, since for the case of the Cohn square FSS the number of gaps per unit cell is double that found in the strip medium, we can write

$$\mu_{zz} = 2 \frac{\epsilon_{\text{avg}}}{\epsilon_{xx}} \quad (26)$$

where it is recognized that the squeezing of the magnetic field lines is a purely geometric effect and therefore any enhancement of the transverse permittivity due to the dielectric supporting the FSS must be ignored. Finally, as discussed during the derivation above, because the FSS is thin, ϵ_{zz} , μ_{xx} , and μ_{yy} are all simply equal to unity.

Thus, using an effective medium model, it is possible to derive closed-form expressions for a two-layer equivalent uniaxial magnetodielectric medium that should mimic all the properties of the AMC. This model is summarized in Fig. 7.

The method of derivation has been detailed above to allow the engineer to obtain equivalent representations for alternative designs. For instance, if a different capacitive FSS is used, it follows that the transverse permittivity of the FSS layer is simply $\epsilon_1 = C_{\text{FSS}}/t_1$. The normal permeability of the FSS, however, is not as easy to determine since it requires solving the quasimagnetostatic eddy current problem for determining the blockage of the magnetic field. As a rule of thumb, any FSS that obtains its capacitance from maximally blocking metal structures will obey Eq. (26). Maximally blocking structures are those where the closed metal paths cover the largest possible area with minimized perimeter. So, for instance,

$$\underline{\underline{\epsilon}} = \begin{pmatrix} \epsilon_{\text{tram}} & 0 & 0 \\ 0 & \epsilon_{\text{tram}} & 0 \\ 0 & 0 & \epsilon_{\text{tram}} \end{pmatrix} \quad \underline{\underline{\mu}} = \begin{pmatrix} \mu_{\text{tram}} & 0 & 0 \\ 0 & \mu_{\text{tram}} & 0 \\ 0 & 0 & \mu_{\text{tram}} \end{pmatrix}$$

$\epsilon_{1\text{tran}} = \frac{2d}{\pi t_1} \ln \left(\frac{d2}{\pi b'} \right) \epsilon_{\text{avg}}$ $\epsilon_{1\text{zz}} = 1$ $\mu_{1\text{tran}} = \mu_D$ $\mu_{1\text{zz}} = \frac{2\epsilon_{\text{avg}}}{\epsilon_{1\text{tran}}} \mu_D$ <p style="text-align: center;">FSS Layer</p>	$\epsilon_{2\text{tran}} = \epsilon_D \left(\frac{1 + \alpha}{1 - \alpha} \right)$ $\epsilon_{2\text{zz}} = \epsilon_D - \frac{1}{\omega^2 \epsilon_0 \frac{\mu A}{4\pi} \left[\ln \left(\frac{1}{\alpha} \right) + \alpha - 1 \right]}$ $\mu_{2\text{tran}} = \frac{\epsilon_D}{\epsilon_{2\text{tran}}} \mu_D \quad \mu_{2\text{zz}} = (1 - \alpha) \mu_D$ <p style="text-align: center;">Via array Substrate</p>
---	--

Figure 7. Summary of effective media parameters for the Sievenpiper AMC.

Cohn squares, hexagonal patches, or even closed square loops are maximally blocking. However, a gapped loop is the opposite of a maximally blocking structure since at low frequency the magnetic field can cross through the area inside the loop, owing to the interruption of eddy current by the gap. In such low-blockage cases the normal permeability can be estimated by rearranging the metal into parallel strips, calculating the capacitance of that “equivalent” strip medium and then using Eqs. (20) and (26).

Clearly, two FSS layers attaining the same capacitance, one using Cohn squares (which maximally block magnetic flux) and one using multilegged dipoles (with minimal blockage) will yield extremely different μ_{normal} values. The consequences of the choice of FSS topology is manifested in the surface-wave suppression properties of the AMC.

3. ELECTROMAGNETIC PROPERTIES IN TERMS OF THE EQUIVALENT EFFECTIVE MEDIA MODEL

The effective media model of the AMC is now used to calculate the surface-wave propagation properties of the structure. It is shown that the negative axial permittivity of the lower layer is the parameter responsible for the TM surface-wave properties and the creation of the lower band edge, while the highly diamagnetic normal permeability of the upper layer pushes the onset of TE surface waves above the resonant frequency of the AMC, thus creating the upper band edge.

The problem of solving the two-layer grounded slab is a boundary value problem, which can be solved completely using the wave equation subject to the appropriate boundary conditions. This solution is simplified by using the transverse resonance method (TRM), whereby the eigenvalue problem for a wave traveling in a preferred direction can be solved as a resonant transmission line in the transverse plane. The transverse resonance condition in the transverse plane is simply

$$Z_{\text{up}} + Z_{\text{down}} = 0 \quad (27)$$

where Z_{up} is the input impedance looking up and Z_{down} the input impedance looking down the transmission line, as seen in Fig. 8. The reference plane where the TRM is applied may be any convenient location along the equivalent transmission line (Fig. 8), and in this analysis it is chosen to be the outer surface of the AMC.

For a grounded two-layer slab as suggested in Fig. 8, the TR condition equality becomes

$$Z_0(Z_1 - Z_2 \tan(k_{z2}t_2) \tan(k_{z1}t_1)) + Z_1(jZ_2 \tan(k_{z2}t_2) + jZ_1 \tan(k_{z1}t_1)) = 0 \quad (28)$$

where Z_0 , Z_1 , and Z_2 are the corresponding wave impedances in layers 0 (air), 1, and 2 and the corresponding propagation constants k_{z1} and k_{z2} are as given in Eqs. (13) and (14). From this point on, the subscripts 0, 1, and 2 will refer to layers 0, 1, and 2, respectively, as shown in Fig. 8. As a rule, the fictitious thickness of the FSS is set to $t_1 = t_2/100$.

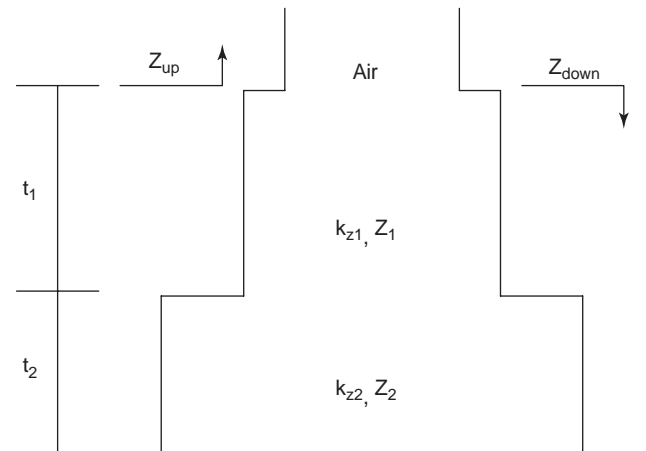

Figure 8. TRM applied to a two-layer grounded slab.

Figure 9. Graphical solution of the transverse resonance equation for TM waves showing the onset of the bandgap (lack of intersection) as frequency is increased: (a) via diameter = 0.51 mm, $d = 2.51$ mm; (b) via diameter = 0.51 mm, $d = 3.05$ mm. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

3.1. TM Surface Waves

Recognizing that the continuity of Maxwell's equations requires a common propagation constant in the x direction, namely k_x , for all the layers, and as we are seeking guided-wave solutions, we restrict the impedance of the air, layer 0, to that of an evanescent wave, defined as follows:

$$Z_0 = \frac{\alpha_z}{j\omega\epsilon_0} \quad (29)$$

Solving (28) for α_z , we have

$$\alpha_z = \frac{k_{z1}}{\epsilon_{x1}} \times \frac{\frac{k_{z2}}{k_0\epsilon_{x2}} \tan(k_{z2}t_2) \cos(k_{z1}t_1) + \frac{k_{z1}}{k_0\epsilon_{x1}} \sin(k_{z1}t_1)}{\frac{k_{z1}}{k_0\epsilon_{x1}} \cos(k_{z1}t_1) - \frac{k_{z2}}{k_0\epsilon_{x2}} \tan(k_{z2}t_2) \sin(k_{z1}t_1)} \quad (30)$$

However, since $k_x = \sqrt{k_0^2 - k_{z0}^2} = \sqrt{k_0^2 + \alpha_z^2}$, and since we are assuming that the propagation constant of air will be that of an evanescent wave, we obtain an equation of the following form:

$$k_x(\text{TM}) = \sqrt{k_0^2 + \alpha(k_{z1}(k_x), k_{z2}(k_x))^2} \quad (31)$$

This is a transcendental equation that cannot be inverted analytically. However, the solution can be illustrated graphically by inserting a real-valued $k_x > 0$, into the right-hand side of (31) and seeing where the curve $y = k_x(\text{TM})$ intersects the line $y = k_x$. The assumption of a solution of the form $e^{-\alpha_z z}$ in air implies that only those solutions with positive α_z correspond to guided waves. The absence of such a solution indicates the onset of the bandgap.

The TM case of the AMC is very similar to the Fakir bed of nails of King et al. [6]. The constitutive properties affecting the results are ϵ_z , ϵ_x , and μ_y . The relevant physical parameters according to the effective medium model are substrate permittivity, rod radius, and rod separation (size of the unit cell). Figure 9a shows a typical solution for a structure with the following characteristics: $t_2 = 1.57$ mm,

$\epsilon_D = 4.5$, via diameter = 0.51 mm, periodicity = 2.51 mm. Three frequencies were selected: 4.36, 5.07, and 5.31 GHz. It can be seen that at low frequencies there are always two intersections with the $y = k_x$ line and therefore two guided-wave solutions.

As frequency is increased, the $y = k_x(\text{TM})$ curve slides to the left, bringing the two solutions closer together until at the band edge the two coalesce into a single solution that then disappears (no intersection). In this example then the lower band edge where TM waves are suppressed occurs just above 5.07 GHz. Figure 9b shows the effect of changing the via separation. Changes in both radius and via separation provide a means for changing the inductance in the effective medium model, but the separation is the stronger control parameter. In Fig. 9b a 20% increase in the via separation moves the band edge to below 5.07 GHz.

It is clear that the appropriate choice of the physical dimensions determines the negative ϵ_{zz} of the via array substrate and therefore the position of the TM surface band edge that may or may not coincide with the $+90^\circ$ normal incidence reflection phase point of the AMC. The solution shown in Fig. 9 has the same characteristics as the King et al. Fakir structure. As those authors mention [6], in addition to the first two solutions, there are an infinite number of additional intersections, with an infinite number of tangential curves (higher-order modes). However, those intersections correspond to modes of extremely high reactance, which would exist only extremely close to the surface. Furthermore, they correspond in the example to values of k_x that exceed the periodic unit limit π/d ; therefore they are not relevant to the physical situation.

3.2. TE Surface Waves

Following the same procedure as for the TM case, the solution for α_z is as follows:

$$\alpha_z = -\frac{k}{\mu_{x1}} \times \frac{\frac{k_{z2}}{\omega\mu_0\mu_{x2}} \cot(k_{z2}t_2) \cos(k_{z1}t_1) + \frac{k_{z1}}{\omega\mu_0\mu_{x1}} \sin(k_{z1}t_1)}{\frac{k_{z1}}{\omega\mu_0\mu_{x1}} \cos(k_{z1}t_1) + \frac{k_{z2}}{\omega\mu_0\mu_{x2}} \cot(k_{z2}t_2) \sin(k_{z1}t_1)} \quad (32)$$

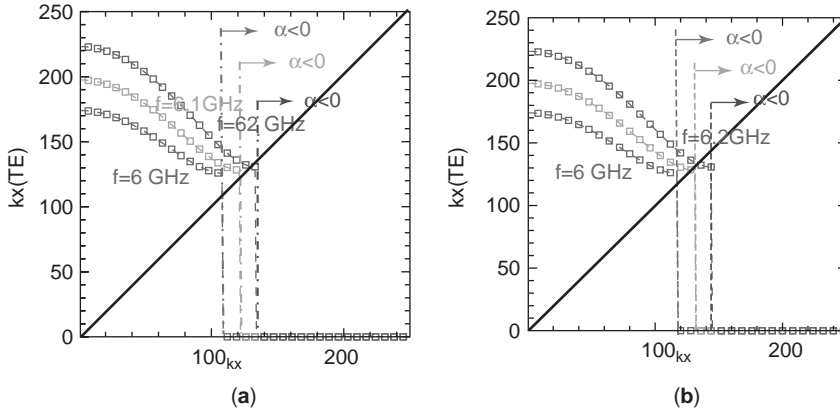

Figure 10. Graphical solution of the transverse resonance equation for TE waves showing the onset of guided surface waves as frequency is increased: (a) typical Cohn square FSS AMC; (b) after artificially raising μ_z by 20%. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Again, setting $k_x = \sqrt{k_0^2 + \alpha_z^2}$, we have the following transcendental equation:

$$k_x(\text{TE}) = \sqrt{k_0^2 + \alpha(k_{z1}(k_x), k_{z2}(k_x))^2} \quad (33)$$

The solution to this transcendental equation can also be illustrated graphically.

For the TE case, the constitutive parameters involved in the solution of Eq. (33) are μ_z , μ_x , and ε_y . But since μ_x is assumed to be one, and since ε_y is higher than 1 and therefore promotes the guidance of surface waves, the only parameter that can lead to suppression of surface waves is μ_z . Figure 10a shows the dependence of this solution on frequency for an AMC with the following characteristics: $t_2 = 1.57$ mm, with a square-shape FSS element supplying a capacitance of 0.4 pF and printed on an $\varepsilon_D = 4.5$ dielectric substrate.

At low frequencies no intersection between the $y = k_x(\text{TE})$ curve and the $y = k_x$ line occurs because the total electrical thickness of the guiding structure is less than a quarter-wavelength. For this AMC the normal incidence reflection coefficient resonance occurs at 5.5 GHz. This means that the electrical thickness of the structure is $\lambda/4$ at that frequency, and if this were a conventional isotropic dielectric structure with high permittivity, TE surface waves would begin to propagate at that frequency. However, as Fig. 10 shows, the intersection does not occur until 6.2 GHz.

To prove that it is the depressed normal μ_z of the FSS that is responsible for this upward shift of the TE band edge, Fig. 10b shows the result for an FSS that blocks less of the magnetic field; μ_z has been raised by 20%. Now the band edge occurs at 6.1 GHz. The structure has the same characteristics as in the previous example: $t_2 = 1.57$ mm, $\varepsilon_D = 4.5$. The reduction in blockage would arise, for instance, by going from a Cohn squares FSS design to a design that uses overlapping dipoles.

In Fig. 10, on the same graphs the boundary at which α_z changes from positive to negative has been denoted. At those boundaries the curve representing the right-hand side of Eq. (33) is stopped, because after that point the solution is an improper mode. The mode goes from proper to improper near the point at which k_x is approximately equal to k_0 .

In summary, the surface-wave suppression properties, and therefore the bandwidth, of the Sievenpiper AMC are controlled by the negative value of the normal permittivity of the via array substrate and the depressed normal permeability of the FSS layer. The position of the band edges relative to the $\pm 90^\circ$ phase shift points of the reflection coefficient is in general arbitrary except for the fact that the TE band edge can occur only above the 0° phase frequency (the reflection coefficient resonance). The physical implementation of these structures and the degree to which the surface-wave suppression bandwidth can be designed is treated in the next section.

3.3. Reflection Coefficient

The reflection coefficient for a generalized two-layer anisotropic grounded slab can be found through the use of Eqs. (13) and (14) and an equivalent transmission-line representation of assumed infinitely wide slabs (Fig. 11).

The input impedance of the AMC is the short circuit rolled back through the two media of lengths t_1 and t_2 . Thus, after finding Z_{12} of Fig. 11, we will use that impedance as the load impedance for the line of length t_1 :

$$Z_{12}^{\text{TE, TM}} = jZ_2^{\text{TE, TM}} \tan(k_{z2}^{\text{TE, TM}} t_2) \quad (34)$$

Figure 11. Equivalent transmission-line representation of a two-layer anisotropic grounded slab.

Table 1. Anisotropic Constitutive Parameters for a 10 mm Thick AMC Resonating at 2 GHz

Layer n	Anisotropic Constitutive Parameters			
	ϵ_{ntr}	ϵ_{nz}	μ_{ntr}	μ_{nz}
1	876.46	1	1	0.01
2	4.8	$\sim(-450)$	1	1

This yields the desired load impedance of the two-layer anisotropic medium:

$$Z_{load}^{TE, TM} = Z_1^{TE, TM} \times \frac{jZ_2^{TE, TM} \tan(k_{z2}^{TE, TM} t_2) + jZ_1^{TE, TM} \tan(k_{z1}^{TE, TM} t_1)}{Z_1^{TE, TM} - Z_2^{TE, TM} \tan(k_{z2}^{TE, TM} t_2) \tan(k_{z1}^{TE, TM} t_1)} \quad (35)$$

Now, using this result and the definition of the reflection coefficient, we can find the generalized reflection coefficient for a two-layer anisotropic grounded slab as a function of frequency and angle of incidence $\theta_i = a \sin(k_x/k_0)$.

Since the structure is grounded and assumed lossless, the magnitude of the reflection coefficient will be 1 for any frequency and angle of incidence. But clearly the phase of the reflected wave will change with frequency and angle since the electrical thickness of the layers will also change. The reflection coefficient was calculated for an AMC 10 mm thick with anisotropic constitutive parameters at the center of the band as shown in Table 1.

The corresponding reflection coefficient phase can be seen in Figs. 12a and 12b for TE and TM waves, respectively, for normal incidence, 45° angle of incidence, and angles almost grazing parallel to the surface.

Clearly, the curve shapes are similar, all exhibiting a change in the reflection coefficient phase from +90° to -90°, crossing the 0° phase point, which signals total in-phase reflection. The angle of incidence dependence of the FSS admittance in the TE case, that is, the presence of $\mu_z < 1$, is what causes the shift in the curves for that case (Fig. 12a). It has been pointed out [9] that a more stationary behavior would be obtained for the TE case if

$\mu_z < 0$ were involved in direct analogy to the negative ϵ_z involved in the TM case. The relevance of these curves to the performance of an antenna extremely close to the AMC is not necessarily obvious. Such a proximate antenna has its near field in contact with the AMC so that the interaction between the antenna and the AMC involves not only reflection of its radiated plane-wave spectrum but also coupling of the evanescent portion of that spectrum to the spectrum of leaky- and surface-wave modes supported by the AMC. In other words, a complete picture of the antenna-AMC interaction involves the complete k -space spectrum of the AMC surface’s complex impedance and reflection coefficient [10]. This is why both analyses have been presented above. However, it is true, on the basis of the reaction theorem [11], that for an observation point far from the (assumed infinite) surface of the AMC, the antenna pattern of a current source such as a horizontal dipole can be entirely determined from the surface’s TE and TM plane-wave reflection coefficients (the only electromagnetic property not so determined is the impedance and therefore the efficiency of the resulting radiator).

Thus consider the case of an end-fed quarter-wave horizontal dipole directly over a thick (33-mm) AMC with a low-dielectric-constant substrate ($\epsilon_D = 1.07$) designed with a resonant frequency of 1080 MHz (FSS capacitance of 0.54 pF) and 1-mm-diameter vias 34 mm apart. The lower (TM) band edge is at 770 MHz and the upper (TE) band edge at 1380 MHz (a 1.77-1 bandwidth). In the E plane of the monopole, the TM reflection coefficient dominates. Figure 13a shows the resulting antenna pattern for 0.699 GHz (just below the band edge), 1.075 GHz (center of the band), 1.376 GHz (above the center but still inside the band), and 1.526 GHz (just outside the band.) A +3 dB gain increase is seen at the center of the band when compared to the other in-band frequencies. Outside the band the gain is lower. In all cases we have a well-behaved nearly identical dipolelike pattern. In the H plane the TE reflection coefficient dominates. The calculated pattern at the same frequencies is shown in Fig. 13b. There we see a more significant change in pattern shape with frequency as expected from the shift in the reflection coefficient phase seen in Fig. 12a.

Figure 12. Reflection coefficient phase versus frequency as a function of angle of incidence for an AMC resonant at 2 GHz: (a) TE case; (b) TM case. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 13. Antenna patterns on the principal planes of a horizontal quarter-wave monopole over an AMC with 0.7 GHz TM band edge and 1.53 GHz TE band edge (red curve = 0.699 GHz, black curve = 1.075 GHz, blue curve = 1.376 GHz inside the band, magenta curve = 1.526 GHz): (a) *E* plane; (b) *H* plane. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The effective medium model allows us to calculate the reflection coefficient of the AMC outside its operational band. If we go well above the band, the TM solution admits of higher-order modes (the modes found by King et al. in Fakir’s bed of nails). Around 2 GHz the first of these modes intersects the $y = k_x$ line with a propagation constant just below k_0 ; in other words, the mode is leaky. This intersection manifests itself in the TM reflection coefficient calculation and leads to an antenna pattern with a sharp cusp, characteristic of leaky-wave antennas [12].

Figure 14a shows this result. The effective medium model allow us to not only predict that result but also devise a method for extinguishing the offending mode selectively. As is well known, higher-order modes are extremely sensitive to loss. Therefore adding a small amount of loss to the substrate ($\epsilon_D = 1.07 - j0.05$) essentially erases the leaky-wave contribution and preserves the dipolelike pattern outside the band as seen in Fig. 14b.

4. DESIGN PROCEDURE FOR AMCs

Although transverse resonance can be used directly to find the propagation characteristics of waves in the AMC, it is a graphical and tedious process. Automatic complex root-finding routines do not add to our physical insight. Unfortunately, the transcendental equations describing the propagating modes involve trigonometric functions that cannot be inverted. In this section equivalent-circuit ele-

ments and approximations regarding the electrical size of the material are used to simplify the equations and thus enable us to locate the guiding solutions of the effective medium model.

4.1. Approximation Method for TM Waves

By noting that the FSS layer is simply a capacitor that contributes the additional phase shift to create a quarter-wave grounded thin slab, the AMC can be modeled by a single uniaxial anisotropic layer over which there is an infinitesimally thin capacitive shunt element. In that case the transverse resonance equation [Eqs. (30) and (31)] become

$$k_{xTM} = \sqrt{\frac{\epsilon_0^2(k_{z2})^2}{(\epsilon_0\epsilon_{xx2} \cot(k_{z2}t_2) - Ck_{z2})^2} + k_0^2} \quad (36)$$

where C is the capacitance of the FSS and of course k_{z2} is a function of k_{xTM} per Eq. (14) (as a further approximation we note that, by definition, the AMC is an electrically thin structure; thus the product $k_{z2}t_2 < 1$ and the cotangent function can be approximated by $1/k_{z2}t_2$).

In the graphical solution illustrated in Fig. 9, we can see the close resemblance of the $y = k_{xTM}$ curves to secant functions. Thus the guiding properties arise when a secantlike curve just grazes the diagonal $y = k_x$ line.

Figure 14. Antenna patterns on the *E* plane of the horizontal monopole of Fig. 13, above the AMC bandgap; the existence of a leaky wave near 2 GHz causes severe distortion of the pattern (a) that can be corrected by adding a small amount of loss to the substrate (b) (red curve = 1.83 GHz, black curve = 1.90 GHz, blue curve = 1.98 GHz). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Thus the guiding properties of the AMC can be characterized by determining the following two parameters that fix the secant function:

- The value of k_x when the secant function approaches infinity,
- The value of y when k_x TM is zero.

The first value must correspond to the pole in k_x of Eq. (36). The pole occurs at

$$k_{x\text{TM}\infty} = k_0 \sqrt{\mu_{yy2} \epsilon_{zz2} \left(1 - \left(\frac{k_{0\text{res}}}{k_0} \right)^2 \right)} \quad (37)$$

where $k_{0\text{res}}$ is the free-space wavenumber at the resonant frequency.

The second value can be found simply by finding the y -axis intercept:

$$k_{x\text{TM}}|_{k_x=0} = k_0 \sqrt{1 + \left(\frac{k_0 \mu_{yy2} t_2 k_{0\text{res}}^2}{k_0^2 - k_{0\text{res}}^2} \right)^2} \quad (38)$$

Therefore, in order to find the curve for the lowest-order mode solution of TM waves, we will use the following secant function

$$y(k_x) = (k_{x\text{TM}}|_{k_x=0}) \sec\left(\frac{\pi}{2k_{x\text{TM}\infty}} k_x\right) \quad (39)$$

where $k_{x\text{TM}\infty}$ and $k_{x\text{TM}}|_{k_x=0}$ are as given in (37) and (38), respectively. Of course, once we have an analytic expression as in Eq. (39), the frequency at which an intersection no longer occurs can be directly determined by recognizing that the osculation point (the band edge) occurs at the point where the secant curve has slope equal to one. Therefore by taking the first derivative of Eq. (39), setting it equal to 1.0 and then finding the frequency at which that point exactly equals k_x reveals the band edge.

Figure 15 shows the close agreement between the exact transcendental equation from Eq. (31) and the analytic secant function from Eq. (39). The error in the prediction of the band edge, that is, the frequency at which the curve detaches the 45° line, is only ~2%.

4.2. Approximation Method for TE Waves

For the TE case we have already seen that the FSS cannot be regarded simply as a shunt capacitor, since the normal component of the permeability is not one. We then proceed by first rewriting the transcendental equation in the form

$$k_{x\text{TE}} = k_0 \sqrt{\frac{\left[\frac{k_{z1}}{k_0} \left(\frac{\mu_{xx1}}{k_{z1}} - \frac{\mu_{xx2}}{k_{z2}} \tan(k_{z1}t_1) \tan(k_{z2}t_2) \right) \right]^2}{\mu_{xx1} \left(\frac{\mu_{xx2}}{k_{z2}} \tan(k_{z2}t_2) + \frac{\mu_{xx1}}{k_{z1}} \tan(k_{z1}t_1) \right)}}} + 1 \quad (40)$$

Figure 15. Comparison of the exact solution and the design equation (39) for a 1.57-mm AMC resonant at 5.5GHz with a substrate dielectric constant of 4.5, rod radius of 0.2mm, and via separation of 2.51 mm. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Simplifying by assuming that $[\tan(k_{z2}t_2)]/k_{z2} = t_2$ (for the substrate layer) introduces a small error, which in the TM case was negligible, but in this case this small error is accentuated when multiplied by the small values from the $\tan(k_{z1}t_1)$ term. Therefore the ratio mentioned above needs to be fixed to a value to ensure that the solution stays close to the exact solution. Since guided waves first appear when k_x is near k_0 , we fix the ratio as follows:

$$c_2 = \frac{\tan\left(k_0 \sqrt{\epsilon_{y2} \mu_{x2} - \frac{\mu_{x2}}{\mu_{z2}} t_2}\right)}{k_0 \sqrt{\epsilon_{y2} \mu_{x2} - \frac{\mu_{x2}}{\mu_{z2}}}} \quad (41)$$

Now we can assume that the FSS layer has an infinitely thin thickness, and therefore, the tangent function involving $k_{z1}t_1$ can be simplified to its argument. Performing all these simplifications leads to the following version of Eq. (40):

$$\left(\frac{k_x}{k_0}\right)^2 = \frac{\left[1 - \mu_{xx2} c_2 t_1 (k_0)^2 \left(\epsilon_{yy1} - \left(\frac{k_x}{k_0}\right)^2 \frac{1}{\mu_{zz1}} \right) \right]^2}{(k_0)^2 (\mu_{xx2} c_2 + \mu_{xx1} t_1)^2} + 1 \quad (42)$$

Solving for k_x , we encounter a second-order polynomial in k_x squared of the form

$$\left(\frac{k_x}{k_0}\right)^4 \left(\frac{\beta}{\mu_{z1}}\right)^2 - \left(\frac{k_x}{k_0}\right)^2 \left(\chi - \frac{2\beta}{\mu_{z1}} + \frac{2\epsilon_{y1}\beta^2}{\mu_{z1}}\right) + \chi + 1 - 2\beta\epsilon_{y1} + \epsilon_{y1}^2\beta^2 = 0 \quad (43)$$

where $\beta = k_0^2 \mu_{y2} t_1 c_2$ and $\chi = (k_0 (\mu_{y2} c_2 + \mu_{y1} t_1))^2$.

The solution of this polynomial will yield four solutions for guided waves. However, only the real solutions with an attenuation constant $\alpha > 0$ are proper solutions. To complete our design equations, we have to find the point at which $\alpha = 0$, or in other words, where proper solutions begin to propagate. Hence, using Eq. (32) and using the same approximations that lead to Eq. (43), this point in k_x becomes

$$k_x = \sqrt{\mu_{z1} \left(k_0^2 \epsilon_{y1} - \frac{1}{\mu_{y2} t_1 c_2} \right)} \quad (44)$$

Figure 16 shows the exact solution and our new approximated design equation (43). The error in the prediction of the TE band edge is less than 0.5%.

4.3. Design of Surface-Wave Bandwidth

The design equations of Sections 4.1 and 4.2 allow us to more easily determine the surface-wave bandwidth of operation of an AMC. For the TM waves the objective is to find the osculation point between the secant function and the $y = k_x$ line. In order to find this point using Eq. (39), we first have to find the value of k_x for which the derivative of the secant function is one. As an intermediate step to this calculation we encounter a quadratic equation in sine functions that, after a change of variable of the form $U = \sin(x)$, can be solved as

$$U = \frac{-\pi(k_{xTM}|_{k_x=0})}{4k_{xTM\infty}} + \sqrt{\left(\frac{\pi k_{xTM}|_{k_x=0}}{4k_{xTM\infty}} \right)^2 + 1} \quad (45)$$

Then, the k_x point of interest is the inverse of this sine function multiplied by a constant,

$$k_{xTM} = \frac{2k_{xTM\infty}}{\pi} \arcsin(U) \quad (46)$$

Figure 16. Comparison of the exact solution and the design equation (43) for a 1.57-mm AMC resonant at 5.5 GHz with a substrate dielectric constant of 4.5. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 17. TM band edge for different via spacing d ; the TM band edge is identified as the zero-crossing values of the curves. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

This point indicates the value of k_x only where a 45° line is tangential to the curve. When this value is substituted into Eq. (39), then the ordinate of this point is found. Therefore, as this ordinate approaches k_{xTM} itself, we have the desired intersection. The resulting equation to find the intersection is still not invertible but its graphical solution allows us to find **all** the TM band edges associated with any range of input physical parameters of the AMC. For instance, Fig. 17 shows the difference $y_{TM} = K_{xTM} - y(K_{xTM})$ versus frequency for an AMC as the via periodic unit length is changed. For each periodic unit length the point where the curve crosses zero is the TM band edge.

For the TE band edge, four roots will be found from Eq. (43). These solutions are proper guided waves only if these are real and positive values, and only when they lie to the left of the k_x value (the $\alpha_z = 0$ boundary) given by Eq. (44). As an example, Fig. 18 shows the roots of Eq. (43) for the resonance frequency ($f_1 = 5.5$ GHz) and for a frequency 11% higher ($f_2 = 6.1$ GHz). For f_1 we have TE surface-wave suppression since the boundary at which $\alpha_1 = 0$ (corresponding to f_1) occurs at $k_x = 0$ and no real solutions exist. As frequency increases, the $\alpha_2 = 0$ (corresponding to f_2) boundary moves to the right and the complex solutions of Eq. (43) approach the real axis of the complex plane. The blue curve of Fig. 18 shows that we have two real solutions for frequency f_2 but that one of them is an improper solution (lying outside the $\alpha_2 > 0$ region) and the other is just inside the region. Hence, a TE surface wave is excited for frequency f_2 and the TE surface-wave suppression band edge is found.

4.4. Design Guidelines

In the design of the AMC the first step is to determine the thickness based on the desired bandwidth of operation [according to Eq. (3)]. Then the FSS capacitance required

Figure 18. TE band edge determination procedure. The roots of equation (43) have to be real and positive and lie in the $\alpha > 0$ region. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

to obtain resonance at the desired thickness is given by

$$C = \frac{1}{\omega_{\text{res}} \eta_0 \sqrt{\frac{\mu_{\text{trans}2}}{\epsilon_{\text{trans}2}}}} \times \cot\left(\frac{\omega_{\text{res}}}{c_0} \sqrt{\mu_{\text{trans}2} \epsilon_{\text{trans}2}} \cdot t_2\right) \quad (47)$$

where ω_{res} is the angular frequency of resonance; η_0 is the intrinsic impedance of free space; $\mu_{\text{trans}2}$ and $\epsilon_{\text{trans}2}$ are the relative transverse permeability and permittivity, respectively, of layer 2 (the via array region); c_0 is the speed of light in free space; and t_2 is the thickness of the via array layer.

If the capacitance required is not too large, a Cohn squares array can be designed approximately using the equations for the strip grating [Eq. (20)]. This will give the engineer a reasonable estimate of the required periodic unit and gap dimensions. The exact design can then be fine-tuned using a full-wave electromagnetic solver. If the required capacitance is large, then equation 20 may give a periodic unit that is too large (too close to $\lambda/4$) or a gap width that is too small to manufacture accurately. Then a multilayer design is required for use of the parallel-plate capacitance obtained from overlapping metal plates. The following rules of thumb for typical AMCs may be used. Up to a capacitance of 1 pF/square, Cohn squares are appropriate; to obtain capacitances as high as 15 pF/square requires overlapping Cohn squares. The choice of FSS design is also driven by cost considerations, where a single-layer design has obvious advantages from minimization of manufacturing steps. To exceed the 1 pF/square limit in a single layer, interdigital capacitor (ICAP)

designs have been fabricated that offer FSS capacitance levels up to 5 pF/square [13].

Almost arbitrarily large values of capacitance are achievable simply by placing the two layers very close to each other, that is by using a very thin dielectric spacer with the metal pattern etched one side and registered appropriately above the first metal pattern on the top of the substrate. However, it must be realized that then the manufacturing tolerance on the thickness of the dielectric spacer becomes the critical parameter in controlling the resonant frequency of the AMC.

Figure 19 shows the most general case of two-overlapping arrays of Cohn squares. Such a design will have both the original edge-to-edge capacitance and a much stronger parallel-plate contribution of the form $C_p = \epsilon A/d$. The capacitance per square of the case in Fig. 19 is deduced by recognizing the equivalent circuit of Fig. 20.

The FSS capacitance would then be

$$C_{\text{eq}} = 2C_e + \frac{C_{p11}C_{p12}}{C_{p11} + C_{p12}} + \frac{C_{p21}C_{p22}}{C_{p21} + C_{p22}} \quad (48)$$

where C_e is the edge-to-edge capacitance (as in the strip medium).

As mentioned earlier, a Cohn square FSS is maximally blocking; therefore Eq. (26) correctly predicts the normal permeability, and the procedure using Eqs. (43) and (44) enables a direct prediction of the maximum attainable TE band edge that results automatically from this choice.

If a maximally blocking design is not required or if adding series inductance to the FSS is desirable (providing an additional measure of tuneability) [13], other shapes, such as overlapping Jerusalem crosses, can be used. Figure 21 shows the basic cross element, while

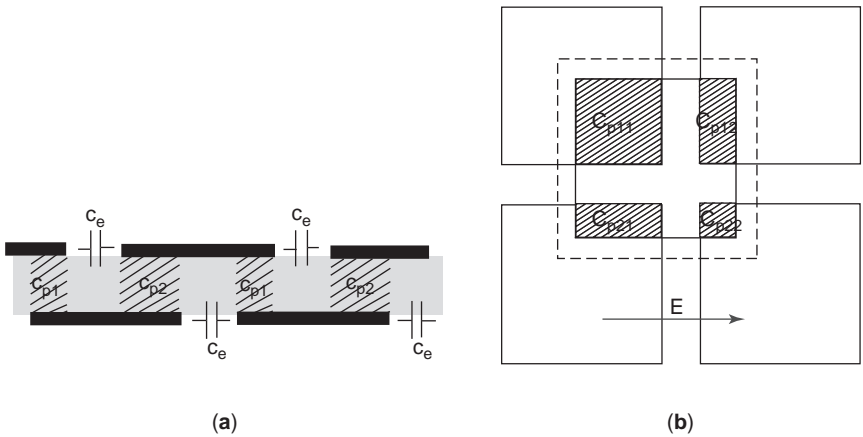

Figure 19. Side (a) and top (b) views of a two-layer FSS with Cohn squares.

Fig. 22 shows how the overlapping is accomplished in a two-layer design. In the Jerusalem cross case, the eddy currents cannot flow around the outer perimeter because of the breaks in the pattern; therefore only small eddy currents will be formed on the arms of the cross and in its center. With the chosen proportions the parallel-plate capacitance in the overlapping regions can be quite high, while making the arms thin enough to yield a significant amount of series inductance.

The design problem is to find the physical dimensions l_1 , l_2 , and l_3 of Fig. 21 in order to achieve the capacitance with a moderate-thickness spacer. The equivalent circuit with a moderate-thickness spacer. The equivalent circuit is the same as in Fig. 20, except that each C_{p11} , C_{p12} , C_{p21} , and C_{p22} is the result of two parallel-plate capacitors in parallel. Also since the crosses are set symmetrically in the center of the cell, then all the capacitances have the same value and the equivalent capacitor is $2C$, where C is the capacitance of one parallel-plate capacitor.

After designing the FSS to attain the needed capacitance and TE blockage, the next step is to ensure that the surface-wave suppression band coincides with or exceeds the $\pm 90^\circ$ phase reflection bandwidth. The via array in the substrate controls the lower band edge. Its primary design parameter is the via spacing or periodic unit cell. This is because most reasonable via diameters chosen will work

well provided the spacing between the vias is adjusted properly. Thus we can assume that selection of the via diameter will be based on manufacturing convenience. The purpose of the via array is to create a negative ϵ_{zz} such that the TM waves guided by the substrate are of the Fakir bed of nails type, and then to place the cutoff of these waves at the desired band edge frequency. These requirements place obvious constraints on the design. It should be noted that the periodicity of the via array must match the periodic unit of the FSS metal patches because it is the termination on a (relatively) large metal plate that allows the current in the short vias to appear almost uniform along the length of the via, and thus enable the finite substrate to behave as the rodged medium with infinitely long rods.

Since the permittivity is a strong function of frequency, the right value of inductance for the via array region must be chosen precisely with respect to the desired bandwidth. Clearly, if the value of the normal permittivity of the substrate becomes greater than one inside the desired

Figure 20. Equivalent circuit of a two-layer FSS with squares as its element shapes.

Figure 21. Jerusalem cross element.

Figure 22. Two-layer Jerusalem cross FSS.

operating band, the substrate will be able to support conventional TM surface waves. Thus, the first general guideline to ensure surface-wave suppression is to maintain the normal permittivity at <1 within the bandwidth of interest. Given a choice of substrate dielectric constant, the normal permittivity is controlled over the band by controlling the zero-crossing frequency, that is, the frequency at which ϵ_{zz} changes from negative to positive values. Figure 23 illustrates the effect of the via spacing on this zero-crossing point for a substrate with a relative dielectric constant of 4.5.

The vertical lines define the extent of the desired bandwidth of operation (Γ_{BW}). In this figure the case in which the vias are one-ninth of a free-space wavelength

apart (at the reflection phase resonance) gives the most negative normal permittivity because its zero-crossing frequency is far above the high-impedance frequency band of operation. However it also gives the most rapidly varying value of ϵ_{zz} over the band, and this turns out to limit the surface-wave suppression bandwidth since the oscillation point will occur at a higher frequency for more negative values of permittivity. To maximize the TM bandwidth, we want the slowest possible varying normal permittivity that nevertheless does not cross 1 inside the band of operation. For this case a via spacing of the order of $\frac{1}{8}$ -wavelength ($\lambda/8$) would be the best. Clearly, in Fig. 23 the dielectric constant ϵ_D of the substrate plays an important role in determination of the bandwidth because it controls the asymptotic high-frequency limit of ϵ_{zz} and therefore the slope of the curve over the bandwidth of operation.

As a rule of thumb, to maximize the TM bandwidth, it is advisable to put the zero crossing of ϵ_{zz} as close as possible to the upper end of the band and to minimize the slope of the curve. This means that substrate dielectric constant is chosen as low as possible and the via spacing is chosen as large as possible within the constraint of not getting close enough to $\lambda/4$ in the dielectric where periodic effects start to alter the zero-crossing frequency. To maximize the TE bandwidth, we have to allow for the normal H field to be blocked as much as possible. FSS consisting of metal squares are maximally blocking, while FSS consisting of crossed dipoles would be minimally blocking. Although it is true that interdigitated capacitor designs enable the creation of high capacitance FSS with only one side of metal (no need for overlap), such metal arrangements are full of gaps and are not maximally blocking; therefore they typically result in a reduced TE surface wave bandgap.

Finally, the blocking performance of the FSS is indirectly affected by the thickness and composition of the via array substrate because to obtain zero-degree reflection

Figure 23. Zero crossing of ϵ_{zz2} as a function of via spacing. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

coefficient at the desired center frequency the total phase shift supplied by the FSS and the substrate must be equivalent to a quarter-wavelength. Therefore, if the substrate is made too thick, or has too high a dielectric constant, the FSS capacitance will be too small, and hence the FSS patches will be too small or the gaps will be too large to adequately block the normal magnetic field.

It should be emphasized that whenever FSS designs are used that utilize thin metal lines, slots, or gaps, that block the current flow on plates, or overlapping regions that require the current to “neck down” to deliver the charge to the parallel-plate capacitors, there is bound to be a significant amount of inductance in series with the capacitance. This inductance may manifest itself as an apparent frequency dependence on the capacitance that raises the capacitance with frequency and therefore reduces the bandwidth of the original design by detuning it. In the extreme case, the inductance can resonate the FSS capacitance and create multiple high-impedance bands, each with its own default value of TE band edge [14]. The use of such inductive FSS also requires additional care in selection of the periodic unit because the ratio of FSS capacitance to FSS inductance is affected by the absolute size of the unit cell. Whereas the capacitance of an overlapping FSS is proportional to the area of the cell, the inductance is clearly proportional to the length of the cell.

5. REVIEW OF MORE RECENT LITERATURE ON AMCs

The operational definition of an artificial magnetic conductor adopted in this article includes the AMC’s response to both free traveling plane waves (the in-phase reflection coefficient) and evanescent plane waves (near-field impedance increase and suppression of surface waves)—in other words, the effect of the AMC on the entire k -space spectrum of the radiator. Both conditions must be present for the AMC to constitute a gain-increasing ultrathin ground plane for low-profile antennas. On purpose we have avoided classifying the AMC as a photonic bandgap (PBG) or electromagnetic bandgap (EBG) structure because such structures typically operate as three-dimensional frequency-selective filters; that is, EBGs and PBGs usually operate in the frequency range where the periodicity of their inhomogeneities is comparable to a quarter of the wavelength in the dielectric [15]. In contrast, the Sievenpiper family of AMCs operates in the range of frequencies where the periodicity is a small fraction of the wavelength. For conventional communication requirements of bandwidths of the order of 10%, the periodic unit can be of the order of $\lambda/50$. Only when the bandwidth has to be pushed to 2–1 does it become necessary to increase the via separation close to the quarter-wave point.

These considerations are important when tracing the heritage and ongoing history of the AMC in the literature. For instance, the term *artificial magnetic conductor* has been applied in the literature to “quarter-wave ground-planes” rendered thin by the inclusion of FSS layers [16]. However, if the ground plane contains no vias to suppress TM surface waves, the only useful suppression will occur

when the filtering properties of the FSS come into play, that is, when the periodic unit of the FSS is comparable to $\lambda/4$. Such a structure should simply be classified as a frequency-selective surface. Similarly, just because a surface exhibits an in-phase reflection coefficient to plane waves does not mean that it will increase the gain of proximate horizontal antennas and qualify it as an AMC. For this reason, references in the literature that consider and measure only plane-wave reflection coefficients are not very useful to the designer of AMCs.

Because the Sievenpiper AMC is used as a surface below the antenna, its “bulk” EBG properties are seldom, if ever, used and appear to be irrelevant in practice. This fact is highlighted by the ease with which a horizontal monopole on the AMC is fed by penetrating the ground plane, thus exposing the center conductor of a coaxial cable (coax) line to an array of vias in its near field. The vias simply play the role of an extension of the coax transmission line’s (absent) outer conductor. Clearly, any wave that might be radiated by the exposed center conductor in the via array region is stymied by the large negative permittivity of that substrate.

There is one structure labeled as PBG in the literature that is very close in spirit to the AMC, and this is the uniplanar compact photonic bandgap (UCPBG) [17]. This structure uses no vias, but its textured ground plane contains both capacitive patches and inductive segments of line. Their combination creates a surface that can guide slow waves up to a resonant forbidden band. Many useful devices have been constructed using that structure ranging from slow-wave compact filters to “TEM” closed waveguides. Indubitably the UCPBG could be analyzed and designed in terms of effective medium theory in the same way as the AMC subject of this article.

The history of the AMC in its present form can be directly traced to Ref. 18, where it was shown that the reflection coefficient band of a tripole array FSS can be moved arbitrarily low in frequency by overlapping tripole layers so that the overlap parallel-plate capacitance tunes the surface. Only plane-wave transmission and reflection coefficients were measured. In Ref. 19 the tripole layers are revisited and it is pointed out that the 100% reflection bandgap disappears at shallow angles of incidence for TM waves because there are no vias connecting the multiple overlapping tripole layers. In Ref. 20 a diamond lattice of multiple overlapping crossed dipole FSS layers connected to each other with vias is studied. A plane-wave reflection coefficient bandgap is reported together with a bulk bandgap assessed by inserting collinear coax probes into the center of the material.

The first reported measurement of a surface-wave bandgap appears in Ref. 21. Overlapped tripole and crossed dipole FSS layers connected with vias were studied for TM surface-wave properties as well as for normal incidence reflection coefficient properties. TM surface waves were found to exist inside only a portion of the reflection bandgap. “Variation of the symmetry” was the approach used to attempt to modify the size and location of the bandgap.

After a symposium paper in 1998 [21], Sievenpiper’s Ph.D. dissertation [1] contains proof of both TE and TM

surface-wave bandgap properties, and subsequent papers, including those noted in Section 5 (above), have thoroughly examined the extent to which the AMC properties can be designed and even dynamically altered. Still, misuse of the AMC happens occasionally as in Ref. 22, where a patch antenna intended to operate at Ku band (13–15 GHz) is surrounded by a Sievenpiper AMC (the PBG of the title), and yet the chosen parameters for the via array region (via diameter 0.2 mm, spacing 2.44 mm, and substrate dielectric constant) can be shown to give a zero-crossing frequency well below the band of operation. In fact, calculation of the ϵ_z properties reveals a normal permittivity varying from 3.6 to 5.7 (positive!) over the range where experiments were performed. It is therefore not surprising that the author's results were unimpressive. For a correct application of the AMC to patch antennas, the reader is referred to Rahmat-Samii's paper [23], which also reports a circularly polarized curl antenna with good axial ratio in the bandgap. The patch antenna had a 3 dB gain enhancement accompanied by skirt suppression and 15 dB suppression of the backlobe. The AMC was also used for mutual coupling reduction (8 dB improvement) in a microstrip patch array.

A careful study of the backlobe suppression properties of the AMC is found in Ref. 24. The authors show that the AMC effect on antenna match (S_{11}) essentially follows the antenna's own trend in free space. Using the AMC as a reflector, very high front-to-back shielding in the near field and somewhat less in the far field are shown. They also investigated a double (back-to-back) AMC versus the regular AMC backed by its PEC ground plane and found that the former has similar backlobe suppression but incurs more dielectric loss. This is contrasted with a full-wave simulation of back-to-back PMC surfaces, which have much poorer backlobe suppression than does the AMC. This result emphasizes that the AMC is not a PMC because it also suppresses TE waves.

Table 2. Summary of the Most Relevant Parameters of the Three Different AMCs Designed

Parameters	Designs		
	I	II	III
$C_{\text{FSS}}(\text{pF})^a$	0.915	$0.915 + L_{\text{FSS}}$	$0.915 + L_{\text{FSS}}$
t_2 (mm)	1.5748	1.5748	1.5748
d (mm)	2.5146	8.3312	3.9624
ϵ_D	4.5	4.5	4.5
11 (mm) ^b	N/A	N/A	0.8382
12(mm) ^b	N/A	N/A	2.3114
13(mm) ^b	N/A	N/A	0.2286
14(mm) ^b	N/A	N/A	1.143
SW BW(GHz)	3.65–4.1	2.85–3.4	3.41–3.5

^a“+” means that the FSS inductance has to be taken into account.

^b“Jerusalem cross” dimensions shown in Fig.21.

6. MORE RECENT APPLICATIONS OF AMC

As an example of the versatility of the design procedure outlined above, we designed three different AMCs whose $\pm 90^\circ$ phase operating bands are not necessarily coincident with the surface-wave band. The fabricated designs are shown in Fig. 24.

The goal of the first design was to set the TM as well as the TE band edges close to the $\pm 90^\circ$ band; therefore the appropriate via separation and magnetic field blockage were calculated to yield the surface-wave bandwidth given in Table 2, while the normal incidence reflection bandwidth is 3.57–4.01 GHz. The goal of the second design was to set the TE band edge just above the -90° phase point by tailoring the magnetic blockage appropriately, while at the same time using the via spacing to move the TM band edge well below the $+90^\circ$ phase point. The normal reflection bandwidth is 3.23–3.33 GHz. The last design is meant only to block TM surface waves using the via array but to allow TE waves to propagate by using a low magnetic blockage (Jerusalem cross) FSS, shown in Fig. 21. Again, the following normal reflection bandwidth for this case is 3.33–3.64 GHz. Table 2 shows the most important dimensions of the AMCs fabricated as well as their predicted surface-wave band, defined by the TM and TE band edge.

Figure 25 shows the equivalent circuit for the FSS. Since in two of these cases the current flow through the FSS is considerably constricted by the geometry of the

Figure 25. Equivalent circuit for the AMC when its FSS inductance is relevant.

Figure 26. Equivalent distributed LC circuit for an FSS with two overlapping layers with Jerusalem crosses as its elements.

pattern, the series inductance of each design must also be taken into account. As a rule of thumb, Marcuvitz' [8, pp. 221–228] results for a strip inductive medium provide a reasonable closed-form estimate for this inductance (with the result that tightly packed Cohn squares have almost zero inductance). Thus, for design I a purely capacitive FSS is appropriate, since the inductance from the FSS is negligible ($L_{\text{FSS}} = 0.03 \text{ nH}$).

For design II we used large Cohn squares that have little overlap capacitance. In this case, the inductance, calculated from Marcuvitz' data [8, pp. 221–228], is not negligible anymore ($L_{\text{FSS}} \approx 0.87 \text{ nH}$) and has to be taken into account in the design. For design III, the FSS equivalent circuit is a distributed LC circuit, shown in Fig. 26, where the series inductances can be calculated using Marcuvitz' method [8, pp. 284–285], and the capacitors are small parallel-plate capacitors. The inductance from the FSS is manifested in the frequency-dependent effective capacitance deduced from the circuit from Fig. 26.

The phase of the reflection coefficient was measured experimentally on a basic Naval Research Laboratory (NRL) arch setup. Figure 27 shows a typical measurement test setup for determining the surface-wave properties of AMCs. A pair of broadband tapered notch antennas is used for linear polarization where TM waves are attained when the antennas are oriented in a vertical plane and TE waves when they are oriented in a horizontal plane. Therefore a through measurement, where the direct ray is blocked with absorbing material, only allows waves tightly attached to the surface to propagate to the receiving antenna. The results are usually referenced to waves over metal (making it notoriously difficult to measure the TE waves). The experimentally and theoretically measured phase of the normal reflection coefficient is shown in Fig. 28. We can observe that the inductance tends to shift the AMC resonance to lower frequencies, and to narrow the $\pm 90^\circ$ frequency band. An oddity of such a plane-wave measurement of the properties of an AMC is

that the magnitude of the reflection coefficient shows a sharp dip exactly at the resonant frequency. This is not entirely unexpected since at resonance any losses in the dielectrics inside a resonator should be magnified. It appears odd, because every measurement made of the gain and efficiency of antennas proximate to an AMC have shown at least a $+3 \text{ dB}$ gain increase at band center. We must remember, however, that the efficiency of an antenna is ultimately connected to its ability to couple energy from its near field into propagating free-space waves and that the mechanism of that coupling is not measured by the plane-wave reflection coefficient.

The TM measurements and the predicted TM band edges for the three designs are shown in Fig. 29. For the TE surface wave, the fields are zero over the metal; therefore, when the AMC can support TE wave propagation, we have the band edge. Figure 30 shows the TE surface-wave measurements and the theoretically predicted TE band edges.

A brief review of the latest applications in which AMCs are used include the following. McKinzie and Fahr [25] used the AMC as part of a low-profile polarization diversity compact antenna. Two orthogonal bent-wire monopoles were placed in close proximity ($\lambda_0/200$) to an AMC right on top of each other, where λ_0 is the free-space wavelength at the AMC's resonance. The monopoles are parallel to the surface, and their centers are coincident. The experiments, compared to a conventional two-port probe-fed patch antenna, show an improved return loss bandwidth, a 5–10 dB reduction in mutual coupling, and improved radiation efficiency.

In applications such as 802.11 and Bluetooth radios, two antennas located on the same platform must have low mutual coupling to minimize interference. Rogers et al. [26] used the AMC as a reactive edge treatment that reduces the mutual coupling of two antennas mounted on the top and side of a 16-mm-wide screen surrogate laptop computer. Two 2.4-GHz AMCs were also placed

between the antennas, on the top and side of the surrogate laptop, so that coupling between the two antennas is reduced. In the resulting experiments, the coupling

between the antennas (S_{21}), shows isolation of 45 dB, 20 dB above the case without edge treatment. The properties of the AMC used were calculated using the design equations in this article and agree with the authors' measurements, except for a slight increase in the band center, mentioned by the authors as due to the truncation of the AMC into a thin strip.

Bandwidth can be increased by magnetically loading the AMC, as seen in Eq. (3). This increase was demonstrated in Ref. 27. It is shown that the bandwidth increases by a factor of >4 . Thus, the AMC of dimensions $411 \times 411 \times 33$ mm operated between 240 and 400 MHz. The magnetic material used was barium cobalt hexaferrite with uniaxial permeability $\mu_{r,xy} = 30 - j1.0$ and $\mu_{r,z} = 1.0 - j0.03$ at approximately 200 MHz. It was engineered in such a way that the reflection bandwidth and surface-wave bandwidth align. In the final design the via array region was subdivided into two parts. In one of them the magnetic material was placed as far as possible from the FSS layer and the vias spaced 9 times closer together than in the rest of the via array region. No surface-wave measurements were available at those low frequencies because of the difficulty associated with the smallness of the AMC.

Sanchez and Paller [28] propose a new method for tuning the AMC. Essentially, it changes the parallel plate capacitance of the FSS by changing its geometry. The authors used concentric square loops for the upper FSS layer. The loops are segmented and can be completed by bridging the gaps using switches, as shown in Fig. 31, and

Figure 29. TM surface-wave propagation measurement and theoretically predicted TM band edges for designs I (a), II (b), and III (c). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

in this way the density of the overlapping patches can be changed by turning the switches on and off. There are 2^N tuning states for an N -loop FSS. It is shown that the

Figure 31. Eight-state concentric square loops shaping the top FSS unit cell. The lower FSS squares are also shown.

surface-wave band will follow the high-impedance band. By changing the capacitance of the FSS, the surface-wave suppression properties will also change accordingly.

Sievenpiper et al. [29] use the AMC as a beamsteering device. By changing the electrical properties of the impedance surface through varactors in the FSS layer, as a function of position, a reflecting surface with controllable phase angle of reflection is created. It is shown that the AMC can therefore be used as a reflecting device that can steer a microwave beam over a $\pm 40^\circ$ range in two dimensions.

Acknowledgments

The authors would like to thank Mr. John Turtle and Dr. Livio Pols of AFRL/SNHA, Hanscom AFB, Massachusetts for their excellent technical management of the Reconfigurable Apertures program (RECAP) under which most of this work was originally developed. Thanks are also given to Prof. James Aberle of ASU, Dr. Will McKinzie of McKintek LLC, Dr. Dave Auckland of Etenna Corporation, Mr. Victor Sanchez, and Dr. Eric Caswell of Titan Corporation for their valuable insight, technical collaboration, and management during the various phases of the program. Special thanks are due to the reviewer of this contribution, whose careful analysis and invaluable comments greatly enhanced our exposition of the subject.

When a signal is sent along any transmission path, many different mechanisms degrade it. Because of finite conductivity, every cable shows a resistive loss. Furthermore, the dielectric loss and the skin effect may be significant at higher frequencies, and imperfect screening of cables leads to radiation losses which might be quite important at higher frequencies. Single-mode optical fibers have two main intrinsic loss mechanisms, scattering loss and absorption loss. Scattering loss is dominated by Rayleigh scattering, and below 1600 nm absorption losses are caused mainly by OH absorption. Fibers that are bent too tightly or cabled too poorly may have, in addition, bend losses because of nonguided modes. Connectors show losses because of nonideal contacts and imperfect impedance matching, which reflect part of the signal to the transmitter. Filters built in the transmission path have

Figure 1. Attenuation measurement in a matched system.

losses in the passband caused by finite conductivity and probably dielectric losses. Wireless transmission paths, such as microwave links, satellite links, and broadcast or mobile communication, are affected by scattering caused by rain, clouds, and multiple reflections.

The two examples following clearly show how additional attenuation or losses influence a system:

In a radar system a total loss of 2 dB in the feeder system and the duplexer wastes 37% of the transmitter power. During the development of the different parts, the losses have to be measured very carefully to minimize the total loss.

Satellite systems quite often operate with cooled front ends at the receiver because the signals to be picked up are extremely weak. Therefore the front ends often operate with noise temperatures of 5 K. An additional loss of 0.1 dB from an uncooled waveguide would raise the noise temperature to 7 K.

These examples show how important it is to measure the losses of the different parts of a transmission system as accurately as possible to optimize system parameters.

Many different methods and a variety of systems for measuring attenuation have been developed. The most important techniques are described in the following sections.

1. ATTENUATION

1.1. Definition

In the field of loss measurement, the most important terms are attenuation, insertion loss, mismatch loss, and voltage loss [1,2]. These terms are discussed in the following sections.

1.1.1. Attenuation. According to Beatty [3], *attenuation* is defined as the decrease in power level at the load caused by inserting a device between a Z_0 source and load, where Z_0 is the characteristic impedance of the line. Figure 1 shows the basic idea of such an attenuation measurement.

Attenuation is mostly expressed by a logarithmic scale in decibels (dB) or in nepers. The attenuation of a two-port device is defined as follows [4]:

In decibels:

$$A = 10 \log \left[\frac{\text{power delivered to a matched load by a matched source}}{\text{power delivered to the same load when the two-port device is inserted}} \right] \quad (1)$$

In nepers:

$$A = \frac{1}{2} \ln \left[\frac{\text{power delivered to a matched load by a matched source}}{\text{power delivered to the same load when the two-port device is inserted}} \right] \quad (2)$$

Because $\log(x) = \ln(x)/\ln(10)$, the following relationship between decibels and nepers is valid:

Attenuation in decibels = $8.6858 \times$ attenuation in nepers.

Attenuation is a property only of a two-port device.

1.1.2. Insertion Loss. In practical applications neither the source nor the load have an impedance exactly equal to Z_0 , the characteristic impedance of a line. Therefore source and load have a reflection coefficient of r_s and r_L , respectively. Let P_1 be the power delivered from the source to the load and P_2 be the power absorbed by the same load when the two-port device is inserted (Fig. 2).

Then the loss is defined by

$$L_1 = 10 \log \frac{P_1}{P_2} \quad (3)$$

The insertion loss depends on the property of the device and the reflection coefficients of the source and the load.

1.1.3. Scattering Parameters. Two-port networks, especially at radiofrequencies, are very well characterized by scattering parameters.

A two-port device inserted between a source and a load is shown in Fig. 3.

Figure 2. Insertion loss measurement in a nonmatched system.

Figure 3. Scattering parameters for a two-port device inserted between source and load.

The complex wave amplitudes a_1 , a_2 , b_1 , and b_2 shown in Fig. 3 are related as follows:

$$b_1 = s_{11}a_1 + s_{12}a_2 \quad (4)$$

and

$$b_2 = s_{21}a_1 + s_{22}a_2 \quad (5)$$

Setting up the signal flow graph for the configuration in Fig. 3 and using the nontouching loop rules of Mason [5,6], the insertion loss is given by the following expression:

$$L_I = 20 \log \frac{|(1 - r_s s_{11})(1 - r_L s_{22}) - r_s r_L s_{12} s_{21}|}{|s_{21}| \cdot |1 - r_s r_L|} \quad (6)$$

For a matched system where $r_s = r_L = 0$, Eq. (6) delivers the attenuation

$$A = 20 \log \frac{1}{|s_{21}|} \quad (7)$$

Equations (6) and (7) clearly show that the insertion loss L_I depends on the property of the two-port device and the reflection coefficients of the source r_s and the load r_L . Otherwise the attenuation is the pure property of the two-port device.

1.1.4. Voltage Loss. Voltage loss is used only for applications in the DC-to-UHF part of the spectrum where voltage is well defined. According to Warner [4], it is defined as follows:

$$L_V = 20 \log \left[\frac{\text{voltage at the input of the two-port device}}{\text{voltage at the output of the two-port device}} \right] \quad (8)$$

and using the scattering parameters

$$L_V = 20 \log \frac{|(1 + s_{11})(1 - r_L s_{22}) + r_L s_{12} s_{21}|}{|s_{21}(1 - r_L)|} \quad (9)$$

Note that L_V is independent of the source reflection coefficient r_s .

When $s_{11} = 0$ and $r_L = 0$, the voltage loss is equal to the attenuation.

1.1.5. Mismatch Loss. At higher frequencies every real two-port device has an input and output reflection coefficient that differs from zero. Therefore, there is always a mismatch between the source and the two-port device and between the two-port device and the load (Fig. 4). This reflects part of the incoming and outgoing wave toward

Figure 4. Mismatch loss of a two-port device between a source and a load.

the source and toward the two-port device, respectively, resulting in additional losses.

The mismatch loss between the source and the two-port device is expressed as:

$$L_{m1} = 10 \log \frac{\text{power absorbed at the input of the two-port device}}{\text{maximal available power from the source}} \quad (10)$$

According to Fig. 3 the mismatch loss is given by

$$L_{m1} = \frac{(1 - |r_s|^2)(1 - |r_1|^2)}{|1 - r_s r_1|^2} \quad (11)$$

Similarly, the mismatch loss between the two-port device and the load is given by

$$L_{m2} = 10 \log \frac{\text{power absorbed by the load}}{\text{maximal available power at the output of the two-port device}} \quad (12)$$

and with the parameters of Fig. 4

$$L_{m2} = 10 \log \frac{(1 - |r_2|^2)(1 - |r_L|^2)}{|1 - r_2 r_L|^2} \quad (13)$$

If several two-port devices are cascaded, the mismatch loss between them has to be calculated similarly and taken into account.

2. ATTENUATOR

Apart from the natural losses in devices and transmission paths, manufactured devices have well-defined losses. These devices, called *attenuators*, are used for measurement and for adjusting power levels to a defined value in transmission systems. Attenuators are probably the most important devices in measurement systems and therefore exist in a large number of different forms [7–9], such as symmetric, coaxial, waveguide, optical, fixed-value, and variable-loss. The important properties of attenuators are frequency range, attenuation accuracy, attenuation variation versus frequency, input and output impedance match (reflection coefficient), power handling capacity, and phase linearity.

2.1. Balanced-Line Attenuator

Balanced lines are used especially in telecommunications and lately in local-area networks and in-house

Figure 5. Basic symmetric double-T and double-Π attenuation circuits.

communications systems. Therefore, there is a demand for balanced-line attenuators. Chains of symmetric double-T or double-Π circuits, as shown in Fig. 5, are mostly used [10].

The reference handbooks [10] give formulas and tables to determine the circuit elements for a given line impedance and different element attenuations. The circuit has to be symmetric to the ground plane and well matched to the line impedance. Special techniques are given to optimize the circuit for small frequency dependence.

Variable-value attenuators are commercially available for different impedances (150 Ω, 120 Ω) in the frequency range from DC to several megahertz and have attenuation ranges from 0 to 132 dB.

2.2. Coaxial-Line Attenuator

2.2.1. Fixed-Value Coaxial Attenuator. Coaxial attenuators generally have multioctave bandwidth or frequently operate from DC to several gigahertz (GHz). Coaxial transmission lines are generally operated in the transverse electromagnetic (TEM) mode and therefore an obvious solution for attenuators is to use lumped elements that are small compared to the wavelength. There are four major constructions: T circuit, Π circuit, distributed lossy line, and distributed thin-film technology.

2.2.1.1. T-Circuit Attenuator. The T-attenuator circuit is shown in Fig. 6. The values of R_1 and R_2 are calculated from the following formulas, where K is the transmission coefficient [7,10]:

$$R_1 = Z_0 \frac{K - 1}{K + 1} \tag{14}$$

$$R_2 = \frac{2Z_0K}{K^2 - 1} \tag{15}$$

The attenuation in decibels is given by

$$A(\text{dB}) = 20 \log K \tag{16}$$

Figure 6. T-attenuator circuit.

Resistive rods for R_1 are often used, and disk resistors are used for R_2 , or film resistors are used for both R_1 and R_2 .

2.2.1.2. Π-Circuit Attenuator. Techniques similar to the T circuit are used for the Π circuit shown in Fig. 7, and the corresponding formulas are as follows [7,10]:

$$R_1 = Z_0 \frac{K + 1}{K - 1} \tag{17}$$

$$R_2 = Z_0 \frac{K^2 - 1}{2K} \tag{18}$$

At higher microwave frequencies the elements of the T and Π attenuators have dimensions comparable to the wavelength, and therefore the reactance of the elements becomes more important and thus degrades the performance of the attenuator.

2.2.1.3. Lossy-Line Attenuator. Distributed lossy-line attenuators, explained by Weber [11], have very favorable performance. As long as the attenuation is not very high, they have a flat attenuation response and an excellent impedance match. The center conductor of the transmission line is made mostly of lossy material using thin film deposited on a substrate with a circular cross section. The disadvantage of lossy-line attenuators is that they have a lower frequency limit depending on their physical length.

2.2.1.4. Thin-Film Attenuator. Distributed thin-film attenuators [12] use a resistive material deposited on a dielectric substrate for the series and shunt losses (Fig. 8).

Strip transmission lines and narrow ground electrodes on the longitudinal sides are added to the input and output terminals. The characteristic impedance and the attenuation are constant and given as follows [7]:

TART numbered equation (19)

$$Z_0 = \rho \sqrt{\frac{D - a}{4a}} \quad (\Omega) \tag{19}$$

$$\alpha = \sqrt{\frac{4}{a(D - a)}} \quad (\text{in nepers per unit length}) \tag{20}$$

Figure 7. Π-attenuator circuit.

Figure 8. Distributed thin-film attenuator element.

Equation (20) shows that the attenuation is independent of the resistivity of the film as long as the film is homogenous. The attenuation depends only on the geometry and therefore is insensitive to temperature changes.

2.2.2. Variable-Value Coaxial Attenuator. There are two types of variable attenuators: continuous variable attenuators and step attenuators. Continuous variable attenuators have the advantage of being noninterruptive when changing attenuation. This feature is important for some measurements, for example, receiver sensitivity measurements. On the other hand, these attenuators may sometimes lack accuracy, settability, impedance match, high insertion loss and have limited bandwidth.

Step attenuators are very accurate and have the following qualities: good reproduceability, low insertion loss, excellent impedance match, and wide operating bandwidth. But most step attenuators are interruptive when changing the attenuation value.

2.2.2.1. Continuously Variable Attenuator

2.2.2.1.1. Piston Attenuator (Waveguide beyond Cutoff Attenuation). The piston attenuator is one of the oldest continuously variable microwave attenuators [13]. It is used especially as a precision attenuator or for handling high power levels. This type of attenuator uses a waveguide below its cutoff frequency. According to transmission-line theory, the amplitude of a wave launched into such a waveguide decays exponentially. So the attenuation is calculable. Most constructions use a circular cross section and a magnetic coupling that generates the lowest cutoff higher-order transverse electric mode (TE_{11}). Figure 9 shows the simplified construction of a piston attenuator. By sliding the two concentric cylinders into each other, the physical displacement of the coupling coil is changed and therefore also the attenuation. Special care must be taken to avoid unwanted higher order modes.

Attenuation as a function of wavelength is given per unit length as [10]

$$A = \frac{2\pi \cdot 20}{\lambda_c \cdot \ln 10} \sqrt{1 - \left(\frac{\lambda_c}{\lambda}\right)^2} \quad \text{in decibels per unit length} \quad (21)$$

Figure 9. Principle of a piston attenuator.

where λ_c is the cutoff wavelength of the waveguide and λ is the free-space wavelength.

If the operating frequency is chosen to be much lower than the cutoff frequency, the term λ_c/λ is negligibly small for the operating frequency band, and a flat attenuation frequency response is achieved. The advantages of cutoff attenuators are that they are calculable and that high accuracy is achieved (0.001 dB/10 dB for 60 dB attenuation). For this reason, cutoff attenuators are often used as standard attenuators. Their main disadvantage is the high insertion loss (15 to 20 dB) because tight coupling has to be avoided so as not to stimulate higher modes.

2.2.2.1.2. Resistant Card, T-, or Π-Type Attenuator. Several constructions of variable attenuators using resistive cards or resistive films are on the market [9]. The variable card attenuator operates like a potentiometer. A resistive film is fixed on a substrate so that the resistance between the input and the output is varied with a movable coaxial wiper, and thus the amount of attenuation changes. This type of attenuator does not have good input and output impedance matches. More sophisticated constructions use T- or Π-type structures where the series and the shunt resistors are changed simultaneously. Therefore the input and output ports of these attenuators are quite well matched. The minimum insertion loss is on the order of 4 dB, and they operate up to several gigahertz.

2.2.2.1.3. Lossy-Line Attenuator. Lossy-line attenuators use a lossy center conductor partly covered with a thin sliding shield [7]. This effectively changes the length of the resistive conductor and thus the attenuation. Some constructions use microstrip lines with variable lossy walls [9]. This type of attenuator is limited in its maximal attenuation because of the length of the device.

2.2.2.1.4. Pin Attenuator. Pin attenuators change the loss in either a step or continuous mode. The series and shunt resistors are by *pin* diodes, electronic devices that change their conductivity. The diodes are controlled by a bias current. Various types of circuits are available, such as series, shunt, bridged T, and Π [9]. *Pin* attenuators are electronic circuits and therefore may produce harmonics. Below about 10 MHz, the *pin* diode exhibits some rectifying behavior. At much higher frequencies,

the *pin* diode behaves more like a variable resistor. Because of the matching circuits for input and output and the bias network, most devices operate in a limited frequency band. Attenuation from 2 to 80 dB is achieved.

2.2.2.1.5. Step Attenuator. Step attenuators always use a set of fixed attenuators that are switched into a line by different mechanisms. The steps are mostly 0.1, 1, and 10 dB. The 0.1-dB steps generally cover a range of 1.1 dB, the 1-dB steps a range of 11 dB, and the 10-dB steps cover a range up to 110 dB. The step attenuator has excellent repeatability, covers a wide frequency range (e.g., DC to 26.5 GHz), has a good impedance match, and mostly has a flat frequency response of the attenuation value.

In the turret-type coaxial attenuator a set of coaxial fixed attenuators is placed in a cylindrical arrangement. With a rotary motion the different elements (e.g., 0 dB, 10 dB, 20 dB, ...) are switched between the junctions of the transmission line.

Another type of step attenuator uses a variety of fixed attenuation elements. The different attenuation elements are cascaded by switches or bypassed. The switches may be activated manually or electrically.

2.3. Waveguide Attenuator

Waveguide attenuators work mostly in the entire usable waveguide bandwidth, which is not quite half an octave. To attenuate a wave propagated in a waveguide, either the electric or the magnetic field or even both are influenced. As an example, a resistive card inserted into the waveguide parallel to the *E* field attenuates it. Another technique uses lossy walls that influence the current in the waveguide wall. Most of these attenuators are not phase-invariant.

2.3.1. Fixed-Value Waveguide Attenuator. The waveguide flap attenuator (Fig. 10) and the side-vane attenuator (Fig. 11) [7] are very popular.

The flap attenuator is based on a resistive card inserted in the center of the waveguide parallel to the *E* field. The more the card dives into the waveguide, the more the *E* field is weakened, and therefore attenuation increases. A smooth card shape is chosen to minimize the reflection caused by the discontinuity.

The side-vane attenuator (Fig. 11) influences the *E* field similarly. The vane is always completely inside the waveguide, but it uses the fact that the *E* field varies along the broad side. For the most popular TE₁₀ mode, the *E* field is zero at the sidewall and has its maximum in the center of

Figure 10. Principle of a waveguide flap attenuator.

Figure 11. Principle of a side-vane attenuator.

the waveguide. Therefore the position of the resistive card defines the attenuation value. A smooth shape minimizes the reflection of the discontinuity.

Several constructions of lossy-wall attenuators exist. One version is shown in Fig. 12 [14].

Section 2 with equally spaced slots filled with a lossy material defines the attenuation. Sections 1 and 3 are configured to minimize the reflection due to the discontinuity in the wall. The lossy-wall attenuator withstands high power because the dissipated heat is transferred to any cooling system.

2.3.2. Variable-Value Waveguide Attenuator

2.3.2.1. Flap and Side-Vane Attenuator. By adding a mechanism that changes the position of the resistive card, the fixed-value-flap and side-vane attenuator are easily transformed into a variable-value attenuator. It is often used as a settable attenuator.

2.3.2.2. Rotary-Vane Attenuator. The rotary-vane attenuator was invented in the early 1950s by E. A. N. Whitebread (Elliot H. Brothers, London) and A. E. Bowen (Bell Telephone Laboratories). It was proposed and developed as a precision waveguide attenuator [15–19]. The rotary-vane attenuator consists of three sections of waveguide that have a resistive film spanned across the waveguide, as shown in Fig. 13. The middle section has a circular cross section and can be rotated with respect to the two fixed-end sections. Figure 13 illustrates the principle of a rotary-vane attenuator. For clarity, the transitions from a round to a rectangular waveguide at both ends are omitted.

The electric field is perpendicular to all resistive films whenever the films are aligned. In this case no current flows in the resistive film, and therefore no attenuation occurs. If the center part is rotated by an angle θ , the component $E_{\sin \theta}$ in θ produce a current flowing in the resistive film and are absorbed. Thus the resulting

Figure 12. Lossy-wall attenuator.

Figure 13. Principle of a rotary-vane attenuator.

attenuation is given by

$$A(\text{dB}) = -40 \log(\cos \theta) + A_0 \quad (22)$$

The rotary-vane attenuator has the following advantages:

- The attenuation is almost independent of the frequency.
- The phase shift is very small. The phase variations are smaller than 1° up to 40 dB attenuation.
- The input and output VSWRs are very low under all conditions.
- The attenuation is not sensitive to the resistive film as long as its attenuation is high enough.
- The attenuation is not sensitive to temperature changes.

Rotary-vane attenuators are commercially available for most of the known waveguide bands. They typically have an accuracy of 2% of the reading in decibels or 0.1 dB, whichever is greater.

2.4. Attenuator for Optical Fibers

Attenuators have to be adapted to an optical fiber system. Therefore different attenuators for single-mode or multi-mode applications are available and mostly operate within

one or two wavelength windows. Various attenuation techniques are used to reduce the transmitting light, such as lateral or axial displacement of the fibers or optical prisms, and inserting absorbing filters.

2.4.1. Fixed- or Adjustable-Value Attenuator. A pair of lenses is used in most fiberoptic attenuators to collimate the light of the input fiber and to refocus it to the output fiber. Any attenuation mechanism, such as absorbing filters or absorbing glass with variable thickness can be inserted into the optical beam path. Attention has to be given to the attenuation mechanism so that there is very little polarization-dependent loss. Fixed-value attenuators are commercially available for a range of 3–40 dB with an accuracy of 0.5–1 dB.

2.4.2. Variable-Value Attenuator. The reflection type variable attenuator often combines a series of 10 dB steps for the high values and a continuous variable attenuation of up to 10 or 15 dB. Figure 14 shows the basic configuration of an optical section [20].

A rod lens collimates the light of the fiber into a spatial beam that passes two neutral-density filters (ND filters). The second rod lens focuses the spatial beam into the output fiber. The ND filter must have high uniformity, little attenuation change with time, and flat spectral transmittance. This is achieved by vacuum-depositing Ni

Figure 14. Basic configuration of an optical section.

and Cr alloys onto a glass substrate. The ND filters are the reflecting type. To avoid multiple reflections and to ensure that the light is not reflected into the input lead, the two filters are inclined at a small angle with respect to the optical axis.

Commercially available attenuators of this type have an insertion loss of about 3.5 dB, a range of up to 65 dB, and an accuracy of about ± 0.5 dB per 10 dB. They are available for wavelengths of 850, 1300, and 1550 nm.

2.5. Calculable Attenuation Standards

Many attenuators have been described in the previous sections, but only a few are suitable as attenuation standards. An attenuation standard is a device that can be traced to the SI units by an unbroken chain. The application of the described standards depend on the frequency band and the technique used in the measurement system.

2.5.1. Kelvin–Varley Divider. The Kelvin–Varley divider (KVD) was described for the first time by Varley in 1866 [21]. It is a resistive voltage divider and operates from DC up to several hundred kilohertz. Figure 15 shows an example of a four-decade Kelvin–Varley divider.

Each decade consists of 11 equal resistors except for the last decade, which has only 10. The decades are connected by switches that always span two resistors. The value of the resistors of each following decade is reduced by a factor of 5. The four-decade Kelvin–Varley divider allows varying the output-to-input voltage ratio from zero to one in steps of one part in 10^4 . The unloaded KVD has a constant input impedance that is independent of the switch setting, whereas the output resistance varies with the setting. The original type of KVD (Fig. 15) requires either very large or very small resistance values because each decade needs 5 times larger values. Due to

stray capacitance, the divider reacts similarly to an RC filter. For example, a 100 k Ω input impedance limits the 3 dB bandwidth to about 100 kHz. To avoid large resistance values, modified constructions with a resistor shunting the decades have been developed.

Two major errors determine the accuracy: deviations of the resistors from nominal values and the resistances of the switch contacts and leads. The first three or four decades are the most sensitive, and therefore these resistors often are adjustable. Several calibration techniques have been developed and are described in the literature [22,23].

Today commercially available Kelvin–Varley dividers have up to seven decades, have an absolute linearity of ± 1 part in 10^7 , and long term stability of ± 1 part in 10^6 per year.

2.5.2. Inductive-Voltage Divider. The inductive-voltage divider (IVD), also called a *ratio transformer*, is an exceptionally accurate variable attenuation standard. It consists of a number of very accurately tapped autotransformers. The autotransformers are connected together by high quality switches. The IVD operates from 10 Hz to about 100 kHz, and the greatest accuracy is achieved at about 1 kHz. In 1962 Hill and Miller [24] described a multidecade IVD with seven decades and a resolution of 1 part in 10^7 . Figure 16 shows the principle of a seven-decade IVD with a setting of 0.4324785. The output-to-input voltage ratio can be set from zero to one.

The tapped autotransformers are constructed by winding exactly equal lengths of copper wire on a high permeability toroidal core. A superalloy having an extremely high permeability ($> 100,000$) and low hysteresis loss is preferred as a core material. For an exact division of the tapped autotransformer, it is not necessary to have a 100% coupling between the ten inductors [4]. But the 10 self-inductances and the 45 mutual inductances have to be exactly equal.

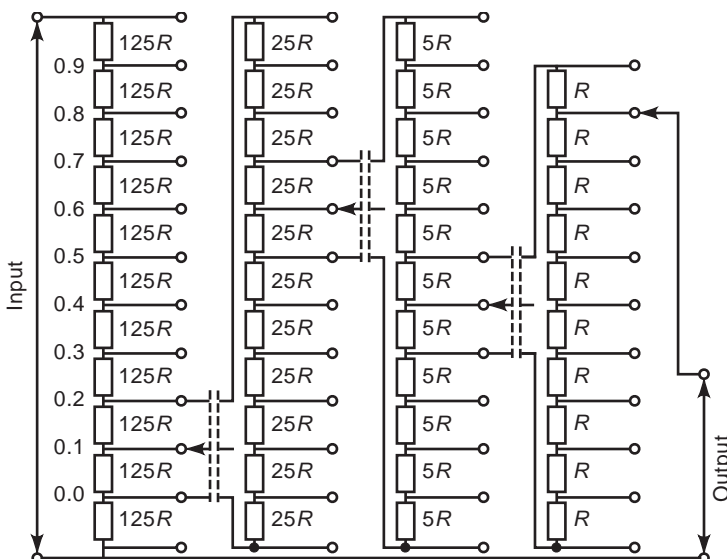

Figure 15. Principle of a four-decade Kelvin–Varley divider.

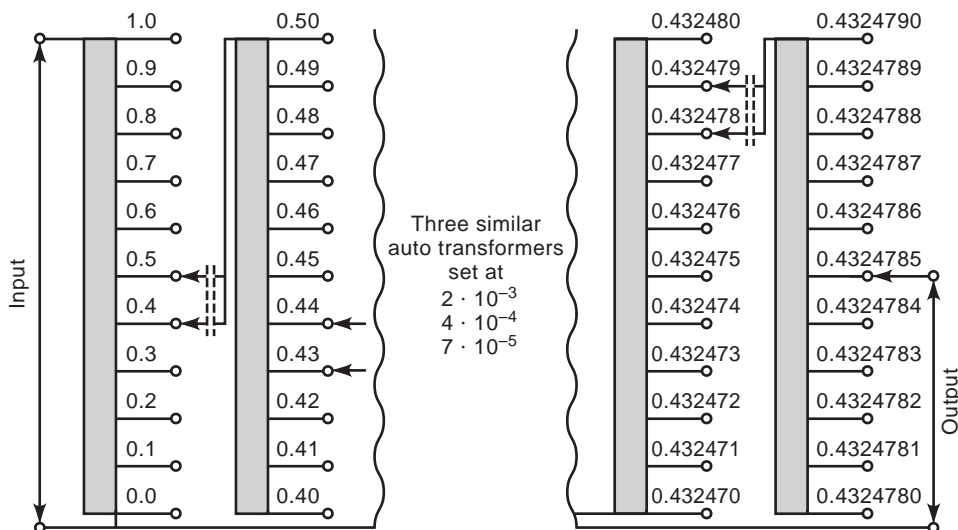

Figure 16. Principle of a seven-decade IVD.

The following error sources limit the accuracy of IVDs:

Inequality in the series resistances and the leakage inductances of the sections in each autotransformer

Inhomogenities in the magnetic cores

Distributed admittances between the windings

Internal loading caused by the later stages

Impedances of the connecting leads and switch contacts

Variations in the input voltage, frequency, and ambient temperature

With careful design, these errors can be minimized. Programmable binary IVDs with 30 bits, a resolution of 1 part in 10^9 , and a linearity of 0.1 ppm have been developed [25].

IVDs with eight decades and an accuracy of four parts in 10^8 are commercially available.

2.5.3. Intermediate-Frequency Piston Attenuator. The IF piston attenuator is based on the same principle as the attenuator previously described for RF, but it is designed to operate at a specific, fixed frequency, mostly 30 or 60 MHz. As Eq. (21) shows, attenuation depends on the cutoff wavelength λ_c , the free-space wavelength λ , and the displacement of the two coils. The waveguide dimensions, which can be determined, define the cutoff wavelength, and the displacement can be measured very precisely. Therefore the IF piston attenuator is used as a calculable standard. Figure 17 shows a simplified diagram of an IF piston attenuator.

The standard IF piston attenuator consists of a high-precision circular cylinder that has excellent conductivity, a fixed coil, and a movable coil mounted on a piston. The piston attenuator operates in the H_{11} (TE_{11}) mode that has the lowest attenuation. A well-designed metal strip filter

in front of the fixed coil attenuates the higher modes. To allow smooth movement and to avoid any scratches, the plunger carrying the moving coil is insulated. Equation (23) expresses the attenuation per unit length more precisely

$$A = \frac{s_{11}}{r} \sqrt{1 - \left(\frac{\lambda_c}{\lambda}\right)^2} \cdot \epsilon - \frac{\delta}{r} \tag{23}$$

in nepers per unit length, where $\lambda_c = 2\pi r/s_{11}$, λ_c is the cutoff wavelength, λ is the free-space wavelength, s_{11} the first zero of the Bessel function $J_1 = 1.8411838$, r the radius of the cylinder, and δ is the skin depth.

Highly accurate standard attenuators use a laser interferometer to accurately determine the displacement of the coil. Yell [26,27] and Bayer [28] developed extremely accurate IF piston attenuators with a dynamic range of 120 dB, a resolution of 0.0001 dB, and an accuracy of 0.0002 dB/10 dB over the linear range of 90 dB.

2.5.4. Rotary-Vane Attenuator. The principle of the rotary-vane attenuator is described in Section 2.3.2.2. Because the attenuation is given by the equation

$$A(\text{dB}) = -40 \log(\cos \theta) + A_0 \tag{24}$$

Figure 17. Simplified IF piston attenuator.

where A_0 is the insertion loss at a setting of $\theta=0$, the device can be used as a calculable primary standard.

The rotating angle θ of the center vane has to be determined very precisely, especially for higher attenuation values. As an example, a rotational angle accuracy of $\pm 0.001^\circ$ results in an attenuation accuracy of ± 0.01 dB at a setting of 60 dB. Especially precise optical readouts have been developed by national standards laboratories [29–31] to allow an angular resolution of $\pm 0.001^\circ$. Following are the main error sources for precision rotary-vane attenuators:

- Misalignment of the end vanes
- Insufficient attenuation of the central vane
- Incorrect readout of the rotational angle
- Eccentricity of the rotor
- Leakage of the rotating joints
- Internal reflections at the ends of the three vanes

Careful design of the attenuator results in an accuracy of ± 0.0015 dB up to 16 dB at 10 GHz.

2.5.5. Comparison of Attenuation Standards. The attenuation standards mentioned previously are used in various precision measurement systems, such as RF, IF, or LF substitution. The standards have very different accuracy depending on the attenuation setting. Figure 18 shows a comparison of different precision

Figure 18. Comparison of attenuation standards.

Figure 19. Principle of an optical chopping system.

attenuation standards used in national metrology laboratories [32].

2.5.6. Optical Attenuation Standards. Imamura [33] shows one solution of a calculable optical attenuation standard that is used to calibrate precision attenuators. The key element is a rotating disk with a well-defined opening. The device operates as an optical chopping system (Fig. 19).

As long as the response of the detector is slow compared to the rotational speed ω , the ratio of P_1 to P_0 defines the attenuation. In this case the attenuation depends only on the opening angle θ (in radians) and is given by the following equation:

$$A = -10 \cdot \log \frac{P_1}{P_0} = -10 \cdot \log \frac{\theta}{2\pi} \quad (25)$$

An opening angle of 36° defines an attenuation of 10 dB. Special care has to be paid to the diffraction of light at the edges of the disk openings and the stability of the light source and the sensor. The overall accuracy is estimated to be ± 0.008 dB for 10 dB attenuation.

3. MEASUREMENT OF ATTENUATION

Various kinds of measurement systems are used depending on the frequency range, the type of attenuator, the required accuracy, and the available standards. Most of the modern attenuation measurement systems are computer- or microprocessor-controlled. They use the same principle as the manual systems but operate much faster. If maximum accuracy is required, manually controlled measurement systems are often preferred.

3.1. Low-Frequency Measurement Systems

Low-frequency attenuation measurements are used mainly in communication systems where voice, video, and data have to be transmitted with as little distortion as possible. Dedicated test systems have been developed for testing and adjusting the communication systems working either with coaxial lines (50 or 75 Ω) or balanced lines (124, 150, or 600 Ω).

3.1.1. Direct Measurement. Operation of communication systems requires a great number of test systems for

Figure 20. Principle of a direct measurement system.

which low-cost test systems that are easily handled were developed. The systems are based on current, voltage, or power measurement and operate in a frequency band from 200 Hz up to 30 MHz. The test system (Fig. 20) consists of a tuneable generator with a known constant output level and a wideband voltmeter or a high-sensitivity, selective superheterodyne receiver.

Many test systems can be switched to operate in either coaxial-line (50 or 75 Ω) or balanced-line (124, 150, or 600 Ω) configuration. In the balanced-line mode the test systems have a limited frequency range of 200 Hz to several MHz depending on the impedance selected. In the selective-level meter mode, bandwidths of 25 Hz–3.1 kHz are used, and the dynamic range achieved is on the order of 80 dB. The attenuation measurement accuracy in the frequency range indicated is about 1 dB.

3.1.2. Low-Frequency Substitution Method. The LF substitution method is based on a precisely calibrated low-frequency reference attenuator used in a parallel or a serial configuration (Fig. 21).

Because the attenuation of the device under test (DUT) is compared with that of the reference attenuator, neither the output level of the generator nor the absolute level indication of the receiver have to be known. The only requirements are that generator and receiver remain stable during measurements. The accuracy is determined mainly by the calibration of the reference attenuator.

3.2. Radiofrequency and Microwave Measurement Systems

In radiofrequency and microwave ranges many different measurement principles are known. They all have their own characteristics; one is meant to measure low values of attenuation, another to measure high values, a third to achieve highest accuracy. The most popular measurement principles are discussed in the following sections.

3.2.1. Power Ratio Method. The power ratio method [4,40] (Fig. 22) is very simple for measuring attenuation.

Figure 22. Principle of the power ratio method.

It is commonly used as long as maximum accuracy is not required.

The method is based on the linearity of the power meter or the receiver used. First the power P_1 of the generator is measured without the device under test (DUT) and then P_2 is measured with the DUT inserted. The attenuation of the DUT is calculated by the ratio of P_2 to P_1 :

$$A(\text{dB}) = 10 \log \frac{P_2}{P_1} \tag{26}$$

To measure attenuation, the insertion points have to be matched by either tuners or matching pads. The square-law characteristic of the power sensors and the noise limit the dynamic range to about 40 dB. If a tuned receiver is used instead of a power meter, the measurement range is extended to about 100 dB.

Several error sources influence the accuracy:

- The stability of the generator and the detector system
- The frequency stability of the generator
- The matching at the insertion points
- The square-law region of the detector system
- The crosstalk for high-attenuation measurement

Commercially available systems using a tuned receiver achieve a measurement uncertainty of 0.1 dB at 50 dB attenuation. These systems are easily automated by controlling the instruments with a computer.

In national standards laboratories very sophisticated systems have been developed resulting in an accuracy of 0.06 dB at 50 dB attenuation [34,35].

3.2.2. Voltage Ratio Method. The voltage ratio method makes use of high-resolution AC digital voltmeters (AC DVMs) available now. Because the AC DVMs work up to only several MHz, the RF signals have to be downconverted to low frequency. Figure 23 shows the principle of a

Figure 21. Principle of a LF substitution method.

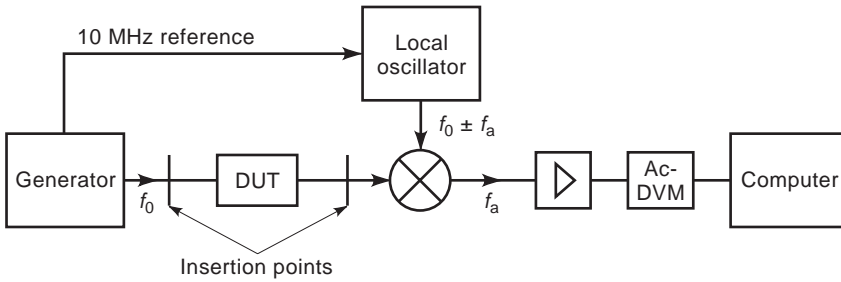

Figure 23. Principle of the voltage ratio method.

voltage ratio system working at an audiofrequency of 50 kHz.

If a synthesizer locked to the same reference frequency is used as a signal generator and local oscillator, a very stable audiofrequency f_a (e.g., 50 kHz) is generated. The audiofrequency signal is amplified and measured with an AC DVM. If U_1 is the voltage measured with the two insertion points clamped together and U_2 is the voltage with the DUT inserted, the attenuation is given by

$$A(\text{dB}) = 20 \log\left(\frac{U_2}{U_1}\right) + C \quad (27)$$

where C is the correction factor in decibels for the non-linearity of the amplifier and the DVM.

The dynamic range of the direct system is about 20–30 dB. More sophisticated systems achieve an uncertainty less than 0.001 dB for 20 dB attenuation. By adding a gauge block technique, for example, a calibrated step attenuator (10, 20, 30, 40, 50, 60, 70 dB) in series with the DUT in the RF path, the range is extended to 90 dB with excellent accuracy of 0.001 dB [32].

The error sources which limit the measurement uncertainty are

- The matching of the insertion points
- The generator output level stability
- The AF amplifier stability
- The AF amplifier and AC DVM linearity
- The mixer linearity
- The gauge block attenuator stability and reproducibility
- The crosstalk for high attenuation measurement

3.2.3. IF Substitution Method. The IF substitution method [4,40] (Fig. 24) gives good accuracy, operates over a large dynamic range, and is used up to very high frequencies. Most systems operate in a parallel substitution mode.

The signal passing through the DUT is mixed to an IF of 30 or 60 MHz. This signal is compared with the signal of the 30-MHz reference oscillator and the standard attenuator by a narrowband 30 MHz receiver (mostly with synchronous detection). In the first phase the insertion points are clamped together, and the standard attenuator is adjusted until there is no switching signal (i.e., 1 kHz)

detectable any longer. The reading A_1 of the standard attenuator is taken. In a second phase the DUT is inserted, the standard attenuator is adjusted so that the signal of the standard attenuator equals the signal of the mixer, and the reading A_2 is taken. The attenuation of the DUT is given by the difference A_2 minus A_1 between readings.

A piston attenuator, an inductive-voltage divider, or a high-precision resistive attenuator can be used as a standard attenuator.

In national standards laboratories very-high-precision piston attenuators with a resolution of 0.0001 dB over a 100 dB range have been used in a parallel substitution system. The accuracy achieved is better than 0.001 dB per 10-dB step [27,32,36].

Accuracy of about 0.002 dB and a dynamic range of 100 dB have been achieved by using a seven-decade 50-kHz inductive voltage divider in a parallel substitution system [37].

Weinert [38] proposed a parallel IF complex vector substitution system using a high precision IF attenuator. The system has a single-step dynamic range of 140 dB and a display resolution of 0.001 dB.

The following error sources limit the accuracy and the dynamic range:

- The matching at the insertion points
- The level stability of the signal source
- The mixer linearity
- The noise balance
- The level stability of the IF reference oscillator
- The standard attenuator resolution and stability
- The crosstalk for high attenuation measurement

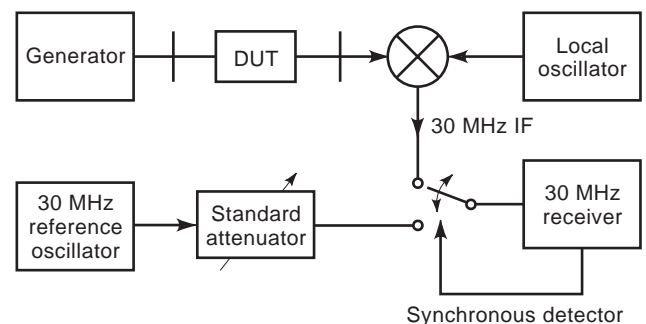

Figure 24. Principle of the IF substitution method.

Figure 25. Principle of the series RF substitution method.

3.2.4. RF Substitution Method. In the RF-substitution method [4,40] (Fig. 25), the reference standard attenuator and the DUT operate at the same frequency. Because the attenuation of the reference standard is compared either in a series or in a parallel substitution system with the DUT, the results are independent of the receiver characteristics. A rotary-vane attenuator, a piston attenuator, or a chain of well-matched and precisely calibrated attenuators (e.g., step attenuator) is used as a reference standard.

In the first step the insertion points are clamped together, and the reference standard is adjusted to a value A_1 according to the estimated attenuation of the DUT. The receiver shows the reading U_1 . In the second step the DUT is inserted, and the reference standard is adjusted to get the same reading U_1 at the receiver A_2 . The attenuation of the DUT is calculated as the difference between the two decibel readings of the reference attenuator, A_1 minus A_2 .

3.2.5. Scalar Measurement. All attenuation measurement systems described in the previous sections provide scalar measurements. There are many commercial scalar network analyzers available (Fig. 26) [8,39]. These analyzers measure the input reflection and the attenuation of the device under test. Because mostly wideband detectors are used, the magnitude of only two quantities can be determined.

The signal of the sweep generator is divided by a power splitter into reference and measurement paths. The directional bridge or coupler measures the reflected wave of the DUT. The analyzer forms the ratio A/R , which is proportional to the input reflection coefficient of the DUT. Using a third detector, the attenuation is measured by calculating the ratio B/R . Most scalar network analyzers are microprocessor- or computer-controlled and offer simple correction methods. The calibration for reflection measurements is frequently done by

using open and short circuits, and a connect through normalization is used for the transmission path. Because these analyzers are broadband systems, they operate very fast and are easily expandable to highest frequencies. Commonly used scalar network analyzers operate from 10 MHz to 18 GHz or 26 GHz, and often their frequency range can be extended to 50 GHz in coaxial lines and to 110 GHz in waveguides. The dynamic range is limited to about 75 dB by the square-law characteristic of the detectors and noise. The measurement accuracy achieved is quite reasonable, for example, 0.6 dB measuring a 30-dB attenuator. The insertion points have to be well matched.

The following errors influence the measurement uncertainty:

- The harmonics of the sweep generator
- The matching of the insertion points
- The square-law characteristic of the detectors
- The sweep generator level stability

3.2.6. Vector Measurement. Vector measurements enable characterization of a two-port circuit completely. In addition to the magnitude, the phase of the scattering parameters is also determined. There are two major concepts for measuring the complex parameters of a two-port device: the vector network analyzer and the six-port technique.

Modern vector network analyzers [8,39,40] measure all four scattering parameters— s_{11} , s_{21} , s_{12} , and s_{22} —without the necessity of turning the DUT around. Therefore they are symmetrical (Fig. 27) and measure in both directions.

The basic concept looks similar to that of the scalar network analyzer. The signal of the generator is divided into reference and measurement paths. In forward measurements, the directional bridge A determines the reflected signal, bridge B determines the transmitted signal,

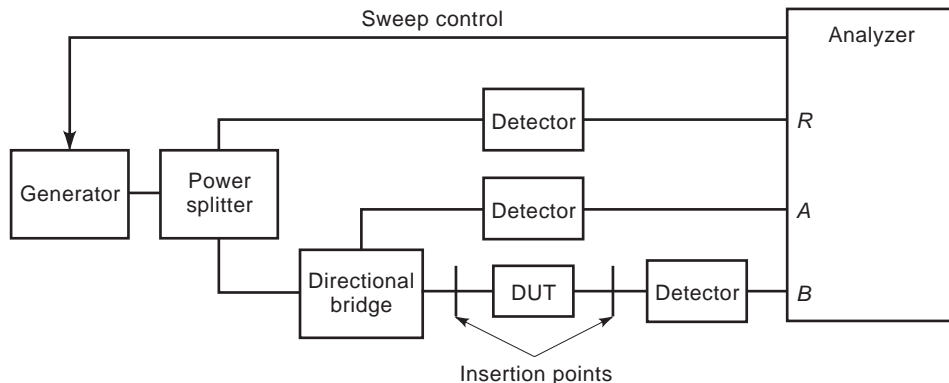

Figure 26. Principle of a scalar network analyzer.

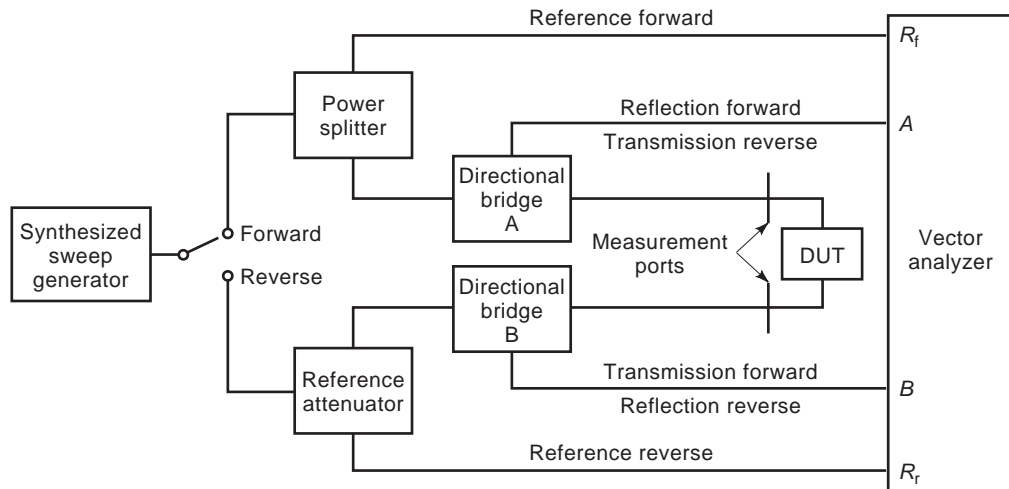

Figure 27. Principle of a vector network analyzer.

and vice versa for the reverse case. Instead of using diode detectors, the signals are downconverted to an intermediate frequency and analyzed in magnitude and phase. Synthesized sweep generators and synchronous detection are being used to obtain high accuracy for magnitude and phase measurements. Because the complex signals are measured, the main errors due to component imperfections may be corrected. Frequently a 12-term error model is applied to correct the source and load match, the bridge characteristics, the transmission leakage crosstalk, and downconverter characteristics. In the first phase well-known standards (e.g., open, short, line) are measured, and the 12 error parameters are determined. In the second phase the DUT is measured and the data corrected according to the calculated error terms. Several different techniques for measuring the error parameters are used, such as open–short–load, transmission–reflect line, and line–reflect line. Each technique uses different kinds of reference standards, such as short and open circuits, well-defined lines, and known loads.

Excellent performance is achieved by using the 12-term error correction technique. For example, at 20 GHz, load and source match better than -38 dB return loss, transmission tracking is better than 0.06 dB and crosstalk is less than -104 dB. As a result a 30 dB attenuator can be measured at 20 GHz with an uncertainty of 0.07 dB.

Vector network analyzers are commercially available in coaxial configurations in frequency bands from about 100 kHz to 50 GHz and in waveguides up to 110 GHz. Some specially dedicated systems operate in waveguides up to 1000 GHz.

The measuring uncertainty is defined mainly by the following parameters:

- Accuracy of the reference standards
- Stability of the generator and of the detection system
- Stability of the connection cables
- Repeatability of the connectors
- Accuracy of the built-in software to calculate the error parameters and DUT scattering parameters

The six-port technique is another method for measuring the complex scattering parameters of a device. The magnitude and the phase of the signal are calculated from four scalar power measurements made with detectors arranged as shown in Fig. 28 [8,40].

The four power sensors gather enough information to calculate the magnitude and phase of the reflection of the DUT and the power launched into it. The calibration of the six-port device is rather complicated because a set of quadratic equations has to be solved. The quadratic equations can be linearized and solved for both calibration and measurement [8,40].

The simplicity of the detection system is an advantage of the six-port device especially for wideband applications and very high operating frequencies. Compared to the vector network analyzer, the six-port device requires more calibration and more complicated mathematics.

Two six-port devices connected in the configuration shown in Fig. 29 are required to provide attenuation measurements.

The dividing circuit includes phase adjustments to obtain different ratios b_1/b_2 at the terminals of the DUT. Using state-of-the-art power sensors the dynamic range of a dual six-port device is as large as 60 dB.

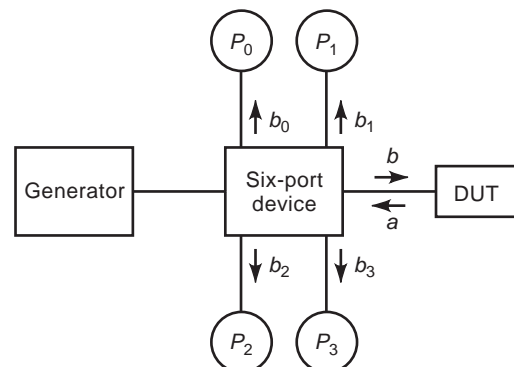

Figure 28. Principle of six-port technique for reflection measurement.

Figure 29. Principle of a dual six-port for s-parameter measurement.

To achieve maximum accuracy, through-connection, reflection line (TRL) calibration is frequently used. Because the six-port device determines the complex parameters during the calibration process, the test ports appear to be well matched. The measurement uncertainties are primarily limited by the calibration standards, mainly the reflection standard (short or open). Real-time operation is limited by the computing time and the response time of the power sensors.

3.3. Fiberoptics

Three main methods [41,42] are used for attenuation measurements: the insertion loss technique, the cutback technique, and the backscattering method. The first two methods perform two-point (end-to-end) measurements and the last performs a one-ended characterization. Some of the methods are standardized [43,44].

3.3.1. Insertion Loss Method. The insertion loss technique consists of a stable laser source and a stable, accurate, optical power meter. The power P_2 of the laser source is sent into the DUT (e.g., an optical fiber), and the power P_3 is measured at the far end. The attenuation is given by the ratio of the two power levels as

$$A(\text{dB}) = 10 \log \left(\frac{P_3}{P_2} \right) \tag{28}$$

To achieve more accurate measurements in the first phase, the power of the source is directly measured and is remeasured in the second phase with the DUT inserted. More sophisticated measuring systems use a configuration shown in Fig. 30.

A second power sensor measures the power level of the source instantaneously by a power divider. In this config-

uration the power stability of the source is less important because P_1 is always used as a reference. By using cooled detectors, a dynamic range of ≤ 90 dB is achieved.

The accuracy of the measurements are determined by the following factors:

- The power level and wavelength stability of the source
- The calibration and stability of the power sensors
- The reproducibility of the connectors
- The linearity of the detectors

The measurement uncertainties for the insertion loss technique are on the order of 0.9 dB including the connector reproducibility. Sophisticated systems reach over a limited dynamic range of 50 dB and uncertainty of 0.2 dB.

3.3.2. Cutback Method. The cutback method [41,45] (Fig. 31) is the most accurate technique, but it is destructive. This method was developed to measure the attenuation of fibers as a function of the wavelength. Using a light source combined with a monochromator, a fiber can be tested at any wavelength from 800 to 1600 nm with a spectral width of 3 nm. The light from the source is projected into the fiber by a lens.

The power $P_2(\lambda)$ is measured at the far end of the fiber (test length l_t) by using a cooled detector. Then the fiber is cut back to a short length of 2–3 m without changing the projecting conditions, and the power $P_1(\lambda)$ is recorded. If the power loss in the short length of fiber is assumed to be negligible, the attenuation is given by the following equation:

$$A(\lambda) = 10 \log \frac{P_2(\lambda)}{P_1(\lambda)} \tag{29}$$

Assuming a uniform fiber, the attenuation coefficient per unit length of the fiber is given by

$$\alpha(\lambda) = \frac{A(\lambda)}{(l_t - l_r)} \tag{30}$$

where l_t and l_r are given in kilometers. The achieved uncertainty for cable length of several kilometers is about 0.02 dB/km for multimode fibers and 0.004 dB/km for single mode.

3.3.3. Backscattering Method. The backscattering method is a one-ended measurement based on Rayleigh scattering in an optical fiber [41,46]. Figure 32 shows

Figure 30. Principle of the insertion loss method.

Figure 31. Principle of the cutback method.

the principle of an optical time-domain reflectometer (OTDR).

A laser pulse is projected into the fiber by a coupler, and the backscattered power is measured. The backscattered power is related to the attenuation loss of the fiber, and the measured time delay is related to the distance in the fiber. The attenuation is calculated by using two values of the backscattered power at different time delays (different locations along the fiber). The OTDR has the advantage of providing attenuation and reflection information along the fiber. A typical recording is shown in Fig. 33.

The length of the pulse is responsible for the deadzone, where no measurement is possible. A lead-in fiber allows masking of the deadzone. From the measured data details in the fiber path, such as connector loss or splice loss, irregularities of attenuation and defects can be analyzed.

Commercially available OTDRs have a dynamic range of about 35 dB and cover distances up to 65 km depending on the fiber loss. A well-calibrated OTDR can produce a measurement uncertainty of about 0.02 dB/km.

4. ERRORS AND UNCERTAINTIES IN ATTENUATION MEASUREMENTS

Whenever measurements are made, the results differ from the true or theoretically correct values. The differences are the result of errors in the measurement system, and it should be the aim to minimize these errors. In practice there are limits because no measurement instruments operate perfectly. A statement of measurement uncertainty reflects the quality of the measured results, and it has to be accompanied by a statement of confidence.

The International Committee for Weights and Measures (CIPM) [47] has published a guide for expressing uncertainty in measurements which has been adopted by the European Cooperation for Accreditation of Laboratories (EA) [48]. According to the guide, uncertainty is grouped in two categories: type A and type B:

Type A evaluation is the result of statistical analysis of a series of repeated observations and therefore includes random effects.

Type B evaluation is by definition other than type A, for example, judgment based on data of calibration certificates, experiences with instruments, and manufacturers' specifications.

4.1. Type A Evaluation of Uncertainty Components

Random effects result in errors that vary unpredictably. For an estimate of the standard deviation $s(q_k)$ of a series of n readings, q_k is obtained from

$$s(q_k) = \sqrt{\frac{1}{(n-1)} \sum_{k=1}^n (q_k - \bar{q})^2} \quad (31)$$

where \bar{q} is the mean of n measurements.

The random component of uncertainty is reduced by repeating the measurements. This yields the standard deviation of the mean $s(\bar{q})$

$$s(\bar{q}) = \frac{s(q_k)}{\sqrt{n}} \quad (32)$$

The standard uncertainty of the input estimate \bar{q} is the experimental standard deviation of the mean (for $n \geq 10$)

$$u(\bar{q}) = s(\bar{q}) \quad (33)$$

4.2. Type B Evaluation of Uncertainty Components

Systematic effects that remain constant during measurements but change if the measurement conditions are altered cannot be corrected and therefore contribute to uncertainty. Other contributions arise from errors that are not possible or impractical to correct for, such as from calibration certificates or manufacturers' specifications. Most of these contributions are adequately represented by a symmetrical distribution. In RF metrology three main distributions are of interest: normal, rectangular, and U-shaped.

Figure 32. Principle of an optical time-domain reflectometer.

Figure 33. Typical backscattering signature of a fiber.

4.2.1. Normal Distribution. Uncertainties derived from multiple contributions are assumed to be normally distributed. Accredited calibration laboratories issue calibration certificates calculated for a normal distribution and a minimum level of confidence of 95% (approximate coverage factor $k = 2$). The standard uncertainty associated with the estimate x_i is given by

$$u(x_i) = \frac{\text{uncertainty}}{k} \tag{34}$$

4.2.2. Rectangular Distribution. This means that there is equal probability that the true value lies between limits. This is the case for most manufacturers' specifications that give a semi-range limit a_i :

$$u(x_i) = \frac{a_i}{\sqrt{3}} \tag{35}$$

4.2.3. U-Shaped Distribution. This distribution is applicable to mismatch uncertainty [49]. Because the phases of the reflection coefficients (of source, DUT, load) in scalar measurement are not known, the mismatch loss has to be taken into account as an uncertainty. The mismatch uncertainty is asymmetric to the measured result, and normally the larger of the two limits $M = 20 \log(1 - |\Gamma_G| |\Gamma_L|)$ is used. The standard uncertainty is calculated as

$$u(x_i) = \frac{M}{\sqrt{2}} \tag{36}$$

4.3. Combined Standard Uncertainty

The combined standard uncertainty for uncorrelated input quantities is calculated as the square root of the sum of the squares of the individual standard

uncertainties:

$$u_c(y) = \sqrt{\sum_{i=1}^m u_i^2(y)} \tag{37}$$

4.4. Expanded Uncertainty

The expanded uncertainty U defines an interval in which there is the true value with a specified confidence level. Normally accredited calibration laboratories are asked to use the coverage factor $k = 2$ (approximately 95% confidence level), giving

$$U = k \cdot u_c(y)$$

4.5. Uncertainty in Attenuation Measurement

Let us assume a simple attenuation measuring setup, shown in Fig. 34, consisting of a generator, two matching circuits, and a receiver. In the first phase, when the two insertion points are clamped together, the receiver measures $P_1(f)$ (often called a *normalization*). In the second phase the DUT is inserted, and the receiver reads the values $P_2(f)$.

Attenuation as a function of the frequency is calculated from the ratio of the two sets of readings:

$$A(f) = 10 \log \left[\frac{P_2(f)}{P_1(f)} \right] \tag{38}$$

The following errors contribute to the uncertainty of the measurement:

The statistical errors of n repeated measurements (type A) are given by the arithmetic experimental standard deviation:

$$s(A) = \sqrt{\frac{1}{(n-1)} \sum_{k=1}^n (A_k - \bar{A})^2} \tag{39}$$

(\bar{A} is the arithmetic mean of the measurements)

The standard uncertainty is calculated from

$$u_s(A) = s(\bar{A}) = \frac{s(A)}{\sqrt{n}} \tag{40}$$

The generator level stability a_G is taken from the manufacturer's specification and is assumed to be rectangularly distributed. The uncertainty is calculated

Figure 34. Example of an attenuation measurement system.

as follows:

$$u_G = \frac{a_G}{\sqrt{3}} \quad (41)$$

The receiver level linearity and stability a_R is taken from the manufacturer's specification. The uncertainty is calculated as

$$u_R = \frac{a_R}{\sqrt{3}} \quad (42)$$

The noise level of the receiver influences the measurement of high attenuation values. It is given in the manufacturer's specification and contributes to the uncertainty as

$$u_N = \frac{a_N}{\sqrt{3}} \quad (43)$$

The crosstalk of the measurement system a_I is determined by measurements and regarded as limits, and therefore contributes to the uncertainty as

$$u_I = \frac{a_I}{\sqrt{3}} \quad (44)$$

Two mismatch losses have to be taken into account, one during the normalization (often also called *calibration*) phase and the second while measuring the DUT.

4.5.1. Normalization Phase. The maximum mismatch loss [49] is calculated from the reflection coefficients of the source and the receiver as

$$M_C = 20 \log(1 - |r_G||r_L|) \quad (45)$$

As in scalar measurements, the phases of the reflection coefficients are unknown. The mismatch loss contributes to the measurement uncertainty and is normally assumed to be U-shaped-distributed:

$$u_C = \frac{M_C}{\sqrt{2}} \quad (46)$$

4.5.2. Measurement Phase. There are two mismatch losses [49] that have to be considered: one between the generator and the input of the DUT and the other between the output of the DUT and the receiver. In addition, for small attenuation values the interaction between the input and the output connections has to be considered. The maximum limits of the mismatch loss that have to be used for the uncertainty are given by

$$M_m = 20 \log \frac{|1 - |r_G s_{11}| - |r_L s_{22}| - |r_G r_L s_{11} s_{22}| - |r_G r_L s_{21} s_{12}|}{1 - |r_G r_L|} \quad (47)$$

The uncertainty is given by

$$u_m = \frac{M_m}{\sqrt{2}} \quad (48)$$

The total uncertainty is calculated either from linear values or from decibel values as long as they are small:

$$u_c(A) = \sqrt{u_s^2 + u_G^2 + u_R^2 + u_N^2 + u_I^2 + u_C^2 + u_m^2} \quad (49)$$

The expanded uncertainty is calculated using a coverage factor $k = 2$ (approximately 95% confidence level) as

$$U(A) = k \cdot u_c(A) = 2 \cdot u_c(A) \quad (50)$$

The uncertainty has to be calculated for all the measurement frequencies to find the maximum value of the uncertainty.

ATTENUATORS

RAJI SUNDARARAJN
EDWARD PETERSON
ROBERT NOWLIN
Arizona State University East
Mesa, Arizona

Attenuators are linear, passive, or active networks or devices that attenuate electrical or microwave signals, such as voltages or currents, in a system by a predetermined ratio. They may be in the form of transmission-line, stripline, or waveguide components. Attenuation is usually expressed as the ratio of input power (P_{in}) to output power (P_{out}), in decibels (dB), as

$$\text{Attenuation (A)} = 10 \log_{10} \frac{P_{in}}{P_{out}} = 20 \log \frac{E_{in}}{E_{out}} = 20 \log \frac{E_1}{E_2} \quad (1)$$

This is derived from the standard definition of attenuation in Nepers (Np), as

$$\text{Attenuation (A)} = \alpha \Delta x = - \ln \frac{|E_2|}{|E_1|} \quad (2)$$

where α is attenuation constant (Np/m) and Δx is the distance between the voltages of interest (E_1 and E_2).

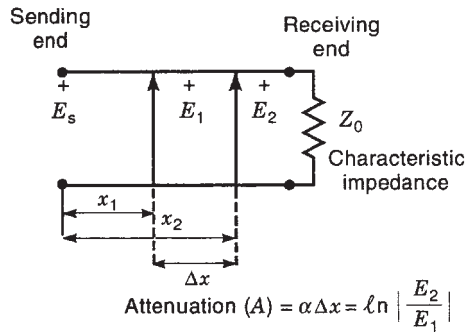

Figure 1. Concept and definition of attenuation.

Figure 1 illustrates this concept. The relation between N_p and dB is

$$1N_p = 8.686 \text{ dB} \tag{3}$$

Here the load and source are matched to the characteristic impedance. The decibels are converted to the attenuation ratio as follows: $P_{in}/P_{out} = \log_{10}^{-1} \text{ dB}/10$ or $V_{in}/V_{out} = \log_{10}^{-1} \text{ dB}/20$.

The most commonly used method in attenuators is to place resistors at the center of an electric field. Due to the electric field, there is current induced, resulting in ohmic loss.

1. APPLICATION

There are many instances when it is necessary to reduce the value, or level, of electrical or microwave signals (such as voltages and currents) by a fixed amount to allow the rest of the system to work properly. Attenuators are used for this purpose. For example, in turning down the volume on a radio, we make use of a variable attenuator to reduce the signal. Almost all electronic instruments use attenuators to allow for the measurement of a wide range of voltage and current values, such as voltmeters, oscilloscopes, and other electronic instruments. Thus, the various applications in which attenuators are used include the following:

- To reduce signal levels to prevent overloading
- To match source and load impedances to reduce their interaction
- To measure loss or gain of two-port devices
- To provide isolation between circuit components, or circuits or instruments so as to reduce interaction among them
- To extend the dynamic range of equipment and prevent burnout or overloading equipment

2. TYPES

There are various types of attenuators based on the nature of circuit elements used, type of configuration, and kind of adjustment. They are as follows:

Figure 2. Fixed coaxial attenuator. (Courtesy of Weinschel Associates.)

- Passive and active attenuators
- Absorptive and reflective attenuators
- Fixed and variable attenuators

A fixed attenuator is used when the attenuation is constant. Variable attenuators have varying attenuation, using varying resistances for instance. The variability can be in steps or continuous, obtained either manually or programmably. There are also electronically variable attenuators. They are reversible, except in special cases, such as a high-power attenuator. They are linear, resistive, or reactive, and are normally symmetric in impedance. They include waveguide, coaxial, and striplines, as well as calibrated and uncalibrated versions. Figures 2–4 show fixed, manual step, and continuously variable commercial attenuators, respectively.

Based on their usage, IEEE Std 474 classifies them as

Class I	Standard
Class II	Precision
Class III	General-purpose
Class IV	Utility

Typical commercial attenuators are listed below:

WA 1 (0–12.4 GHz), WA 2 (0–3 GHz), coaxial, fixed attenuators: 1–60 dB; 5 W av./1 kW peak

Figure 3. Manual step attenuator. (Courtesy of Weinschel Associates.)

953B - 10 - 34

953K - 3

Figure 4. Continuously variable attenuator. (Courtesy of Weinschel Associates.)

WA 115A manual step attenuators: 0–18 GHz, 0–9 dB, 1-dB steps

VA/02/100 continuously variable attenuators, resistive, 0–2 GHz, 5 W av./0.5 kW peak

HP 84904L programmable step attenuator, direct current (DC) to 40 GHz, 0–11 dB, 1-dB steps

HP 84906K programmable step attenuator, DC to 26.5 GHz, 0–90 dB, 10-dB steps

HP 84904L programmable step attenuator, DC to 40 GHz, 0–70 dB, 10-dB steps

HP 8495B manual step attenuator, DC to 18 GHz, 0–70 dB, 10-dB steps

HP 355F programmable step attenuator, DC to 1 GHz, 0–120 dB, 10-dB steps

HP 8493A coaxial fixed attenuator, DC to 12.4 GHz

Based on their utility, military attenuators are classified as:

Class I	For use as a primary standard
Class II	For use as a secondary standard, and in lab and precision test equipment
	A—with lumped constant or distributed shunt and series elements
	B—with lossy-line pads
Class III	For use in general field equipment
Class IV	For use in equipment where precision and stability are secondary considerations

Typical military specifications for fixed coaxial attenuators are as follows:

Mil-A-3933/1: attenuators, fixed, coaxial line, DC to 3 GHz, class IIA, low power

Mil-A-3933/2: attenuators, fixed, coaxial line, 1–4 GHz, class IIB, medium power

Mil-A-3933/10: attenuators, fixed, coaxial line, DC to 18 GHz, class III, medium power

Mil-A-3933/26: attenuators, fixed, coaxial line, 0.4–18 GHz, class IV low power

3. SPECIFICATIONS

To specify an attenuator, the purpose of the attenuator should be known. Attenuators are used to provide protec-

tion, reduce power, and extend the dynamic range of the test equipment. In choosing an attenuator, the frequency range of operation should be considered since the accuracy depends on the frequency. Attenuation involves placing resistive material to absorb the signal's electric field. This means, there will always be some reflection. So, attenuators must be designed to minimize reflection. This is quantified in terms of voltage standing-wave ratio (VSWR). Another factor to be considered is the insertion loss, which is the ratio of power levels with and without the component insertion. If it is a variable step attenuator, the step size is to be known. Thus, the parameters available in the specs are as follows:

dB rating

VSWR

Accuracy

Power rating

Stepsize (if variable)

Frequency band

Degree of stability (measured by the change in attenuation due to temperature, humidity, frequency, and power level variations)

Characteristic impedance of attenuator

Repeatability

Life

Degree of resolution (difference between actual attenuation and measured value)

The definitions of various parameters used in selecting attenuators are given below.

3.1. Electrical Parameters and Definitions (from MIL-HDBK-216)

Attenuation. A general transmission term used to indicate a decrease in signal magnitude. This decrease in power is commonly expressed in decibels (dB) as

$$\text{Attenuation (A)} = 10 \log_{10} \frac{P_{\text{in}}}{P_{\text{out}}}$$

Deviation of Attenuation from Normal. Difference in actual attenuation from the nominal value at 23°C and an input power of 10 mW at a specified reference frequency or frequency range. When used in a frequency range, it involves the frequency sensitivity.

Frequency Sensitivity. This is the peak-to-peak variation in the loss of the attenuator through the specified frequency range.

Frequency Range. Range of frequency over which the accuracy of attenuator is specified.

Insertion Loss. Amount of power loss due to the insertion of the attenuator in the transmission system. It is expressed as a ratio of the power delivered to that part of the system following the attenuator, before and after the insertion.

Characteristic Insertion Loss. This is the insertion loss in a transmission line or waveguide that is reflectionless in both directions from the inserted attenuator.

Power-Handling Capabilities. Maximum power that can be applied to the attenuator under specified conditions and durations without producing a permanent change in the performance characteristics that would be outside of specification limits.

Power Sensitivity. This is the temporary variation in attenuation (dB/W) under steady-state conditions when the input power is varied from 10 mW to maximum input power.

Stability of Attenuation. Capability of attenuator to retain its parameters when subjected to various environmental conditions.

Operating Temperature Range. Temperature range of the attenuator can be operated with maximum input power.

Temperature Sensitivity. Temperature variation in attenuation [dB/(dB × °C)] over the operating range.

Input VSWR. This is the level of reflected signal created at the attenuator input when the output is terminated with a load with the same characteristic impedance as the source.

Output VSWR. This is the level of reflected signal created at the attenuator output when the input is terminated with a load with the same characteristic impedance as the source.

4. PASSIVE ATTENUATORS

4.1. Resistance Networks for Attenuators

Typically T, pi, or L designs are used for attenuators. Figure 5 shows four commonly used symmetric (input and output resistors of equal value) configurations. The formulas for the resistance values in ohms for these pads when the characteristic resistance $R_0 = 1 \Omega$ are given

Figure 6. Unsymmetric matching L attenuator.

below. If R_0 is other than 1Ω , multiply each of the resistance values (a , b , c , $1/a$, $1/b$, and $1/c$) by R_0 , where

$$a = \frac{10^{\text{dB}/20} - 1}{10^{\text{dB}/20} + 1} \tag{4}$$

$$b = \frac{2 \times 10^{\text{dB}/20}}{10^{\text{dB}/10} - 1} \tag{5}$$

$$c = (10^{\text{dB}/20} - 1) \tag{6}$$

Simple wirewound resistors are used in audio applications. Nonreactive wirewound resistors, such as mica card, Aryton-Perry winding, woven resistors are used for high frequencies. For coaxial applications (over 26.5 GHz), thin-film resistors are used. For higher frequencies, distributive resistive films, such as nichrome alloy film, on a high-quality ceramic substrate, such as alumina or sapphire, is used. An unsymmetrical pad is shown in Fig. 6, and the formulas for this pad are

$$j = \frac{R_1 - kR_2}{k + R_2} \tag{7}$$

$$k = \left[\frac{R_1 R_2^2}{(R_1 - R_2)} \right]^{1/2} \text{ where } R_1 > R_2 \tag{8}$$

$$\text{Minimum loss (dB)} = 20 \log \left\{ \left[\frac{(R_1 - R_2)}{R_2} \right]^{1/2} + \left(\frac{R_1}{R_2} \right)^{1/2} \right\} \tag{9}$$

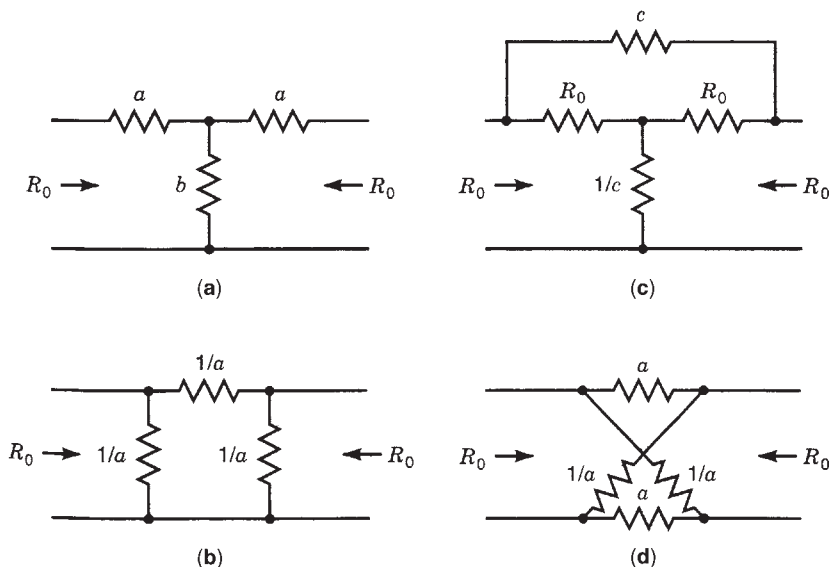

Figure 5. Symmetric pads with matched impedances: (a) T pad; (b) pi pad; (c) bridged T pad; (d) balanced pad.

^aIf $R_0 \neq 1 \Omega$, multiply all values by R_0 . (From Ref. data for *Radio Engineers*, 1985.)

^bFor other decibel values, use formulas in text.

^cThese values have been multiplied by 10^3 .

Typical values for the pads in Fig. 5 are shown in Table 1, and those of Fig. 6 are shown in Table 2.

For a broadband match between impedances R_1 and R_2 , use the minimum-loss L pad (Fig. 6).

4.2. Power Dissipation within a T Pad

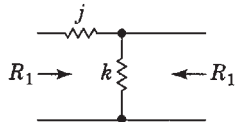

Table 3 lists values of power dissipation within a T pad. The values are for an input of 1 W; for other input powers, multiply the values by the input power.

5. INSERTION LOSS

An attenuator is used to introduce attenuation between a source and a load. Due to the introduction of the attenuator, there is change in the current. This loss is designated as insertion loss, which depends on the configuration.

Usually, the load and source impedances are matched. Figure 7 illustrates this concept. If I_{L0} is the load current without the attenuator pad and I_L is the current with the attenuator pad, then the ratio I_L/I_{L0} is called the *insertion loss*, one of the parameters of the attenuates. Figure 7a shows the source and load connected without an attenuator, and Fig. 7b shows the same system with an attenuator. (The quantities I_L , R_{in} , and R_{out} depend on the attenuator configuration.) The quantities insertion loss (I_L), input resistance (R_{in}), and output resistance (R_{out}) depend on the attenuator configuration. The value of each of the three resistors of the T (Fig. 8) and pi (Fig. 9) attenuators can be chosen independently of others. This enables the three-design criteria of input resistance, output resistance, and insertion loss to be met. In many situations, the only function of the pad is to provide matching between source and load; and although attenua-

^aFor $R_2 = 1\Omega$ and $R_1 > R_2$. If $R_2 \neq 1\Omega$, multiply values by R_2 . For ratios not in the table, use the formulas in the text. (From Ref. data for *Radio Engineers*, 1985.)

Examples of use of table:

If $R_1 = 50\Omega$ and $R_2 = 25\Omega$, then $R_1/R_2 = 2.0$, and $j = k = 1.414 \times 25\Omega = 35.35\Omega$.

If $R_1/R_2 = 1.0$, minimum loss = 0 dB.

For $R_1/R_2 = 2.0$, the insertion loss with the use of j and k for matching is 7.66 dB above that for $R_1/R_2 = 0$.

tion will be introduced, this may not be a critical design parameter. This allows a simpler type of pad to be designed, requiring only two resistors; it is known as an “L pad.”

Figure 10 shows an L attenuator, which can be derived from either a T or a pi attenuator, simply by removing one of the resistors. As shown, different configurations are required depending on whether $R_S > R_L$ or $R_S < R_L$.

5.1. T Attenuator Insertion Loss

The T attenuator contains resistors R_1 , R_2 , and R_3 ; these form a T configuration, as shown in Fig. 6. Insertion loss is usually measured in dB, defined as $I_L(\text{dB}) = -20 \log I_L$ or $|20 \log I_L|$, the amount of attenuation required. The insertion loss I_L is given as

$$I_L(\text{dB}) = \frac{I_L}{I_{L0}} = \frac{R_3(R_S + R_L)}{(R_S + R_1 + R_3)(R_2 + R_3 + R_L) - R_3^2} \quad (10)$$

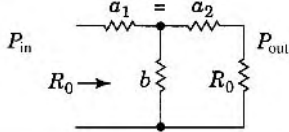

The input and the output of resistances of the attenuator are given by

$$R_{in} = R_1 + \frac{R_3(R_2 + R_L)}{R_2 + R_3 + R_L} \quad (11)$$

and

$$R_{out} = R_2 + \frac{R_3(R_1 + R_S)}{R_1 + R_3 + R_S} \quad (12)$$

^aFor 1 W-input and matched termination. If input $\neq 1\text{w}$, multiply values by P_{in} . (From Ref. data for *Radio Engineers*, 1985.)

In many cases, the attenuator also has to match the load and the source impedance. In this case, $R_1 = R_2 = R$ and $R_{in} = R_{out} = R_0$. Thus

$$R_0 = R + \frac{R_3(R + R_0)}{(R_3 + R + R_0)} \quad (13)$$

and the insertion loss is given by

$$I_L = \frac{R_3}{R_3 + R + R_0} \quad (14)$$

and

$$R = R_0 \frac{1 - I_L}{1 + I_L} \quad (15)$$

Figure 7. Definition of characteristic insertion loss: (a) original setup without attenuator; (b) original setup with attenuator between source and load.

and

$$R_3 = \frac{2R_0 I_L}{1 - (I_L)^2} \tag{16}$$

Example 1 (T Attenuator). A T-type attenuator is required to provide 3×0 dB insertion loss and to match 50Ω input and output. Find the resistor values,

using the following equations:

$$R = R_0 \frac{1 - I_L}{1 + I_L} = 50 \left(\frac{1 - 0.708}{1 + 0.708} \right) = 8.55 \Omega$$

$$R_3 = \frac{2R_0 I_L}{1 - (I_L)^2} = \frac{2 \times 50 \times 0.708}{1 - (0.708)^2} = 141.6 \Omega$$

Figure 8. T attenuator configuration.

Figure 9. Pi attenuator configuration.

Check:

$$I_L = \frac{R_3}{R_3 + R + R_0} = \frac{141.6}{141.6 + 8.55 + 50} = 0.708$$

5.1.1. The Pi Attenuator Insertion Loss. Figure 9 shows a pi attenuator formed by resistors R_a , R_b , and R_c . The insertion loss and conductances G_{in} and G_{out} are given by

$$I_L = G_c \frac{G_S + G_L}{(G_S + G_a + G_c(G_b + G_c + G_L) - G_c^2)} \tag{17}$$

$$G_{in} = G_a + \frac{G_c(G_b + G_L)}{G_b + G_c + G_L} \tag{18}$$

$$G_{out} = G_b + \frac{G_c(G_a + G_S)}{G_a + G_c + G_S} \tag{19}$$

where $G = 1/R$; thus $G_L = 1/R_L$ and so on.

The same pi attenuator can be realized using a T attenuator with R_1 , R_2 , and R_3 values using the Y- Δ

Figure 10. L attenuator configuration:(a) $R_S < R_1$; (b) $R_S > R_1$.

transformation:

$$R_a = \frac{R_1 R_2 + R_1 R_3 + R_2 R_3}{R_2} \quad (20)$$

$$R_b = R_a \frac{R_2}{R_1} \quad (21)$$

$$R_c = R_a \frac{R_2}{R_3} \quad (22)$$

The selection between pi and T is based on the value of resistors that can be used in practice. With matching source and load impedances, the values of the pi attenuator are

$$R_a = R_b = R_0 \frac{1 + I_L}{1 - I_L} \quad (23)$$

and

$$R_c = R_0 \frac{1 - (I_L)^2}{2I_L} \quad (24)$$

Example 2 (Pi Attenuator). Repeat Example 1 using a pi attenuator

$$R_L \text{ (dB)} = 3 = -20 \log I_L$$

$$I_L = 10^{(-3/20)} = 0.708$$

using the following equations:

$$R_A = R_B = R_0 \frac{1 + I_L}{1 - I_L} = 50 \left(\frac{1 + 0.708}{1 - 0.708} \right) = 292.46 \Omega$$

$$R_C = R_0 \left(\frac{1 - (I_L)^2}{2I_L} \right) = 50 \left(\frac{1 - (0.708)^2}{2 \times 0.708} \right) = 17.61 \Omega$$

5.1.2. The L Attenuator Insertion Loss. An L attenuator can be derived from a T or pi attenuator by removing one resistor. As shown in Fig. 10, two configurations are obtained depending on $R_S > R_L$ or $R_S < R_L$. Simple circuit theory shows that for $R_S > R_L$, we have

$$R_S = R_{in} = R_1 + \frac{R_3 R_L}{R_3 + R_L} \quad (25)$$

and

$$R_L = R_{out} = \frac{R_3 (R_1 + R_S)}{R_3 + R_1 + R_S} \quad (26)$$

from which it can be shown that

$$R_1 = \sqrt{R_S (R_S - R_L)} \quad (27)$$

and

$$R_3 = \frac{R_S^2 - R_L^2}{R_1} \quad (28)$$

and when we put $R_2 = 0$, the insertion loss is calculated as

$$I_L = \frac{R_3 (R_S + R_L)}{(R_S + R_1 + R_3)(R_3 + R_L) - R_3^2} \quad (29)$$

Example 3. Design an L attenuator to match a 300-Ω source to a 50-Ω load and determine insertion loss. Here $R_S > R_L$ using the following equation:

$$R_1 = \sqrt{R_S (R_S - R_L)} = \sqrt{300(300 - 50)}$$

$$= \sqrt{300 \times 250} = 273.86 \Omega$$

Using the following equation:

$$R_3 = \frac{R_S^2 - R_L^2}{R_1} = \frac{300^2 - 273.86^2}{273.86} = 54.775 \Omega$$

$$R_L = \frac{R_3 (R_S + R_L)}{(R_S + R_1 + R_3)(R_3 + R_L) - R_3^2}$$

$$= \frac{54.775 (300 + 50)}{(300 + 273.86 + 54.775)(54.775 + 50) - (54.775)^2}$$

$$= 0.305$$

$$R_L \text{ (dB)} = -20 \log 0.305 = 10.3 \text{ dB}$$

For $R_S < R_L$, we have

$$R_{in} = \frac{R_3 (R_2 + R_L)}{R_2 + R_3 + R_L} \quad (30)$$

and

$$R_{out} = R_2 + \frac{R_3 R_S}{R_3 + R_S} \quad (31)$$

and

$$R_2 = \sqrt{R_L (R_L - R_S)} \quad (32)$$

and

$$R_3 = \frac{R_L^2 - R_S^2}{R_2} \quad (33)$$

The corresponding insertion loss is

$$I_L = \frac{R_3 (R_S + R_L)}{(R_S + R_3)(R_2 + R_3 - R_L) - R_3^2} \quad (34)$$

Example 4. Design an L attenuator to match 50-Ω source to 75-Ω load and determine the insertion loss $R_S < R_L$,

using the following equation:

$$R_2 = \sqrt{R_L(R_L - R_S)} = \sqrt{75(75 - 50)} = 43.3 \Omega$$

using the following equations:

$$R_3 = \frac{R_L^2 - R_2^2}{R_2} = \frac{75^2 - 43.3^2}{43.3} = 86.6 \Omega$$

$$R_L = \frac{R_3(R_S + R_L)}{(R_S + R_3)(R_2 + R_3 + R_L) - R_3^2}$$

$$= 0.0123 = 38.2 \text{ dB}$$

6. FIXED ATTENUATORS

Fixed attenuators, commonly known as “pads,” reduce the input signal power by a fixed amount, such as 3, 10, and 50 dB. For example, an input signal of 10 dBm (10 mW) passing through a 3-dB fixed attenuator will exit with a power of 10 dBm – 3 dB = 7 dBm (5 mW). Figure 2 shows a fixed coaxial commercial attenuator. A typical datasheet for a fixed coaxial attenuator is as follows (courtesy of Weinschel Associates):

Frequency	0–3 GHz
Attenuation	50 dB
Accuracy	±0.10 dB (DC) ±0.15 dB (0–2 GHz) ±0.13 dB (0–3 GHz)
VSWR	1.15 (0–1 GHz) 1.20 (1–3 GHz)
Input power	1 W av., 1 kW peak at –30°–70°C
Connectors	Type N; St. St.; m, f
Length	68 mm (2.7 in.)
Diameter	210 mm (0.83 in.)
Weight	100 g (3.6 oz)
Power sensitivity	<0.005 dB/dB × W; bidirectional in power
Temperature stability	<0.0004 dB/dB × °C

6.1. Applications

Fixed attenuators are used in numerous applications. In general, they can be classified into two distinct categories:

1. Reduction in signal level
2. Impedance matching of a source and a load

Those in the first category are used in the following situations:

- Operation of a detector in its square-law range for most efficient operations.
- Testing of devices in their small signal range.

- Reduction of a high-power signal to a level compatible with sensitive power measuring equipment, such as power sensors and thermistor mounts.

Those in the second category are used in the following situations:

- Reduction of signal variations as a function of frequency. The variations here are caused by a high VSWR. The attenuator provides a reduction in these variations and a better match.
- Reduction in frequency pulling (changing the source frequency by changing the load) of solid-state sources by high reflection loads.

6.2. Types

Based on construction, fixed attenuators are available in coaxial, waveguide, and stripline configurations. The various types are:

1. Waveguide vane
2. Rotary vane (fixed)
3. Directional coupler
4. T or pi
5. Lossy line
6. Distributed resistive film

6.2.1. Coaxial Fixed Attenuators. T or pi configurations are most commonly used both at low and high frequencies. At low frequencies, normal wirewound resistors are used. At high frequencies, thin-film resistors are used. Figures 11 and 12 show T and pi fixed attenuators. Thin-film resistors designed for microwave frequencies are used in place of carbon resistors. These resistors employ a nichrome alloy film on a high-quality ceramic substrate to ensure a firmly bonded film with low-temperature coefficients. This type of construction makes the resistors extremely stable at high frequencies. The skin effect of these resistors is excellent, used extensively in the microwave applications.

The T and pi configurations are obtained by placing the resistors in series on the center conductor and in shunt, contacting both the center and outer conductor. Thus, the T configuration can be fabricated with one shunt flanked by two series resistors and the pi configuration, with one series flanked by two shunt resistors. The series resistors in the T and pi configurations have less than 1 W capacity, thereby severely limiting the use at high-power applications, unless an elaborate heatsinking is provided. Power attenuators usually have huge sinks to handle high-power applications.

6.2.2. Resistive Card Attenuator. In a fixed dissipative, waveguide-type resistive card attenuator, the card is bonded in place (Fig. 13). It is tapered at both ends to maintain a low-input and low-output VSWR over the useful waveguide band. Maximum attenuation per length is obtained when the card is parallel to the *E* field

Figure 11. T/pi fixed attenuator configuration: (a) T section; (b) pi section.

and at the center, where the TE_{10} mode is maximum. The conductivity and the dimensions of the card are adjusted, by trial and error, to obtain the desired attenuation, which is a function of frequency. The attenuation increases with increase in frequency. In power applica-

Figure 13. Fixed resistive card attenuator configuration.

tions, ceramic-type absorbing materials are used instead of a resistive card.

7. VARIABLE ATTENUATORS

A variable attenuator has a range, such as 0-20 dB or 0-100 dB. The variation can be continuous or in steps, obtained manually or programmably.

7.1. Step Attenuators

A series of fixed attenuators are mechanically arranged to offer discrete-step variation. The fixed attenuators are arranged in a rotatable drum or in a slab for switching between contacts. This arrangement provides discrete values of attenuation in each position and a high reliability factor. The step size can be 0.1, 1, or 10 dB. Stationary coaxial contacts provide the input and output of the device. These are used in applications requiring broadband flatness with low VSWR and satisfactory resettability over ranges from 0 to 120 dB. Their application range is DC to 18 GHz.

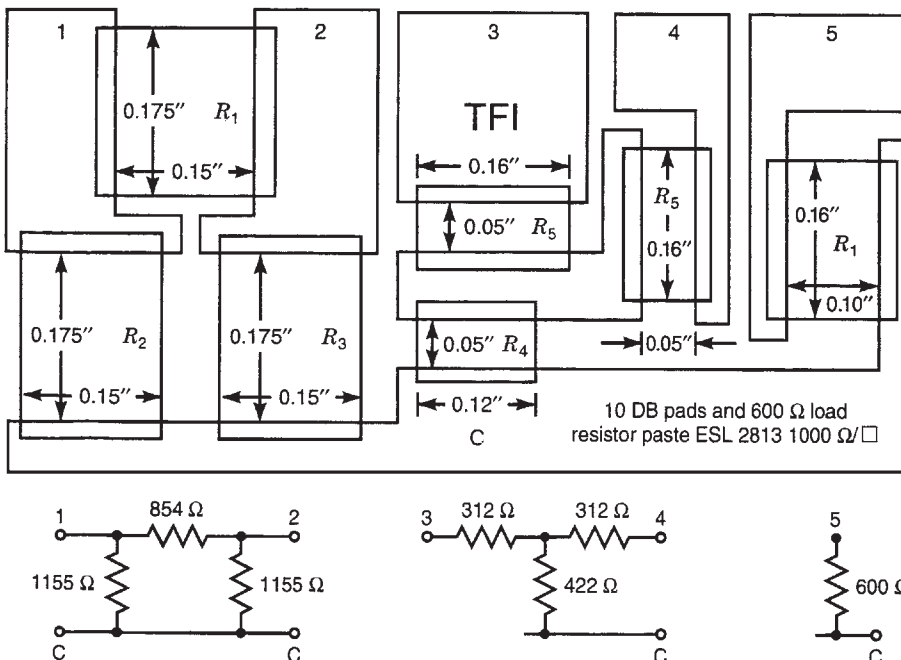

Figure 12. T/pi fixed-attenuator construction.

7.2. Manual Step Attenuators

Figure 3 shows a manual step attenuator. A typical datasheet looks as follows:

Frequency	0–4, 0–8, 0–12.4, 0–18 GHz
Attenuation	0–9, 0–60, 0–69
Stepsize	1, 10, 1 dB, respectively, for the range given above
VSWR	1.20, 1.25, 1.40, 1.50 for the frequency ranges given above 1.25, 1.30, 1.45, 1.60, for the frequency range given above
Connectors	N/SMA; St. St.
Height	83 mm (3.3 in.)
Depth	79 mm (3.1 in.) (excludes shaft and knob)
Width	65, 65, 118 mm (2.6, 2.6, 4.7 in.) for the three attenuation ranges given above

7.3. Continuously Variable Attenuators

Figure 4 shows a continuously variable attenuator. Typical specs are

Frequency	1–18 GHz, 1 W av./1 kW peak
Connectors	St. St., M, F; type N, SMA
Zero loss	Typically 0.5–1 dB
Attenuation	0–9, 0–60, 0–69 dB

The various types of continuously variable attenuators are

- Lossy wall
- Movable vane (Flap)
- Rotary vane
- Variable coupler
- Absorptive type
- Coaxial resistive film
- Variable T
- Waveguide below cutoff (piston)

7.4. Programmable and Solenoid Attenuators

7.4.1. Programmable. These are rapid switching attenuators with high accuracy and repeatability, useful for remote and computerized applications. Switching speeds can be as low as 30 ns. Two varieties of the programmable attenuators are the step-controlled and voltage-controlled types. The attenuation is varied by controlling the electrical signal applied to the attenuator. These signals can be in the form of either a biasing current or binary digit. The biasing can be pulses, square waves, or sine waves. A typical datasheet for coaxial programmable step attenuator is as follows:

Frequency	DC to 40 GHz
Attenuation	0–11 dB, in steps of 1 dB
Maximum VSWR	1.3–12.4 GHz 1.7–34 GHz 1.8–40 GHz

Insertion loss	0.8 dB + 0.04 GHz 0 dB setting
Repeatability	0.03 dB
Power rating average	1 W
Peak	50 W
Maximum pulse width	10 μ s
Life	5 million cycles per section minimum

7.4.2. Solenoid. A typical datasheet would be as follows:

Voltage	20–30 V
Speed	< 20 ms
Power	2.7 W
RF connectors	2.4 mm, F
Shipping weight	291 g (10.3 oz)

7.5. Lossy Wall Attenuator

Figure 14 shows lossy wall variable attenuator. It consists of a glass vane coated with a lossy material, such as aquadag or carbon. For maximum attenuation, the vane is placed in the center of the guide's wide dimension, where the electric field intensity is the maximum. A drive mechanism with a dial then shifts the vane away from the center so that the degree of attenuation is varied. This needs calibration by a precise attenuator. To match the attenuator to the waveguide, the vane can be tapered at each end; usually a taper of $\lambda g/2$ provides an adequate match. Thus, it is frequency sensitive and the glass dielectric introduces appreciable phase shift.

Attenuation may also be obtained by inserting a resistive element through a shutter. The plane of the element lies in the distribution of the electric field across the wide dimension of the waveguide and the result is a degree of attenuation, which increases with the depth of insertion. However, due to the discontinuity, there is reflection of energy.

7.6. Movable-Vane (Flap) Attenuator

Figure 15 shows a waveguide variable, dissipative attenuator. The card enters the waveguide through the slot in the broad wall, thereby intercepting and absorbing a portion of the TE_{10} wave. The card penetration, and hence the attenuation, is controlled by means of the hinge arrangement to obtain variable attenuation. The ratings are typically 30 dB and are widely used in microwave equipment. However, the attenuation is frequency sensitive and the phase of the output signal is a function of card penetration and hence attenuation. This may result in nulling when the attenuator is part of a bridge network. Since it is not simple to calculate the loss in dB, this type of attenuator has to be calibrated against a superior standard. To overcome these drawbacks, a rotary-vane attenuator is used.

7.7. Rotary-Vane Attenuator

The rotary-vane attenuator is a direct-reading precision attenuator that obeys a simple mathematical law, $A = -20 \log \cos^2 \theta = -40 \log \cos \theta$ dB. As such, it is frequency-independent, which is a very attractive criterion

Figure 14. Lossy wall attenuator configuration: (a) minimum attenuator; (b) maximum attenuator.

for an attenuator. A functional diagram illustrates the operating principle of this attenuator. It consists of three sections of waveguide in tandem as shown (Fig. 16). A rectangular-to-circular waveguide transition containing a horizontal attenuator strip is connected to a rotatable circular waveguide containing an attenuator strip. This in turn is connected to a circular-to-rectangular waveguide transition containing a horizontal attenuator strip.

The incoming TE_{10} mode is transformed into the TE_{11} mode in the circular waveguide by the rectangular-to-circular waveguide transition with negligible reflections. The polarization of the TE_{11} mode is such that the e field is perpendicular to the thin resistive card in the transition section. As such, this resistive card has a negligible effect on the TE_{11} mode. Since the resistive card in the center can be rotated, its orientation relative to the electric field

of the incoming TE_{11} mode can be varied so that the amount by which this mode is attenuated is adjustable.

When all the strips are aligned, the electric field of the applied wave is normal to the strips and hence no current flows in the attenuation strips and therefore no attenuation occurs. In a position where the central attenuation strip is rotated by an angle θ , the electric field of the applied wave can be resolved into two orthogonally polarized modes; one perpendicular and one parallel to the resistive card. That portion which is parallel to the resistive slab will be absorbed, whereas the portion, which is polarized perpendicular to the slab, will be transmitted.

7.8. Variable Coupler Attenuator

These are basically directional couplers where the attenuation is varied by mechanically changing the coupling between two sections. This is accomplished by varying the spacing between coupled lines. These attenuators have a large range, high power handling capability, and retain calibration over a range of ambient conditions. They have a higher insertion loss at lower frequencies (Fig. 17).

7.9. Absorptive Attenuator

Figure 18 shows an absorptive variable attenuator. Attenuation is obtained by using a lossy dielectric material. The TEM electric field is concentrated in the vicinity of the center strip of the stripline. When the absorbing material is inserted in the high-field region, a portion of the TEM wave is intercepted and absorbed by the lossy dielectric. Thus, the attenuation increases. Since the characteristic impedance of the stripline changes with the dielectric

Figure 15. Movable-vane (flap) variable attenuator configuration.

Figure 16. Rotary-vane attenuator configuration.

material insertion, the SWR tends to increase as the attenuation increases. To minimize this, the ends of the lossy material are tapered to provide a smooth impedance transformation into and out of the lossy section. SWR values of > 1.5 are possible over a limited frequency range. In general, the SWR deteriorates at low frequencies. The attenuation increases with increasing frequency for a fixed setting. This is another disadvantage, since this makes the calibration a cumbersome procedure. Compensation techniques are occasionally used to reduce this variation with frequency.

7.10. Coaxial Resistive Film Attenuator

Figure 19 shows a coaxial resistive film attenuator. In this configuration, if r is the RF resistance per unit length, by adjusting the length l , the series resistance $R = rl$ of the center conductor is changed; thus, the attenuation is variable. If I is the conduction current on the center conductor, the voltage drop is $V = RI = Ir l$. If E_i is the input voltage, then the output voltage is $E_o = E_i - r l I$ and the attenuation is

$$A = 20 \log \frac{E_i}{E_i - r l I} \text{ (dB)} \tag{35}$$

7.11. Variable T

The variable T attenuator is the same as the fixed attenuator except that the resistors are variable (Fig. 20). All three resistors are variable simultaneously to give good input/output VSWR.

Figure 17. Variable coupler attenuator configuration.

7.12. Waveguide below Cutoff or Piston Attenuator

The simple principle of cutoff below frequency is used in the piston or the cutoff attenuator. The cylindrical waveguide used is operating at a frequency below cutoff. For high-power applications, a coaxial configuration is used. A simple waveguide cutoff attenuator is shown in Fig. 21. A metal tube, acting as a waveguide, has loops arranged at each end to couple from the coaxial lines into and out of the waveguide. One of the loops is mounted on a movable plunger or hollow piston so that the distance between the loops is variable. The input coupling loop converts the incoming TEM wave into the TE_{11} mode in the circular waveguide, while the output loop converts the attenuated TE_{11} mode back to TEM. The attenuator can be matched by adding Z_0 resistors. The attenuation is given as

$$A(\text{dB}) = 54.6 \frac{l}{\lambda_c} \sqrt{1 - \left(\frac{f}{f_c}\right)^2} \tag{36}$$

By choosing the diameter such that $\lambda_c \ll \lambda_o$, and hence $f/f_c \ll 1$, this equation reduces to

$$A(\text{dB}) = 54.6 \frac{l}{\lambda_c} \tag{37}$$

This was obtained from

$$\alpha = \frac{2\pi}{\lambda_{oc}} \text{ Np/m or } \alpha = \frac{54.6}{\lambda_{oc}} \text{ dB/m where } 1 \text{ Np} = 8.686 \text{ dB} \tag{38}$$

[If $\lambda_{oc} = 10 \text{ cm}$, and λ_o is much greater (10 times or more—in this case, 1 m or more), the attenuation

Figure 18. Absorptive-type variable attenuator configuration.

Figure 19. Coaxial resistive film attenuator configuration.

increases 5.45 dB per cm of outward movement of the plunger.]

The sliding cylindrical conductors allow length l to be varied, which varies the attenuation, since attenuation $A = \alpha l$, where α is the attenuation constant due to the cutoff effect, and l is the length of the circular guide. The cutoff wavelength is $\lambda_c = 1.706D$, where D is the diameter of the waveguide. Thus the attenuation is

$$A(\text{dB}) = 54.6 \frac{l}{\lambda_c} = 32 \frac{l}{D} \quad (39)$$

or

$$\Delta A(\text{dB}) = \frac{32}{D} \Delta l \quad (40)$$

The attenuation is independent of frequency; it depends only on the physical dimensions and hence can be accurately controlled by maintaining tight tolerances on the length and diameter of the circular guide. With ΔA linearly proportional to Δl , the cutoff attenuator is easily calibrated and hence particularly useful as a precision variable attenuator.

The cutoff attenuator is one of the most widely used precision variable attenuators in coaxial measurement equipment. This is a reflective-type attenuator, since the waveguide is essentially dissipationless. The signal is reflected rather than absorbed. For higher attenuation (> 10 dB), the SWR at both ports is very high (> 30). This can cause problems in certain applications.

This type of attenuator is very useful, but has the disadvantage of high insertion loss. Due to the nature of cutoff, the insertion loss is high, up to 15–20 dB. If this loss is overcome, piston attenuators are one of the most accurate attenuators available. Values of 0.001 dB/10 dB of attenuation over a 60 dB range are common. A good input/output match is obtained using inductive loops within the waveguides. Excellent matching is obtained over the entire range of attenuation due to inductive loop coupling. Figure 22 shows a commercially available standard variable piston attenuator and the various calibration curves. It contains an accurately dimensioned tube acting

Figure 20. Variable T attenuator.

Figure 21. Coaxial variable cutoff attenuator configuration.

as a circular waveguide, below cutoff TE_{11} mode. Typical specifications are (courtesy of Weinschel Associates)

Frequency	30 MHz
Mode	TE_{11} cutoff
Range	0–120 dB
	12.5 dB zero insertion loss
VSWR	1.2 max in 50- Ω system
Connectors	Type N, panel-mounted
Accuracy	0.01 dB from 0 to 15 dB
	0.005 dB/10 dB from 15 to 100 dB
	0.01 dB/10 dB from 100 to 120 dB
Resolution	0.001 dB direct-reading digital indicator

7.12.1. Laser Piston Attenuator. Figure 23 shows a laser piston attenuator. The heart of this instrument is a precise stainless steel circular waveguide, operated in the TE_{11} cutoff mode. Laser light, traveling between two antennas in the center of the circular waveguide, measures directly the changes in actual separation of the two antennas along the same path as the TE_{11} mode propagates. The laser signal is converted to attenuation in dB and corrected for skin effect, the refractive index of air, and changes relative to temperature of the waveguide and pressure. The specifications are (courtesy of Weinschel Associates)

Operating frequency	Dual frequency 1.25 MHz + 0.05 MHz and 30.0 MHz + 0.1 MHz
Waveguide mode	TE_{11} , below cutoff
Incremental attenuation range	100 dB
Minimum insertion loss	10 dB nominal
Resolution	0.0001 dB for Δ dB, 0.002 dB for total loss
Attenuation readout	Front panel 7-digit LED or remotely via IEEE bus
Connectors	Type N jacks
VSWR (input and output)	1.2 max at 1.25 and 30 MHz in 50- Ω system
Accuracy	0.001 dB/10 dB + 0.0005 dB between 15 and 115 dB total loss
Weight	Net: 77 kg (170 lb); shipping: 145 kg (320 lb)
Accessories	Power supply, controller, calibration tape, two power cables, one 22-wire power cable, instruction/maintenance manual

8. ACTIVE ATTENUATORS

8.1. pin Diode Attenuators

The normal diode junction consists of a p-type material brought together with an n-type material to form the familiar pn junction. The pin diode is distinguished from the normal pn junction type by an area called an *intrinsic region* sandwiched between the p⁺-doped and n⁺-doped

silicon layers. This intrinsic layer has almost no doping and thus has a very large resistance. When a variable DC control voltage forward-biases the pin diode, the DC bias or control current causes it to behave as almost a pure resistance at RF frequencies, with a resistance value that can be varied over a range from 1 Ω to 10 kΩ. As the bias current is increased, the diode resistance decreases. This relation makes the pin diode ideally suited as a variable

Figure 23. Laser piston attenuator. (Courtesy of Weinschel Associates.)

attenuator for leveling and amplitude modulating a RF signal.

These attenuators provide local oscillator, IF, and RF signal level control throughout communications, measurement, and control circuits. One example is the reduction in the output of a receive mixer in a code-division multiple-access (CDMA) base station prior to the IF amplifier. Also, to provide one step of transmit level control with little degradation of the noise figure (NF), it could be used in a CDMA handset transmit chain between the mixer (upconverter) and the bandpass filter (Fig. 24). Since the attenuator is purely passive, it produces no additive noise and the NF is essentially its insertion loss. Even in the attenuator mode, the effect on the noise figure would be minimal.

In personal communication service (PCS) systems, the base stations may be fed from multiple picocells that are physically separated from it by up to 100ft or more of coaxial cable. The signal levels coming into the base station will vary depending on the cable length and individual transponder power. It is desirable to keep the signals at uniform levels coming into the base station; to do so, it may be necessary to attenuate the stronger signals. An attenuator can be easily inserted for this purpose.

The upper end of a receiver's linear dynamic range is determined by the largest signal it can handle without being overdriven and producing unacceptable levels of distortion caused by device nonlinearities. Inserting an attenuator before a low-noise amplifier (LNA) in the presence of strong, in-band signals produces better reception by preventing them from overdriving the receiver's front end. This effectively shifts the dynamic range

Figure 24. CDMA handset transmit application.

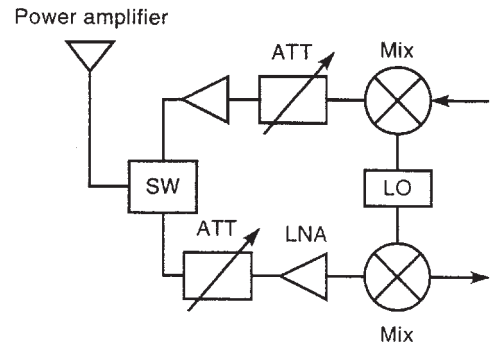

Figure 25. Functional block diagram of a digital cellular phone, using variable attenuators.

upward by the amount of attenuation. It must be remembered that when inserted into the system, the attenuator will also present a load and a source impedance to the previous and succeeding stages, respectively, hence the importance of the attenuator impedance match.

RF variable attenuators are used to control the transmitting and receiving signal power levels to prevent strong-weak adjacent signals from seriously degrading the bit error rate (BER) of digital mobile communication systems, such as TDMA or CDMA. Figure 25 shows the basic RF functional block diagram of a typical digital cellular phone system, where variable attenuators are required.

8.2. Characteristics of the pin Diode

The approximate high frequency equivalent circuit of a pin diode is shown in Fig. 26. Here, R_I is the effective resistance of the intrinsic (I) layer, given by

$$R_I = \frac{k}{I_{DC}^x} \tag{41}$$

where I_{DC} is the DC bias current in mA, and k and x are device-dependent empirical constants. Although shown as a variable, this resistance is constant with respect to the RF signal. The high-frequency resistance function is plotted in Fig. 27 for the Hewlett-Packard HPND-4165 diode. For a specific diode design, the exponent X is usually a constant. For the HPND-4165, X is typically 0.92. The constant k and therefore R_I , however, are highly dependent on the fabrication and process control and its value can vary by as much as 3:1 from diode to diode. For analog applications, such as a variable attenuator, where repeatable attenuation with bias current is desired, the variation of R_I must be controlled. The HPND-4165 is

Figure 26. pin diode high-frequency equivalent circuit.

Figure 27. Typical RF resistance versus DC bias current for HPND-4165.

precisely controlled in manufacturing, and resistance values at specific bias points are specified and the slope of resistance versus bias matched with narrow limits. The specification limits of these parameters are shown in Table 4.

8.3. Applications

The pin diode is ideally suited to switch and attenuate RF signals. Since the pin diode is a RF variable resistor, the logical application is that of a variable attenuator. This attenuator may be either a step or a continuously variable type. Two of the simplest circuits are the series and shunt attenuators shown in Figs. 28 and 29.

Attenuation in the series pin circuit is decreased (more power appears at the output) as the RF resistance of the diode is reduced. This resistance is reduced by increasing the forward bias control current on the diode. The opposite occurs for the shunt configuration. The attenuation in the shunt circuit is decreased when the RF resistance of the diode increases because less power is absorbed in the diode and more appears at the output. If the control bias is switched rapidly between high and low (zero) values, then the circuit acts simply as a switch. When used as a switch, the attenuation that exists when the switch is ON is called

Table 4. HPND-4165 pin Diode Specifications

Parameter	HPND-4165	Test Conditions
High-resistance limit, R_H	1100–1660 Ω	10 μ A
Low-resistance limit R_L	16–24 Ω	1 mA
Maximum difference in resistance versus bias slope x	0.04	10 μ A and 1 mA

insertion loss. The attenuation provided when the switch is OFF is called *isolation*. If the diode is a pure resistance, the attenuation for the series and shunt circuit can be calculated as

$$A(\text{series}) = 20 \log \left(1 + \frac{R_I}{Z_0} \right) \tag{42}$$

$$A(\text{shunt}) = 20 \log \left(1 + \frac{Z_0}{2R_I} \right) \tag{43}$$

where $Z_0 = R_G = R_L =$ circuit, generator, and load resistance, respectively. In reviewing these equations, it is seen that the attenuation is not a function of frequency but only a ratio of circuit and diode resistances, which is a great advantage. As the bias on the diode is varied, the load resistance experienced by the source also varies. These circuits are generally referred to as reflective attenuators because they operate on the principle of reflection.

Many RF systems require that the impedance at both RF ports remain essentially constant at the design value Z_0 . Four such circuits and their pin diode counterparts are shown in Fig. 30. All four circuits operate on the principle of absorbing the undesired RF signal power in the pin diodes. In circuits (a), (b), and (c), the control current variation through each diode is arranged in such a way that the impedance at both RF ports remain essentially constant at the characteristic impedance (Z_0) of the system while the attenuation can be varied over a range of less than 1 dB to greater than 20 dB. In circuit (d), the input impedance is kept constant by using a distributed structure with a large number of diodes. The impedance variation of each diode is also shaped so that the diodes in the center of the structure vary more than those near the ports. The resulting tapered impedance

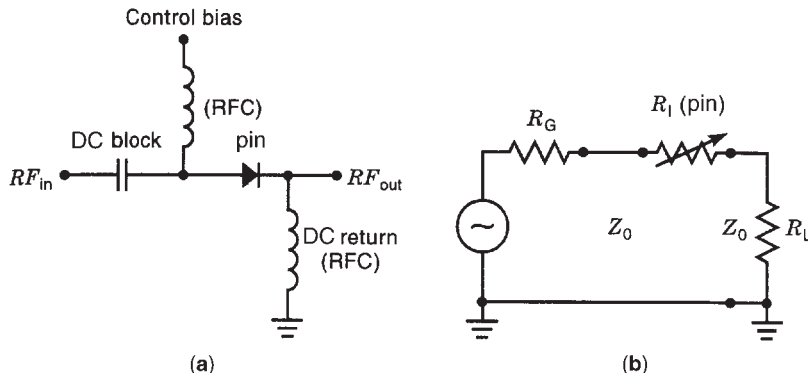

Figure 28. Series pin RF attenuator or switch: (a) complete circuit; (b) idealized RF equivalent circuit.

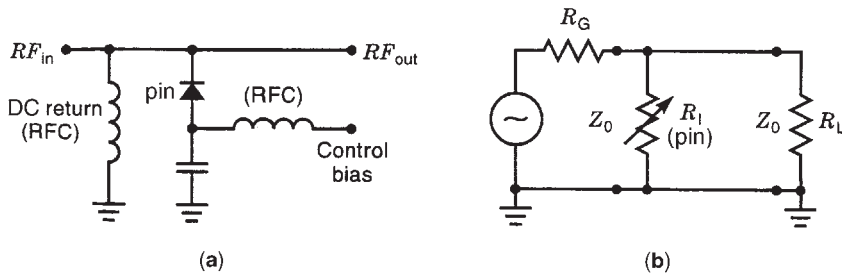

Figure 29. Shunt pin RF attenuator or switch: (a) complete circuit; (b) idealized RF equivalent circuit.

structure results in an essentially constant impedance at the ports, while the overall attenuation can be varied up to a range of 40–80 dB, depending on the length of the structure.

A pin diode pi attenuator such as that in Fig. 30a is often selected when designing a variable attenuator. The basic pi fixed attenuator is shown, along with its design equations, in Fig. 31. Shunt resistors R_1 and the series

resistor R_3 are set to achieve a desired value of attenuation, while simultaneously providing an input and output impedance that matches the characteristic impedance Z_0 of the system.

Three pin diodes can be used as shown in Fig. 32 to replace the fixed resistors of the pi circuit to create a variable attenuator. The attenuator provides good performance over the frequency range of 10 MHz to over

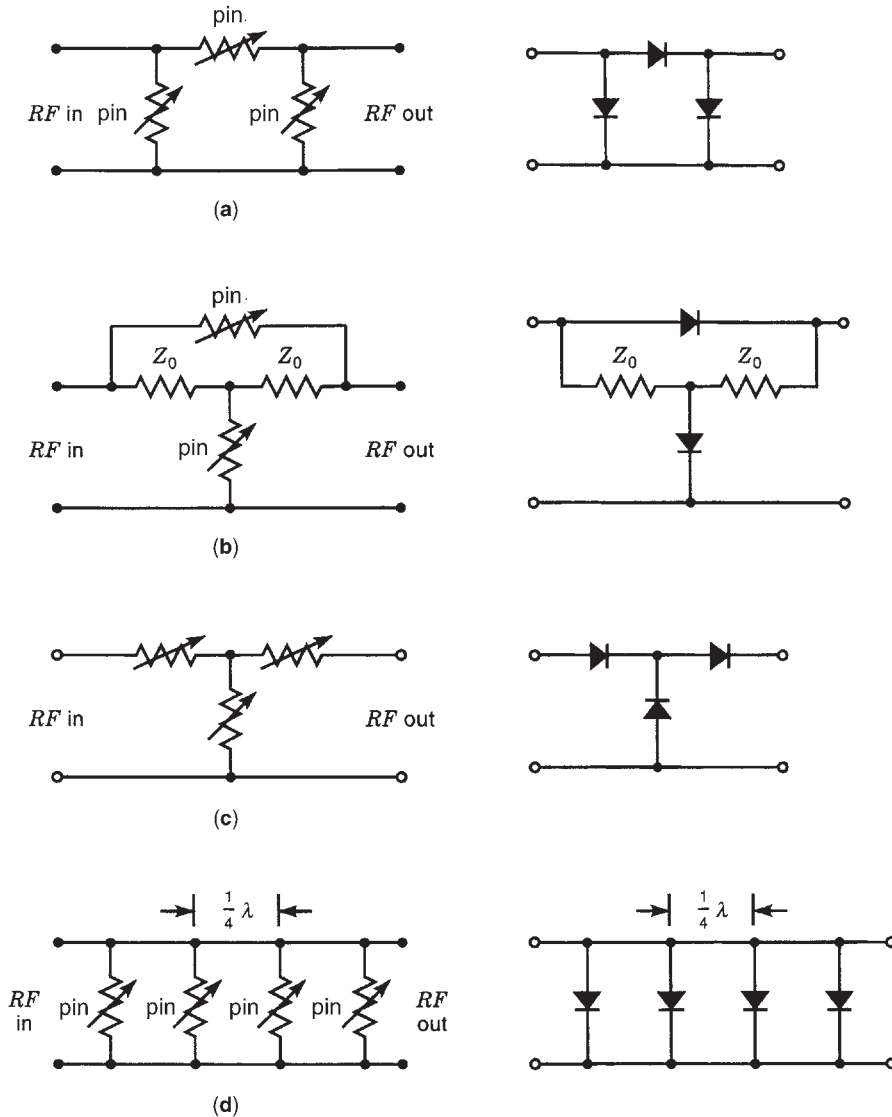

Figure 30. Constant impedance pin diode attenuators: (a) pi attenuator; (b) bridged T attenuator; (c) T attenuator; (d) resistive line attenuator.

Figure 31. Fixed pi attenuator.

500 MHz. However, the use of three diodes as the three variable resistors in a pi attenuator results in a complex unsymmetric bias network. If resistor R_3 is replaced by two diodes, as shown in Fig. 33, the resulting attenuator is symmetric and the bias network is significantly simplified. V_+ is a fixed voltage, and V_c is the variable control voltage, which controls the attenuation of the network. The only drawback to using two series diodes in place of one is the slight increase in insertion loss. Resistors R_1 and R_2 serve as bias returns for series diodes D_2 and D_3 . Resistors R_3 and R_4 are chosen to match the specific characteristics of the pin diodes used. Properly selected, they will provide the correct split of bias current between series and shunt diodes required to maintain a good impedance match over the entire dynamic range of attenuation.

The pin diode variable attenuator is an excellent circuit used to set the power level of an RF signal from a voltage control; it is used widely in commercial applications, such as cellular phones, PCN (personal communication networks), wireless LANs (local-area networks), and portable radios.

8.4. GaAs NMESFET Attenuator

The GaAs *N*-semiconductor metal semiconductor field effect transistor (NMESFET) is used in microwave attenuator designs. The metal–semiconductor FET (MESFET) is a field-effect transistor that operates on the principle that the gate-to-source voltage controls the drain current. The MESFET is a device extension of a JFET, where the gate structure is a Schottky MN (metal–*N* semiconductor) junction.

Figure 33. Wideband four-diode II attenuator.

In GaAs NMESFET attenuator designs, the devices are operated either in the linear region where the device is modeled as a voltage variable resistor or as an ON/OFF switch in conjunction with thin-film nichrome resistors to provide appropriate levels of attenuation. The channel resistance of the GaAs NMESFET is known to follow the classical theory for a FET in the linear region of operation. With the FET biased in the linear region, the resistance varies inversely to the gate voltage as shown below:

$$R_{ds} = R_{ds0} \left(\frac{1}{1 - (V_g/V_p)} \right) \tag{44}$$

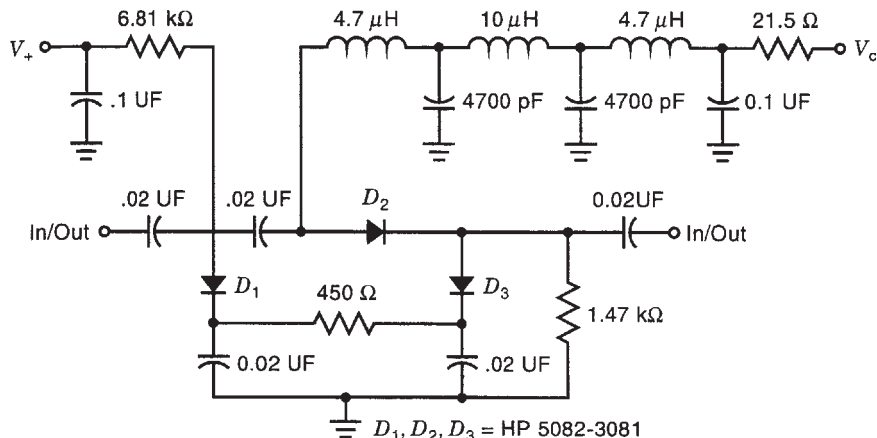

Figure 32. Three-diode pi attenuator.

$D_1, D_2, D_3 = \text{HP } 5082-3081$

Figure 34. MESFET T attenuator.

where V_g = gate bias voltage (V), V_p = pinchoff voltage (V), and R_{ds0} = channel resistance (Ω) with $V_g = 0$ V.

As the gate voltage approaches the pinchoff voltage, the resistance becomes very high (relative to $50\ \Omega$). Conversely, as the gate voltage approaches zero, so does the channel resistance. For each attenuator configuration, two independent gate bias voltages are used; one to control the series MESFETs and one to control the shunt MESFETs. The T attenuator configuration is shown in Fig. 34, with one voltage controlling the series resistance arms, and another the shunt resistance arm. Table 5 gives the resistor values of the series and shunt resistances in a $Z_0 = 50\ \Omega$ system. The channel resistances of the MESFETs are matched as closely as possible for these resistances. A matched condition at the input and output port to Z_0 occurs when

$$Z_0^2 = R_1^2 + 2R_1R_2 \quad (45)$$

The resulting matched attenuation is

$$A = 20 \log \left(\frac{R_1 + R_2 + Z_0}{R_2} \right) \quad (46)$$

The pi attenuator configuration is shown in Fig. 35, with one voltage controlling the shunt resistance arms, and another the series resistance arm. Table 6 gives the values of the series and shunt resistances for different levels of attenuation in a $Z_0 = 50\ \Omega$ system. Shunt resistor R_1 and series resistor R_2 provide an input and output impedance that matches the characteristic impedance $Z_0 = 50\ \Omega$ of the system, while setting the desired level of attenuation. The

Table 5. T Attenuator Resistor Values for Different Levels of Attenuation

Attenuation (dB)	R_1 (Ω)	R_2 (Ω)
2	5.73	215.24

12	29.92	26.81
14	33.37	20.78
22	42.64	7.99

design equations are

$$R_1 = Z_0 \left[\frac{K + 1}{K - 1} \right] \quad (47)$$

$$R_2 = \frac{Z_0}{2} \left[K - \frac{1}{K} \right] \quad (48)$$

$$A(\text{dB}) = 20 \log K \quad (49)$$

where K is the input to output voltage ratio.

GaAs NMESFET digital attenuators allow a specific value of attenuation to be selected via a digital n bit programming word. In these designs, the NMESFET operates as an ON/OFF switch and is used in conjunction with nichrome thin-film resistors to provide the desired level of attenuation. Figure 36 shows the circuit configurations used for individual attenuator bits. The switched bridged T attenuator consists of the classical bridged T attenuator with a shunt and series FET. These two FETs are switched on or off to switch between the two states. The attenuation in dB is given by

$$A(\text{dB}) = 20 \log \left(\frac{Z_0 + R_2}{R_2} \right) \quad (50)$$

where $Z_0^2 = R_1R_2$.

The performance is determined by the FET characteristics in the on and off states and the realizability limit on required resistance values and their associated parasitics. The switched T or pi attenuators are similar in principle to the switched bridged T attenuator except for the circuit topology. These attenuators are normally used for high attenuation values. To obtain smaller values of attenuation, the thin-film resistors are replaced with appropriate channel resistances.

There are GaAs NMESFET digital RF attenuators on the market with excellent performance, in both step and continuously variable types. The variable or programmable class allows a specific value of attenuation to be selected from an overall range via an N -bit programming word. They are more flexible than step attenuators, as they allow any amount of attenuation to be set, but the cost is greater circuit complexity. Both types have a bypass state when no attenuation is selected, and the attenuation is just the insertion loss of the device. An example of each type is presented.

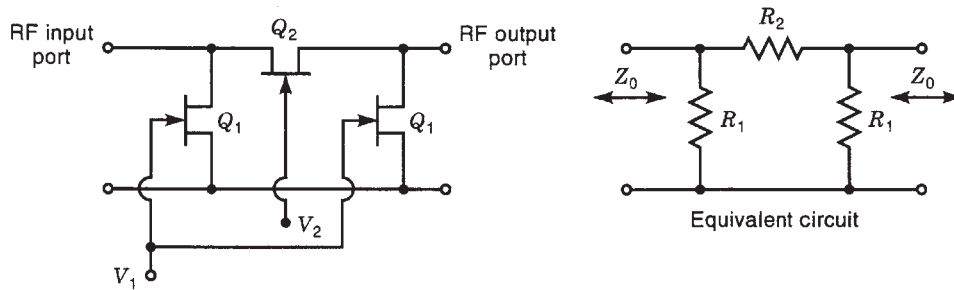

Figure 35. MESFET pi attenuator.

The RF Microdevices RF 2420 is a multistage monolithic variable or programmable attenuator that has as attenuation programmability over a 44 dB range in 2-dB steps. The attenuation is set by 5 bits of digital data. A functional block diagram of the RF 2420 is shown in Fig. 37. It consists of five cascaded, DC-coupled attenuator sections, each with its own logic translator. The logic translator converts the one-bit control signal, which uses logic levels approximating standard TTL logic, to the voltage levels required to switch the attenuator stage FETs. The RF input and output signal lines are biased at approximately V_{DD} , and therefore external DC blocking capacitors are required. An external V_{DD} bypass capacitor is also required.

A functional schematic of the RF portion of one attenuator section is shown in Fig. 38. A MESFET bridges the series resistor in a resistive pi attenuator, and two more MESFETs are connected as a double-pole single-throw (DPST) RF switch connecting the shunt branches of the pi attenuator to RF ground. In the bypass state, the bridge MESFET is in its high conductance state, and the DPST switch is open, so that the pi-attenuator is effectively removed from the circuit. When the attenuator bit is selected, the bridge MESFET is put into its low conductance state or cutoff state and the shunt FETs are put into their on state, so that the pi attenuator is connected into the RF series path. This attenuator has only moderate variation across a broad band of operation from 100 to 950 MHz, as illustrated in Fig. 39.

Furthermore, the attenuation varies smoothly and consistently with attenuator switch settings. Other features of the device are single 3–6-V supply operation, and

Table 6. Pi Attenuator Resistor Values for Different Levels of Attenuation

Attenuation (dB)	R_1 (Ω)	R_2 (Ω)
2	436	11.61
4	221	23.85
6	150.5	37.35
8	116.14	52.84
10	96.25	71.15
12	83.54	93.25
14	74.93	120.31
22	58.63	312.90

4 dB insertion loss, and the input and output have a low-VSWR 50- Ω match. All these features make the RF 2420 an excellent component for communications systems that require RF transmit power control by digital means. Typical applications are in dual mode IS-54/55 compatible cellular transceivers and TETRA systems. Figure 40 shows the complete schematic details of the RF 2420 being employed in a typical RF/IF switching attenuator application.

The RF Microdevice RF 2421 is a GaAs MESFET-switched step attenuator. It has a single-step digitally controlled attenuation of 10 dB. A functional block diagram of the device is shown in Fig. 41. The supply voltage range required is 2.7 V to 6 V DC. The input and output of the device have a low-voltage standing-wave ratio (VSWR) 50- Ω match, and the RF output can drive up to +16 dBm. It has 1.0 dB of insertion loss over the specified 500 MHz–3 GHz operating frequency range. The resistors are nickel chromium (nichrome) and provide excellent temperature stability. The RF ports are reversible, which means that the input signal can be applied to either port. The attenuation control pin has an internal pulldown resistor that causes the attenuator to be turned off when it is not connected. Figure 42 illustrates the RF 2421 being used to set the RF signal level in a communications system.

8.5. MOSFET Attenuators

Active voltage attenuators have many useful applications in analog integrated circuit design. Some of the applications are in the feedback loops of finite gain amplifiers and in the input stages of transconductance amplifiers. In discrete circuit design, the most popular way to design a finite-gain amplifier with precisely controlled gain, high linearity, and low output noise is to use operational amplifier and a voltage attenuator in the feedback loop. Here the voltage attenuator consists of two resistors connected in series as shown in the classical noninverting and inverting op amp gain configurations of Fig. 43. Resistor attenuators are not useful in integrated circuit design because of their large areas, low input impedance, large power dissipation, and parasitic capacitances, and precise resistance values cannot be realized.

Three MOS active voltage attenuator configurations useful for the realization of finite-gain amplifiers in mono-

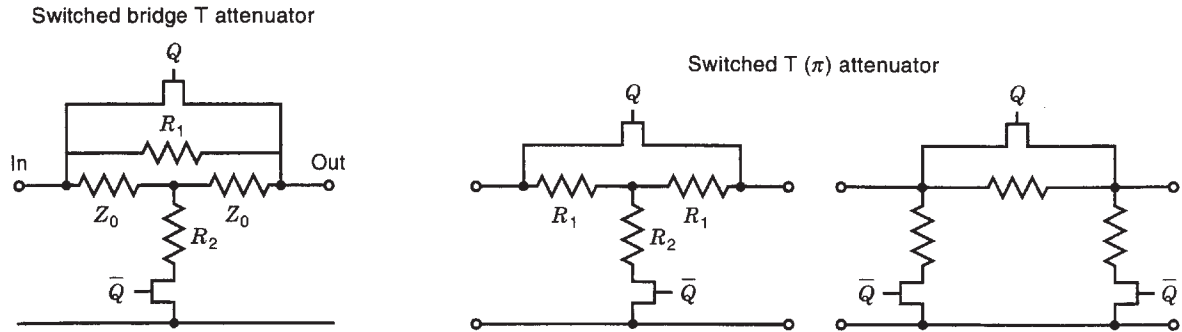

Figure 36. GaAs digital attenuator circuit configuration.

lithic circuits are presented. The attenuators are two single-input attenuators and a summing attenuator that has two inputs. These attenuators are simple in structure, consisting only of MOSFETs. Therefore, they are easy to fabricate in standard CMOS semiconductor processes. The attenuation factor is precisely controlled over a wide range of gains because it ideally depends only on the ratios of the dimensions of the MOSFETs.

Attenuator I, shown in Fig. 44, is an active linear voltage attenuator consisting of two n-channel MOSFETs fabricated in a common substrate. The capability to fabricate the MOSFETs in a common substrate has several advantages. First, both n-channel and p-channel attenuators can be monolithically fabricated in a standard CMOS process. Second, the required area of the attenuator is much smaller. As seen in Fig. 44, the substrate is common for both MOSFETs and is connected to the source of the bottom transistor M1. The circuit operates as a linear voltage attenuator when M1 is in the ohmic region and M2 is in the saturation region.

The operating conditions of the MOS attenuators in this section are derived as in the following equations,

where

V_{in}	Input voltage
V_{out}	Output voltage
V_{DD}	Drain supply voltage
V_B	Bias supply voltage 1
V_{BB}	Bias supply voltage 2
$V_{TON} = V_{TON1} = V_{TON2}$	Zero bias threshold voltage of M1 and M2
V_{T2}	Threshold voltage of M2 due to body bias effect
V_1	Input voltage 1
V_2	Input voltage 2
γ	Body effect parameter
ϕ	Barrier potential
I_D	Drain current
W	Width of channel
L	Length of channel
W_1, W_2	Width of channels 1,2
L_1, L_2	Length of channels 1,2
K'	Device constant, $\mu_n CoX$
μ_n	Mobility of electron
CoX	Gate oxide capacitance per unit area

The zero-bias threshold voltage of both MOSFETs is $V_{TON1} = V_{TON2} = V_{TON}$. The proper operating conditions will be met, provided

$$V_{TON} < V_{in} < V_{DD} + V_{T2} \tag{51}$$

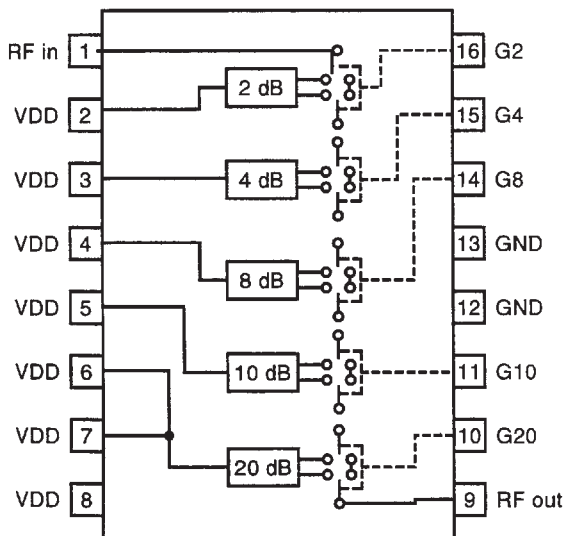

Figure 37. RF 2420 functional block diagram.

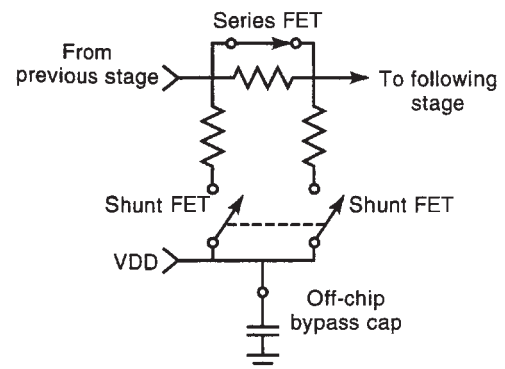

Figure 38. Functional schematic of RF 2420 (one attenuator section).

Figure 39. Attenuation and frequency response characteristics of RF 2420 5-bit digital RF attenuator.

where

$$V_{T2} = V_{TON} + \gamma(\sqrt{\phi + V_{out}} - \sqrt{\phi}) \quad (52)$$

Since M1 is operating in the ohmic region and M2 is in the saturation region, the drain current of each MOSFET is given by

$$I_{D1} = K' \frac{W_1}{L_1} \left(V_1 - V_{TON} - \frac{V_{out}}{2} \right) V_{out} \quad (53)$$

and

$$I_{D2} = K' \frac{W_2}{2L_2} (V_1 - V_{T2} - V_{out})^2 \quad (54)$$

Equating the two drain currents, the relationship between V_{in} and V_{out} is obtained as

$$2R \left(V_{in} - V_{TON} - \frac{V_{out}}{2} \right) V_{out} = \left\{ V_{in} - V_{TON} - V_{out} - \gamma(\sqrt{\phi + V_{out}} - \sqrt{\phi}) \right\}^2 \quad (55)$$

where

$$R = \frac{W_1/L_1}{W_2/L_2} \quad (56)$$

If each MOSFET in the attenuator is fabricated in a separate substrate and the substrate of each

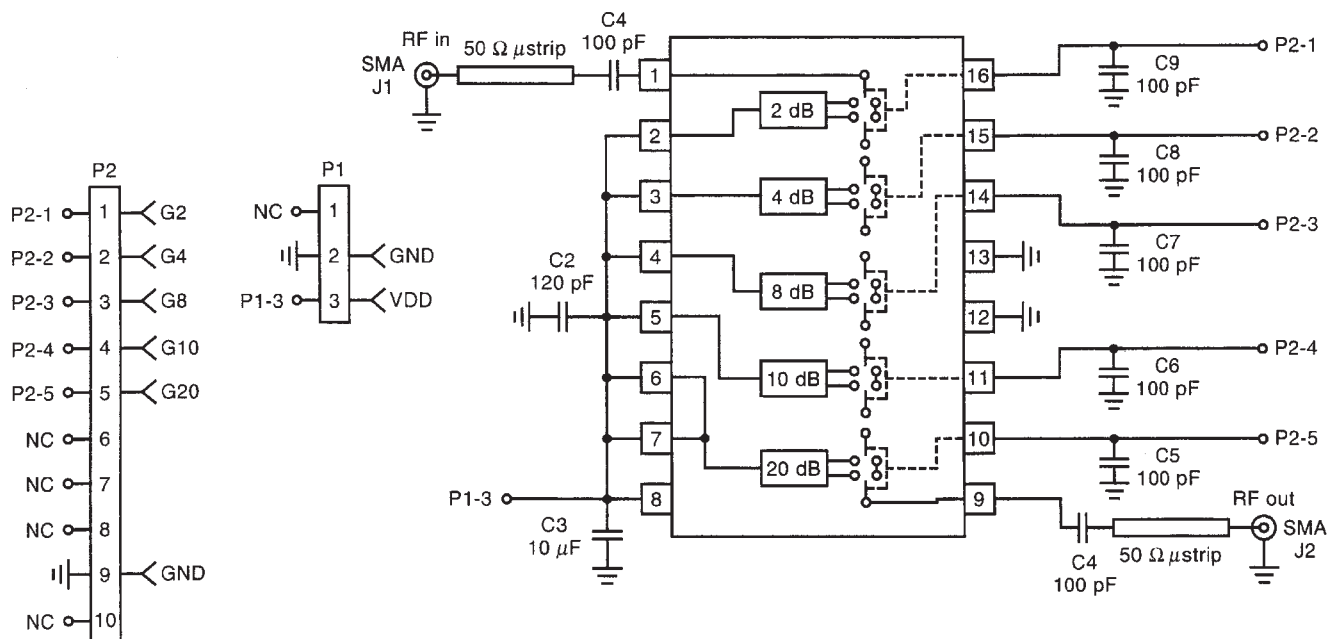

Figure 40. RF 2420 RF/IF switching attenuator schematic.

Figure 41. RF 2421 functional block diagram.

MOSFET is connected to its source ($\gamma = 0$), the DC transfer characteristic relating V_{in} and V_{out} becomes a linear equation:

$$V_{out} = \alpha(V_{in} - V_{TON}) \quad (57)$$

where α is the small-signal attenuation factor.

In this case, α is

$$\alpha = 1 - \sqrt{\frac{R}{R+1}} = 1 - \sqrt{\frac{W_1/L_1}{W_1/L_1 + W_2/L_2}} \quad (58)$$

Equation (57) is a special case of Eq. (55), when the bulk effect term due to γ is ignored. When the substrate is separate, the small-signal attenuation factor from Eq. (58) is precisely determined by width/length ratios. If the substrate is common, the relationship between the input and output is still very linear as given by Eq. (55) even though the equation appears to be a nonlinear quadratic.

Figure 45 shows the typical DC transfer characteristic of the attenuator consisting of M1 ($12 \times 10 \mu\text{m}^2$) and M2 ($3 \times 10 \mu\text{m}^2$) when the substrate is common ($\gamma \neq 0$) and $V_{DD} = 5\text{V}$. The DC transfer characteristic exhibits a high degree of linearity for the input range 2–5 V. The small-signal attenuation factor (α), which is the slope of the DC

transfer characteristic is 0.07824 at an input quiescent voltage of 3.5 V.

A finite-gain amplifier consisting of an ideal op amp and attenuator I in the feedback loop is shown in Fig. 44. Since the op amp is assumed ideal, we obtain

$$V_{in} = V_{out} = \alpha V'_{in} = \alpha V'_{out} \quad (59)$$

or

$$V'_{out} = \frac{1}{\alpha} V'_{in} \quad (60)$$

Thus, the DC transfer function of the amplifier is the inverse function of the DC transfer function of the attenuator in the feedback loop. Thus, the transfer function between the input V'_{in} and the V'_{out} of the amplifier is given by Eq. (55) when V_{out} is replaced by V'_{in} and V'_{in} by V'_{out} . The small-signal voltage gain

$$\left(A_V = \frac{V'_{out}}{V'_{in}} = \frac{1}{\alpha} \right)$$

is the reciprocal of the attenuator's attenuation factor in the feedback loop. Figure 46 illustrates the DC transfer characteristic of the finite-gain amplifier.

Two slightly different linear inverting voltage attenuator configurations consisting of two n-channel MOSFETs are shown in Fig. 47. These circuits operate as a linear inverting voltage attenuator when both transistors are in the saturation region. Assuming the zero-bias threshold of both of the MOSFETs is V_{TON} , the condition will be met, provided

$$V_{out} + V_{T2} < V_B < V_{DD} + V_{T2} \quad (61)$$

and

$$V_{TON} < V_{in} < V_{out} + V_{TON} \quad (62)$$

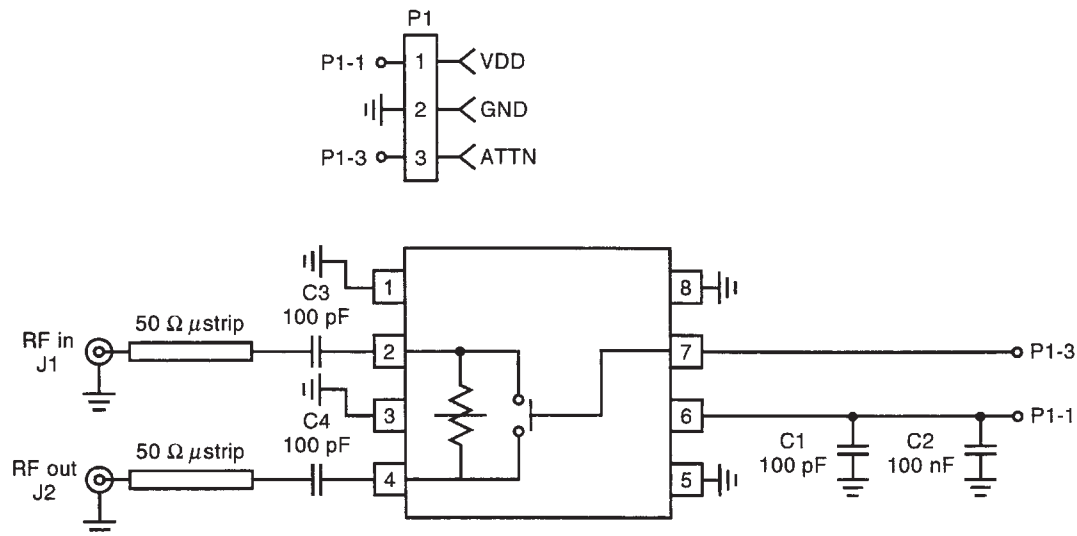

Figure 42. RF 2421 single-step 10-dB attenuator application.

Figure 43. Op amp noninverting (a) and inverting (b) gain configuration.

Under this condition, the drain currents of the transistors are given by

$$I_{D1} = K' \frac{W_1}{2L_1} (V_{in} - V_{TON})^2 \tag{63}$$

$$I_{D2} = K' \frac{W_2}{2L_2} (V_B - V_{out} - V_{T2})^2 \tag{64}$$

where

$$V_{T2} = V_{TON} + \gamma(\sqrt{\phi + V_0} - \sqrt{\phi}) \tag{65}$$

Since the two drain currents are the same for the circuit, the DC transfer function relating V_{in} and V_{out} is found by equating Eqs. (63) and (64):

$$\begin{aligned} V_{out} + \gamma(\sqrt{\phi + V_{out}} - \sqrt{\phi}) \\ = -R_1 V_{in} + \{V_B + (R_1 - 1)V_{TON}\} \end{aligned} \tag{66}$$

where

$$R_1 = \sqrt{\frac{W_1/L_1}{W_2/L_2}} \tag{67}$$

If $\gamma = 0$ in Eq. (66), which corresponds to the case of circuit (b) in Fig. 47, where the substrate is separate, the DC transfer characteristic reduces to a linear equation:

$$V_{out} = \alpha V_I + \{V_B - (\alpha + 1)V_{TON}\} \tag{68}$$

In this case, the small-signal attenuator factor is

$$\alpha = -R_1 \tag{69}$$

which is precisely determined by the width/length ratios of the MOSFETs. From Eqs. (66) and (68), it is noted that the output DC operating voltage is controlled by V_B , independent of the attenuation factor.

The DC transfer characteristic between V_{in} and V_{out} calculated from Eq. (66) for the common substrate case, $R_1 = 0.1149$ and $V_B = 3.993$, and the DC transfer characteristics calculated from Eq. (68) for the separate substrate case, $R_1 = 0.1$ and $V_B = 3.449$ are shown in Fig. 50 for the range restricted by Eq. (62). The parameter values ($\gamma = 0.525 V^{1/2}$, $\phi = 0.6 V$, and $V_{TON1} = V_{TON2} = V_{TON} = 0.777 V$) were used in the calculation. The DC transfer function given by Eq. (66) for the common substrate case appears nonlinear, but the degradation from linearity due to practical values of γ is not significant. The small-signal attenuation factor α , the slope of transfer characteristic in Fig. 48, is -0.1 . The high degree of linearity supports the usefulness of both configurations in precision attenuator or finite-gain amplifier applications.

Figure 49 shows a finite-gain amplifier with attenuator II in the feedback loop of an op amp. Assuming that the op amp is ideal, we obtain

$$V'_{out} = \frac{1}{\alpha} V'_{in} \tag{70}$$

The transfer function of the amplifier is the inverse function of the transfer function of the attenuator in the feedback loop. The DC transfer function of the amplifier is given by Eq. (66) when V_{in} is replaced by V'_{out} and V_{out} is replaced by V'_{in} . If the substrate is separate, V_{in} replaces V'_{out} and V_{out} replaces V'_{in} in Eq. (68); then

$$V'_{out} = \frac{1}{\alpha} V'_I - \frac{1}{\alpha} \{V_B - (\alpha + 1)V_{TON}\} \tag{71}$$

where the small-signal attenuator factor $\alpha = -R_1$.

A summing attenuator is necessary to realize versatile multiple-input finite-gain amplifiers in integrated circuits. Figure 50 shows a two-input active linear inverting voltage summing attenuator that consists of two attenuators cascaded. For the summing attenuator, V_{BB} is used to control the output DC operating voltage, and input signals are designated as V_1 and V_2 .

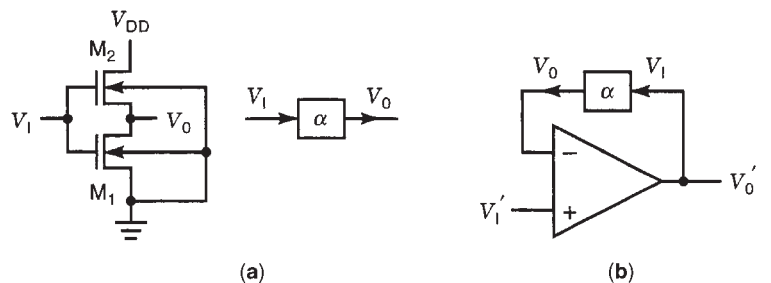

Figure 44. (a) Circuit and block diagram of attenuator I consisting of two n-channel MOSFETs, and (b) block diagram of amplifier consisting of an op amp and attenuator.

Figure 45. DC transfer characteristic of attenuator I ($\alpha = 0.07824$).

As for the inverting attenuator, the summing attenuator works when all the MOSFETs M1–M4 are operating in the saturation region. The DC transfer characteristics are found by equating the drain currents in the saturation region for each transistor. Assuming that the zero-bias threshold voltages for the four MOSFETs are matched at V_{TON} , the four transistors are in the saturation region, provided

$$2(V_{TON} + \gamma(\sqrt{\phi + V_{TON}} - \sqrt{\phi})) + V_{out} < V_{BB} < V_{DD} + V_{T4} \quad (72)$$

$$V_{TON} < V_1 < V_0 + V_{TON} \quad (73)$$

$$V_{TON} < V_2 < V_B + V_{TON} \quad (74)$$

By equating the drain currents of M3 and M4 given by

$$I_{D3} = K' \frac{W_4}{2L_3} (V_2 - V_{TON})^2 \quad (75)$$

and

$$I_{D4} = K' \frac{W_4}{2L_4} (V_{BB} - V_B - V_{T4})^2 \quad (76)$$

where

$$V_{T4} = V_{TON} + \gamma(\sqrt{\phi + V_0} - \sqrt{\phi}) \quad (77)$$

Figure 46. DC transfer characteristic of amplifier ($A_V = 1/\alpha = 12.78$).

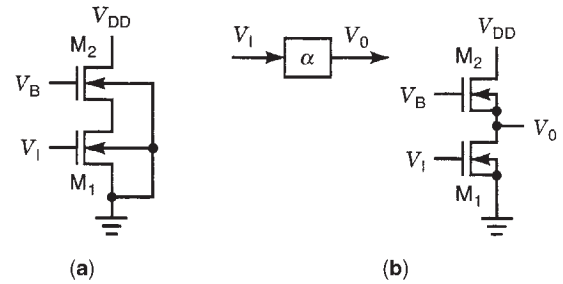

Figure 47. Circuit and block diagrams of linear inverting voltage attenuators consisting of two n-channel MOSFETs.

The DC transfer function between V_2 and V_B is obtained as

$$\begin{aligned} V_B + \gamma(\sqrt{\phi + V_B} - \sqrt{\phi}) \\ = -R_2 V_2 + \{V_{BB} + (R_2 - 1)V_{TON}\} \end{aligned} \quad (78)$$

where

$$R_2 = \sqrt{\frac{W_3 L_4}{L_3 W_4}} \quad (79)$$

Similarly, it can be shown that the DC transfer function between V_1 and V_0 is obtained as

$$\begin{aligned} V_0 + \gamma(\sqrt{\phi + V_0} - \sqrt{\phi}) \\ = -R_1 V_1 + \{V_B + (R_1 - 1)V_{TON}\} \end{aligned} \quad (80)$$

where

$$R_1 = \sqrt{\frac{W_1 L_2}{L_1 W_2}} \quad (81)$$

If $\gamma = 0$ in Eqs. (78) and (80), the equations become linear. This is realized if each transistor is fabricated in a separate substrate and the substrate of each transistor is connected to its source. In this case, the attenuation

Figure 48. DC transfer characteristics of attenuator II linear inverting voltage attenuators.

Figure 49. Amplifier consisting of op amp and attenuator II in the feedback loop.

factors are given by $\alpha_1 = -R_1$, and $\alpha_2 = -R_2$. Even when $\gamma \neq 0$, which is the case when the substrates are common, the transfer characteristics between V_1 and V_0 and between V_2 and V_0 are nearly linear as shown in Fig. 53 for practical values of γ . In the calculation of Fig. 51, $\gamma = 0.5255 \text{ V}^{1/2}$, $\phi = 0.6 \text{ V}$, and $V_{\text{TON}} = 0.777 \text{ V}$ were used, which are standard for a 2μ CMOS process and $R_1 = 0.1149$ and $R_2 = 0.1290$ were set such that the small-signal attenuation factors for V_1 and V_2 are both -0.1 . The operating points were set by $V_{\text{BB}} = 5.712 \text{ V}$ such that $V_{0\text{Q}} = 2.5 \text{ V}$ ($V_{\text{BQ}} = 3.993 \text{ V}$) when $V_{1\text{Q}} = V_{2\text{Q}} = 2.5 \text{ V}$.

Summing and subtracting amplifier configurations using the inverting attenuator and the inverting summing attenuator are shown in Fig. 52.

Circuit (a) in Fig. 52 functions as a summing amplifier and the circuit (b) functions as a subtracting amplifier, with controllable weights. Assuming ideal op amps and attenuators, we obtain

$$V_- = \alpha_1 V_1 + \alpha_2 V_2 + \{V_{\text{BB}} - (\alpha_1 + \alpha_2 + 2)V_{\text{TON}}\} \quad (82)$$

$$V_+ = \alpha V_0 + \{V_{\text{B}} - (\alpha + 1)V_{\text{TON}}\} \quad (83)$$

Equating V_- and V_+ , the output is given by

$$V_0 = \frac{\alpha_1}{\alpha} V_1 + \frac{\alpha_2}{\alpha} V_2 + \frac{1}{\alpha} \{V_{\text{BB}} - V_{\text{B}} - (\alpha_1 + \alpha_2 - \alpha + 1)V_{\text{TON}}\} \quad (84)$$

From Eq. (84), the circuit in Fig. 52a is a summing amplifier with a wide range of available gain from each

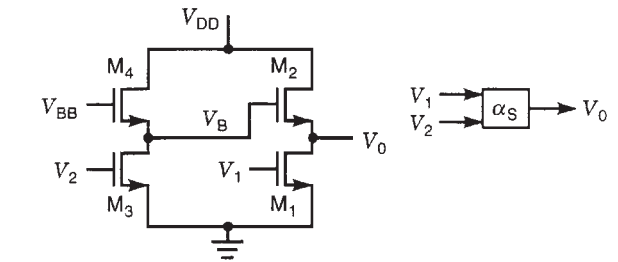

Figure 50. Circuit and block diagram of summing attenuator.

input. Similarly, for the circuit in Fig. 52b, we obtain

$$V_+ = \alpha_1 V_0 + \alpha_2 V_2 + \{V_{\text{BB}} - (\alpha_1 + \alpha_2 + 2)V_{\text{TON}}\} \quad (85)$$

$$V_- = \alpha V_1 + \{V_{\text{B}} - (\alpha + 1)V_{\text{TON}}\} \quad (86)$$

Equating V_+ and V_- , the output is given by

$$V_0 = \frac{\alpha}{\alpha_1} V_1 - \frac{\alpha_2}{\alpha_1} V_2 - \frac{1}{\alpha_1} \{V_{\text{BB}} - V_{\text{B}} - (\alpha_1 + \alpha_2 - \alpha + 1)V_{\text{TON}}\} \quad (87)$$

From Eq. (87), the circuit in Fig. 52b is a subtracting amplifier with a wide range of available gain for each input.

The active attenuator and the active summing attenuator have many desirable characteristics such as small size, nearly infinite impedance, low power dissipation, and precisely controllable attenuation ratio with excellent linearity. These attenuators and the finite-gain amplifiers obtained from these attenuators and op amps will find increased applications in analog integrated circuits.

8.6. Noise

Noise in a communication system can be classified in two broad categories, depending on its source. Noise generated by components within a communication system, such as resistive, extender, and solid-state active devices, comprise internal noise. The second category, external noise, results from sources outside a communication system, including atmospheric, manmade, and extraterrestrial sources.

Figure 51. DC transfer characteristics of summing attenuator.

Figure 52. (a) Summing amplifier; (b) subtracting amplifier.

External noise results from the random motion of a charge carrier in electronic components. The three types are

1. Thermal noise: caused by random motion of free electrons in a conductor or semiconductor excited by thermal agitation
2. Shot noise: caused by random amount of discrete charge carriers in such devices as thermionic tubes or semiconductors in devices
3. Flicker noise: produced by semiconductors by a mechanism not well understood and is more severe the lower the frequency

Atmospheric noise results primarily from spurious radiowaves generated by the natural discharges within the atmosphere associated with thunderstorms. Manmade noise sources include high-voltage power-line discharge and computer-generated noise in electric motors.

Other noises include

- Generation–recombination noise: due to free carriers being generated and recombining in semiconductor material. They are random and can be treated as a shot noise process.
- Temperature fluctuation noise: the result of the fluctuating heat exchange between a small body, such as a transistor, and its environment due to the

fluctuations in the radiation and heat conduction processes.

9. RECENT TRENDS

Figure 53 shows a 4-dB step, 28-dB variable attenuator for a 1.9-GHz personal handy phone system transmitter fabricated using silicon bipolar technology with f_T of 15 GHz. The GaAs MESFET variable attenuator is configured with resistive pi attenuators and GaAs switches as shown. Step accuracy within 1.2 dB and total vector modulation error of less than 4% were realized for -15 dBm output. The attenuator consumes 21 mA with 2.7 V power supply and occupies 1.1×0.5 mm. This unit is being developed. This shows the technology trend.

Figure 54 shows the top view and cross section of a prototype optical microwave attenuator that can be

Figure 54. Microstrip–slotline attenuator on a silicon substrate with an override ferrite slab.

controlled by illuminating the silicon substrate. The maximum attenuation is 30 dB using laser diode illumination. It is a microstrip line whose substrate consists of silicon and ferrite slabs. The ferrite slab is overlaid on the microstrip. There is a slot on the ground plane under the strip. A white light from a xenon arc lamp with a parabolic mirror is focused by a lens to the silicon surface through the slot. The intensity of the light is not uniform along the slot direction. Due to the light, electron-hole pairs are induced and the permittivity and conductivity of the silicon are changed, which vary the phase and amplitude of the microwave. With 240 mW optical power illumination, an attenuation in the range of 17–26 dB was obtained in the frequency range from 8 to 12 GHz.

BACKSCATTER

PYOTR YA. UFIMTSEV
 University of California at
 Irvine
 Irvine, California

The scattering of waves from an object is a diffraction process that transforms the incident wave into the waves propagating from the object in all possible directions. The *backscatter*, or *backscattering*, is the scattering of waves back toward the source of the incident wave. This process substantially depends on material properties of the scattering object, its shape, size, and spatial orientation relative to the incident wave, as well as on the frequency and polarization of the incident wave. One distinguishes three frequency regions with different physical properties of scattered waves. They are quasistatic, resonance, and quasioptical regions.

1. QUASISTATIC SCATTERING

In the quasistatic region (sometimes called the *Rayleigh region*), the wavelength λ of the incident wave is much greater than the maximum linear dimension l of the scattering object ($\lambda \gg l$). At a certain time t , the scattered field at small distances ($r \ll \lambda$) from the object is approximately the static field created by dipoles and multipoles induced by the incident wave in the scattering object at the same time t . Far from the object, the scattered field is an outgoing spherical wave. Its average power flux density (over one period of oscillations) relative to that of the incident wave, or radar cross section (RCS), is determined by the object's volume rather than the shape of the object, and it is proportional to λ^{-4} . Specifically, this dependence explains the blue color of the cloudless sky during the day. This color is due to the predominance of blue light scattered by small inhomogeneities of the air caused by fluctuations of its density. The violet light, which is shorter in wavelength, undergoes stronger relative scattering and as a result suffers higher attenuation while propagating through the atmosphere. Analytical expressions for quasistatic RCS of some scattering objects can be found in Refs. 1–3. For example, the axial RCS of perfectly conducting bodies of revolution is determined by the following approximation (p. 145 of Ref. 1)

$$\sigma \approx \frac{4}{\pi} k^4 V^2 \cdot \left(1 + \frac{e^{-\tau}}{\pi\tau}\right)^2 \quad (1)$$

where $k = 2\pi/\lambda$ is the wavenumber, V is the object's volume, and τ is the characteristic length-to-width ratio of the object. The quantity τ is found for each object's shape by the allowing the axial dimension of the object to

go to zero so as to obtain the correct result

$$\sigma = \frac{64}{9\pi} k^4 a^6 \quad (2)$$

for the circular disk with radius a . Table 8.2 in Ref. 2 (Vol. 2, pp. 558–561) contains explicit expressions for RCS found in this manner for a variety of bodies of revolution. The first term in this table (Eq. 8.1-87a on p. 558) contains a misprint. The letter b should be replaced by h .

In this frequency region, the scattered field can be expressed in terms of a convergent series in positive integer power of the wavenumber $k = 2\pi/\lambda$. The expansion coefficients are found from the solution of the recursive system of boundary value problems in potential theory (pp. 848–856 of Ref. 4). In practice it is possible to find only a few first coefficients. Direct numerical methods are efficient tools for the solution of quasistatic scattering problems [5–7].

2. RESONANCE SCATTERING

In the resonance frequency region, linear dimensions of scattering objects are comparable to the wavelength of the incident wave. Eigenoscillations excited by the incident wave in the scattering object can substantially influence the scattering properties. Frequencies of these oscillations are complex quantities. Their imaginary parts determine both the internal (thermal) losses inside the object and the external losses that are due to radiation into the surrounding medium. A major contribution to RCS is given by the radiation of those eigenoscillations, whose eigenfrequency real part and polarization are close to the incident wave frequency and polarization. If the quality factor of these oscillations is quite large, the amplitude and the intensity of the scattered wave sharply increase as the frequency of the incident wave approaches the real part of the frequency of eigenoscillations. This phenomenon is referred to as “resonance scattering.” It reveals itself, for example, in scatterings from thin metallic half-wavelength long wires and narrow strips (pp. 293–303 of Ref. 2). These scatterers are used, in particular, to create a chaff clutter for radars. Analytical and numerical data for scattering by thin wires are collected in Chap. 12 of Ref. 3. Recent analytical results for resistive wires are presented in Ref. 8.

The resonance scattering from wires can also be explained as being due to the constructive interference of multiple current waves arising from the wire ends. This process is investigated in detail in Refs. 9, 10, and 30. The total current generated by the incident plane wave in the perfectly conducting wire (Fig. 1) equals

$$J(z) = J_0(z) + \sum_{n=1}^{\infty} [J_n^+(z) + J_n^-(z)] \quad (3)$$

Figure 1. A thin wire excited by an incident wave. The radius of the wire is small compared with the wavelength. Such a wire can support traveling waves arising due to the multiple edge diffractions. A constructive interference of these waves results in the resonance behavior of the surface current and scattered field.

with the time dependence $\exp(-i\omega t)$ assumed and suppressed here and later. The term $J_0(z)$ is the current induced by the incident wave in the infinitely long wire ($-\infty \leq z \leq +\infty$). The terms $J_n^+(z)$ and $J_n^-(z)$ are multiple current waves. Waves $J_n^+(z)$ run in the positive z -direction from the left wire end $z = -l$ to the right end $z = +l$. Waves $J_n^-(z)$ run in the negative z direction from the right end $z = +l$ to the left end $z = -l$. The total length of the wire is $L = 2l$. When the wave $J_n^\pm(z)$ reaches the opposite end it undergoes diffraction and transforms into the wave $J_{n+1}^\mp(z)$. At the end points of the wire the total current and its components satisfy the conditions

$$J(\pm l) = 0, \quad J_1^+(-l) = -J_0(-l), \quad J_1^-(l) = -J_0(l) \quad (4)$$

$$J_{n+1}^+(-l) = -J_n^-(l), \quad J_{n+1}^-(l) = -J_n^+(l), \quad n = 1, 2, 3, \dots \quad (5)$$

In thin wires ($ka < 0.2$, a is the wire radius), the multiple current waves are described by the following approximate expressions

$$\begin{aligned} J_{2n}^+(z) &= -J_1^-(l) [\psi(kL) e^{ikL}]^{2n-2} \psi[k(l+z)] e^{ik(l+z)} \\ J_{2n+1}^+(z) &= J_1^+(l) [\psi(kL) e^{ikL}]^{2n-1} \psi[k(l+z)] e^{ik(l+z)} \\ J_{2n}^-(z) &= -J_1^+(l) [\psi(kL) e^{ikL}]^{2n-2} \psi[k(l-z)] e^{ik(l-z)} \\ J_{2n+1}^-(z) &= J_1^-(l) [\psi(kL) e^{ikL}]^{2n-1} \psi[k(l-z)] e^{ik(l-z)} \end{aligned} \quad (6)$$

with $n = 1, 2, 3, \dots$. Function $\psi(kz)$ is defined in Refs. 10 and 30 as

$$\psi(kz) = \frac{2 \ln \frac{i}{\gamma ka}}{\ln \frac{2ikz}{\gamma q} - E(2kz) e^{-2ikz}} \quad (7)$$

where

$$q = (ka)^2, \quad \gamma = 1.781 \dots, \quad \ln(i) = i\pi/2$$

and

$$E(x) = - \int_x^\infty \frac{e^{it}}{t} dt = \text{Ci}(x) + i\text{Si}(x) \quad (8)$$

Functions $\text{Ci}(x)$ and $\text{Si}(x)$ are the well-tabulated cosine and sine integrals, respectively. For small arguments ($x \ll 1$), function $E(x)$ reduces to $E(x) = \ln(\gamma x) - \ln(i) + O(x)$ and ensures the equality $\psi(0) = 1$. Equation (6) shows that all multiple edge waves starting with secondary waves ($n = 2, 3, 4, \dots$) are expressed approximately by the same function $\psi(x)$. As a result, the substitution of expressions (6) into Eq. (3) leads to the geometric series

$$\begin{aligned} \sum_{n=2}^{\infty} [J_n^+(z) + J_n^-(z)] &= f(k, z, l, a) \sum_{m=0}^{\infty} \{[\psi(kL) e^{ikL}]^2\}^m \\ &= \frac{f(k, z, l, a)}{D} \end{aligned} \quad (9)$$

which contains the resonance denominator $D(ka, kL) = 1 - [\psi(kL) e^{ikL}]^2$. The equation $D(ka, kL) = 0$ defines the complex resonant frequencies $\omega_{\text{res}} = ck_{\text{res}} = \omega'_{\text{res}} + i\omega''_{\text{res}}$, where c is the light velocity in vacuum. Due to the radiation loss, the quantity $\omega''_{\text{res}} = \text{Im}(\omega)$ is always negative ($\omega''_{\text{res}} < 0$). Therefore, for real frequencies ($\omega'' = 0$), the denominator $D(ka, kL)$ does not vanish. But it acquires minimum values when the frequency of the incident wave is close to the real part of the resonant, frequency ($\omega \approx \omega'_{\text{res}}$). This occurs when $kL \approx n\pi$ or $L \approx n\lambda/2$ with $n = 1, 2, 3, \dots$ and results in the current resonance. Under the normal incidence (the direction of the incident wave is

Figure 2. Integral cross section of thin wires (from Ref. 11). This quantity has the maximum (resonance) values for wires with the total length $L = 2l \approx (2n + 1)\lambda/2$, $n = 0, 1, 2, 3, \dots$. Along such wires from one end to another, each multiple edge wave acquires the phase shift of $(2n + 1)\pi$. Due to reflection at the end, it acquires an additional phase shift of π . As a result, this wave becomes equiphased with all other multiple edge waves. This leads to the resonance behavior for the current and scattered field.

perpendicular to the wire axis), only the odd resonances ($n=1,3,5,\dots$) are realized, due to the symmetry of the incident field [$E_z^{\text{inc}}(-z)=E_z^{\text{inc}}(z)$]. Figure 2, taken from a classic paper [11], illustrates the resonance behavior of scattering from thin wires. The incident wave direction is perpendicular to the wire axis. The quantity A in Fig. 2 is the total power of the field scattered in all directions. The maximum scattering occurs in the directions perpendicular to the wire and therefore in the backscattering direction as well. In Fig. 2, the quantity $\chi = 1/[2|\ln(ka)|]$ depends on the wire radius a , $2l=L$ is the wire length, and $a=kl$.

A similar interference of a specular reflection with surface diffracted rays (Fig. 3) explains the backscattering from perfectly conducting spheres and prolate spheroids at the upper end of the resonance region (p. 149 of Ref. 2 and pp. 822–848 of Ref. 4). However, an important difference exists between the resonances in scattering from wires and spheres. The resonance backscattering from wires is caused by the current resonance in the wires and it is accompanied by a simultaneous increase of the scattered field in other directions. This is a true resonance effect. The resonance scattering from spheres and spheroids is a simple equiphase interference in the single (backward) direction without the field increase in other directions. Additional data for the resonance backscattering can be found in Ref. 4 (pp. 822–848). As in the case of quasistatic scattering, direct numerical methods are also efficient for RCS calculations in the resonance frequency region [5–7].

3. QUASIOPTICAL SCATTERING

In the quasioptical frequency region, which is often referred to as the *high-frequency region*, linear dimensions of scatterers are much greater than the wavelength of the incident wave. For example, this occurs in the scattering of decimeter and centimeter radar waves by such objects as ships, airplanes, and missiles. In contrast to the quasistatic and resonance frequency regions, the scatterings by objects in the quasioptical region are determined mainly by the objects' local properties rather than by their whole volume.

Large dimensions and complex shapes of scattering objects allow the existence of various types of scattered fields. Some of them are illustrated in Fig. 4. Geometric

Figure 3. Backscattering from a body of revolution. The total scattered field consists of two components. One of them is a specular reflected ray (1); the other is a beam of diffracted rays (2) radiated by creeping waves traveling along the shadow side of the scattering body. The equiphase interference of these two components results in the resonance like increase of the scattered field.

Figure 4. Backscattering from a convex opaque object. The main contributor to the scattered field is beam A reflected from the front planar facet of the object. Edge waves B are created at the edges. Edge waves C are created at the curvature discontinuities. At the shadow boundary, the incident wave excites creeping waves D , which propagate along the object's surface and radiate surface diffracted rays E . Additional creeping waves are excited at the curvature discontinuities.

optics rays and beams (A) reflected from the object provide the main contributions to backscattering. Diffraction of the incident wave at edges and at lines of curvature discontinuity or material discontinuity creates edge waves (B and C), which can be interpreted as diffracted rays. They represent the second-order contributions [12–15]. Diffracted waves arising from corners provide the third-order contributions [12–14]. At the shadow boundary on a smooth scattering surface, the incident wave excites creeping waves (D), which propagate along the shadow side of the object and radiate surface diffracted rays (E). Due to continuous radiation of these rays, the creeping waves attenuate exponentially and for this reason the contribution of surface diffracted rays (E) to backscattering is small [12,13]. However, for the objects with dimensions comparable to the wavelength, surface diffracted rays can give appreciable contributions, as it is mentioned already in the previous section (see also Fig. 3). Diffracted waves propagating along the scattering object can undergo multiple diffractions at geometric and material discontinuities and can transform into other types of waves. This process creates high-order contributions to backscattering [12–15]. A visual description of scattering from large objects, simple quantitative estimations of some contributions to backscattering, and relevant references are presented in Ref. 16.

High-frequency asymptotic methods are widely used to predict scatterings in this frequency region. They include geometric optics (GO) and its extension, geometric theory of diffraction (GTD); physical optics (PO) and its extension, physical theory of diffraction (PTD); and various modifications and extensions of GTD and PTD. These asymptotic techniques are discussed in ELECTROMAGNETIC WAVE SCATTERING and RADAR CROSS SECTIONS. The present article supplements these and concentrates mainly on the physical optics. This method is not so precise as GTD, PTD, and their extensions, but it allows useful estimations for the scattered fields in many practical problems that cannot be treated with other techniques.

Figure 5. Reflection from a planar surface. The reflected ray lies in the plane that contains the incident ray and the unit normal vector \mathbf{n} to the reflecting surface.

Direct numerical methods, in their classical forms, are not efficient in the high-frequency region. Various combinations of these methods with the asymptotic techniques (so-called hybrid methods) represent a promising direction in the prediction of high-frequency scattering [17]. Additional information about numerical, hybrid, and asymptotic techniques used for the solution of scattering problems can be found in Ref. 6,13, and 18 and in the Further Reading list at the end of this article.

3.1. Geometric Optics Approximation

GO is used for approximate estimations of backscattering in many practical problems. The basic notion of GO involves the concept of rays. A ray is an infinitely narrow stream of the wave field moving with the light velocity along the lines perpendicular to the phase fronts. These lines are called *ray trajectories*. In free space they are straight lines. Electric and magnetic vectors of the ray field are perpendicular to each other and to the direction of propagation. GO reflected rays obey simple rules [19,20]: (1) the reflected ray lies in the incidence plane which contains the incident ray and the normal to the scattering surface at the reflection point (Fig. 5), (2) the angle of reflection equals the angle of incidence (Snell’s reflection law), and (3) the power inside an elementary hypothetical tube confined by neighboring rays is constant.

GO is a good approximation for the field reflected from large smooth scattering objects. It provides the leading term in the exact high-frequency asymptotic expansion of the reflected field. The reflection coefficient is found from

Figure 6. A scattered field at the reflection point on a coated scattering object is equal asymptotically (with $kR_{1,2} \rightarrow \infty$) to the field that would be reflected from a tangential layer with the same material properties. Due to losses, the contributions of rays and waves propagating along the object (inside the coating) become small and can be neglected.

the solution of an appropriate canonical problem. For opaque homogeneous objects, this is the Fresnel reflection coefficient, which determines the amplitude and phase of plane waves reflected from a planar boundary of a semi-infinite homogeneous medium [2, pp. 474–479]. For opaque objects coated with thin layers, the canonical problem is the reflection of plane waves from an infinite planar layer. This canonical layer is tangential to the scattering object (Fig. 6). It is homogeneous in the directions parallel to its surface and has the same material structure in depth as a real layer at the reflection point T . The canonical layer is placed on the planar boundary of a homogeneous medium with the same material properties as a real object at the tangency point. This implies that the field on a real coated object is determined exclusively by its local properties in the vicinity of the reflection point. Nonlocal contributions from various waves propagating along the object are not treated with this approach. Creeping and traveling waves [2, pp. 120 and 130] are examples of such waves.

According to this GO approach, the backscattering RCS of smooth coated objects equals

$$\sigma = |\mathbf{r}(0)|^2 \cdot \pi R_1 R_2 \text{ (m}^2\text{)} \tag{10}$$

where $r(0)$ is the reflection coefficient for the normal incidence ($\theta = 0$) and R_1, R_2 are principal radii of the curvature of the scattering surface at the reflection point T . In the case of isotropic objects and coatings, the reflection coefficient $r(0)$ does not depend on the incident wave polarization. Equation (10) is not valid for objects with planar faces when $R_1 = R_2 = \infty$. It also fails for objects that contain ruled elements (cylindrical, conical) with a rectilinear generatrix whose radius of curvature is infinite. In this case, the rays reflected by the object form the so-called reflected beams, which undergo the transverse diffusion while propagating from the object and for this reason lose their geometrical optics structure in the far zone.

3.2. Physical Optics Approximation

This method goes back to Macdonald [21] and is based on three concepts: GO, canonical planar layer, and equivalency principle.

The first step in the physical optics (PO) approximation is to use GO for the description of fields right on the scattering surface where GO approximation is still valid. The second step is to calculate the scattered field outside the object using the equivalency principle described in the following. Tangential components ($\mathbf{n} \times \mathbf{E}, \mathbf{n} \times \mathbf{H}$) of electric and magnetic vectors of the total field on the scattering surface (with the external unit normal \mathbf{n}) can be interpreted as equivalent magnetic and electric currents

$$\begin{aligned} \mathbf{j}_m &= -\mathbf{n} \times \mathbf{E} \text{ (V/m)} \\ \mathbf{j}_e &= \mathbf{n} \times \mathbf{H} \text{ (A/m)} \end{aligned} \tag{11}$$

In the PO approach, the equivalent currents are defined in the GO approximation. The total electromagnetic field on the scattering object is considered approximately as the

sum of the GO incident and reflected waves ($\mathbf{E}^{\text{GO}} = \mathbf{E}^{\text{inc}} + \mathbf{E}^{\text{ref}}$, $\mathbf{H}^{\text{GO}} = \mathbf{H}^{\text{inc}} + \mathbf{H}^{\text{ref}}$). Thus, the PO surface currents are defined as

$$\begin{aligned} \mathbf{j}_e^{\text{PO}} &= \mathbf{n} \times \mathbf{H}^{\text{GO}} \\ \mathbf{j}_m^{\text{PO}} &= -\mathbf{n} \times \mathbf{E}^{\text{GO}} \end{aligned} \quad (12)$$

This equation defines equivalent currents only on the illuminated side of the opaque scattering object. On the shadow side, these currents are assumed to be zero. In the particular case of perfectly conducting objects, the magnetic current does not exist ($\mathbf{j}_m^{\text{PO}} = \mathbf{0}$) due to the boundary condition $\mathbf{n} \times \mathbf{E} = \mathbf{0}$, and the electric current equals $\mathbf{j}_e^{\text{PO}} = 2\mathbf{n} \times \mathbf{H}^{\text{inc}}$ according to the GO approximation.

The scattered field is found by the integration of equivalent currents over the scattering surface S . Geometry of a sample scattering problem is shown in Fig. 7, where the quantity r is the distance between the integration (ρ, θ, ϕ) and observation (R, ϑ, φ) points. In the far zone ($R > k\rho_{\text{max}}^2$), the scattered field determined as

$$E_{\vartheta} = Z_0 H_{\phi} = ik(Z_0 A_{\vartheta}^e + A_{\vartheta}^m) \quad (13)$$

$$E_{\phi} = -Z_0 H_{\vartheta} = ik(Z_0 A_{\phi}^e - A_{\phi}^m)$$

$$\mathbf{A}^{e,m} = \frac{1}{4\pi R} \int_S \mathbf{j}_{e,m} e^{-ik\rho \cos \Omega} dS \quad (14)$$

$$\cos \Omega = \cos \vartheta \cos \theta + \sin \vartheta \sin \theta \cos(\varphi - \phi) \quad (15)$$

Here, $E_{\vartheta, \phi}$ is the electric field intensity (V/m), $H_{\vartheta, \phi}$ is the magnetic field intensity (A/m); \mathbf{A}^e is the electric potential vector (A), \mathbf{A}^m is the magnetic potential vector (V), and $Z_0 = \sqrt{\mu_0/\epsilon_0} \cong 377 \text{ } (\Omega)$ is the impedance of vacuum.

The PO approximation for the scattered field follows from Eqs. (13) and (14) when the PO approximation given by Eq. (12) is used for equivalent surface currents and the integration region is restricted to the illuminated part of the scattering surface. The line Γ shown in Fig. 7 is the boundary between the illuminated and shadow sides of the scattering surface S . The PO approach is usually

Figure 7. Schematics of a scattering problem: S is the surface of the scattering object; the dashed part of this surface (with the boundary Γ) is located in the shadow region which is hidden from the incident rays.

applied to large convex objects. However, it is also applicable to concave objects when the multiple GO reflections are taken into account.

3.2.1. Accuracy of PO. Approximate estimations for the PO scattered field [Eq. (13)] can be found by the application of asymptotic techniques to the integrals [Eq. (14)] with the PO currents [Eq. (12)]. The first term of the asymptotic expansion found in this way is correct for the fields scattered by smooth convex objects and planar plates in the specular directions predicted by GO. All higher-order terms in the PO asymptotic expansion are incorrect. Only two exceptions exist when PO provides the exact solution. The first is the scattering from the infinite perfectly conducting plane. The second is the scattering from the semiinfinite perfectly conducting paraboloid of revolution illuminated by the plane wave incident along the symmetry axis (22). In the latter case, the scattered field consists of only the GO reflected rays. Reference 22 also shows that PO provides the correct second term in the high-frequency asymptotic expansion for the specular backscattering from any convex perfectly conducting bodies of revolution when the incident wave propagates in the direction parallel to the symmetry axis.

The first term of the PO asymptotic expansion for the field scattered by smooth convex objects in specular directions represents the GO reflected rays [2, pp. 50–62]. Therefore, for such objects the PO value of RCS in specular directions is asymptotically (with $k \rightarrow \infty$) equivalent to the GO estimation. However, it is well known that GO is valid only away from the forward direction, i.e., from the shadow boundary of the incident rays. But PO is more general than GO and is applicable in the vicinity of this direction. All known results show that the first term of the PO asymptotic expansion for the field scattered in the forward direction is correct and leads to the following RCS for large opaque objects:

$$\sigma = 4\pi \frac{A^2}{\lambda^2} \text{ (m}^2\text{)} \quad (16)$$

Here, the quantity A is the area of the scattering object projection on the plane perpendicular to the direction of the incident wave propagation.

Reference 23 contains similar PO estimations for thin semitransparent plates. The field on the plate surface is defined by complex reflection and transmission coefficients which depend on the incidence angle (γ) and polarization of the incident wave. The incident wave with an arbitrary linear polarization can be decomposed into two independent waves with orthogonal polarizations. A decomposition is chosen such that either the electric or magnetic vector of the incident wave is parallel to the plate. In the first case, denote the reflection and transmission coefficients for the electric vector as $r_e(\gamma)$ and $t_e(\gamma)$, respectively. Similar coefficients, $r_h(\gamma)$ and $t_h(\gamma)$, for the magnetic vector describe the plate when the magnetic vector of the incident wave is parallel to the plate. Reference 2 (pp. 479–499) contains instructions for the calculation of these coefficients. Two directions of scattering are of

Figure 8. Directions of the forward ($\vartheta = \gamma$) and specular ($\vartheta = \pi - \gamma$) scattering from the plate S . The dashed line A denotes the projection of the plate S .

greatest interest. The first is the direction of specular reflection, $\vartheta = \pi - \gamma$, and the second is the forward direction, $\vartheta = \gamma$ (Fig. 8). According to (23), the PO approximations of RCS in the specular direction are given by

$$\sigma_e(\pi - \gamma) = 4\pi \frac{A^2}{\lambda^2} |r_e(\gamma)|^2 \tag{17}$$

$$\sigma_h(\pi - \gamma) = 4\pi \frac{A^2}{\lambda^2} |r_h(\gamma)|^2$$

and in the forward direction by

$$\sigma_e(\gamma) = 4\pi \frac{A^2}{\lambda^2} |1 - t_e(\gamma)|^2 \tag{18}$$

$$\sigma_h(\gamma) = 4\pi \frac{A^2}{\lambda^2} |1 - t_h(\gamma)|^2$$

where the quantity A is the same as in Eq. (16). This is the area of the plate projected on the plane perpendicular to the direction of the incident wave. Equations (17) and (18) are applicable for planar plates of an arbitrary shape under the condition $A \gg \lambda^2$. This means that the grazing angles ($\gamma \approx \pi/2$) cannot be treated with these equations.

Known results for perfectly conducting plates ($|r_{e,h}(\gamma)| = 1, |t_{e,h}(\gamma)| = 0$) show that PO estimations given in Eqs. (17) and (18) are correct. These equations also give the correct result, $\sigma_h(\pi/2) = 0$, for perfectly conducting plates under the grazing incidence. In this case, the incident wave does not undergo diffraction because its electric vector is perpendicular to the plate surface. PO describes satisfactorily the field scattered from large conducting plates not only in the specular and forward directions corresponding to mainlobes in the directivity pattern, but also in the directions of neighboring sidelobes. However, PO fails to predict a field level in minimums of the directivity pattern (Figs. 7–19 and 7–20 on p. 509 of Ref. 2) and does not satisfy the reciprocity principle.

The PO currents given by Eq. (12) are discontinuous on the shadow boundary of a scattering surface. The PO field

Figure 9. The PO current given by Eq. (12) is discontinuous at the shadow boundary of the scattering surface. This leads to spurious waves (1 and 2) in the case of a smooth scattering surface.

contains spurious waves from such a boundary in the case of smooth scattering surfaces (Fig. 9). A similar current discontinuity on scattering objects with edges results in edge waves. If the scattering edge is visible from the observation point, such an edge wave does exist. The PO edge waves coming from invisible edges are spurious shooting-through waves (Fig. 10). Such shooting-through waves do not occur in the backscattering direction. All PO spurious waves can be removed by neglecting the corresponding terms in the asymptotic expansion of the integral in Eq. (14). For real edge waves, even the first-order term of their PO asymptotic expansion is incorrect. This defect is remedied in PTD by the inclusion of the field radiated by the so-called nonuniform currents arising from the diffraction of the incident wave at edges [14,15,30].

One should emphasize a special role of PO in PTD. PO is a constitutive part of PTD. Therefore, the PO's first- and higher-order asymptotic terms are integral parts of the PTD asymptotic expansions for the total scattered field. For example, the terms with coefficients $(3d/16a)$ in the PTD equations (99) and (100) of (15) are exactly the PO's second-order terms in the asymptotic expansion of the field scattered by a perfectly conducting cylinder of finite length.

3.2.2. Polarization of the PO Scattered Field. In general cases, components E_ϑ and E_ϕ in Eq. (13) have different amplitudes and phases. This results in the elliptic polarization of the scattered field even in the case when the incident wave is linearly polarized. This means that the electric vector of the scattered field rotates with the angular frequency $\omega = k \cdot c$ and its endpoint traces an ellipse. The direction of rotation (clockwise or

Figure 10. A scattered field is generated by the induced surface currents. Any approximations for these currents can result in the appearance of nonphysical components in the scattered field. In particular, the PO currents create spurious shooting-through edge waves (1, 2, and 3) passing through an opaque object.

Figure 11. Backscattering without depolarization from a symmetric perfectly conducting surface S . The incident wave direction is parallel to the symmetry plane y - z . Vectors E_{cr} are the cross-polarized components of the reflected field. Due to the symmetry, they cancel each other.

counterclockwise) is determined by the phase shift between components E_β and E_ϕ . The lengths of the elliptical axes are determined by the amplitudes of these components. Due to diffraction, the scattered field can contain an electric field component perpendicular to the incident wave polarization. This phenomenon is known as *depolarization*, or *cross-polarization*.

The PO field scattered by arbitrary perfectly conducting objects in the backscattering direction does not contain the cross-polarized component [2, p. 56]. It is assumed only that no multiple GO reflections occur on the object's surface. This PO result is correct for scattering objects with certain symmetry. These are objects with a symmetry plane parallel to both the electric (or magnetic) vector of the incident wave and the direction of its propagation. Each element of such a scattering object may create the cross-polarized component. But because of the symmetry, the cross-polarized components from symmetric elements cancel each other in the backscattering direction (Fig. 11). A convex smooth body of revolution whose symmetry axis is parallel to the incident wave direction is a simple example of such an object. A symmetric plate, illuminated by the plane wave whose electric (or magnetic) vector and direction of propagation are parallel to the symmetry plane, is another example where the backscattered field does not contain a cross-polarized component (Fig. 12).

As stated previously, the first term of the PO high-frequency asymptotic expansion represents the GO reflected ray. This ray contains the cross-polarized component when the electric vector of the incident ray makes any angle different from 0° and 90° with the incidence plane at the reflection point. This is the case when PO correctly describes depolarization of the scattered field in the high-frequency asymptotic limit ($k \rightarrow \infty$). However, PO fails to predict all depolarization effects caused by the diffraction part of equivalent surface currents.

3.2.3. Bistatic RCS. Bistatic RCS determines the power flux density of electromagnetic waves scattered by the object in an arbitrary direction. The angle between the directions to the transmitter and receiver is called

Figure 12. Backscattering without depolarization from a perfectly conducting plate S . The incident wave direction is parallel to the symmetry plane y - z . Cross-polarized components scattered by the left and right parts of the plate are symmetric and completely cancel each other.

the *bistatic angle*. Monostatic, or backscattering, RCS is a particular case of bistatic RCS when the bistatic angle equals zero. Some PO results for bistatic RCS have already been discussed. This section addresses the interrelationships between bistatic and monostatic RCS.

Using PO, one can prove the following statement:

For perfectly conducting bodies which are sufficiently smooth, in the limit of vanishing wavelength, the bistatic cross section is equal to the monostatic cross section at the bisector of the bistatic angle between the direction to the transmitter and receiver. [1, pp. 157–160; 2, p. 11]

There is a simple physical explanation for this result. As already stated, the first term of the PO asymptotic expansion for the field scattered by smooth objects exactly equals the GO expression for the reflected rays. The monostatic RCS caused by these rays is given by Eq. (10). In the case of perfectly conducting objects, this equation reduces to

$$\sigma = \pi R_1 R_2 \quad (19)$$

It should be noted that this equation is valid also for the bistatic RCS, which therefore *does not depend on the bistatic angle* $\beta = 2\vartheta$ (Figs. 5 and 6). This follows directly from Eqs. (5.32), (6.19), and (6.20), given by Fock [19, Chap. 8]:

$$\begin{aligned} \mathbf{E}(r) &= \frac{1}{2} \mathbf{E}(0) \sqrt{R_1 R_2} \frac{e^{iks}}{s} \\ \mathbf{H}(r) &= \frac{1}{2} \mathbf{H}(0) \sqrt{R_1 R_2} \frac{e^{iks}}{s} \end{aligned} \quad (20)$$

These expressions describe the field reflected by smooth convex objects at a far distance ($s \gg R_{1,2}$) from the reflection point for *any incidence angle* ($0 \leq \vartheta < \pi/2$). In the case of reflection from concave surfaces, the reflected field acquires the additional phase shift of $(-\pi/2)$ in passing through a focus of reflected rays. Vectors $\mathbf{E}(0)$ and $\mathbf{H}(0)$

denote the reflected field at the reflection point. Expressions (20) clearly show that the GO reflected field really does not depend on the incidence angle. As a result, the bistatic RCS does not depend on the bistatic angle and is the same as the monostatic RCS at the bisector direction that is perpendicular to the scattering surface at the reflection point. Thus, the cited equivalence between the bistatic and monostatic RCS is a pure GO effect and is fulfilled asymptotically (with $k \rightarrow \infty$) only in the ray region, away from the shadow boundary behind the scattering object. It is also clear that this equivalence is not valid when the scattered field contains multiple reflected rays arising from concave parts of the scattering surface. Reference 1 (pp. 160–183) presents additional results for bistatic RCS of some typical objects found using PO and other approximations.

In the case of coated smooth objects, Eq. (20) leads to the bistatic RCS

$$\sigma(\vartheta) = |r_{e,h}(\vartheta)|^2 \pi R_1 R_2 \tag{21}$$

where the reflection coefficients $r_{e,h}(\vartheta)$ depend on the polarization and direction of the incident wave. Therefore, the asymptotic equivalence between bistatic and monostatic RCS can be valid only for those bistatic angles where $|r_{e,h}(\vartheta)| = |r_{e,h}(0)|$.

This discussion relates to the situation where the bistatic scattered field is produced by a single scattering source (the reflection point). The field scattered by complex objects can have many sources (scattering centers) on the object’s surface. Figure 13 illustrates the bistatic scattering from the center located at the point (x_n, y_n, z_n) . The origin of Cartesian coordinates is somewhere inside the scattering object. The z axis is directed along the bisector of the bistatic angle β . In the far zone, the bistatic scattered field can be represented as the sum of partial contributions from all scattering centers [4, pp. 983–988]:

$$\mathbf{u}(\beta) = \frac{e^{ikR}}{R} \sum_n \mathbf{v}_n e^{-2ikz_n \cos(\beta/2)} \tag{22}$$

Here, \mathbf{u} is either the electric or magnetic vector of the total scattered field; R is the distance from the origin to the observation point. Vector \mathbf{v}_n determines the amplitude and

Figure 13. Geometry of the bistatic scattering problem. A solid winding line represents a scattering object with many scattering centers (x_n, y_n, z_n) . The scattering direction forms the angle β with the direction of the incident wave.

polarization of the wave generated by the n th scattering center. Suppose that vectors \mathbf{v}_n and the number of scattering centers are constant inside the $0 \leq \beta \leq \beta_{\max}$. Assume also that coordinates z_n of scattering centers do not depend on the bistatic angle β , while coordinates x_n and y_n can be functions of this angle. Under these conditions, the monostatic field scattered in the bisector direction equals

$$\mathbf{u}(0) = \frac{e^{ikR}}{R} \sum_n \mathbf{v}_n e^{-2ikz_n} \tag{23}$$

Comparisons of Eqs. (22) and (23) show that the bistatic RCS, $\sigma(\beta, k)$, at the frequency $\omega = c \cdot k$ will be equal to the monostatic RCS, $\sigma[0, k \cos(\beta/2)]$, at the frequency $\omega = c \cdot k \cdot \cos(\beta/2)$. This equality requires the additional assumption that each vector \mathbf{v}_n is constant in the frequency band $[c \cdot k \cos(\beta/2) \leq \omega \leq c \cdot k]$. The derivation, some applications, and restrictions of this equivalence relation are presented in Ref. 4 (pp. 983–988). In particular, this reference notes that this equivalence is not true for the bistatic scattering from spheres when the bistatic angle exceeds one degree and the sphere radius is less than 6λ . Before applying this equivalence in practice, we must first check carefully that all assumptions made in this scattering model are really fulfilled. One can expect that this approximate model can be reasonable only for small bistatic angles.

3.2.4. PTD as an Extension of PO. PTD is a natural extension of PO [14,15,24,30]. In PTD, the PO current given by Eq. (12) is considered as the uniform component (j^0) of the total surface current and is supplemented by the additional, nonuniform component (j^1). In contrast to the PO current that has the GO origin, the nonuniform current is caused by diffraction at smooth bendings, sharp edges, corners, and any other geometric discontinuity and material inhomogeneity on the scattering surfaces. Creeping and edge current waves are examples of such a current. The field generated by the nonuniform current represents the PTD contribution to the scattered field. Exact analytical expressions for nonuniform currents are not available. Therefore, one has to find their high-frequency approximations by the solution of appropriate canonical problems. In this manner, Fock developed special functions that describe the nonuniform current on smooth convex objects in the vicinity of the shadow boundary [19]. The Sommerfeld solution of the wedge canonical problem is used for the asymptotic description of the nonuniform current near perfectly conducting edges [14,15,24,30]. The concept of uniform and nonuniform currents plays a key role in PTD and those hybrid techniques that combine direct numerical methods with high-frequency asymptotic approximations [6,17,18]. Reference 15 shows that PTD properly defines the leading term in the high-frequency asymptotic expansions for primary and multiple edge waves. A close connection exists between PTD and GTD. The latter automatically follows from the PTD integrals when they are evaluated

by the stationary phase technique [15, pp. 136–138]. Some PTD results are presented in the next section.

4. BACKSCATTERING RCS OF SIMPLE SHAPES

This section contains examples of PO estimations for RCS of simple objects. Whenever possible, these estimations are accompanied by more precise PTD counterparts that include the contributions of primary edge waves generated by the nonuniform edge currents. Only objects with symmetry of revolution are considered. All given data are taken from Refs. 15, 16, and 30. Exact, numerical solutions of scattering problems for bodies of revolution can be found, for example, in Refs. 6, 18, and 25.

4.1. Semitransparent Disk

The geometry of this scattering problem is shown in Fig. 8. The backscattering direction is determined by the spherical coordinates $\vartheta = \pi - \gamma$, $\varphi = -\pi/2$. The disk radius is denoted by the letter a . The incident wave can have either E or H polarization. In the first case, the electric vector is perpendicular to the incidence plane and parallel to the disk face. The reflection and transmission coefficients, $r_e(\gamma)$, $t_e(\gamma)$, with respect to the electric vector. In the case of H polarization, the magnetic vector of the incident wave is perpendicular to the incident plane and parallel to the disk face. The reflection and transmission coefficients, $r_h(\gamma)$, $t_h(\gamma)$, determine the magnetic vector on the front ($z = -0$) and rear ($z = +0$) faces of the disk, respectively. According to Eq. (67) in (23), the backscattering RCS is given by

$$\begin{aligned}\sigma_e^{\text{PO}}(\gamma) &= |r_e(\gamma)|^2 \pi a^2 [J_1(2ka \sin \gamma)]^2 \cot^2 \gamma \\ \sigma_h^{\text{PO}}(\gamma) &= |r_h(\gamma)|^2 \pi a^2 [J_1(2ka \sin \gamma)]^2 \cot^2 \gamma\end{aligned}\quad (24)$$

where $J_1(x)$ is the Bessel function and the incidence angle is restricted by the values $0 \leq \gamma < \pi/2$. For perfectly conducting disks, one should put $r_e(\gamma) = -1$ and $r_h(\gamma) = +1$. Then, in the case of the normal incidence ($\gamma = 0$), Eq. (24) reduces to

$$\sigma_e^{\text{PO}} = \sigma_h^{\text{PO}} = \pi a^2 (ka)^2 \quad (25)$$

Figure 7-24 on p. 514 of Ref. 2 shows that this equation is in good agreement with the exact results when $ka \geq 5$. Note also that Eq. (18), with $A = \pi a^2 \cos \gamma$, determines the PO bistatic RCS of this disk for the forward direction ($\vartheta = \gamma$). PTD estimations for RCS of a perfectly conducting disk are presented in Chaps. 2 and 5 of Ref. 14. See also pp. 514–521 of Ref. 2. Some important corrections in the PTD expressions for bistatic scattering from a disk are given in Ref. 24. Contributions of multiple edge waves to forward scattering are presented in Ref. 15 (pp. 149–151).

4.2. Circular Cone

Geometric parameters of a perfectly conducting cone are shown in Fig. 14. The incident wave direction is parallel to the symmetry axis of the cone. The PO backscattering

Figure 14. Backscattering from a truncated cone. The base diameter of the cone ($2a$) is large compared to the wavelength. The length of the cone (l) can be arbitrary. In the limiting case $l = 0$, the cone transforms into a disk.

RCS is given by Eqs. (17.06) and (17.09) in (4) [see also Eqs. (2.4.7) and Eq. (2.4.10) in Ref. 30]

$$\sigma^{\text{PO}} = \pi a^2 \cdot \left| \frac{1}{ka} \tan^2 \alpha \sin kl - \tan \alpha e^{ikl} \right|^2 \quad (26)$$

where the cone length equals $l = a \cot \alpha$. To clarify the physics in this equation, we rewrite it as

$$\sigma^{\text{PO}} = \pi a^2 \left| \frac{i}{2ka} \tan \alpha e^{-ikl} - \left(\tan \alpha + \frac{i}{2ka} \tan \alpha \right) e^{ikl} \right|^2 \quad (27)$$

The first term (with exponential e^{-ikl}) is related to the wave scattered by the cone tip. Comparison with the exact solution [3, Fig. 18.15, p. 691] shows that this PO approximation is quite satisfactory for all cone angles ($0 \leq \alpha \leq \pi/2$). The second term (with the exponential e^{ikl}) describes the edge wave contribution. This PO approximation is incorrect. PTD takes into account the additional contribution from the nonuniform (diffraction) currents located near the cone edge and provides a more accurate result, given by Eqs. (17.06) and (17.08) in Ref. 14 [see also Eqs. (2.4.7) and (2.4.9) in Ref. 30]

$$\sigma^{\text{PTD}} = \pi a^2 \cdot \left| \frac{1}{ka} \tan^2 \alpha \sin kl + \frac{\frac{2}{n} \sin \frac{\pi}{n}}{\cos \frac{\pi}{n} - \cos \frac{2\alpha}{n}} e^{ikl} \right|^2 \quad (28)$$

where $n = \frac{3}{2} + \alpha/\pi$. When the cone transforms into the disk ($\alpha \rightarrow \pi/2$, $l \rightarrow 0$) the previous expressions reduce to

$$\sigma^{\text{PO}} = \sigma^{\text{PTD}} = \pi a^2 (ka)^2 \quad (29)$$

which coincides with Eq. (25).

4.3. Paraboloid

The directrix of a paraboloid is given by the equation $r = 2pz$ where $p = a \tan \alpha$ (Fig. 15). The length of the paraboloid equals $l = a^2/(2p) = (a/2) \cot \alpha$. The angle α is formed by the symmetry axis z and the tangent to the directrix at the point $z = l$. The radius of the paraboloid base equals a . The incident wave propagates in the positive direction of the z axis. According to Eq. (18.02)

Figure 15. Backscattering from a truncated paraboloid. The base diameter of the paraboloid ($2a$) is large compared to the wavelength. The length of the paraboloid (l) can be arbitrary. In the limiting case $l = 0$, the paraboloid transforms into a disk.

in Ref. 14 (see also Sect. 2.5 in Ref. 30), the PO backscattering RCS of a perfectly conducting paraboloid equals

$$\sigma^{PO} = 4\pi a^2 \tan^2 \alpha \sin^2 kl \quad (30)$$

This equation can be written in another form as

$$\sigma^{PO} = \pi a^2 \tan^2 \alpha \cdot |e^{-ikl} - e^{ikl}|^2 \quad (31)$$

which is more convenient for the physical analysis. The term with the exponential e^{-ikl} gives the correct contribution of the specular reflection from the paraboloid tip. The term with the exponential e^{ikl} represents the edge wave contribution and is wrong. PTD includes the additional contribution from the nonuniform edge currents and provides the correct result, given by Eq. (18.04) in Ref. 14 [see also Eq. (2.5.4) in Ref. 30]

$$\sigma^{PTD} = \pi a^2 \left| \tan \alpha + \frac{\frac{2}{n} \sin \frac{\pi}{n}}{\cos \frac{\pi}{n} - \cos \frac{2\alpha}{n}} e^{2ikl} \right|^2 \quad (32)$$

where $n = \frac{3}{2} + \alpha/\pi$. When the paraboloid transforms into the disk ($\alpha \rightarrow \pi/2$ and $l \rightarrow 0$), these expressions reduce to Eq. (29).

4.4. Truncated Sphere

The geometry of this scattering problem is shown in Fig. 16. The angle α is formed by the tangent to the sphere generatrix and the symmetry axis. The sphere radius equals $\rho = a/\cos \alpha$, where a is the base radius. The length of the truncated sphere equals $l = \rho \cdot (1 - \sin \alpha)$. It is assumed that $l \leq \rho$. The PO backscattering RCS of a perfectly conducting sphere equals [14, Eq. (19.05); 30, Eq. (2.6.2)]

$$\sigma^{PO} = \pi a^2 \left| \frac{1}{\cos \alpha} - \frac{i}{2ka} - \left(\tan \alpha - \frac{i}{2ka} \right) e^{2ikl} \right|^2 \quad (33)$$

In this equation, the first two terms represent the specular reflection from the sphere, and both are correct. The third term (with the exponential e^{2ikl}) gives the contribution

Figure 16. Backscattering from a truncated sphere. The base diameter of the sphere ($2a$) is large compared to the wavelength. The length of the sphere (l) can be arbitrary. In the limiting case $l = 0$, the sphere transforms into a disk.

from the edge and it is wrong. With $ka \gg 1$, Eq. (33) simplifies to

$$\sigma^{PO} = \pi a^2 \left| \frac{1}{\cos \alpha} - \tan \alpha e^{2ikl} \right|^2 \quad (34)$$

When $\alpha = 0$, the latter gives the RCS of a hemisphere, $\sigma = \pi a^2$. The PTD backscattering RCS is determined by Eq. (19.12) in Ref. 14 [Eq. (2.6.8) in Ref. 30]

$$\sigma^{PTD} = \pi a^2 \left| \frac{1}{\cos \alpha} + \frac{\frac{2}{n} \sin \frac{\pi}{n}}{\cos \frac{\pi}{n} - \cos \frac{2\alpha}{n}} e^{2ikl} \right|^2 \quad (35)$$

where $n = \frac{3}{2} + \alpha/\pi$. When the sphere transforms into the disk ($\alpha \rightarrow \pi/2, \rho \rightarrow \infty, l \rightarrow 0$), Eqs. (34) and (35) reduce exactly to Eq. (29).

4.5. Circular Cylinder with Flat Ends

The diameter and length of a perfectly conducting cylinder are assumed to be large as compared with the wavelength of the incident wave. PO and PTD estimations for backscattering RCS are developed in Chap. 3 of Ref. 14. They are also presented in Ref. 2 (pp. 308–312). PTD asymptotic expressions for bistatic RCS are given in Ref. 15 (pp. 152–154).

5. BACKSCATTERING FROM COMPLEX OBJECTS AND STEALTH PROBLEMS

Computer codes based on GTD, PTD, and on their hybridizations have been developed for prediction of high-frequency scattering from complex perfectly conducting objects. Relevant references can be found in Refs. 16 and 18 and in special issues of *Proc. IEEE* (1989), *IEEE Trans. Anten. Propag.* (1989), and *Annales des Telecommunications* (1995), which are mentioned in the Further Reading list. Note also the XPATCH code (based on the shooting-and-bouncing ray technique and PTD), which allows the calculation of backscattering from complex geometries. Information about this code is published in *IEEE Trans.*

Anten. Propag. Mag. **36**(1):65–69 (1994). Computer codes interfaced with graphical utilities of workstations can display three-dimensional chromatic views of scattering centers and magnitudes of their contributions to RCS. This is the end result of complicated computations. However, a part of this can be obtained without any computations. Nature can show us the location of all scattering centers if we bring a small metallized model of the scattering object into an anechoic optical chamber and illuminate the model by the light. Bright shining points (scattering centers) seen on a scattering object are exactly those from which the radar waves will be reflected toward the radar, if we look at the object from the light source direction. (The following text is taken from Ref. 16 and slightly modified.)

The locations of these points do not depend on the frequency of incident electromagnetic waves, and they are determined completely by the location of the light source (the radar), the observer, and the scattering object. These shining points obey the Fermat principle. This means that the path along the ray between the source, the reflection point, and the observer is extremal (minimal or maximal) in comparison with similar paths corresponding to neighboring points on the object's surface. A more detailed description of the Fermat principle is presented, for example, in Sect. 3.3.2 in Ref. 20.

Waves reflected from discrete shining points located on the smooth parts of the scattering object represent the usual geometric optics reflected rays. Waves reflected from discrete shining points located on edges, tips, and corners are diffracted rays. The farthest shining points on a smooth object—those located on the boundary between visible and invisible sides of the object—create surface diffracted rays.

As the orientation of the object is changed, the shining points move along the object. Some of them can merge with each other and create a brighter point. In this case our eyes (i.e., the radar) are located on a caustic that is the envelope of merged rays.

We can also observe bright shining lines and bright shining spots on the object, which contain an *infinite* number of continuously distributed shining points. Their important property is that the optical path through a shining point from the source to the observer is constant for all of these points. It is assumed here that the source and observer are far from the scattering object. All waves reflected from these points reach the observer with the same phase. From the mathematical point of view, each such point is a stationary point of the infinite order; the derivatives (of any higher order) of the wave phase along the shining line (or along the shining spots) are zero at these points.

Shining spots and lines located on smooth parts of the scattering surface generate powerful reflected beams (such as those radiated by reflector antennas) that represent the strongest contributors to RCS. Shining edge lines create edge-diffracted beams whose contributions can be comparable with those from ordinary reflected rays.

It is difficult to model in optics the electromagnetic properties of realistic scattering surfaces for the radar frequency band. But the optical modeling can be used to

identify the scattering centers and to control them by an appropriate shaping of the scattering surface. As it is well known, one of the basic ideas of the current stealth technology is to use an appropriate body shaping and to shift all reflected beams and rays away from the directions to the radar. See, for example, Refs. 2 and 16, and the radar cross-section handbooks mentioned in the reading list. Some interesting details about the development of stealth technology in the United States are presented in Refs. 26–28.

The second idea of stealth technology is traditional: to use radar absorbing materials (RAMs) and composite structures in order to reduce the intensity of reflected beams and rays. References 2, 16, and 29, and radar handbooks (mentioned in the reading list) describe fundamental concepts used in the design and application of RAMs. We present here some details taken from Ref. 16. In order to use RAMs efficiently, it is necessary to place an electric (magnetic) RAM in the region where the average electric (magnetic) field is maximal. Location of these regions in the vicinity of real objects depends on many factors, such as the radar frequency, geometry, size, and electrical properties of the object, as well as properties of materials intended for absorption. Identification of such regions and optimization of the RAM parameters to minimize RCS is a very complex problem. Its solution is attainable only in some simple cases. Most of these relate to absorbing layers on an infinite metallic plane. From the physical point of view such absorbing layers can be considered as open resonators that can support eigenoscillations. Frequencies of eigenoscillations are complex quantities. Their imaginary part is responsible for the loss inside the resonator and radiation from the resonator. It turns out that the minimal reflection from such resonators happens when the frequency of an incident wave is close to the real part of the resonator eigenfrequency.

Note that thin electric RAMs are not efficient when applied on metallic objects. This is due to the boundary condition; the tangential component of the electric field is very small on the metal surface. On the contrary, magnetic absorbing materials can be applied directly to the surface of a metallic object. This is an important advantage of magnetic materials over electric ones.

However, any RAMs (electric, magnetic, and hybrid) homogeneous in the direction parallel to the reflecting plate are not efficient for grazing incidence ($\theta \approx 90^\circ$, in Fig. 5). In this case, the reflection coefficient tends to unity independently of the incident wave polarization when $\theta \rightarrow 90^\circ$. This is a fundamental limitation of ordinary RAMs. They do not work against grazing incident waves. That is why ordinary RAMs do not reduce forward scattering. Actually, the RAM terminology is justified only for incidence angles that are not too far from $\theta = 0$ and when the reflection coefficient is small enough.

There is another reason why RAMs are not efficient against the forward scattering. Any large opaque scattering objects act like a lens focusing the scattered field in the forward direction. As shown in Refs. 15, 23, and 30, the forward scattering can be interpreted as the *shadow radiation* generated by the *black bodies* (perfectly absorbing objects whose reflection coefficient equal zero). In Ref. 23 (see also Refs. 15 and 30), it was established that the total

power of the shadow radiation in all directions equals *one-half* of the total power scattered by a *perfectly reflecting* body (of the same shape and size as the black body). This fundamental law means that the total power of the scattered field cannot be reduced with application of any radar absorbing coatings more than by a factor of 1/2.

Various geometric and material inhomogeneities on the scattering surface can partially transform the incident wave into surface waves propagating along absorbing layers. This may be used to further reduce the RCS. However, this idea has two essential defects: (1) any inhomogeneity creates an additional undesirable scattered field and (2) it is not a simple problem to design an absorbing layer that would allow the propagation of surface waves. To support surface waves with electric vector parallel to the incidence plane, the surface impedance must be inductive. But the surface impedance must be capacitive to support surface waves with the electric vector perpendicular to the incidence plane. This means that the surface impedance, and therefore the absorbing layer, must depend on the radar polarization with respect to the incidence plane. But this plane is different at different points of the scattering surface and different at the same point when the scattering object changes its orientation with respect to radar. It is very difficult and probably impossible to design such an absorber, especially against radars with circular polarization. However, for some chosen orientations of the object and for an appropriate polarization of the incident wave, this might not be a hopeless problem.

Development of efficient hybrid techniques and computer codes to predict RCS of large complex objects with realistic materials and research efforts to overcome the abovementioned physical limitations in RCS reduction represent challenging problems for future stealth technology. One can expect that future advanced computer codes will contain as necessary constitutive components the known high-frequency techniques (such as GTD, PTD, and the uniform theory of diffraction) extended for coated and composite objects. Diffraction coefficients used in these techniques can be determined by the numerical solution of appropriate canonical problems. Direct numerical methods should be used for calculation of scattering from those elements of the scattering object that cannot be treated by high-frequency methods. Diffraction interaction between the object's elements handled by high-frequency techniques and by direct numerical methods can be described by the surface integral equations.

contains key papers on GTD, asymptotic solutions of some canonical problems, and applications-oriented papers.)

Many scattering objects contain nonmetallic materials, composites, and various layered structures. To simplify the solution of scattering problems for such objects, it is often practical to apply approximate boundary conditions. These conditions are enforced on the external surface of the object and contain important information about the internal structure of the scattering object. As a result, this approximation allows one to substantially reduce the spatial region under investigation. The two following books present the development and applications of this approximation technique.

- T. B. A. Senior and J. L. Volakis, *Approximate Boundary Conditions in Electromagnetics*, The Institution of Electrical Engineering, London, 1995.
- D. J. Hoppe and Y. Rahmat-Samii, *Impedance Boundary Condition in Electromagnetics*, Taylor & Francis, Washington, DC, 1995.
- P. Ya. Ufimtsev, *Theory of Edge Diffraction in Electromagnetics*, Tech Science Press, Encino, CA, 2003. [Among the fundamental results of this theory are the following: (1) The theory of black bodies that is important for understanding of physics of diffraction, especially of scattering at large bistatic angles. This theory also determines the diffraction limit for reduction of the total scattered power by application of radar absorbing coatings. (2) PTD estimations of RSC for bodies of revolution. (3) Extension of PTD for scattering objects with concave elements. (4) Analysis of diffraction problems (wedge, strips, dipoles) based on the parabolic equation method. (5) Investigation of multiple edge diffraction at a single strip and at an open resonator formed by two strips. Exact and asymptotic expressions are found for the current on the strip and for the far field that are valid for arbitrary directions of incidence and observation. These expressions allow the calculation of the current and the far field with arbitrary high precision].

BANDPASS FILTERS

JAIME RAMIREZ-ANGULO
New Mexico State University
Las Cruces, New Mexico

A bandpass filter is an electrical device that passes the spectral components of an electrical signal around a certain frequency f_0 with little or no attenuation, while it mostly rejects other spectral components (Fig. 1). Bandpass filters are common building blocks of many electronic systems. They find applications in diverse fields such as communications, audio, instrumentation, and biomedicine. To illustrate a typical application of a bandpass filter, consider the simultaneous transmission of n signals in one communications channel using frequency multiplexing techniques. The signals can share the same channel because their individual frequency spectra are shifted so that they occupy nonoverlapping regions (or bands) of the frequency spectrum. Frequency modulation is used to shift the baseband spectrum of each of the signals (centered originally at zero frequency or dc) to center frequencies $f_{01}, f_{02}, \dots, f_{0n}$ (Fig. 2). In order to avoid overlapping,

Figure 1. Frequency response of ideal bandpass filter.

the center frequencies must have a minimum separation of at least the bandwidth of the signals. Bandpass filters are used on the receiver side in order to select or “filter out” only one of the signals transmitted in the channel. A process called demodulation is used to shift the spectrum of the selected signal back to baseband (to a zero center frequency).

1. IDEAL BANDPASS FILTERS

Ideally, a bandpass filter is characterized by its center frequency f_0 and its bandwidth BW. The bandwidth is defined in terms of upper and lower passband edge frequencies f_{p1} and f_{p2} , respectively, and given by $BW = f_{p2} - f_{p1}$. Typically, f_{p1} and f_{p2} specify frequency points at which the gain decreases by a factor $\sqrt{2}$. The frequency response plot of Fig. 1 shows the gain A as a function of frequency f of an ideal bandpass filter. An important parameter of a bandpass filter is its selectivity factor S_F , which is expressed by $S_F = f_0/BW$. The selectivity is a measure of the filter’s ability to reject frequencies outside its passband. It is also a relative measure of the reciprocal bandwidth. Highly selective filters (also denoted narrowband filters) have a bandwidth that constitutes only a small fraction of f_0 . Narrowband filters with large selectivity factors (e.g., $S_F > 50$) are commonly required in communication systems. For ideal bandpass filters, the frequency range is divided into three regions: the passband region where the gain is approximately constant ($f_{p1} < f < f_{p2}$) and the lower and upper stopbands ($f < f_{p1}$ and $f > f_{p2}$, respectively), where the gain is ideally zero or the attenuation or reciprocal gain is infinite. The ideal bandpass filter has sharp transitions between the passband and the two stopbands.

Figure 2. Spectrum of n signals in a communication channel.

2. PRACTICAL BANDPASS FILTERS

The typical frequency response of a practical passband filter is shown in Fig. 3. It has a relatively constant gain possibly with fluctuations (ripple) with maximum amplitude A_p within the passband. The passband edge frequencies f_{p1} and f_{p2} are defined, in this case, as the minimum and maximum frequencies with gain, $A - A_p$. The center frequency f_0 is commonly the center of geometry of the passband edge frequencies: $f_0 = \sqrt{f_{p1}f_{p2}}$. In a practical filter, there is a gradual transition between the passband and the upper and lower stopbands. Therefore, besides the passband and stopband there are also two transition bands. Two frequencies f_{s1} and f_{s2} , each denoted lower and upper stopband edge frequencies, respectively, define the stopbands in a practical bandpass filter. Stopband regions are characterized by a small gain with maximum value, $1/A_s$, where A_s is the stopband attenuation. Passband ripple A_p and stopband attenuation A_s are commonly specified in a logarithmic unit denoted decibel according to A_s (dB) = $20 \log A_s$. Practical bandpass filters can have monotonic decreasing gain or equal gain fluctuations (ripple) within both the passband and the stopband.

3. MATHEMATICAL CHARACTERIZATION OF A BANDPASS FILTER

The simplest bandpass filter is the second-order filter. It is characterized by the input-output relation or transfer function:

$$T(f) = \frac{jBwf}{f_0^2 + jBwf - f^2} \quad (1)$$

This transfer function is a complex function with magnitude and phase. The magnitude (frequency response) obtained from Eq. (1) has the form

$$|T(f)| = \frac{Bwf}{\sqrt{(f_0^2 - f^2)^2 + (Bwf)^2}} \quad (2)$$

The pole-zero plot (in the complex frequency plane also known as the *s plane*) of a second-order bandpass filter is shown in Fig. 4. It has a zero at the origin (shown as a circle) and two complex conjugate poles (shown as marks).

Figure 3. Practical bandpass filter.

Figure 4. Pole-zero plot of second-order bandpass filter.

The selectivity is associated with the relative distance of the poles from the imaginary axis in the *s* plane. The distance from the origin to the poles corresponds to the center frequency in radians, $\omega_0 = 2\pi f_0$.

4. BANDPASS FILTER IMPLEMENTATIONS

Depending on the center frequency and selectivity, there exist several possible implementations of bandpass filters. In general, the higher the selectivity and the center frequency, the more complex the filter becomes. Two very important aspects are miniaturization and compatibility with very large scale integration (VLSI) systems technology. These have dictated the evolution of bandpass filters and of most other electronic circuits. *Compatibility* refers to the fact that the filter can be fabricated on a CMOS integrated circuit as a part of a VLSI system in CMOS technology. This technology allows for the fabrication of very complex analog and digital electronic systems with hundreds of thousands or even millions of transistors on a single integrated circuit. CMOS compatibility is crucial in order to reduce manufacturing costs and to increase system reliability. Automatic tuning and low power consumption are also important aspects for bandpass filters. Tuning consists in the process of adjusting the filter's response to compensate for unavoidable fabrication tolerances in the values of the filter elements. These tolerances cause the filter's response to deviate from the ideal (nominal) response. Low power is important for portable equipment like cellular phones and bioimplantable devices.

4.1. Passive Filters

For many years, most filters were exclusively implemented as *passive RLC* circuits using resistors, inductors, and capacitors [1]. Figure 5 shows an example of a resonant *RLC* circuit used as a bandpass filter. This filter is characterized by the transfer function of Eq. (1) with

Figure 5. Second-order *RLC* bandpass filter.

Figure 6. Second-order RC active filter.

$f_0' = 1/2\pi \cdot 1/\sqrt{LC}$ and $BW = 1/(CR)$. The transfer function of this circuit has the pole-zero plot shown in Fig. 4. Ceramic filters based on bulk electromechanical resonance phenomena in piezoelectric materials have been used in the radio frequency range specially for requirements of high selectivity and accurate center frequency. Inductors have several problems: (1) they have large physical dimensions and cannot be integrated unless their value is very small, (2) they are temperature-dependent, and (3) their value is subject to large manufacturing tolerances. They also have poor characteristics at low frequencies, and their value tends to change with time. RLC passive filters cannot be automatically tuned at the manufacturing stage. Additionally, RLC and ceramic filters are not compatible with CMOS VLSI technology.

4.2. RC Active Filters

In the 1960s, RC active filters using operational amplifiers, capacitors, and resistors led to the implementation of highly selective low-cost filters without inductors (Fig. 6). These filters are known as RC active filters [2]. They constituted the first step toward filter miniaturization. RC active filters were mass-produced in miniaturized form using thin-film and/or thick-film technology. These filters still required individual tuning. This was automatically done using computer-controlled laser beams that burn sections of resistor material to change the resistance and achieve the desired filter response. Within a short time, RC active filters replaced most inductor-based filters in the audio frequency range.

4.3. Monolithic Analog Filters

In the mid-1980s, RC active filters were replaced by fully integrated switched-capacitor filters [3]. These use only switches, operational amplifiers, and capacitors and can be fabricated in CMOS VLSI technology (see Fig. 7). Switched-capacitor filters require no tuning and can operate at center frequencies up to a few hundred kilohertz. Starting in the mid 1970s, surface acoustic wave (SAW) filters—another family of filters—were developed to implement filters for center frequencies spanning from 10 to several hundred megahertz. These filters are miniaturized filters that also require no tuning. They are based on the controlled propagation of electromechanical waves on the surface of a piezoelectric crystal with very small dimensions. SAW filters are not compatible with CMOS technology. But because of their excellent performance characteristics and low cost, they are currently

Figure 7. Second-order switched-capacitor filter.

being used to implement the intermediate frequency filter of most televisions.

More recently, electronically tunable elements in CMOS technology have allowed the integrated circuit implementation of active filters for center frequencies up to a few tens of megahertz. These filters are compatible with CMOS VLSI technology. Most of these implementations are based on electronically tunable elements called operational transconductance amplifiers (transconductors or OTAs) and include on-chip automatic tuning circuitry [4]. The tuning circuit continuously (or periodically) monitors the filter’s response and electronically adjusts the gain of the OTAs to tune the frequency response of the bandpass filter. This family of filters is known as OTA-C filters (see Fig. 8). They require no tuning and can be integrated as part of a VLSI system [5]. Figure 8a shows a conventional “voltage mode” filter, while Fig. 8b shows a “current mode” filter where input, output, and intermediate variables are represented by electrical currents rather than voltages as it is done in conventional “voltage mode” filters [6]. In analog signal processing systems, the range above 100 MHz is still based, to a large extent, on passive RLC filters. At these frequencies, high-quality, small-dimension inductors are available. A very recent trend for the implementation of high-frequency high-selectivity

Figure 8. Second-order OTA-C bandpass filter: (a) voltage-mode implementation; (b) current-mode implementation.

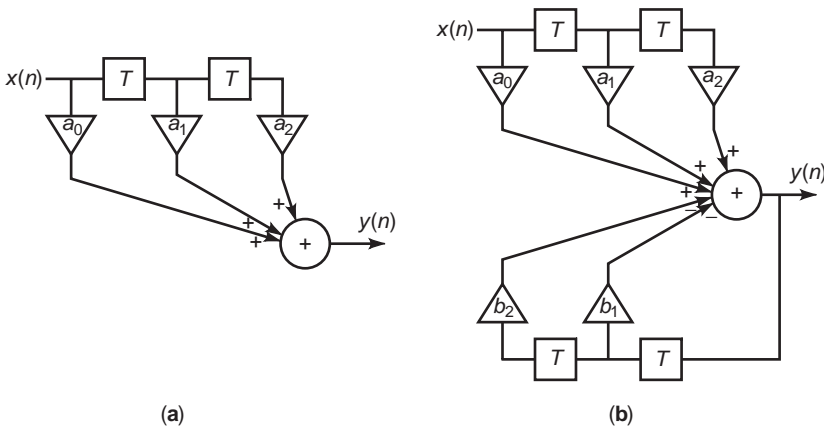

Figure 9. Second-order digital filters: (a) FIR filter; (b) IIR filters.

integrated analog filters is based on microelectromechanical (MEM) structures, which are based on electromechanical resonance. This approach has shown potential for the implementation of bandpass filters operating in the radio frequency range and with very high selectivity factors similar to those achievable with ceramic and SAW structures. These MEM-based filters, unlike the SAW filters, are CMOS VLSI-compatible.

4.4. Digital Filters

Currently, the availability of low-cost digital circuitry in VLSI systems has made it convenient to replace many traditional analog functions by digital ones and to process signals in the digital domain rather than in analog form. Successful implementation of digital filters for center frequencies up to a few megahertz, as standalone units or as part of a VLSI system has been achieved. Digital filters are fully integrated filters that are compatible with CMOS technology and require no tuning [7]. Their characteristics (f_0 , BW, or Q) can be easily reprogrammed for many different applications. A digital filter consists basically in various addition, multiplication, and delay operations applied to an ordered sequence of numbers that represent the digitized values of a signal. These digitized values are obtained by sampling the signal at regular time intervals ($t = T, 2T, 3T, \dots$) and transforming the sampled values into binary codes. In digital filters, present values $x(n) = x(nT)$ and past values $x(n-1) = x((n-1)T)$, $x(n-2) = x((n-2)T) \dots$ of both input and output signals are processed. The steps performed on these digitized values lead to an output sequence $y(n), y(n-1), y(n-2), \dots$, which can be transformed by means of a digital-to-analog converter into a filtered output signal $y(t)$. A digital filter is, therefore, an algorithm or sequence of mathematical steps that relates input and output sequences by means of multiplication, addition, and delay operations. A digital filter is mathematically characterized by a difference equation. There are two types of digital filters: finite impulse response (FIR) filters, where the current value of the output signal $y(n)$ depends only on the current and past values of the input signal; and infinite impulse response (IIR) filters, where the current value of the output signal depends also on past values of the output signal. For example, the difference equation of a second-order FIR

filter is expressed by

$$y(n) = a_0x(nT) + a_1x(n-1) + a_2x(n-2) \quad (3)$$

while the difference equation of a second-order IIR digital filter has the form

$$y(n) = a_0x(n) + a_1x(n-1) + a_2x(n-2) - b_1y(n-1) - b_2y(n-2) \quad (4)$$

where $a_0, a_1, a_2, b_1,$ and b_2 are multiplying coefficients; $x(n)$ and $y(n)$, stand for $x(t=nT)$ and $y(t=nT)$, are the current values of the input and output signals; and $x(n-1), x(n-2), y(n-1),$ and $y(n-2)$ correspond to the two previous values of the input and output signals, respectively. The values of the multiplying coefficients and the sampling frequency, $f_s = 1/T$, determine the selectivity and center frequency of the digital filter and can be easily reprogrammed. Figures 9a and 9b illustrate the block diagram of second-order FIR and IIR filters, respectively.

High-speed digital filters can be implemented using special-purpose VLSI hardware in the form of digital signal processors [6] or as relatively low-speed filters using software in general-purpose digital systems such as computers or microprocessors.

BANDSTOP FILTERS

CHIU H. CHOI
 University of North Florida
 Jacksonville, Florida

A bandstop filter (also known as *band-reject*, *band-elimination*, or *notch filter*) suppresses a band of frequencies of a signal, leaving intact the low- and high-frequency bands. A bandstop filter specification can be expressed as shown in Fig. 1. In the stopband from f_3 Hz to f_4 Hz, the attenuation is at least A_s dB. In the passbands (below f_1 Hz and above f_2 Hz), the maximum attenuation is A_p dB. The bands from f_1 to f_3 and from f_4 to f_2 are called the *transition bands*. The filter requirement is said to be geometrically symmetric if $f_1 f_2 = f_3 f_4$.

An approach to designing a circuit (a bandstop filter) with a frequency response that satisfies the bandstop requirements shown in Fig. 1 is described below. It consists of two steps: the approximation of the requirements by a transfer function and the synthesis of the transfer function.

In the approximation part of the design process, it is desirable to find a transfer function with a frequency response that satisfies the bandstop requirements. To find that transfer function, first convert the bandstop requirements into the normalized lowpass requirements. For the case that the bandstop requirements are symmetric, the corresponding normalized lowpass requirements are shown in Fig. 2. The normalized passband frequency $F_p = 1$ and the passband attenuation is A_p dB. The normalized stopband frequency is

$$F_s = \frac{f_2 - f_1}{f_4 - f_3}$$

and the stopband attenuation is A_s dB.

Figure 1. Bandstop filter specification.

Figure 2. Normalized lowpass requirements.

With such lowpass requirements, we can obtain the corresponding lowpass transfer function $T_{LP}(s)$. (See LOWPASS FILTERS for more information about how to obtain the transfer function.) The bandstop filter transfer function $T_{BS}(s)$ is obtained by making the transformation

$$T_{BS}(s) = T_{LP}(s) \Big|_{s = \frac{B_s}{s^2 + (2\pi f_0)^2}}$$

where B is the bandwidth of the bandstop filter defined as

$$B = 2\pi(f_2 - f_1)$$

and f_0 is the center frequency of the bandstop requirement defined as

$$f_0 = \sqrt{f_1 f_2} = \sqrt{f_3 f_4}$$

To use this method when the requirement is not symmetric for the case where $f_1 f_2 > f_3 f_4$, we form a more stringent requirement by either decreasing f_2 or increasing f_4 , so that the symmetrical condition is met. The bandstop transfer function that satisfies the new requirements must also satisfy the original requirements. In case $f_1 f_2 < f_3 f_4$, we either increase f_1 or decrease f_3 and then apply the same procedure.

A simple example is provided to illustrate this concept. For the bandstop requirements $A_s = 25$ dB, $A_p = 3.01$ dB, $f_1 = 1$ kHz, $f_2 = 100$ kHz, $f_3 = 8$ kHz, and $f_4 = 12.5$ kHz; the corresponding normalized lowpass requirements are $A_s = 25$ dB, $A_p = 3.01$ dB, $F_p = 1$, and $F_s = 22$. Choosing a single-pole Butterworth approximation, the lowpass transfer function for the normalized lowpass requirements is

$$T_{LP}(s) = \frac{1}{s + 1}$$

which meets the stopband requirements easily. The bandstop transfer function is obtained by the transformation

$$T_{BS}(s) = \frac{1}{S + 1} \Big|_{S = \frac{2\pi(100 \times 10^3 - 1 \times 10^3)s}{s^2 + (2\pi 100 \times 10^3)(2\pi 1 \times 10^3)}}$$

which simplifies to

$$T_{BS}(s) = \frac{s^2 + 3.948 \times 10^9}{s^2 + 6.220 \times 10^5 s + 3.948 \times 10^9}$$

Note that the single-pole lowpass function has been transformed to a two-pole bandstop function. The above bandstop transfer function is in the so-called biquadratic form, which is an expression of the form

$$\frac{s^2 + a_1 + a_2}{s^2 + b_1 s + b_2} \quad (1)$$

There are a number of ways to synthesize and biquadratic function as an active network, such as the Friend biquad circuit [1,5], the Boctor circuit [2], and the summing four-amplifier biquad circuit [3,5]. The Friend or Boctor circuit uses one operational amplifier. The summing four-amplifier biquad circuit is much easier to tune. When $a_1 = 0$, the Bainter circuit can be used. The Bainter circuit [4] is shown in Fig. 3. For higher performance circuits, see Ref. 5 for the description of different bandstop circuit topologies.

The transfer function is

$$\frac{V_{out}(s)}{V_{in}(s)} = \frac{s^2 + \frac{R_{12}}{R_{11}R_{21}R_{31}C_1C_2}}{s^2 + \left(\frac{1}{R_{31}C_1} + \frac{1}{R_{32}C_1}\right)s + \frac{1}{R_{22}R_{31}C_1C_2}}$$

Comparing with Eq. (1), we obtain

$$a_1 = 0, \quad a_2 = \frac{R_{12}}{R_{11}R_{21}R_{31}C_1C_2}$$

$$b_1 = \frac{1}{R_{31}C_1} + \frac{1}{R_{32}C_1}, \quad b_2 = \frac{1}{R_{22}R_{31}C_1C_2}$$

Choose $C_1 = C_2 = 1$, $R_{12}/R_{11} = K$, $R_{31} = R_{32}$. Solving for the other values, we obtain

$$R_{21} = \frac{Kb_1}{2a_2}, \quad R_{22} = \frac{b_1}{2b_2}, \quad R_{31} = \frac{2}{b_1}$$

The impedance scaling method can be used to scale the values of R and C into the practical ranges. In general, a higher-order bandstop transfer function can be factorized

Figure 3. Bainter circuit.

into a product of biquadratic functions. Each biquadratic function can be synthesized by using the Bainter or other circuits. By cascading all the circuits together, the bandstop filter is realized.

University of Central Florida
Orlando, Florida

1. INTRODUCTION

Since the late 1980s, the wireless communication market has expanded explosively mainly driven by increasing needs for high-performance, low-cost personal wireless communication equipments. Worldwide intensive research is being done in process technologies, circuit designs, system architectures, and communication standards to meet such demands. Technology advances in silicon germanium (SiGe) heterojunction bipolar transistors (HBTs) have created innovations in the semiconductor industry. The RF performance improvement of SiGe HBT by adding germanium to the base of the device will have a strong impact on modern radiofrequency integrated circuit (RFIC) design. Since IBM introduced the first commercial silicon germanium (SiGe) BiCMOS process in 1997, more and more SiGe products have emerged in the market, such as cellphones, wireless LAN, global positioning system (GPS) ICs, TV tuners, hard-disk-drive ICs, and optical carrier ICs. The estimated worldwide SiGe market growth is expected to exceed \$2.5 billion by the end of 2006 [1].

In this article, BiCMOS technology development focusing on the most recent achievements of SiGe BiCMOS technology is reviewed first. Several important figures of merit of SiGe device for RFIC designers such as f_T , f_{max} , BV_{CEO} (collector-emitter breakdown voltage with open base), and NF_{min} are discussed in detail. Next, from the RFIC designer's point of view, we begin with the stringent

system requirements of typical modern wireless communication standards. Commercial available technology options for RFIC are compared according to performance, power consumption, level of integration, and cost, with special emphasis on GaAs, RF CMOS, and SiGe BiCMOS. As a result, SiGe BiCMOS is an optimal device technology for implementing high-performance, low-power, and high-integration RFIC products. As important integration elements in the SiGe BiCMOS process, passive devices are also explored with respect to their impacts on RFIC design. This is expected to be followed by the design of key wireless system building blocks using SiGe BiCMOS technology. The most recently reported results of SiGe low-noise amplifiers (LNAs), power amplifiers (PAs), and integrated voltage-controlled oscillators (VCOs) are reviewed. Finally, future trends of RF integrated system adopting SiGe BiCMOS technology are discussed with respect to SiGe HBT technology (e.g., SiGe:C), integration level [e.g., RF SoC (RF system on chip)], and performance of on-chip passive devices (e.g., substrate transfer techniques).

2. BiCMOS DEVICES

It is well known that bipolar devices offer superior performance attributes for analog and RF circuits compared with plain CMOS [2]: more reliably modeled, less component variation, exhibiting better device-to-device matching, lower noise, increased bandwidth, easier matching to off-chip RF passive components, higher gain for a given layout size and power consumption level, and greater transconductance for a given current level. CMOS devices are also preferred because of their excellent switching performance with very high OFF-state resistance and lack of voltage drop when in the ON state. BiCMOS is a technology combining MOSFETs and bipolar devices into integrated circuits, which was proposed as early as 1969 [3]. Since then, BiCMOS technology has been applied to digital logic applications, which utilize the characteristics of high-speed bipolar and low-power CMOS on the same chip and RF and mixed-signal applications, which utilize bipolar RF and analog performance and CMOS digital integration capability. But as CMOS power supply voltage scaled down, the performance gap between bipolar and CMOS in digital logic began to narrow. Consequently, since the early 1990s there have been very few reports on developing BiCMOS for digital applications [4]. As

Figure 1. Engineered band diagram of SiGe HBT [6].

inspired by performance improvement of GaAs technology using heterojunction structure, germanium is introduced to the base of silicon BJT to form silicon germanium (SiGe) heterojunction bipolar transistors (HBTs) with enhanced RF performance. Since SiGe-based BiCMOS technology is currently a topic of great interest for research and wireless products development, our discussions will focus mainly on SiGe BiCMOS technology and its impact on RFIC design.

Table 1 demonstrates technology milestone for SiGe BiCMOS early development in IBM, a leader in SiGe BiCMOS technology. After that IBM introduced the first commercial silicon germanium (SiGe) BiCMOS process in 1997.

The essential operational differences between the SiGe HBT and the Si BJT are best illustrated by considering a schematic energy band diagram (Fig. 1). Two approaches are generally applied [7]. In the first approach, a graded germanium profile creates an electric field in the base region to accelerate the carriers that are diffusing from the emitter to the collector junction. In the second approach, the mobility of the minority carriers is increased in the base and the base resistance is reduced. Both approaches result in a higher f_T and lower base resistance.

A scanning electron microscopy (SEM) cross-sectional view of a 0.2- μm self-aligned selective epitaxial growth (SEG) SiGe HBT by ultrahigh vacuum/chemical vapor deposition (UHV/CVD) is shown in Fig. 2 [8], including an enlarged view of the active region, the key part of the SiGe HBT.

Device parameters such as f_T , f_{max} , NF_{min} , and BV_{CEO} are important figures of merit considered by RFIC designers for specific applications. f_T (short-circuit unity current

Table 1. SiGe BiCMOS Technology Early Development History from IBM Onward

Year	Key Technology
1982	UHV/CVD growth technique developed
1986	UHV/CVD epitaxial base silicon transistors fabricated
1987	SiGe based HBTs fabricated using MBE
1988	Graded-base SiGe polyemitter HBTs demonstrated, utilizing learning of double-polysilicon bipolar transistors
1993	Analog LSI circuit (1 gbps, 12 bits DAC) demonstrated, utilizing CMOS base processing
1993	SiGe HBTs with $f_T > 100$ GHz fabricated
1994	BiCMOS process in 200-mm CMOS fabricated, aligning processing with CMOS base
1996	RF technology with passive components, models, and design kit

gain frequency) and open emitter) to influence the dynamic range of device operation. The product of f_T and BV_{CEO} is referred to as the *Johnson limit* [12], which is an important figure of merit for high-frequency device. Many commercial foundries offer SiGe HBTs with several different BV_{CEO} values by using selective collector implantation optimized for both high-speed and wide-dynamic-range applications. We will discuss it later in SiGe RFIC power amplifier design.

Table 2 summarizes major SiGe HBT figures of merit that are important for RFIC applications. In addition, as with CMOS technologies, progressive vertical and lateral scaling of SiGe HBT results in better performance at lower power as indicated in Table 2.

Compared with III-V technologies, SiGe HBTs based on silicon substrate can inherently integrate with silicon CMOS, and standard silicon CMOS processes are by far one of the cheapest IC processing technologies available. Obviously, it is a cost-effective and processing-compatible way for SiGe BiCMOS processes to integrate the SiGe HBT into existing silicon CMOS core processes. That's exactly the method adopted by successful SiGe BiCMOS foundries. Historically, two different integration approaches have been used in SiGe BiCMOS processes [13]:

Table 2. IBM SiGe HBT Development across Four Generations

Parameter	0.5 μm	0.25 μm	0.18 μm	0.13 μm
Beta	100	100	200	400
V_A (V)	65	75	120	> 150
BV_{CEO} (V)	3.35	3.35	2.5	1.9
BV_{CBO} (V)	10.5	10.5	7.5	6
Peak f_T (GHz)	47	47	120	210
Peak f_{max} (GHz)	65	65	100	185
NF_{min} (dB)	0.8	0.8	0.4	< 0.3

base-during-gate (BDG) integration and base-after-gate (BAG) integration. In the former approach, the HBTs are fabricated during the CMOS process (e.g., the IBM 0.5- μm SiGe BiCMOS process). In BAG, the HBTs are fabricated after the CMOS process to decouple the CMOS thermal cycle from the bipolar (e.g., IBM 0.25- and 0.18- μm SiGe BiCMOS) processes. The BAG approach is used in the most advanced SiGe BiCMOS technology such as 0.25 and 0.18 μm generations because it's difficult to fabricate HBT during a high thermal cycle of CMOS in these generations. f_{max} (maximum unity power gain frequency) are the parameters determining the frequency bandwidth of the device. f_T and f_{max} have been significantly improved over 200 GHz in the state-of-art SiGe BiCMOS 0.13- μm generation as shown in Fig. 3 [9].

In practical design, a good rule for high-quality RFIC design is $f_{design} < \frac{1}{10}f_T$. According to this rule, when f_T is over 200 GHz, SiGe HBT can be used for ultra-high-speed optical network applications that were previously the realm of III-V technologies.

The *noise figure* (NF), a standard metric of system noise performance, is defined as the degradation of signal-to-noise ratio (SNR) of an input signal as it passes through the system; NF is minimized when the device is presented with an optimized source reactance. A simplified formula for a SiGe HBT device is given as [6]

$$NF_{min} = 1 + \frac{1}{\beta} + \sqrt{2g_m r_b} \sqrt{\frac{1}{\beta} + \left(\frac{f}{f_T}\right)^2} \quad (1)$$

where β is the device current gain, g_m is the device transconductance, r_b is the base resistance, and f is the operation frequency. From this formula, the key to lower the noise figure is to reduce r_b and increase f_T [6]. Most recently reported SiGe transistors have $f_T > 350$ GHz [10] and $NF_{min} \leq 0.4$ dB at 10 GHz [11].

BV_{CEO} refers to the collector-emitter breakdown voltage with an open base. This parameter is quoted in device specifications of IC technology together with BV_{CBO} (collector-base breakdown voltage with an Passive elements such as inductors, capacitors, and resistors are also integrated into a typical SiGe BiCMOS process. Metallization and back-end processing in IC processes produce several metal layers utilized to build these passive components. A

Figure 3. SiGe HBT f_T/f_{max} improvement across generations [9].

Figure 4. SEM cross section of a SiGe BiCMOS processes [8].

SEM cross-sectional view of a SiGe BiCMOS processes with the passives and metallization is shown in Fig. 4 [8]. High-quality-factor (Q) on-chip passive components are difficult to acquire in silicon substrate technology compared with III–V technology because of high silicon substrate loss. For example, it has been particularly challenging to achieve integrated inductors with Q values of 15–20 in the silicon process. Typical Q values for inductors in standard BiCMOS process can maximally reach about 10 (for inductances > 1 nH) [13]. In modern advanced SiGe BiCMOS processes, two types of methods are usually adopted to improve the performance of integrated inductors by decreasing metal series resistance and reducing substrate loss effects [14]: (1) additional thick top metal layer, copper metallization, deep-trench isolation, lightly doped substrate and (2) thick dielectric between inductor and substrate. Improved performance of passives in the IBM 0.18- μm SiGe BiCMOS process can be found in Table 3 [15]. We will discuss passive components for RFIC design using SiGe BiCMOS technology in Section 3.3.

3. BiCMOS RADIOFREQUENCY INTEGRATED CIRCUIT DESIGN

In the late 1980s, the first CMOS baseband analog and digital chips for the first-generation GSM (Group Special Mobile, now known as Global System Mobile) were fabricated in a 1.2- μm CMOS technology. Together with the progress of silicon bipolar technology (cutoff frequency f_T above 10 GHz) and worldwide spread use of mobile digital phones, a new and exciting area, radiofrequency integrated circuit (RFIC) technology, was created [7]. RF design moved from the PCB (printed circuit board) with discrete components to large-scale integration in silicon technology. Until recently, single-chip radio integration capabilities based on SiGe BiCMOS technology have been demonstrated [9]. A true single-chip radio supporting multiband, multistandard, and broadband communication may not just be a dream in the near future.

As stated above, RFIC is a relatively new area in contrast to other types of analog or microwave circuits. RFIC design has borrowed from both analog design techniques used at low frequencies and high-frequency design techniques used at microwave frequencies. However, RFIC design as a multidisciplinary area requires knowledge of many other areas besides integrated circuits, such as semiconductor device physics, wireless communication standards, signal and communication theory, microwave engineering, and system architectures.

From the circuit designer point of view, well-developed low-frequency analog circuit design and analysis techniques are fundamental knowledge references. Classical circuit building blocks can be used as prototypes or starting references for RFIC design. S parameters, shielding, impedance matching, and standing-wave ratios, which are important microwave system design concepts, are not totally but partially adopted in RFIC design. With the increasing of integration level of RFIC, new RFIC design has gradually acquired its own features [7]. The 50- Ω impedance matching culture has been stepped away. SPICE-like tools and system-level simulation packages including noise analysis have been adopted for highly integrated RFIC due to high-frequency substrate crosstalk and parasitic coupling.

3.1. Representative Wireless System Requirements

The rapidly growing commercial wireless personal and data communication market has been the strongest force driving the rapid development of RFIC technology. Since the early 1980s, the industry has undergone several generations of revolutionary changes. Figure 5 [16] schematically presents the scope of RFIC technologies in terms of the interplay among commercial wireless communication applications, available spectrum, and the kinds of elemental and compound semiconductors likely to be used.

From Fig. 5, we can find that modern RFIC designers are confronting with a wide range of system requirements with respect to different kinds of wireless applications. Table 4 compares some important specifications of several representative wireless communication standards.

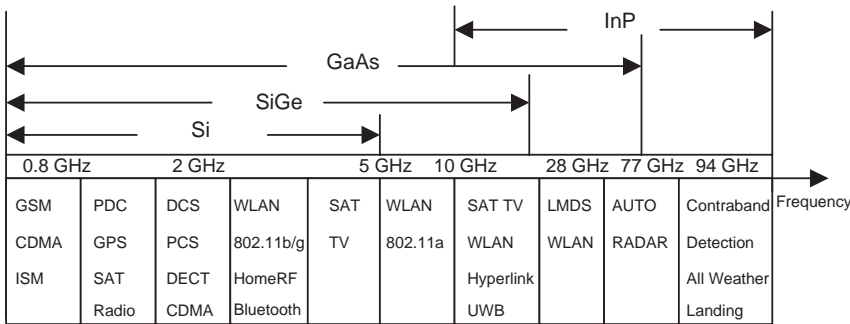

Figure 5. Commercial wireless communication applications [16].

It is clear that application-orientated system specifications vary in frequency, transmitter output power, receiver minimum sensitivity, and modulation schemes. In order to address such a broad application market, RFIC designers must satisfy constraints of not only performance but also flexibility and cost.

3.2. Technology Trends and Options for RFIC

Semiconductor technologies commercially available for RFIC design can be categorized as silicon and III–V compounds according to substrate type. Several semiconductor devices are based on these materials, including the silicon bipolar junction transistor (Si BJT), SiGe HBT, RF CMOS, GaAs metal semiconductor field-effect transistors (MESFETs), and GaAs and InP high-electron-mobility transistors (HEMTs). Each type of device has its own advantages or disadvantages as shown in Table 5.

Table 5 lists the key figures of merit normally considered by RFIC designers for various RF application standards. Obviously, no device technology does well in everything. Fortunately, different RF components require different device parameters. For example, the low-noise amplifier (LNA) needs devices with low-noise characteristics, the voltage-controlled oscillator (VCO) employs devices with low $1/f$ noise, and the power amplifier (PA) requires devices with high output power and high breakdown voltage. As a result, commercial wireless transceivers typically utilize a combination of different device technologies.

From the early 1980s, GaAs-based III–V compound technology has been the choice for RF and microwave applications because of their high level of performance for

GHz (gigahertz-range) frequency. Compared with silicon, they have higher electron mobility and saturation drift velocity, which means high device speed and a low noise figure. Because they are wide-bandgap materials, they also have high breakdown voltage, which is useful in high-power applications. The semiinsulating property of the III–V materials provides high device isolation and low dielectric loss for high-frequency integrated circuits. This property also decreases the loss of integrated passive components. The increased quality factor of passive elements can greatly improve the performance of the overall RF system. However, III–V technologies also suffer from inherent problems such as cost, integration level, and reliability issues. The III–V material wafer is normally smaller and more expensive than silicon. In addition, much effort should be taken to reduce leakage current and increase uniformity and yield. The overall high cost of III–V compounds is a tradeoff for their high performance.

Advances in silicon bipolar technology in the late 1980s, particularly in increasing the cutoff frequency, created an epoch in silicon RFIC. Some low-GHz RF front-end building blocks formerly implemented in GaAs technology have been replaced by silicon bipolar devices, while GaAs is still employed for low-noise amplifiers, power amplifiers, and RF switching, which belong to the high-frequency area near the antenna. But the vertical diffusion depth of base and the mobility of carriers in silicon set a limit of 30 GHz cutoff frequency for the bipolar transistor, which confines this bipolar component to the low-GHz front-end and analog mixed-signal area [7]. As discussed before, inspired by the heterobipolar approach in GaAs technologies, the SiGe HBT was introduced as an enhanced bipolar approach with superior RF performance.

Source: Refs. 6 and 17.

Several practical RFIC design advantages for SiGe HBT are summarized as follows [18]:

- Low DC power consumption
- High breakdown voltage
- Improved noise performance with higher f_T and lower r_b
- Superior performance in 1/f noise characteristics over MOSFETs and MESFETs
- Higher early voltage V_A and βV_A
- Improved linearity over that in SiBJTs

With RF performance comparable to that of GaAs technology, LNA and PA, high-RF performance demanding blocks have been designed using SiGe technology rather than GaAs technology. We will investigate such a trend in detail later in this article. Besides the abovementioned high device performance, SiGe HBT can potentially be integrated with CMOS on the same silicon substrate (SiGe BiCMOS). This high integration ability creates the possibility of implementing a true single-chip RF system.

In the mid-1990s, at approximately the same time when SiGe HBT technology emerged, and driven by the tendency of increasingly shrinking microprocessor size, the scaling of CMOS resulted in marked improvement in RF performance at submicrometer feature size. Consequently, CMOS has become a viable option for RFIC design. Foundries also provide RF CMOS process optimized for RF applications [19]. But RF CMOS technology achieves the same performance level using novel circuit techniques, which may need higher power consumption or larger chip die size compared with SiGe BiCMOS.

The optimum technology option for RFIC in terms of performance, cost, and market is the first line for successful RFIC product developments. But for practical RFIC designers, this is always complicated by various application performance requirements (Table 4) regarding different building blocks, various device characteristics (Table 5), system cost, and market factors. For a whole RF system, a combination of technologies may achieve optimum system performance and cost compromise. In addition, this multidimensional decision function is strongly related with the development of device, circuit, and sys-

tem technology. The cost of SiGe BiCMOS technology will be gradually lowered with its wider applications. Combining performance, integration, and cost advantages together, SiGe BiCMOS should be one of the most promising technologies for RFIC design.

3.3. RFIC Passive Design in SiGe BiCMOS Technology

Passive components also play important roles in RFIC design. To reduce board-level components, passive devices should be integrated on chip as active devices. Integrated inductors, capacitors, varactors, and resistors have been developed based on the existing SiGe BiCMOS fabrication processes while avoiding any significant process alterations.

3.3.1. Inductor. RFIC designs require high-performance passive components, particularly the on-chip inductors. Integration of spiral inductors has numerous challenges. In particular, high Q (inductor quality factor), high self-resonance frequency, and low cost must be balanced in order to provide a competitive inductor. Circular and rectangular spirals are two popular shapes for on-chip inductors. The circular spiral is known to provide somewhat higher Q , while the rectangular version is more area-efficient [20]. For both of these inductor configurations, the bulk of the spirals are usually implemented in the topmost available metal, and connection to the center of the spiral is made with a crossunder of some lower level of metal.

Losses in inductors are due primarily to currents flowing in the inductors. Substrate and radiation losses also exist. The quality factor Q and the self-resonance frequency are the most common figures of merit. Q is used to describe loss performance of inductors. Many factors can influence the Q value, such as operating frequency, conductor metal conductivity, substrate resistivity, and geometric characteristics of inductor [21,22]. Q is frequency-dependent, increasing with the frequency up to a peak value, and drops at higher frequencies, owing to the fact that the reactance of input impedance dominated by the inductance at lower frequency rolls off at higher frequency because of the parasitic capacitances, which consist of the overlap capacitance between the spiral and underpass,

fringing capacitance between adjacent metal lines, and substrate capacitance between metal layer and grounded substrate.

In practical integrated inductor design, the geometric characteristics, such as linewidth, line spacing, number of turns, and inner diameter, should be carefully chosen to optimize the inductor Q at operating frequencies. The rise of Q is usually found with increasing linewidth, while there is no wide variation in inductance. This is because of the fact that the resistance of inductor decreases with increasing linewidth. The inner diameter also affects the inductor Q . The contribution of innermost turn to the total inductance is very small. The main effect of the innermost turn is on resistance. For this reason, hollow spirals are commonly used in RF applications to increase the Q factor. Increasing the number of turns of a given inductor always yields higher inductance. This increase in inductor design, as the increase of linewidth, spacing between the turns, or the inner diameter, may result in larger area. Usually, the larger the area, the higher the parasitic capacitance, and the lower the self-resonance frequency. Therefore, it is important to ensure that the self-resonance frequency is beyond the operating frequency range.

3.3.2. Capacitor. Besides inductors, capacitors with high Q at the operating frequency are also essential for the integration of RF circuits. The design goal is to achieve both a small series resistance for a high Q and a high capacitance/area ratio to minimize the area consumption. Three basic types of capacitors have been developed in SiGe technology: MOS (polysilicon gated capacitors on single-crystal silicon), PIP (polysilicon-insulator-polysilicon), and MIM (metal-insulator-metal)/MOM (metal-oxide-metal) capacitors. Each has its own place for use in different application spaces depending on capacitance desired and performance at the application frequency.

MOS capacitors are simply built from the gate oxide. These devices consist of silicided gate polysilicon, thin gate oxide, and FET well-doped silicon. They have the highest capacitance density among all the capacitors owing to the ultrathin oxide. But the Q value of these capacitors is relatively poor because of the high resistance of the doping. PIP capacitors are fabricated in double-polysilicon BiCMOS processes [23]. The capacitor structure is formed using p^+ -doped gate polysilicon as the bottom plate, a deposited oxide layer for the capacitor dielectric, and silicided extrinsic base polysilicon as the top electrode. The drawback of MOS and PIP capacitors is low quality factor (Q) due to high-resistance plates and capacitive losses at RF frequencies. This limits their use at RF. They are typically used for power supply bypass and decoupling. In contrast, MIM or MOM capacitors can be built using two interconnect layers with a very small series resistance for high Q . These capacitors are achieved by using a thin oxide film to form the capacitors in place of the thick intermetal dielectrics. MIM or MOM capacitors are preferred in narrowband applications, such as resonators, filters, and tank circuits, where high Q is needed [24].

3.3.3. Varactor. Voltage-variable capacitors (varactors) are required for tuning circuit designs, such as voltage-controlled oscillators (VCOs) for on-chip carrier frequency generation. The key figures of merit for varactors are (1) tunability (C_{\max}/C_{\min}), (2) C_V linearity for VCO gain variation, (3) quality factor Q , (4) tolerance, and (5) capacitance density. Two basic types of varactors are supported by SiGe BiCMOS technology: MOS varactors and junction varactors.

An accumulation-mode MOS varactor is achieved by connecting the drain and the source only, while adding the control voltage on the bulk [25]. The capacitance of this varactor is high in accumulation and decreases sharply as the device enters and goes further into depletion. This results in excellent tunability. However, it has the drawback of a narrow range across which the capacitance varies significantly from a low value to a high value. This in turn could limit the tuning range of the VCOs based on such varactors. Junction varactors are offered as an alternative to provide wider capacitance variation range and also more linearity. The collector-base (CB) junction varactor provides wider capacitance variation while maintaining a relatively high Q .

3.4. Wireless System Key Building Blocks

Figure 6 gives us a general view of RF heterodyne transceiver system. Some important building blocks that are necessary in all types of transceiver are listed in Table 6, with their main features and technology requirements. During practical RFIC design, several tradeoffs must be made under product performance and cost constraints. These tradeoffs have been summarized in the “RF design hexagon” as shown in Fig. 7 [26]. We will discuss some tradeoffs in the design of each building block.

3.4.1. Low-Noise Amplifiers (LNAs). The LNA is one of the key building blocks in the RF system. In the receiving chain closest to the antenna, the LNA receives a variety of signals coming from the antenna, and its function is to boost the signal without adding much noise. Since the LNA is at the first stage of receiving chain, its noise performance is the most critical for the entire receiver. Because of the wide amplitude range of the receiving signal, low noise and high linearity are both important figures of merit for LNA design [27]. The third-order input intercept point (IIP3) is the most common parameter used to measure circuit linearity by applying the two-tone test. The noise figure (NF) is often used to measure system noise performance. Application-dependent system specifications such as minimum detectable signal (MDS) or minimum sensitivity and spurious-free dynamic range (SFDR) can be determined from IIP3 and NF [26].

From the perspective of LNA designers, a seemingly simple structure with a few components means easy design, but the tradeoffs complicate the design. A matching network needs to be designed to satisfy both noise and power matching. The progressive decrease of supply voltage and maximum allowed power consumption with an almost constant dynamic range requirement of the system leads to great challenges in modern LNA design.

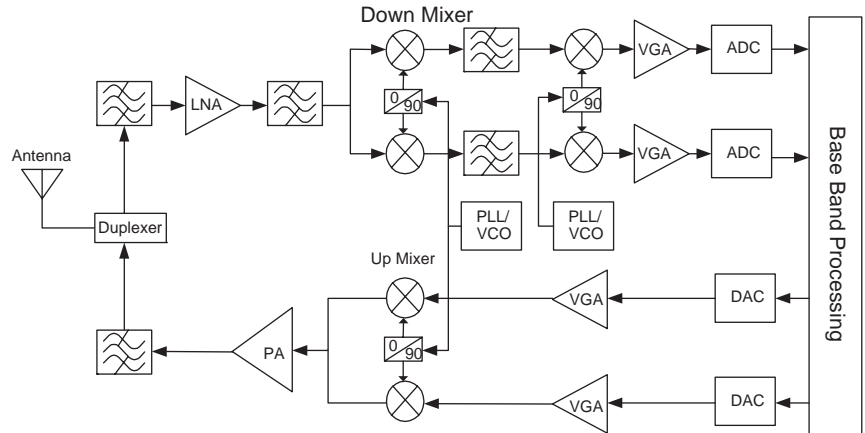

Figure 6. A general RF transceiver system.

Additionally, the LNA must provide enough gain to decrease the noise contributions from the following stages and consequently minimize the overall system noise. However, maximum gain is often limited by system linearity performance [28].

Noise figure (NF), DC power consumption (P_{DC}), power gain, and IIP3 are the most important design considerations for the LNA. They can be summarized into two figures of merit: $gain/(P_{DC} \cdot NF)$ and $IIP3/P_{DC}$. The results of comparing these two parameters for the best reported results in silicon and GaAs technology at 2 GHz [29] have indicated the potential advantage of SiGe technology for LNA, if DC power dissipation is a major consideration.

Table 7 summarizes the most recently reported results of RF LNA using SiGe BiCMOS technology, demonstrating a competitive noise figure and linearity compared with GaAs technology for various wireless applications.

3.4.2. Power Amplifier (PA). The power amplifier is the last building block in the transmitter chain of a transceiver system. Its function is to amplify the signal power to a level that is high enough for signal propagation through

an appropriate antenna into the air. It is one of the most challenging building blocks in a transceiver system.

The typical figures of merit of a practical power amplifier are efficiency, linearity, output power, ruggedness, and power gain. The most commonly used metric for efficiency is power-added efficiency (PAE), which indicates how power drawn from the supply is efficiently converted to RF power delivered to the load. The linearity of PA is usually specified as an adjacent-channel power ratio (ACPR) in dBc (decibels with respect to carrier), a measure of the spectral “spillover” due to amplifier nonlinearity into an adjacent frequency band by a digitally modulated waveform. Ruggedness is the ability to survive power mismatch conditions at the output using specific DC and RF drive conditions. Output power is defined by a wireless standard (see Table 4) and often exhibits a wide range of variation for mobile applications. Power gain is implicitly set by the maximum power generated by the preceding stage of the power amplifier together with output power requirements [37].

The linearity varies with different signal modulation schemes employed by different wireless standards (see

Table 6. Features and Requirements for Basic Wireless Building Blocks

Building Blocks	Main Features	Technology Requirements
LNA	Low-noise figure Gain per stage High linearity	Low NF_{min} , low HBT R_b High early voltage High f_T/f_{max}
Mixer	High linearity High port isolation Carrier leakage	High early voltage High f_T/f_{max} Isolation technologies (DT) Small mismatch
VCO	Low-phase noise	High-Q passives farther from carrier Low- $1/f$ -noise HBT closer to carrier Varactor tuning range (C/V)
Synthesizer	Tuning range (frequency/V) Low gain (K_v) variation Low-phase noise Low reference spurs Power consumption Chip area	Same as VCO Small FET asymmetry Small gate length for low supply operation Reduced area
PA	Power-added efficiency Gain per stage Robustness	Low loss matching and interconnect circuits (high-Q inductor, thick metal) Maximum available gain HBT High-breakdown-voltage HBT

Source: Ref. 15.

Figure 7. RFIC design hexagon [26].

Table 4). For wireless standards such as GSM, DECT, and Bluetooth employing constant envelope modulation schemes, nonlinear power amplifier (classes C, D, E, and F) can be used. For other wireless standards such as WLAN and WCDMA employing variable envelope modulation schemes, linear power amplifier (class AB) is typically used. Linearity can be a tradeoff with power-added efficiency in a practical power amplifier design, where nonlinear amplifiers often achieve higher efficiency than do linear ones [37].

In a practical RF power amplifier design several challenges are presented [29]. The PA must satisfy all the figures of merit discussed above under the constraint of cost for specific applications; the current trend toward decreased power supply (from 5 to 3 V and even lower) has also made it difficult to maintain the required output power and efficiency due to impedance matching limitations; power-added efficiency should not degrade significantly with a wide range of output power.

Key device figures of merit for RF power amplifiers are f_{\max} (bandwidth and high power gain), linearity, and breakdown voltage. Currently available technologies for RF commercial power amplifier are GaAs, SiGe, and CMOS. Because of the high linearity, efficiency, output power, and breakdown voltage, GaAs has been the dominant technology for the RF power amplifier since the early 1990s. However, GaAs amplifiers have the disadvantages of relatively high cost, low substrate thermal conductivity, and low integration ability with CMOS technology. More recent SiGe HBT technology with high f_{\max} , improved ruggedness, high linearity, and relatively high breakdown voltage has made SiGe a technology contender for RF power amplifier applications. As discussed before, SiGe devices can be engineered to have even higher breakdown voltage but with the compromise of lower f_{\max} . In portable wireless applications, a progressively reduced power supply makes breakdown voltage less critical, where SiGe can

be a good choice [29]. In addition, SiGe BiCMOS provides the ability to integrate the power amplifier with some related logic power amplified functions (implemented by CMOS). High-quality passive components offered by commercial SiGe BiCMOS processes enable the manufacture of fully integrated RF power amplifiers, including on-chip impedance matching and filtering.

The power amplifier is probably one of the last building blocks to be integrated into a single radio chip. By far, the only reported real single radio chip including PA is Bluetooth [38], which is a relatively low-RF performance demanding wireless standard.

More recently a significant amount of research effort has been taken to design RF power amplifiers using SiGe BiCMOS technology (see Table 8), which have demonstrated competitive power efficiency and linearity compared with GaAs technology for various wireless applications.

3.4.3. Integrated Voltage Controlled Oscillator (VCO).

The voltage-controlled oscillator (VCO) is a very important building block in the RF system and is often integrated into a phase-locked loop (PLL) or frequency synthesizer to serve as a frequency reference in a transceiver system [47]. For example, it is used as a local oscillator together with a mixer to downconvert the received RF signal to an IF signal. Typical figures of merit for VCO are frequency of oscillation, phase noise, frequency tuning range, output power, gain variation, and thermal stability. Phase noise is perhaps the most important characteristic of a VCO. Ideally, a VCO output signal is expected to have all signal power concentrated in one discrete frequency; however, all practical VCOs suffer from spectrum impurity. *Phase noise* is any noise that changes the frequency or phase of the oscillator signal and is usually specified in dBc/Hz, meaning noise power in a 1 Hz bandwidth with respect to carrier power.

A good equation for relative phase noise of a VCO can give us some insight into its function [48]:

$$\frac{1}{4Q^2} \left(\frac{\Delta\omega}{\omega_0} \right)^2 \frac{P_{\text{noise}}}{P_{\text{carrier}}} \quad (2)$$

Here, Q is the open loop quality factor, $\Delta\omega$ is the frequency offset, ω_0 is the center frequency, P_{noise} is the spectral density of each noise source, and P_{carrier} is the spectral density of the carrier. From this equation, there are several rules for decreasing the phase noise: (1) use high- Q passive components, (2) maximize the oscillation

Table 7. Some Recently Reported SiGe BiCMOS LNAs Compared with GaAs LNAs

Technology	Frequency (GHz)	Noise Figure (dB)	Gain (dB)	IIP3 (dBm)	Power Dissipation (mW)	Ref.

swing, and (3) minimize the number of active and lossy passive devices in the oscillation path. Consequently, high- Q passive components such as inductors and varactors are critical limiting factors for the performance of VCO. Fully integrated VCO suffers from low-quality on-chip inductors and varactors. In addition to phase noise, frequency tuning range and VCO gain variation parameters also require high-quality passive components. Because of the lower $1/f$ noise of SiGe HBT compared with that of GaAs or Si CMOS, SiGe HBT is preferred for $1/f$ noise-sensitive circuits such as VCO. As discussed previously, more recent advances of SiGe BiCMOS passive device technology have greatly increased VCO performance. Table 9 summarizes the most recently reported VCO design using SiGe BiCMOS and GaAs technology.

4. FUTURE TRENDS

According to ITRS (International Technology Roadmap for Semiconductors) 2003 [16], the challenges for future RF transceivers using BiCMOS technology include the following: aggressive scaling of passive elements (capacitors and inductors); reducing the cost of BiCMOS technology while improving power and performance tradeoffs; improving signal isolation as more functions are integrated on a single chip; increasing difficulty with integrating bipolar devices in aggressively scaled CMOS nodes due to conflicting thermal budget requirements; improving the performance of active devices to levels that enable reconfiguration of the RF transceiver in a software-defined radio, a funda-

mental architectural simplification of the RF transceiver such as the direct synthesis and/or direct analog-to-digital conversion of the RF signal; enabling the scaling of bipolar power supply to reduce power consumption versus CMOS technology; and integrating new materials in a cost-effective manner to realize the high- Q inductors and high-density metal-insulator-metal (MIM) capacitors.

Future challenges can be summarized as follows: SiGe HBT device performance improvement, RFIC design technique development, and on-chip passive component performance and isolation enhancement.

4.1. SiGe HBT Device Performance Improvement

Carbon doping of SiGe HBTs (SiGe:C) is rapidly becoming the preferred approach for commercial SiGe technologies as a means to effectively suppress boron outdiffusion during fabrication [6], consequently facilitating management of the overall thermal budget and profile control. Continuous lateral and vertical scaling, novel device structure design, and improved fabrication techniques will further enhance SiGe HBT peak f_T and f_{max} . Improved device performance has led to optical and communication applications at frequencies greater than 20 GHz. The further increased performance of SiGe HBT also makes it possible to design a reconfiguring RF transceiver in a software-defined radio, which implements most of RF functions in the digital domain.

4.2. RFIC Design Technology Development

RF system-on-chip (RF SoC) usually means that RF analog/digital circuits are all integrated with memory blocks

Table 9. Some Recently Reported SiGe BiCMOS VCOs Compared with GaAs VCOs

Technology	Frequency (GHz)	Tuning Range (GHz)	Phase Noise	Power Supply (V)	Power Dissipation (mW)	Ref
GaAs HBT	5	0.290	– 118 dBc/Hz at 1 MHz	3.5	13.2	49
0.35 μmSiGe	4.7	0.509	– 107 dBc/Hz at 1 MHz	3	54	50
0.35 μmSiGe	11	0.5	– 85 dBc/Hz at 100 kHz	3.3	N/A	51
0.35 μmSiGe	47	7.05	– 104 dBc/Hz at 1 MHz	5.5	290	52
0.25 μmSiGe	2.3	N/A	– 102 dBc/Hz at 100 kHz	3	15.6	53
0.35 μmSiGe	20	0.600	– 85 dBc/Hz at 1 MHz	3.6	43.2	54
0.4 μmSiGe	28	4.1	– 84.2 dBc/Hz at 1 MHz	5	129	55
0.18 μmSiGe	6/9	0.3/0.45	– 106 dBc/Hz at 1 MHz/ – 104 dBc/Hz at 1 MHz	1.8	19.44	56

Figure 8. Highly integrated SoC solution using SiGe BiCMOS technology [9].

and microprocessors as a single-chip radio. High integration ability with superior RF performance has made SiGe BiCMOS a preferred choice for future RF SoC implementations [18]. IBM has demonstrated a highly integrated SoC design using 0.18- μm SiGe BiCMOS technology [9] (see Fig. 8). Multistandard and multiband wireless handsets employing RF SoC technique will not be a dream in the near future. Future developments of RFIC CAD techniques may change the RFIC design methodology to digital cell library-like designs (see Fig. 9) [57]. After picking up existing RF/analog cell libraries or IPs (intellectual properties) for different building blocks (e.g., LNA, PA, VCO) according to various applications (e.g., GSM, CDMA), future RF system designers can simply assemble them together to functionalize the whole system. Consequently, RFIC design will be an easy and quick instead of

tedious and complicated process. Available highly accurate RF/analog models that support scaling will enable RF SoC simulations, including all on-chip coupling parasitic effects.

4.3. On-Chip Passive Component Performance and Isolation Enhancement

The performance of active devices has been improved significantly, as discussed earlier. In contrast, relatively slow development of passive components will be the key bottleneck in the future RFIC designs. This is mostly the result of high RF loss of silicon substrate, which leads to not only low- Q passive devices but also large coupling through substrates. A lot of research has been done on substrate technologies for RF applications. A good review of modern substrate transfer techniques for RFIC, such as silicon-on-insulator (SoI), silicon-on-glass (SoG), and silicon-on-anything (SoA) is given in Ref. 58. Micromachining techniques have also been applied to RFIC to produce high-performance passive devices [59].

5. CONCLUSION

In this article, we have reviewed the advances of SiGe BiCMOS technologies. SiGe BiCMOS technology has exhibited many advantages over other existing RF semiconductor technologies, such as III-V compounds and RF CMOS, which will have a strong impact on future RFIC design. RFIC designs using SiGe BiCMOS technology are discussed in terms of passive components and some key RF building blocks. Future trends of RF integrated system adopting SiGe BiCMOS technology are also summarized.

BIOLOGICAL EFFECTS OF RADIOFREQUENCY ENERGY AS RELATED TO HEALTH AND SAFETY

KENNETH R. FOSTER
University of Pennsylvania
Philadelphia, Pennsylvania

1. BIOLOGICAL EFFECTS OF RADIOFREQUENCY FIELDS—AN ONGOING CONTROVERSY

The biological effects of radiofrequency (RF) and microwave energy is a large and heterogeneous subject that spills over into biophysics, medicine, and engineering—and more recently, epidemiology, risk assessment, law, and public policy. The primary scientific literature on biological effects of RF fields contains several thousand papers, including many written in the 1960s or before.

This article examines biological effects of RF fields (3 kHz–300 GHz) with emphasis on potential hazards,

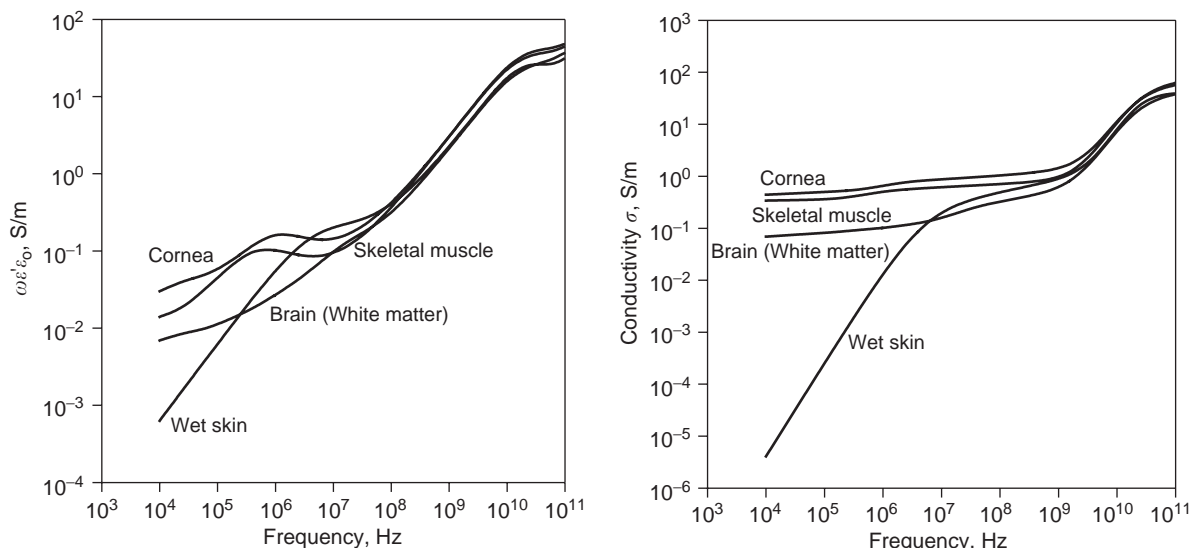

Figure 1. Dielectric properties of selected tissues: conductivity Φ and $\omega\epsilon'\epsilon_0$ (both in S/m) of selected tissues at 37°C. (Data from Ref. 2.)

specifically, effects that a person would perceive as adverse to health and safety. Its approach is tutorial rather than comprehensive, and its perspective follows that of major international exposure limits [established by IEEE and ICNIRP (International Committee on Non-Ionizing Radiation Protection)]. Its main emphasis will be on unequivocal effects that are potentially hazardous, which are principally thermal in nature. A concluding section will review major areas of controversy. Issues related to electromagnetic compatibility, for example, the interaction of RF fields with medical devices, are excluded from discussion. Additional sources are included in an annotated bibliography (see Further Reading section following the numbered references list).

2. EXPOSURE AND DOSE

In toxicology, *exposure* is the concentration or a potentially toxic agent in the external environment of a subject, and *dose* is the concentration of the substance in target tissues. For RF fields, the corresponding quantities are field levels external to the body, and those induced within body tissues by the exposure. The bioeffects literature refers to assessment of both quantities as “dosimetry.” Exposure is very different from risk, which is the probability of an adverse effect in an exposed individual and the severity of the effect.

The coupling between RF fields and the human body depends on the characteristics of the field (including frequency, polarization, and field strength) as well as the electrical characteristics of the biological target. Because of the wide range in these characteristics over the frequency range considered here, these coupling properties are quite diverse.

2.1. Bulk Electrical Properties of Tissue

The bulk electrical properties (dielectric properties) of tissue determine the propagation characteristics of

RF fields inside tissue; for a review, see Ref. 1. The bulk properties consist of the permittivity ϵ and conductivity σ . It is convenient to define the complex conductivity σ^* :

$$\sigma^* = \sigma + j\omega\epsilon\epsilon_0 \quad (1)$$

where ω is the frequency [in radians per second (rad/s)] and ϵ_0 is the permittivity of space (a constant). The real and imaginary parts of σ^* are shown in Fig. 1 for several representative soft tissues [2].

The dielectric properties of tissues exhibit dispersions (variations with frequency) due to the charging of cell membranes, dipolar losses in tissue water, and other effects. Charging of cellular membranes is chiefly responsible for the dispersion observed in tissue at megahertz (MHz) frequencies and below, while dipolar relaxation of tissue water is the dominant source of dispersion above ~ 1 GHz. Above ~ 100 MHz, tissue water content is the chief factor determining the dielectric properties of soft tissues.

2.2. Quantities Used to Characterize Exposure

Depending on the exposure scenario, different quantities are useful in characterizing exposure and dose. These include

1. For assessing external fields:
 - a. *External field strength* E_0 , measured in volts/meter (electric field) or amperes per meter (A/m) (magnetic field) (used principally at frequencies below 100 MHz¹ or in the near-field region of antennas).
 - b. *Incident power density* S , in W/m² (used principally at frequencies above 0.5 GHz or in the far fields of radiators).

¹All frequency ranges in this discussion are approximate.

2. For assessing internal fields:

- a. *Current density within the body* J_i (in A/m^2), used principally in the frequency range up to 10 MHz; a related measure is internal field strength E_i (V/m), which is related to the current density by Ohm's law

$$J_i = \sigma E_i \quad (2)$$

- b. *Total current passed into tissue* J , used chiefly to characterize contact currents, principally in the frequency range up to 100 MHz.
- c. *Internal electrical field strength* E_i , specifically, the electric field induced within body tissues, the *induced current density* J_i in A/m^2 .
- d. *Specific absorption rate* (SAR), defined as the power dissipation in watts per kilogram of tissue. In terms of the electric field E_i in the tissue

$$SAR = \frac{\sigma |E_i|^2}{\rho} \quad (3)$$

where ρ is the density (kg/m^3) of the tissue. The SAR can be expressed as a point value at a given instant in time, a value averaged over a specified time and distance, or a value averaged over the whole body of an animal (the whole-body SAR).

Under most circumstances, the SAR is the preferred dosimetric quantity for RF fields, particularly over the frequency range 100 kHz–10 GHz, and journal editors and referees typically insist that this information be included in papers submitted for publication. However, the SAR becomes less useful at frequencies above 10 GHz, where the energy is absorbed close to the tissue surface and the incident power density can be a more appropriate measure of exposure. The SAR is also less useful below 100 kHz, where little energy is absorbed by the tissue from the external field and contact currents become the dominant source of hazard.

Another parameter is specific-energy absorption (S.A.), the total absorbed energy in a pulse per kilogram of tissue, used principally for pulsed fields in the frequency range 300 MHz–10 GHz.

The SAR can be determined in a number of ways:

- By measuring the transient rate of temperature increase in the exposed object. A SAR of 1 W/kg produces a rate of temperature increase of $0.015^\circ C/min$ in high-water-content tissues. The rate of temperature increase can be measured using small temperature sensors, notably “nonperturbing” fiberoptic probes that are designed specifically for measurements in RF fields. Another approach is thermal imaging of the surface of the exposed object using an infrared camera, typically using phantom models to mimic animals. In either case, it is important to correct for effects of heat conduction in measurements of the rate of temperature increase.
- By modeling the exposure situation by computer, to determine the rate of absorption of the incident energy in the exposed object.

- By measuring the internal electric field in the exposed object with a small probe (taking care to avoid electrical artifacts).

Additional information may be necessary to characterize exposure, including the peak field strength or peak incident power density (for pulsed fields) or other description of the modulation characteristics of the field.

Inadequate dosimetry has been a longstanding problem in bioeffects studies. Many earlier studies reported only the incident field intensity, but did not determine the absorbed power in the exposed animals, and consequently the studies are difficult or impossible to interpret. Inadequate dosimetry is a particularly noticeable problem in numerous bioeffects studies in the Russian scientific literature, which frequently lacks even rudimentary information about the frequency and intensity of exposure.

A related problem has been the difficulty in distinguishing effects due to heating of the sample from those due to the fields themselves, that is, distinguishing thermal from nonthermal effects, due to the difficulty in adequately controlling temperature during an experiment. With careful experimental design, these problems are now solvable. However, adequate dosimetry and temperature control remain difficult and expensive to achieve. Typically, bioeffects studies, particularly those involving exposure of large animals and humans, require specially designed facilities and extensive engineering support including in some cases elaborate computational studies to determine exposure (Fig. 2).

3. COUPLING CONSIDERATIONS

The coupling between external fields and body tissues depends on the characteristics of exposure, which vary greatly in different exposure scenarios, as well on the geometry and electrical characteristics of the exposed subject.

There are numerous ways in which human subjects can be exposed to RF energy. The exposure scenarios can often be classified in one of three ways, which entail significant technical differences in determining exposure, described in the following text.

3.1. Contact Currents

In this exposure scenario, RF currents are passed into the body when a subject touches a conductive object in the presence of a field. Contact currents are a major potential occupational hazard in some occupational settings. For example, contact currents induced by touching broadcast transmission towers or secondary metallic structures (buildings, guywires, fencing, etc.) near the towers can induce hazardous contact currents.

The magnitude of the contact current is a function of source impedance and the impedance of the subject to ground, and is not simply related to the field strength in the vicinity of the subject. Contact currents can be measured by placing an ammeter between the source and the subject.

Figure 2. Eleanor R. Adair, noted bioeffects investigator [and immediate past chair of the ICES (formerly known as IEEE C95.1) standards committee] in microwave anechoic chamber used for RF bioeffects studies at Brooks Air Force Base, Texas.

3.2. Near-Field or Partial-Body Exposure

In localized regions near RF sources, very high RF fields can exist, possibly at acutely hazardous levels. Sources include medical equipment [such as magnetic resonance imaging (MRI) scanners], industrial equipment (e.g., induction heaters or microwave drying equipment), and radar and broadcast transmitters. Exposures to RF fields from such equipment typically occur in the near fields of RF sources, and to parts of the body. Partial-body exposure (albeit at thermally innocuous levels) is an everyday occurrence to a user of a mobile telephone or other portable transmitter.

Because of the complex electrical interaction between the transmitting antenna and the subject's body, exposure assessment in near-field exposures is a difficult matter. Exposure is typically determined using computer modeling or physical measurements on "phantom" models whose electrical properties approximate those of tissue at the pertinent frequency [3]. The measurements can include thermal measurement of SAR or direct measurement of the local field using small electrical probes inserted into the model. Figure 3 shows a commercial apparatus that employs a robot to move a small electric field probe about a "phantom" model of the head, which has become the most widely used method to measure SARs produced in the human head by mobile telephone handsets.

Figure 3. Commercial instrument used to measure SAR distribution produced by a mobile telephone in model of a human head. The robot arm moves an electric field probe inside a phantom model filled with a liquid whose electrical properties resemble those of a tissue. (From Ref. 3 with permission; available at <http://www.dasv4.com/welcome.html>.)

3.3. Far-Field Exposure

In a typical far-field exposure scenario, plane-wave energy is incident on large areas of the subject's body. This exposure scenario is important because of public concern about possible health hazards from broadcast transmitters, as well as in some occupational exposure settings, for example, for workers near radar transmitters.

Far-field exposure can be modeled by computer or measured experimentally, and, in comparison to with near-field exposures, is comparatively easy to accomplish. Consequently, a large literature exists on the subject (e.g., see Ref. 4). Initial studies, beginning in the 1960s, modeled the human body and experimental animals using homogeneous spheroids exposed to plane-wave irradiation. More recent studies have employed detailed anatomical models of the body with millimeter spatial resolution. A variety of thermal measurements have also been reported, most commonly for measurement of whole-body SAR [4].

As with other exposure scenarios, the coupling between an incident field and the body depends strongly on the frequency and other characteristics of the field. Figure 4 shows the whole-body average SAR in an isolated ellipsoid modeling an adult human, exposed to plane-wave irradiation of varying polarization. Below ~ 70 MHz, the SAR is proportional to the square of the frequency, and most of the energy is deposited near the body surface. This model exhibits a maximum near 70 MHz due to an electrical resonance, reflecting the antenna properties of the model. At higher frequencies, the whole-body SAR decreases (for a given incident power density) because the energy is deposited close to the surface. In addition, various parts of the body exhibit their own resonances; for example, the human head exhibits an antenna resonance at approximately 1 GHz. If the model is placed in contact with

Figure 4. Whole-body average SAR in a prolate spheroidal model of man in a plane wave, as a function of frequency of the incident wave. The semi-major axis is 0.875 m, semi-minor axis 0.138 m, volume 0.07 m^3 . The SAR is given in W/kg, normalized to an incident power density of 10 W/m^2 (from Ref. 4). Three curves are shown, for E (electric field vertical), H (magnetic field vertical), and K (wave propagating from the top) polarizations.

ground, the induced currents (particularly those near the point of contact with ground) are increased as a result of image effects. Similar resonances occur in animals, but at higher frequencies reflecting the smaller body size, and with different SAR levels for a given incident exposure level (Fig. 5).

At sufficiently high frequencies, the wavelength of the incident energy is much smaller than the dimensions of the model and the exposure approaches the “quasi-optical” regime. In this case, the distribution of energy within the body is similar to that produced by a plane wave incident on an absorbing surface. For a plane wave incident on a plane surface of tissue, the SAR as a function of depth x into the tissue is given by

$$\text{SAR} = \frac{I_0 T}{\rho L} e^{-x/L} \quad (4)$$

where T is the fraction of energy transmitted in the tissue (the remaining part of the incident energy being reflected) and L is the energy penetration depth. In terms of the relative permittivity and conductivity of the tissue (ϵ' , σ), these quantities are

$$T = 1 - \frac{\sqrt{\epsilon^*} - 1}{\sqrt{\epsilon^*} + 1}^2 \quad (5)$$

$$L = \frac{-c}{2\omega \text{Im}(\sqrt{\epsilon^* \epsilon_0})}$$

where $\epsilon^* = \epsilon' - (j\sigma/2\pi f\epsilon_0)$ and c is the velocity of light. Energy penetration depths of microwaves

Figure 5. Whole-body absorption rates for spheroidal models of a human, a squirrel monkey, and a mouse, exposed to plane-wave irradiation at 10 W/m^2 in the E polarization. (From Ref. 4.)

into soft tissue such as muscle range from about 1 cm at 1 GHz to a few tenths of a millimeter at 100 GHz (Fig. 6).

4. INTERACTION MECHANISMS

The energy of photons of radiofrequency and microwave fields is several orders of magnitude (at least) below that needed to disrupt the weakest chemical bonds and create free radicals. Consequently, RF fields are nonionizing, in contrast to ionizing radiation such as X rays or ultraviolet light, which disrupt chemical bonds and create highly reactive free radicals.

Nevertheless, RF fields can interact with biological systems, most obviously by exerting forces on charges in tissue [5]. These forces act in the presence of random thermal agitation, which will overwhelm the effects of the fields if the forces are too small. The absorbed power in tissue will also generate heat and increase the local temperature, an obvious thermal mechanism for biological effects.

4.1. Thermal Mechanisms

Thermal mechanisms arise from the deposition of power in the biological system (as opposed to nonthermal effects, which result from direct interaction with the electric or magnetic fields).

4.1.1. Direct Effects of Temperature Increase. Biochemical reactions typically vary in rate by about $3\%/^\circ\text{C}$. However, some biological structures (e.g., thermal receptors in the human body or infrared receptors in some snake species) respond to very small changes in temperature, as little as a few hundredths of a degree or less. Thus, even modest temperature increases, particularly if they persist

Figure 6. Energy penetration depths and transmission coefficients for several tissues.

over appreciable times, can elicit biological effects. Several classes of thermal effects can be identified.

4.1.2. Effects of Thermal Load on the Body. An additional heat load on the body due to exposure to RF energy can also elicit effects due to thermoregulatory responses. The natural rate of power generation in the human body (the basal metabolic rate) is about 1 watt per kilogram of body mass. Addition of heat by a RF field at levels comparable to or above this rate can produce significant physiological effects even in the absence of thermally damaging temperature increases anywhere in the body. These changes can be interpreted as normal thermoregulatory responses, and may explain, in part, various subtle physiological effects that have been reported in animals subjected to moderate levels of RF energy exposure. With typical values of the conductivity of tissue, field levels inside the body ranging from 100 V/m (3 kHz) to 30 V/m (1 GHz) will produce a SAR of 1 W/kg.

4.1.3. Effects of Local Temperature Increases. At SAR levels somewhat above 1 W/kg, depending on the duration of exposure, rate of cooling of the tissue by bloodflow, and other factors, local heating effects in tissue can become significant or even damaging. These include a variety of biological changes and, at sufficient heating levels, frank tissue damage.

4.1.4. Effects Due to Rate of Temperature Increase. Some thermal mechanisms depend on the rate of temperature increase (as opposed to the magnitude of increase). Pulsed microwave energy will generate acoustic transients in tissue by transient heating of tissue water with corresponding thermal expansion. These transients, under appropriate exposure conditions, can be perceived by human subjects as “clicks,” the so-called microwave auditory effect. This typically requires that the head of the subject be exposed to microsecond pulses of RF energy with a carrier frequency near 1 GHz, and peak field intensities

above 10,000 W/m². The pulses produce transient increases in tissue temperature of a few microdegrees, at a rate of about 1°C/s. This is sufficient to produce acoustic transients in the head in excess of 100 dB peak sound pressure [6]. The subject perceives these acoustic transients through normal hearing mechanisms.

Under more extreme exposure conditions, changes in membrane potentials and stimulation of cell membranes can occur, also related to the rates of temperature increase [7]. For example, mice exposed in the head to intense microwave pulses, leading to brain temperature increases of a few tenths of a degree within one second, exhibit a variety of involuntary body movements and other “stun” phenomena [8]. The extreme exposure levels needed to produce such effects are far above those encountered in realistic environments, and to achieve them generally requires that the animals be placed inside waveguides that are connected to high-powered military transmitters.

4.2. Nonthermal Mechanisms

Electric fields can exert forces on charges, and magnetic fields exert torques on magnetic dipoles in biological systems. This gives rise to several classes of “nonthermal” interaction mechanisms. (Whether the mechanisms result in observable biological effects under realistic exposure conditions is a different question, however.) Examples are described below.

4.2.1. Membrane Excitation. The dominant hazard mechanism for low-frequency currents is shock and other membrane excitation phenomena. Above a few kilohertz, the threshold current needed to excite membranes increases rapidly with frequency. With a few exceptions, over the entire frequency range considered in this article, the thresholds for producing biologically significant heating are lower than those for directly exciting cell

Figure 7. Estimated thresholds for different stimulatory effects (excitation of 10- μ m nerve fibers in the brain, excitation of cardiac fibers, production of phosphenes, together with current level for a SAR of 1 W/kg.

membranes (Fig. 7). Consequently, the dominant hazard mechanisms at RFs are thermal in nature.

4.2.2. Electroporation. Electric fields can create pores in cell membranes (electroporation) by inducing electrical breakdown. This requires membrane potentials of ~ 1 V, which in turn requires tissue field strengths that can exceed 10^4 – 10^5 V/m, which would be thermally damaging if sustained for more than brief periods. However, electroporation can be produced in the absence of thermal damage using brief pulses of RF fields, typically with carrier frequencies below 1 MHz. Electroporation is considered to be a factor in some kinds of electrical injury [9].

4.2.3. Field-Induced Forces. Electric fields exert forces on ions and torques on permanent dipoles, as well as forces and torques on induced dipoles (dielectrophoretic forces). Magnetic fields exert torques on magnetic dipoles. These forces are opposed by viscous drag from the surrounding medium, and occur in the face of random thermal agitation.

Dielectrophoretic forces on cells are well documented, and have important applications in biotechnology. However, biophysical considerations show that the forces to be expected on cells from RF fields at normal environmental levels are far too weak to overcome naturally occurring thermal agitation.

4.3. Other Proposed Mechanisms

Various scientists, including some prominent physicists, have suggested mechanisms for biological effects of weak RF fields. These include various quantum phenomena, nonlinear effects such as creation of solitons, and kinetic effects including disruption of “bound” water and excitation of molecular resonances (to name only a few proposed mechanisms). These theories remain speculative, and of-

ten are susceptible to criticism, for example, for failing to consider the effects of thermal agitation or viscous drag or other dissipative processes [10]. This remains a highly uneven and, in many places, highly contentious literature.

5. POTENTIAL ADVERSE EFFECTS OF RADIOFREQUENCY FIELDS IN HUMANS

This subject is wide and, particularly as it relates to possible chronic health effects in humans, very controversial. This article first considers the well-established hazards of RF energy, which underlie major exposure standards for electromagnetic fields. It then comments on possible effects of chronic exposure to RF and microwave fields on humans.

5.1. Thermal Death

Numerous studies have been conducted, beginning in the early 1960s, to determine lethal levels of exposures to RF and microwave energy for animals. The exposure level, in terms of incident power density, that will kill an animal varies considerably depending on species, frequency of the field, environmental conditions, pretreatment by drugs or other physiological manipulation, and other factors. In part this reflects the different absorption characteristics of different species for RF energy, and in part physiological differences among species, such as different capabilities for thermoregulation. Prior to death, animals typically exhibit circulatory failure and other signs of extreme heat stress, and the thresholds for lethality typically correlate with an increase in body temperature of several degrees above normal [11]. Clearly, similar effects would occur in a human, in the unlikely circumstance that he or she were exposed at comparable levels.

5.2. Perception and Pain

Thresholds for perception of contact currents have been measured for humans at several frequencies (Table 1). At frequencies below ~ 10 kHz, subjects report “mild tickling or pricking” sensations near the threshold for perception; at higher frequencies subjects report “faint warmth” [12], evidently reflecting two different mechanisms for perception (direct stimulation of membranes at low frequencies and cutaneous perception of warmth at higher frequencies).

The thresholds for perception of microwave energy have been measured by Blick et al. [13] over a wide range of microwave frequencies. These experiments used brief (10-s) exposures to microwave energy over an area of 0.024 m² on the backs of human volunteers (Table 2) [13]. The estimated increase in skin temperature at the threshold for perception is about 0.07°C over this entire frequency range [14]. The threshold for perception decreases with increasing frequency because of the shorter penetration depth into tissue and corresponding increase in SAR near the skin surface. Thresholds for pain under similar exposure conditions are approximately 100 times higher, and correspond to peak temperature increases of

Table 1. Ranges of Threshold Currents for Indirect Effects, Including Children, Women, and Men

Indirect Effect	Threshold Current (mA) at Frequency			
	50/60 Hz	1 kHz	100 kHz	1 MHz
Touch perception	0.2–0.4	0.4–0.8	25–40	25–40
Pain on finger contact	0.9–1.8	1.6–3.3	33–55	28–50
Painful shock/let-go threshold	8–16	12–24	112–224	Not determined
Severe shock/breathing difficulty	12–23	21–41	160–320	Not determined

Source: From Ref. 25.

several degrees Celsius at the surface of the skin [15]. These thresholds clearly reflect thermal phenomena.

5.3. Burns

Burns and other thermal damage are clear potential hazards of RF and microwave energy. Typically, human tissues can tolerate temperatures up to $\sim 43^\circ\text{C}$ for prolonged periods without damage; progressively higher temperatures will cause thermal damage in progressively shorter times [16].

While RF burns are an obvious potential hazard, few such injuries are reported. The exposures are very painful, causing the victim to withdraw from exposure before thermal injury occurs. Serious injuries generally require extreme exposure levels in which damage occurs quickly, or circumstances in which the victim is unable to voluntarily leave the area of exposure. There is a scattering of reports of burns produced by microwave ovens whose interlock mechanisms (which turn off the microwave power when the door is opened) have failed, and of burns to patients from medical treatments involving RF and microwave energy. There have been at least two reported cases of infants being placed deliberately in microwave ovens and suffering severe burns [17].

5.4. Other Adverse Thermal Effects

Many thermal effects have been demonstrated in animals, and analogous effects can be anticipated in humans as well. Deleterious effects include the following:

1. *Cataracts.* These are an established hazard of microwave energy, and have been reported occasionally in humans exposed to high intensity microwaves. Cataracts can be produced in animals at high exposure levels, generally $> 1000 \text{ W/m}^2$, where they are associated with temperature increases of several degrees in the eye. Such exposure levels are similar to those capable of producing skin burns. Occasional claims of cataract from low-level

microwave exposure have not been substantiated by animal studies and remain controversial [18].

2. *Adverse Reproductive Effects.* Development abnormalities have been convincingly demonstrated in animals exposed to microwave energy at near-lethal levels. These effects are associated with significant increases in body temperature, which is itself a well-established cause of birth defects [19,20]. Heating the testes to microwave energy to induce temporary sterility has been explored in China as a means of contraception. Some men have received more than 100 treatments, each raising the surface temperature of the scrotum to $40\text{--}42^\circ\text{C}$. No significant abnormalities were reported in a follow-up study in these men after cessation of treatment [21].

3. *Behavioral Disruption.* This has been observed in several species of animals exposed to microwaves at whole-body exposures of $4\text{--}6 \text{ W/kg}$, at several frequencies above 100 MHz [22]. In such studies, the animals are trained to carry out a task (e.g., pressing a lever to obtain food pellets) and exposed to microwave energy. At sufficient exposure levels, the animals stop performing the assigned task and begin a different behavior, typically one associated with thermoregulation (in rats, spreading saliva on the tail). The threshold SAR for behavioral disruption is approximately 4 W/kg in several species, and does not vary greatly with frequency (Table 3). The effect is reversible; that is, no lasting effects are observed in the animals after the exposure is terminated. Consequently it is not considered deleterious, although exposures that are sufficient to produce behavioral disruption are undoubtedly close to those that would be thermally injurious if sustained for sufficient lengths of time.

5.5. Mobile Phones and Health

The hazards discussed above are principally (if not exclusively) thermal in nature, and require high exposure levels. Much public and legal controversy has concerned the possibility of hazards from use of mobile telephones or

Table 2. Thresholds for Perception of Microwave Energy by Humans

Frequency (GHz)	Threshold for Perception (10 s Exposure, 0.024 m^2 Exposure Area) (W/m^2)	Approximate Energy Penetration Depth (m)	Approximate Temperature Increase at Skin Surface ($^\circ\text{C}$) at Threshold
2.45	630	0.01	0.06
7.5	195	0.003	0.05
10	196	0.002	0.07
35	88	4×10^{-4}	0.08
94	45	1×10^{-4}	0.05

Table 3. Thresholds for Behavioral Disruption in Different Animals

Species and Conditions	225 MHz	1.3 GHz (Pulsed)	2.45 GHz	5.8 GHz (Pulsed)
	(Continuous-Wave)		(Continuous-Wave)	
Norwegian rat power density SAR	—	10 mW/cm ² (2.5 W/kg)	128 mW/cm ² (5.0 W/kg)	20 mW/cm ² (4.9 W/kg)
Squirrel monkey power density SAR	—	—	45 mW/cm ² (4.5 W/kg)	40 mW/cm ² (7.2 W/kg)
Rhesus monkey power density SAR	8 mW/cm ² (3.2 W/kg)	57 mW/cm ² (4.5 W/kg)	67 mW/cm ² (4.7 W/kg)	140 mW/cm ² (8.4 W/kg)

Source: Adapted from Ref. 34.

living near cellphone base stations. The exposure levels encountered in these two situations are very different, but both are far below any threshold for a thermal hazard.

Certainly the most visible public issue has been the possibility that use of mobile telephones can cause brain cancer. Since the issue was first raised (by a nonscientist on a U.S. television show in 1992), several epidemiology studies have been completed, together with several long-term animal studies designed as cancer assays. The results so far have failed to identify a link between use of mobile telephones and cancer. A review of the literature published in 1999 found the evidence for a causal relationship between RF radiation from cellphones and cancer to be “weak to nonexistent” [23]. However, given the long time that it takes brain tumors to develop (years to decades between initiation and clinical diagnosis), the studies completed to date have only limited ability to address the question of possible long-term effects from use of mobile telephones.

A number of studies have been conducted to address health issues other than cancer. Many of them have reported effects of using mobile telephones on neurological function, response time, sleep, and other functions in human subjects. However, the effects have generally been insignificant, with no clear health significance. Reviews of the issue by a number of expert committees have generally concluded that no convincing evidence exists for a hazard from mobile phones or their base stations, but also that numerous open questions still remain.

6. TWO MAJOR WESTERN EXPOSURE LIMITS

Government and nongovernment agencies throughout the world have established guidelines for human exposure to electromagnetic fields. The rationale for two major Western limits [Institute of Electrical and Electronics Engineers (IEEE) standard C95.1-1999 [24] and the International Commission on Non-Ionizing Radiation Protection (ICNIRP) guideline [25]] is now considered (see also Table 4). The IEEE committee has recently been renamed International Committee on Electromagnetic Safety (ICES).

The standards are complex, and readers should refer to the original documents for authoritative statements of the limits. They have similar rationales but differ in many particulars. ICNIRP limits include “basic restrictions,” which are limits on absorbed power (or other measure of internal field) based directly on adverse health effects, and “reference levels,” which are limits on external field strength designed to ensure that the basic restrictions are not exceeded.

Each standard has two tiers: for “controlled” and “uncontrolled” environments (IEEE) or for occupational groups and the general public (ICNIRP). The “controlled” limits in IEEE C95.1 are intended for environments in which the exposed subjects are aware of the potential for exposure, and correspond roughly to occupational exposure guidelines in ICNIRP.

Table 4. Comparison of ICNIRP and IEEE Limits for Contact Current

A. ICNIRP Reference Levels for Time-Varying Contact Currents from Conductive Objects

Exposure Characteristics	Frequency Range	Maximum Contact Current (mA)
Occupational exposure	≤2.5 kHz	1.0
	2.5–100 kHz	0.4f ^a
	100 kHz–110 MHz	40
General public exposure	≤2.5 kHz	0.5
	2.5–100 kHz	0.2f ^a
	100 kHz–110 MHz	20

B. IEEE Induced and Contact Radiofrequency Currents^b

Frequency Range	Maximum Current (mA)		
	Through Both Feet	Through Each Foot	Contact
3–100 kHz	0.9f ^a	0.45f ^a	0.45f ^a
100 kHz–100 MHz	90	45	45

^aFrequency in kilohertz.

^bLimits for uncontrolled environments; limits for controlled environments are higher by a factor of ~2.

6.1. Limits to Whole-Body SAR

Both the IEEE and ICNIRP limits are designed to limit the whole-body average SAR to 0.4 W/kg (“controlled” or occupational) or 0.08 W/kg (“uncontrolled” or general public limits). The rationale, as described in ICNIRP is [25]

Established biological and health effects in the frequency range from 10 MHz to a few GHz are consistent with responses to a body temperature rise of more than 1°C. This level of temperature increase results from exposure of individuals under moderate environmental conditions to a whole-body SAR of approximately 4 W kg⁻¹ for about 30 minutes. A whole-body average SAR of 0.4 W kg⁻¹ has therefore been chosen as the restriction that provides adequate protection for occupational exposure. An additional safety factor of 5 is introduced for exposure of the public, giving an average whole-body SAR limit of 0.08 W kg⁻¹.

The IEEE and ICNIRP limits are compared for one exposure situation (general public for ICNIRP, uncontrolled environments for IEEE) in Fig. 8. The antenna resonance in the human at 70 MHz accounts for the lower limits near that frequency in both limits.

6.2. Limits to Partial-Body SAR

For the head and trunk, ICNIRP limits for partial body exposures are 2 W/kg (general public) and 10 W/kg (occupational), averaged over any 10 g mass of contiguous tissue. Limits elsewhere in the body are a factor of 2 higher. The corresponding limits in the present IEEE limit are 1.6 and 8 W/kg, averaged over 1 g of tissue (but is anticipated to change with a new edition of the limit to be released in 2003).

Figure 8. Comparison of ICNIRP and IEEE limits for general population/uncontrolled environments. Limits for occupational groups/controlled environments are generally 5 times higher than for the general public/uncontrolled environments.

6.3. Contact Currents

The limits in these two standards are compared in Fig. 8. The ICNIRP limits are somewhat more restrictive, but both sets of limits are clearly rather similar.

7. CONTROVERSIES AND UNRESOLVED ISSUES

The literature on biological effects and health hazards of RF energy is complex and frequently inconsistent and controversial even among scientists. Several areas of controversy are discussed below.

7.1. Many Reported Biological Effects of RF Energy

The scientific literature abounds with reports of biological effects of RF energy, including some at low exposure levels that the investigators considered “nonthermal.” The studies vary greatly in biological endpoint, exposure level, quality, and relevance to health and safety. Many of the studies are controversial, due to technical criticisms of the studies or the inability of other studies to confirm the initial findings [26].

Faced with an inconsistent and incomplete literature (the normal state of affairs in environmental health issues), health agencies typically employ a “weight of evidence” approach, using panels of experts to evaluate critically all relevant information. These panels normally give little weight to studies that are technically deficient or whose relevance to health is unclear. Health agencies typically point to the incompleteness of the scientific literature and the existence of open questions. For example, a 1999 review by the Royal Society of Canada concluded [27]

Scientific studies performed to date suggest that exposure to low intensity non-thermal RF fields do not impair the health of humans or animals. However, the existing scientific evidence is incomplete, and inadequate to rule out the possibility that these non-thermal biological effects could lead to adverse health effects. Moreover, without an understanding of how low energy RF fields cause these biological effects, it is difficult to establish safety limits for non-thermal exposures.

7.2. Reports of Adverse Health Effects of RF Energy at Low Exposure Levels

A major factor in the public controversy about the safety of RF energy is the existence of a scattering of reports in the medical literature of associations between adverse health outcomes and presumed exposure to RF energy. For example, there is one report of clusters of testicular cancer cases among police officers using radar guns [28]. One investigator has reported an increase in cancer mortality in Polish soldiers whose job classifications suggest exposure to RF radiation, compared to other soldiers used as controls [29]. A more recent epidemiology study by a French investigator reported an association between nonspecific health symptoms and residence near a mobile base station [30].

Perhaps even more perplexing, the medical literature of the former Soviet Union and its former Warsaw Pact

Table 5. Comparison of Five Different Exposure Limits for RF Energy at 2000 MHz^a.

Country	Limit for General Public Exposure to RF Fields (2000 MHz) for Extended Periods of Exposure (W/m ²) (Applies to Far-Field Exposure, Extended Duration)	Basis
ICNIRP (adopted in numerous countries worldwide)	10	Science-based
U.S. Federal Communications Commission Bulletin 65, <i>Evaluating Compliance with FCC Guidelines for Human Exposure to Radiofrequency Electromagnetic Fields</i> , Washington, DC, 1997.	10	Science-based
China: UDC 614.898.5 GB 9175-88	0.1	Science-based
Russia: <i>Sanitary Norms and Regulations 2.2.4/2.1.8.055-96</i>	0.1	Science-based
Switzerland: <i>Ordinance on Protection from Nonionising Radiation</i> (NISV) of Dec. 23, 1999	0.1	Precautionary
Typical maximum exposure from cellular base station mounted on 50-m tower (assuming a total effective radiated power of 2500 W in each sector, summed over all channels)	0.01	

^aThis 2000-MHz limit is similar to that used by many cellular telephones throughout the world. The limits are for long-term exposure to the general population.

allies contains numerous reports of adverse health effects in people exposed to RF energy. For example, Russian physicians have identified a “neurasthenic” syndrome among workers in radio equipment factories, which is characterized by diverse and nonspecific symptoms such as fatigue, anxiety, headache, and impotence [31]. The exposures to these subjects was undocumented, but almost certainly the levels of RF energy were far below Western exposure limits.

So far, these reports have carried little weight in Western assessments of possible health risks of RF energy, in part because of technical deficiencies in the studies and in part because of lack of independent confirming evidence. However, these reports would certainly tend to convince many nonscientists that health hazards do exist from low-level exposures to RF energy.

7.3. Large Variations in Exposure Limits to RF Energy throughout the World

The underlying philosophy in setting exposure limits to RF and microwave energy varies greatly in different countries, and there is a corresponding large variation in exposure limits. These limits can be classified as “science-based” (in that they were designed to avoid identified hazards, on the basis of detailed analysis of the relevant scientific literature) and “precautionary” (not designed to exclude particular hazards). The limits for general public exposure to 2000 MHz energy (similar to that emitted by many mobile telephone base stations) are compared in Table 5.

7.4. Science-Based Limits

One group of science-based limits consists of the IEEE and ICNIRP limits discussed above.

A very different group of science-based limits is in effect in Russia and most of its former Warsaw Pact allies. These limits are far lower (as much as 100 times, if the limits are expressed in terms of incident power density) than the

ICNIRP and the IEEE limits (as well as those of many other Western countries). The Russian standards clearly reflect a conviction that prolonged exposure to low-level RF fields causes health problems of many sorts. It has so far proved impossible to reconcile these two sets of limits, in part because of the brief nature of the Russian reports (many of which lack sufficient technical detail to permit expert evaluation) and in part because of technical limitations of the studies (which seldom provide information about exposure) [32]. This situation goes back for many years and is not likely to be resolved anytime soon.

7.5. Precautionary Limits

More recently, Italy, Switzerland, and a few other countries have adopted strict limits for RF exposure that are even below those of Russia. To a large extent, these limits reflect public fears about the safety of mobile telephone masts (whose exposure levels are invariably far below ICNIRP and other Western limits). These limits are not science-based, but are justified by the precautionary principle, and thus are designed to be highly restrictive due to uncertainty about the safety of RF energy at low exposure levels.

BOUNDARY-VALUE PROBLEMS

BENJAMIN BEKER
 GEORGE COKKINIDES
 MYUNG JIN KONG
 University of South Carolina
 Columbia, South Carolina

Many problems in electrical engineering require solution of integral or differential equations that describe physical phenomena. The choice as to whether integral or differential equations are used to formulate and solve specific problems depends on many factors, whose discussion is beyond the scope of this article. This article strictly concentrates on the use of the finite-difference method (FDM) in the numerical analysis of boundary value problems associated with primarily static and to some extent quasistatic electromagnetic (EM) fields. Although all examples presented herein deal with EM-related engineering applications, some numerical aspects of FDM are also covered. Since there is a wealth of literature in numerical and applied mathematics about the FDM, little will be said about the theoretical aspects of finite differencing. Such issues as the proof of existence or convergence of the numerical solution will not be covered, while the appropriate references will be provided to the interested reader. Instead, the coverage of FDM will deal with the details about implementation of numerical algorithms, compact storage schemes for large sparse matrices, the use of open boundary truncation, and efficient handling of inhomogeneous and anisotropic materials.

The emphasis will be placed on the applications of FDM to three-dimensional boundary value problems involving objects with arbitrary geometric shapes that are composed of complex dielectric materials. Examples of such problems include modeling of discrete passive electronic components, semiconductor devices and their packages, and crosstalk in multiconductor transmission lines. When the wavelength of operation is larger than the largest geometric dimensions of the object that is to be modeled, static or quasistatic formulation of the problem is appropriate. In electrostatics, for example, this implies that the differential equation governing the physics (voltage distribution) is of Laplace type for the source-free environment and of Poisson type in regions containing sources. The solution of such second-order partial-differential equations can be readily obtained using the FDM.

Although the application of FDM to homogeneous materials is simple, complexities arise as soon as inhomogeneity and anisotropy are introduced. The following discussion will provide essential details on how to overcome any potential difficulties in adapting FDM to boundary value problems involving such materials. The analytical presentation will be supplemented with abundant illustrations that demonstrate how to implement the theory in practice. Several examples will also be provided to show the complexity of problems that can be solved by using FDM.

1. BRIEF HISTORY OF FINITE DIFFERENCING IN ELECTROMAGNETICS

The utility of the numerical solution to partial-differential equations (or PDEs) utilizing finite-difference approximation to partial derivatives was recognized early [1]. Improvements to the initial iterative solution methods, discussed in Ref. 1, by using relaxation were subsequently introduced [2,3]. However, before digital computers became available, the applications of the FDM to the solution of practical boundary value problems was a tedious and often impractical task. This was especially true when a high level of accuracy was required.

With the advent of digital computers, numerical solution of PDEs became practical. They were soon applied to various problems in electrostatics and quasistatics such as in the analysis of microstrip transmission lines [4] among many others. The FDM found quick acceptance in the solution of boundary value problems within regions of finite extent, and efforts were initiated to extend their applicability to open region problems as well [5].

As a point of departure, it is interesting to note that some of the earliest attempts to obtain the solution to practical boundary value problems in electrostatics involved experimental methods. They included the electrolytic tank approach and resistance network analog technique [6], among others, to simulate the finite-difference approximations to PDEs.

Finally, it should be mentioned that in addition to the application of FDM to static and quasistatic problems, the FDM was also adapted for use in the solution of dynamic, full-wave EM problems in time and frequency domains. Most notably, the use of finite differencing was proposed for the solution to Maxwell's curl equations in the time domain [7]. Since then, a tremendous amount of work on the finite-difference time-domain (or FDTD) approach was carried out in diverse areas of electromagnetics. This includes antennas and radiation, scattering, microwave integrated circuits, and optics. The interested reader can consult the authoritative work in Ref. 8, as well as other articles on eigenvalue and related problems in this encyclopedia, for further details and additional references.

2. ENGINEERING BASICS OF FINITE DIFFERENCING

It is best to introduce the FDM for the solution of engineering problems, which deal with static and quasistatic electromagnetic fields, by way of example. Today, just

about every elementary text in electromagnetics—as well as newer, more numerically focused introductory EM textbooks—will have a discussion on FDM (e.g., pp. 241–246 of Ref. 9 and Sect. 4.4 of Ref. 10) and its use in electrostatics, magnetostatics, waveguides, and resonant cavities. Regardless, it will be beneficial to briefly go over the basics of electrostatics for the sake of completeness and to provide a starting point for generalizing FDM for practical use.

3. GOVERNING EQUATIONS OF ELECTROSTATICS

The analysis of electromagnetic phenomena has its roots in the experimental observations made by Michael Faraday. These observations were cast into mathematical form by James Clerk Maxwell in 1873 and verified experimentally by Heinrich Hertz 25 years later. When reduced to electrostatics, they state that the electric field at every point in space within a homogeneous medium obeys the following differential equations [9]

$$\nabla \times \vec{E} = 0 \quad (1)$$

$$\nabla \cdot \epsilon_0 \epsilon_r \vec{E} = \rho_v \quad (2)$$

where ρ_v is the volumetric charge density, ϵ_0 ($\approx 8.854 \times 10^{-12}$ F/m) is the permittivity of freespace, and ϵ_r is the relative dielectric constant. The use of the vector identity $\nabla \times \nabla \phi = 0$ in Eq. (1) allows for the electric field intensity, \vec{E} (V/m), to be expressed in terms of the scalar potential $\vec{E} = -\nabla \phi$. When this is substituted for the electric field in Eq. (2), a second-order PDE for the potential ϕ is obtained

$$\nabla \cdot (\epsilon_r \nabla \phi) = -\rho_v / \epsilon_0 \quad (3)$$

which is known as the *Poisson equation*. If the region of space, where the solution for the potential is sought, is source-free and the dielectric is homogeneous (i.e., ϵ_r is constant everywhere), Eq. (3) reduces to the Laplace equation $\nabla^2 \phi = 0$.

The solution to the Laplace equation can be obtained in several ways. Depending on the geometry of the problem, the solution can be found analytically or numerically using integral or differential equations. In either case, the goal is to determine the electric field in space due to the presence of charged conductors, given that the voltage on their surface is known. For example, if the boundaries of the charged conductors are simple shapes, such as a rectangular box, circular cylinder, or sphere, then the boundary conditions (constant voltage on the surface) can be easily enforced and the solution can be obtained analytically. On the other hand, when the charged object has an irregular shape, the Laplace equation cannot be solved analytically and numerical methods must be used instead.

The choice as to whether integral or differential equation formulation is used to determine the potential depends heavily on the geometry of the boundary value problem. For example, if the charged object is embedded within homogeneous medium of infinite extent, integral equations are the preferable choice. They embody the boundary conditions on the potential ϕ at infinity and

Figure 1. Charged circular cylinder embedded between two different dielectrics.

reduce the numerical effort to finding the charge density on the surface of the conductor (see Sect. 5.2 or 4.3 of Ref. 9 or 10 for further details).

On the other hand, when the boundary value problem includes inhomogeneous dielectrics (i.e., ϵ_r varying from point to point in space), the surface integral equation methods are no longer applicable (or are impractical). Instead, such problems can be formulated using volumetric PDE solvers such as the FDM.

It is important to note that similar considerations (to those stated above) also apply to the solution of the Poisson equation. In this case, in addition to the integration over the conductor boundaries, integration over the actual sources (charge density) must also be performed. The presence of the sources has the same effects on PDEs and FDM, as their effects must be taken into account at all points in space where they exist.

3.1. Direct Discretization of Governing Equation

To illustrate the utility and limitations of FDM and to introduce two different ways of deriving the numerical algorithm, consider the geometry shown in Fig. 1. Note that for the sake of clarity and simplicity, the initial discussion will be restricted to two dimensions.

The infinitely long, perfectly conducting circular cylinder in Fig. 1 is embedded between two dielectrics. To determine the potential everywhere in space, given that the voltage on the cylinder surface is V_0 , the FDM will be used. There are two approaches that might be taken to develop the FDM algorithm. One approach would be to solve Laplace (or Poisson) equations in each region of uniform dielectric

Figure 2. "Staircase" approximation to boundary of circular cylinder and notation for grid dimensions.

and enforce the boundary conditions at the interface between them. The other route would involve development of a general volumetric algorithm, which would be valid at every point in space, including the interface between the dielectrics. This would involve seeking the solution of a single, Laplace-type (or Poisson) differential equation:

$$\nabla \cdot (\epsilon_r(x, y) \nabla \phi) = \epsilon_r(x, y) \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} \right) + \left(\frac{\partial \epsilon_r}{\partial x} \frac{\partial \phi}{\partial x} + \frac{\partial \epsilon_r}{\partial y} \frac{\partial \phi}{\partial y} \right) = \begin{cases} 0 \\ -\frac{\rho(x, y)}{\epsilon_0} \end{cases} \quad (4)$$

which is valid everywhere, except for the surface of the conductor.

The numerical approach to solving Eq. (4) starts with the approximation to partial derivatives using finite differences. This requires some form of discretization for the space (area or volume in two or three dimensions) where the potential is to be computed. The numerical solution of the PDE will lead to the values of the potential at a finite number of points within the discretized space. Figure 2 shows one possible discretization scheme for the cylinder in Fig. 1 and its surroundings. The points form a two-dimensional (2D) grid and need not be uniformly spaced. Note that the gridpoints, where the potential is to be computed, have to be defined all along the gridlines to allow for properly approximating the derivatives in Eq. (4). In other words, the gridlines cannot abruptly terminate or become discontinuous within the grid.

Using finite differences, the first-order derivative at any point in the grid can be approximated as follows

$$\begin{aligned} \left(\frac{\partial \phi}{\partial x} \right)_{i,j} &\approx \frac{(\phi_{I,J} - \phi_{I-1,j})}{(h_i + h_{i-1})/2} \\ &= \left[\left(\frac{\phi_{i+1,j} + \phi_{i,j}}{2} \right) - \left(\frac{\phi_{i,j} + \phi_{i-1,j}}{2} \right) \right] \frac{1}{(h_i + h_{i-1})/2} \\ &= \frac{\phi_{i+1,j} - \phi_{i-1,j}}{h_i + h_{i-1}} \end{aligned} \quad (5)$$

with the help of intermediate points I, J (darkened circles in Fig. 2). The approximation for the second derivatives can be obtained in a similar manner and is given by

$$\begin{aligned} \left[\frac{\partial}{\partial x} \left(\frac{\partial \phi}{\partial x} \right) \right]_{i,j} &\approx \frac{\left(\frac{\partial \phi}{\partial x} \right)_{I+1,j} - \left(\frac{\partial \phi}{\partial x} \right)_{I-1,j}}{(h_i + h_{i-1})/2} \\ &= \left[\left(\frac{\phi_{i+1,j} - \phi_{i,j}}{h_i} \right) - \left(\frac{\phi_{i,j} - \phi_{i-1,j}}{h_{i-1}} \right) \right] \\ &\quad \times \frac{1}{(h_i + h_{i-1})/2} \end{aligned} \quad (6)$$

Once all derivatives in Eq. (4) are replaced with their respective finite-difference approximations and all similar terms are grouped together, the discrete version of Eq. (4) takes on the following form:

$$\phi_{i,j} \approx \frac{1}{Y_{i,j}} (Y_{i+1}\phi_{i+1,j} + Y_{i-1}\phi_{i-1,j} + Y_{j+1}\phi_{i,j+1} + Y_{j-1}\phi_{i,j-1}) + \left\{ \begin{array}{c} 0 \\ \frac{(\rho_{i,j} + \rho_{i-1,j} + \rho_{i,j-1} + \rho_{i-1,j-1})}{\epsilon_0} \end{array} \right. \quad (7)$$

In this equation, the Y factors contain the material parameters and distances between various adjacent gridpoints. They are expressed below in a compact form:

$$Y_{i\pm 1} = \frac{2}{(h_i + h_{i-1})^2} \left\{ \begin{array}{l} (\epsilon_{i,j-1} + \epsilon_{i,j}) \left(\frac{3h_i + h_{i-1}}{h_i} \right) \\ (\epsilon_{i-1,j-1} + \epsilon_{i-1,j}) \left(\frac{h_{i-1} - h_i}{h_i} \right) \\ \left(\frac{h_i + 3h_{i-1}}{h_{i-1}} \right) \end{array} \right\} \quad (8)$$

$$Y_{j\pm 1} = \frac{2}{(h_j + h_{j-1})^2} \left\{ \begin{array}{l} (\epsilon_{i-1,j} + \epsilon_{i,j}) \left(\frac{3h_j + h_{j-1}}{h_j} \right) \\ (\epsilon_{i-1,j-1} + \epsilon_{i,j-1}) \left(\frac{h_{j-1} - h_j}{h_j} \right) \\ \left(\frac{h_j + 3h_{j-1}}{h_{j-1}} \right) \end{array} \right\} \quad (9)$$

$$Y_{i,j} = Y_{i+1,j} + Y_{i-1,j} + Y_{i,j+1} + Y_{i,j-1} \quad (10)$$

It is important to add that in deriving these equations, a particular convention for associating the medium parameters to individual grid cells was employed. Specifically, it was assumed that the medium parameter values of the entire grid cell were associated with (or assigned to) the lower left corner of that cell. For example, $\epsilon_{i,j}$ is assumed to be constant over the shaded grid cell area shown in Fig. 2, while $\epsilon_{i,j-1}$ is constant over the hatched area, which is directly below.

Observe what are the consequences of converting the continuous PDE given in Eq. (4) to its approximate discrete form stated in Eq. (7). First, the boundary value problem over the continuous space, shown in Fig. 1, was “mapped” onto a discrete grid (see Fig. 2). Clearly, if the number of gridpoints increases, then spacing between them will become smaller. This provides a better approximation to the actual continuous problem. In fact, in the

limit as the number of gridpoint reaches infinity, the discrete and continuous problems become identical.

In addition to illustrating the “mapping” of a continuous problem to its discrete analog, Fig. 2 also clearly demonstrates one of FDM’s undesirable artifacts. Note that objects with smooth surfaces are replaced with a “staircased” approximation. Obviously, this approximation can be improved by reducing the discretization grid spacing. However, this will increase the number of points where the potential has to be calculated, thus increasing the computational complexity of the problem. One way to overcome this is to use a nonuniform discretization, as depicted in Fig. 2. Specifically, finer discretization can be used in the region near the smooth surface of the cylinder to better approximate its shape, followed by gradually increasing the gridpoint spacing between the cylinder and grid truncation boundary.

At this point, it is also appropriate to add that other, more rigorous methods have been proposed for incorporating curved surfaces into the finite-difference type of algorithms. They are based on special-purpose differencing schemes, which are derived by recasting the same PDEs into their equivalent integral forms. They exploit the surface or contour integration and are used to replace the regular differencing algorithm on the curved surfaces or contours of smooth objects. This approach was already implemented for the solution of dynamic full-wave problems [11] and could be adapted to electrostatic boundary value problems as well.

Finally, Eq. (7) also shows that the potential at any point in space, which is source-free, is a weighted average of the potentials at the neighboring points only. This is typical of PDEs, because they represent physical phenomena only locally—that is, in the immediate vicinity of the point of interest. As will be shown later, one way to “propagate” the local information through the grid is to use an iterative scheme. In this scheme, the known potential, such as V_0 at the surface of the conducting cylinder in Fig. 1, is carried throughout the discretized space by stepping through all the points in the grid. The iterations are continued until the change in the potential within the grid is very small.

3.2. “Indirect” Discretization of Governing Equation

As shown in the previous section, appropriate finite-difference approximations were required for the first- and second-order derivatives in order to convert Eq. (4) to a discrete form. Intermediate points (I, J) were used midway between the regular grid nodes for obtaining average values of the potential, its first derivatives, and dielectric constants to facilitate the derivation of the final update equation for the potential. This can be avoided and an alternative, but equally valid finite-differencing scheme to that given in Eq. (7), which for the sake of brevity is restricted to the Laplace equation only, can be obtained. The first step is to simplify Eq. (4) by recasting it into an integrodifferential form. To achieve this, Eq. (4) should be integrated over a volume that completely encloses any one of the grid nodes. This will be referred to as the volume of the unit cell (V_U), which is bounded by

surface S_U (see Fig. 3). Stoke’s theorem is applied to replace the volume integration by a surface integral:

$$\int_{V_U} \nabla \cdot (\epsilon_r(x,y)\nabla\phi) dv = \oint_{S_U} (\epsilon_r(x,y)\nabla\phi) \cdot \hat{n} ds$$

$$= \oint_{S_U} \epsilon_r(x,y) \frac{\partial\phi}{\partial n} ds = 0 \tag{11}$$

where \hat{n} is the unit vector, normal to S_U and pointing out of it.

To illustrate this “indirect” discretization procedure in two dimensions, consider surface $S_{U,i,j}$ (i.e., just a contour) shown in Fig. 3, which completely encloses gridpoint i, j . The integral in Eq. (11) reduces to four terms, each corresponding to one of the faces of $S_{U,i,j}$. For example, the integral over the right edge (or face) of $S_{U,i,j}$ can be approximated as

$$\frac{\phi_{i+1,j} - \phi_{i,j}}{h_i} \left(\frac{h_{j-1}}{2} \epsilon_{i,j-1} + \frac{h_j}{2} \epsilon_{i,j} \right) \tag{12}$$

When the remaining integrals are evaluated and the like terms are grouped together, the final form of the “indirect” FDM algorithm is obtained. This algorithm is identical in form to that given earlier in Eq. (7). However, the weighting Y factors are different from those appearing in Eqs. (8) and (9). Their complete expressions are given by

$$Y_{\{i+1\}}^{\{i-1\}} = \left(h_{j-1} \epsilon_{\{i,j-1\}} + h_j \epsilon_{\{i,j\}} \right) \frac{1}{2h_{\{i-1\}}} \tag{13}$$

where $Y_{i,j}$ is the sum of all other Y s, the same as before [see Eq. (10)].

It should be added that this approach has been suggested several times in the literature—for example, in Refs. 12 and 13. Therein, Eq. (11) was specifically used to enforce the boundary conditions at the interface between different dielectrics only in order to “connect” FDM algorithms based on the Laplace equation for the homogeneous regions. However, there is no reason not to use Eq. (11) at every point in space, especially if the boundary

Figure 3. Closed surface completely enclosing a grid node.

value problem involves inhomogeneous media. This form of FDM scheme is completely analogous to that presented in the previous section. In fact, it is a little simpler to derive and involves fewer arithmetic operations.

3.3. Numerical Implementation in Two Dimensions

There are several important numerical issues that must be addressed prior to implementing FDM on the computer. Questions such as how to terminate the grid away from the region of interest and which form of the FDM algorithm to choose must be answered first. The following discussion provides some simple answers, postponing the more detailed treatment until later.

3.3.1. Simplistic Grid Boundary Truncation. Clearly, since even today’s computers do not have infinite resources, the computational volume (or space) must somehow be terminated (see Fig. 4). The simplest approach is to place the truncation boundary far away from the region of interest and to set the potential on it equal to zero. This approach is valid as long as the truncation boundary is placed far enough not to interact with the charged objects within, as for example the “staircased” cylinder shown in Fig. 4. The downside of this approach is that it leads to large computational volumes, thereby requiring unnecessarily high computer resources. This problem can be partly overcome by using a nonuniform grid, with progressively increasing spacing from the cylinder toward the truncation boundary. It should be added that there are other ways to simulate the open-boundary conditions, which is an advanced topic and will be discussed later.

3.3.2. Iteration-Based Algorithm. Several iteration methods can be applied to solve Eq. (7), each leading to different convergence rates (i.e., how quickly an acceptable solution is obtained). A complete discussion of this

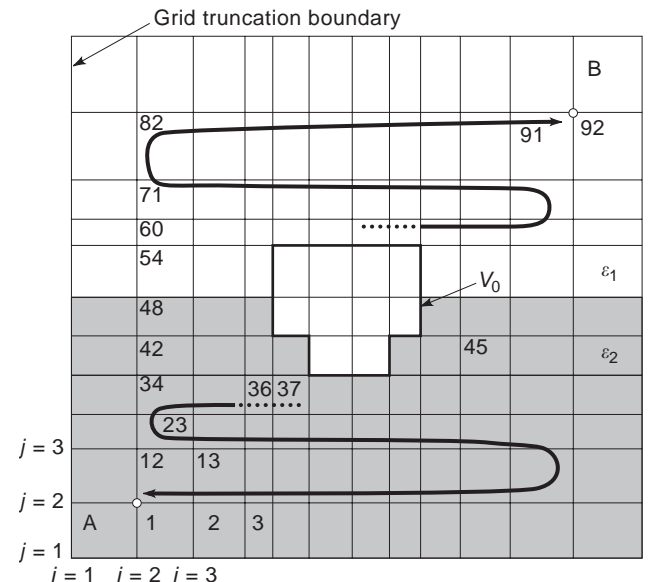

Figure 4. Complete discretized geometry and computational space for cylinder in Fig. 2.

topic, as well as of the accuracy of the numerical approximations in FDM, appears in Ref. 14 and will not be repeated here. The interested reader may also find Ref. 15 quite useful, because it covers such topics in more rigorous detail and includes a comprehensive discussion on the proof of the existence of the finite-differencing solution to PDEs. However, for the sake of brevity, this article deals with the most popular and widely used approach, which is called successive overrelaxation (SOR) (see, e.g., Ref. 14).

SOR is based on Eq. (7), which is rearranged as

$$\begin{aligned} \phi_{i,j}^{p+1} &\approx \phi_{i,j}^p + \frac{\Omega}{Y_{i,j}} (Y_{i+1}\phi_{i+1,j}^p + Y_{i-1}\phi_{i-1,j}^{p+1} + Y_{j+1}\phi_{i,j+1}^p \\ &\quad + Y_{j-1}\phi_{i,j-1}^{p+1} - Y_{i,j}\phi_{i,j}^p) \\ &= (1 - \Omega)\phi_{i,j}^p + \frac{\Omega}{Y_{i,j}} (Y_{i+1}\phi_{i+1,j}^p + Y_{i-1}\phi_{i-1,j}^{p+1} \\ &\quad + Y_{j+1}\phi_{i,j+1}^p + Y_{j-1}\phi_{i,j-1}^{p+1}) \end{aligned} \tag{14}$$

In this equation, superscripts p and $p + 1$ respectively denote the present and previous iteration steps and Ω is the so-called overrelaxation factor, whose value can vary from 1 to 2. Note that Ω accelerates the change in the potential from one iteration to the next at any point in the grid. It can be a constant throughout the entire relaxation (solution) process or be varying according to some heuristic scheme. For example, it was found that the overall rate of convergence is improved by setting Ω near 1.8 at the start of the iteration process and gradually reducing it to 1.2 with the numbers of iterations.

At this point, the only remaining task is to define the appropriate criteria for terminating the FDM algorithm. Although there are rigorous ways of selecting the termination criterion, the following approach, which seems to work quite well, is presented instead. As stated below, it is based on calculating the change in the potential between successive iterations at every point in the grid and comparing the maximum value to the (user-selectable) error criterion:

$$\text{ERR}_{\max} = \sum_{i=1}^{N_x} \sum_{j=1}^{N_y} \max(|\phi_{i,j}^{p+1} - \phi_{i,j}^p|) \tag{15}$$

Although it is simple, the redeeming feature of this approach is that the error is computed globally within the grid, rather than within a particular single grid node. The danger in monitoring the convergence of the algorithm at a single node may lead to premature termination or to an unnecessarily prolonged execution.

Now that an error on which the algorithm termination criterion is based has been defined, the iteration process can be initiated. Note that there are several ways to “march” through the grid. Specifically, the updating of the potential may be started from point A , as shown in Fig. 4, and end at point B , or vice versa. If the algorithm works in this manner, the solution will tend, to be artificially “biased” toward one region of the grid, and the potential is “more converged” in regions where the

iteration starts. The obvious way to avoid this is to change the direction of the “marching” process after every few iterations. As a result, the potential will be updated throughout the grid uniformly and will converge at the same rate. Note from Fig. 4 that the potential only needs to be computed at the internal points of the grid, since the potential at the outer boundary is (for now) assumed to be zero. Moreover, it should also be evident that the potential at the surface of the cylinder, as well as inside it, is known (V_0) and need not be updated during the iteration process.

3.3.3. Matrix-Based Algorithm. Implementation of the finite-difference algorithms is not restricted to relaxation techniques only. The solution of Eq. (4) for the electrostatic potential can also be obtained using matrix methods. To illustrate this, the FDM approximation to Eq. (4)—namely, Eq. (7)—will be rewritten as

$$\begin{aligned} (Y_{i+1}\phi_{i+1,j} + Y_{i-1}\phi_{i-1,j} + Y_{j+1}\phi_{i,j+1} + Y_{j-1}\phi_{i,j-1} \\ - Y_{i,j}\phi_{i,j}) \approx 0 \end{aligned} \tag{16}$$

This equation must be enforced at every internal point in the grid, except at the surface of and internal to the conductors, where the potential is known (V_0). For the particular example of the cylinder shown in Fig. 4, these points are numbered 1 through 92. This implies that there are 92 unknowns, which must be determined. To accomplish this, Eq. (16) must be enforced at 92 locations in the grid, leading to a system of 92 linear equations that must be solved simultaneously.

To demonstrate how the equations are set up, consider nodes 1, 36, and 37 in detail. At node 1 (where $i=j=2$), Eq. (16) reduces to

$$Y_3^i\phi_{12} + Y_3^j\phi_{2} - Y_{2,2}\phi_1 = 0 \tag{17}$$

where the fact that the potential at the outer boundary nodes $(i,j)=(1,2)$ and $(2,1)$ is zero was taken into account and superscripts i and j on Y were introduced as a reminder whether they correspond to $Y_{i\pm 1}$ or $Y_{j\pm 1}$. In addition, the potential at nodes $(i,j)=(2,2)$, $(3,2)$, and $(2,3)$ was also relabeled as ϕ_1 , ϕ_2 , and ϕ_{12} , respectively. Similarly, at nodes 36 ($i,j=4,5$) and 37 ($i,j=5,5$), Eq. (16) becomes

$$Y_5^i\phi_{37} + Y_3^i\phi_{35} + Y_6^j\phi_{44} + Y_4^j\phi_{25} - Y_{4,5}\phi_{36} = 0 \tag{18}$$

and

$$Y_4^i\phi_{36} + Y_4^j\phi_{26} - Y_{5,5}\phi_{37} = -Y_6^iV_0 - Y_6^jV_0 = V_{37} \tag{19}$$

where [in Eq. (19)] the known quantities (the potentials on the surface of the cylinder at nodes 5,6 and 6,5) were moved to the right-hand side.

Similar equations can be obtained at the remaining free grid nodes where the potential is to be determined. Once Eq. (16) has been enforced everywhere within the grid, the resulting set of equations can be combined into the following matrix form:

arrays can be used to find the index k (to identify ϕ_k) for grid coordinates (i, j) in the following manner:

1. Given i and j , compute $code = i \cdot N_y + j$.
2. Find the array index m , such that $code = CODE(m)$, using the bisection search algorithm.
3. Look up k using $k = INDEX(m)$, thereby identifying the appropriate ϕ_k , given i, j .

The criteria for selecting a particular sparsity coding scheme for the matrix $[Y]$ are (1) the minimization of storage requirements and (2) optimization of matrix operations—in particular, multiplication and LU factoring. One very efficient scheme is based on storing $[Y]$ using four one-dimensional arrays:

1. Real array $DIAG(i) =$ diagonal entry of row i
2. Real array $OFFD(i) =$ i th nonzero off-diagonal entry (scanned by rows)
3. Integer array $IROW(i) =$ index of first nonzero off-diagonal entry of row i
4. Integer array $ICOL(i) =$ column number of i th nonzero off-diagonal entry (scanned by rows)

Assuming a system of N equations, the arrays $DIAG$, $IROW$, $OFFD$, and $ICOL$ have N , $N+1$, $4N$, and $4N$ entries, respectively. Therefore, the total memory required to store a sparsity-coded matrix $[Y]$ is approximately 40N bytes (assuming 32-bit storage for both real and integer numbers). On the other hand, $4N^2$ bytes would be needed to store the full form of $[Y]$. For example, in a system with 1000 equations, the full storage mode requires 4 megabytes (MB), while the sparsity-coded matrix occupies only 40 kilobytes (KB) of computer memory.

Perhaps the most important feature of sparsity coding is the efficiency with which multiplication and other matrix operations can be performed. This is best illustrated by a sample FORTRAN code needed to multiply a matrix stored in this mode, by a vector $B(i)$:

```

DO I = 1, N
    C(I) = DIAG(I) * B(I)
    DO J = IROW(I), IROW(I+1) - 1
        C(I) = C(I) + OFFD(J) * B(ICOL(J))
    ENDDO
ENDDO

```

(23)

This double loop involves $5N$ multiplications and $4N$ additions, without the need of search and compare operations. To perform the same operation using the brute-force, full-storage approach would require N^2 multiplications and N^2 additions. Thus, for a system of 1000 unknowns, the sparsity-based method is at least 200 times faster than the full-storage approach in performing matrix multiplication.

To solve Eq. (20), $[Y]$ can be inverted and the inverse multiplied by $[V_0]$. However, for sparse systems, complete matrix inversion should be avoided. The reason is that, in

most cases, the inverse of a sparse matrix is full, for which the advantages of sparsity coding cannot be exploited. The solution of sparsity coded linear systems is typically obtained by using the LU decomposition, since usually the L and U factors are sparse. Note that the sparsity of the L and U factor matrices can be significantly affected by the ordering of the grid nodes (i.e., in which sequence $[\phi]$ was filled). Several very successful node ordering schemes that are associated with the analysis of electrical networks were reported for the solution of sparse matrix equations (see Ref. 16). Unfortunately, the grid node connectivity in typical FDM problems is such that the L and U factor matrices are considerably fuller than the original matrix $[Y]$, even if the nodes are optimally ordered. Therefore, direct solution techniques are not as attractive for use in FDM as they are for large network problems.

Unlike the direct solution methods, there are iterative techniques for solving matrix equations, which do not require LU factoring. One of them is the conjugate-gradient method [17–19].

This method uses a sequence of matrix/vector multiplications, which can be performed very efficiently using the sparsity coding scheme described above.

3.3.4. Convergence. Given the FDM equations in matrix form, either direct [16] or iterative methods [17–19] such as the conjugate-gradient method (CGM) can be readily applied. It is important to point out that CGM-type algorithms are considerably faster than direct solution, provided a good initial guess is used. One simple approach is to assume that the potential is zero everywhere, but on the surface of the conductor, and let this be an initial guess to start the CGM algorithm. For this initial guess, the convergence is very poor and the solution takes a long time. To improve the initial guess, several iterations of the SOR-based FDM algorithm can be performed to calculate the potential everywhere within the grid. It was found that for many practical problems, 10–15 iterations provide a very good initial guess for CGM.

From the performance point of view, the speed of CGM was most noticeable when compared to the SOR-based algorithm. In many problems, CGM was found to be an order of magnitude faster than SOR. In all fairness to SOR, its implementation, as described above, can be improved considerably by using the so-called multigrid/multilevel acceleration [20,21]. The idea behind this method is to perform the iterations over coarse and fine grids alternatively, where the coarse gridpoints also coincide with and are a part of the fine grid. This means that iterations are first performed over a coarse grid, then interpolated to the fine grid and iterated over the fine grid. More complex multigrid schemes involve several layers of grids with different levels of discretization, with the iterations being performed interchangeably on all grids.

Finally, it should be pointed out that theoretical aspects of convergence for algorithms discussed thus far are well documented and are outside the main scope of this article. The interested reader should consult Ref. 15, 18, or 19 for detailed mathematical treatment and assessment of convergence.

4. ADVANCED TOPICS

4.1. Open-Boundary Truncation

If the electrostatic boundary value problem consists of charged conductors in a region of infinite extent, then the simplest approach to truncate the computational (or FDM) boundary is with an equipotential wall of zero voltage. This has the advantage of being easy to implement, but leads to erroneous solution, especially if the truncation boundary is too close to the charged conductors. On the other hand, placing it too far from the region of interest may result in unacceptably large computational volume, which will require large computational resources.

Although some early attempts to overcome such difficulties [5] provided the initial groundwork, rigorous absorbing boundary truncation operators were more recently introduced [22–24] for dynamic problems, which can be modified for electrostatics. They are based on deriving mathematical operators that help simulate the behavior of the potential on a virtual boundary truncation surface, which is placed close to charged conductors (see Fig. 5). In essence, these operators provide the means for numerically approximating the proper behavior of the potential at infinity within a computational volume of finite extent.

Such absorbing boundary conditions (ABCs) are based on the fact that the potential due to any 3D charge distribution is inversely proportional to the distance measured from it. Consider an arbitrary collection of charged conductors shown in Fig. 5. Although it is located in free unbounded space, a fictitious surface will be placed around it, totally enclosing all conductors. If this surface is far away from the charged conductor system—namely, if \vec{r} is much greater than \vec{r}' —then the dominant radial variation of potential, ϕ , will be given by

$$\frac{1}{|\vec{r} - \vec{r}'|} \rightarrow \frac{1}{r} \quad (24)$$

If the fictitious boundary is moved closer toward the conductor assembly, then the potential will also include additional terms with higher inverse powers of r . These

Figure 5. Virtual surface used for boundary truncation.

terms will contribute to the magnitude of the potential more significantly than those with lower inverse powers of r , as r becomes small.

The absorbing boundary conditions emphasize the effect of leading (dominant) radial terms on the magnitude of the potential evaluated on the fictitious (boundary truncation) surface. The ABCs provide the proper analytic means to annihilate the nonessential terms, instead of simply neglecting their contribution. Numerically, this can be achieved by using the so-called absorbing boundary truncation operators.

In general, absorbing boundary operators can be of any order. For example, as shown in Ref. 23, the first- and second-order operators in 3D have the following forms:

$$B_1 u = \frac{\partial u}{\partial r} + \frac{u}{r} = O\left(\frac{1}{r^3}\right) \rightarrow 0 \quad \text{as } r \rightarrow \infty \quad (25)$$

$$B_2 u = \left(\frac{\partial}{\partial r} + \frac{3}{r}\right) \left(\frac{\partial u}{\partial r} + \frac{u}{r}\right) = O\left(\frac{1}{r^5}\right) \rightarrow 0 \quad \text{as } r \rightarrow \infty \quad (26)$$

where u is the scalar electric potential function, ϕ , that satisfies the Laplace equation, and $r = |\vec{r}|$ is the radial distance measured from the coordinate origin (see Fig. 5). Since FDM is based on the iterative solution to the Laplace equation, small increases in the overall lattice (discretized 3D space whose planes are 2D grids) size do not slow the algorithm down significantly, nor do they require an excessive amount of additional computer memory. As a result, from a practical standpoint, the fictitious boundary truncation surface need not be placed too close to the region of interest, therefore not requiring the use of high-order ABC operators in order to simulate proper behavior of the potential at lattice boundaries accurately. Consequently, in practice, it is sufficient to use the first-order operator, B_1 , to model open boundaries. Previous numerical studies suggest that this choice is indeed adequate for many engineering problems [25].

To be useful for geometries that mostly conform to rectangular coordinates, the absorption operator B_1 , when expressed in Cartesian coordinates, takes on the following form

$$\frac{\partial u}{\partial x} \approx \mp \left(\frac{u}{x} + \frac{y}{x} \frac{\partial u}{\partial y} + \frac{z}{x} \frac{\partial u}{\partial z} \right) \quad (27)$$

$$\frac{\partial u}{\partial y} \approx \mp \left(\frac{u}{y} + \frac{x}{y} \frac{\partial u}{\partial x} + \frac{z}{y} \frac{\partial u}{\partial z} \right) \quad (28)$$

$$\frac{\partial u}{\partial z} \approx \mp \left(\frac{u}{z} + \frac{x}{z} \frac{\partial u}{\partial x} + \frac{y}{z} \frac{\partial u}{\partial y} \right) \quad (29)$$

where \mp signs correspond to the outward pointing unit normal vectors $\hat{n} = \pm(\hat{x}, \hat{y}, \hat{z})$ for operators in Eqs. (27), (28), and (29), respectively.

The finite-difference approximations to the preceding equations that have been employed in the open boundary

FDM algorithm are given by

$$u_{i+1,j,k} = u_{i-1,j,k} - \frac{(h_i + h_{i-1})}{(x_{i,j,k} - x_{\text{ref}})} \left[u_{i,j,k} + \frac{(y_{i,j,k} - y_{\text{ref}})(u_{i,j+1,k} - u_{i,j-1,k})}{(h_j + h_{j-1})} + \frac{(z_{i,j,k} - z_{\text{ref}})(u_{i,j,k+1} - u_{i,j,k-1})}{(h_k + h_{k-1})} \right] \quad (30)$$

$$u_{i,j+1,k} = u_{i,j-1,k} - \frac{(h_j + h_{j-1})}{(y_{i,j,k} - y_{\text{ref}})} \left[u_{i,j,k} + \frac{(x_{i,j,k} - x_{\text{ref}})(u_{i+1,j,k} - u_{i-1,j,k})}{(h_i + h_{i-1})} + \frac{(z_{i,j,k} - z_{\text{ref}})(u_{i,j,k+1} - u_{i,j,k-1})}{(h_k + h_{k-1})} \right] \quad (31)$$

$$u_{i,j,k+1} = u_{i,j,k-1} - \frac{(h_k + h_{k-1})}{(z_{i,j,k} - z_{\text{ref}})} \left[u_{i,j,k} + \frac{(x_{i,j,k} - x_{\text{ref}})(u_{i+1,j,k} - u_{i-1,j,k})}{(h_i + h_{i-1})} + \frac{(y_{i,j,k} - y_{\text{ref}})(u_{i,j+1,k} - u_{i,j-1,k})}{(h_j + h_{j-1})} \right] \quad (32)$$

where $(x, y, z)_{\text{ref}}$ are the x, y, z components of a vector pointing (referring) to the geometric center of the charged conductor assembly, with other quantities that appear in Eqs. (30)–(32) shown in Fig. 6. It is important to add that the $(x, y, z)_{i,j,k} - (x, y, z)_{\text{ref}}$ terms are the x, y, z components of a vector from the truncation boundary to the geometric center of the charged conductor system.

Notice that Fig. 6 graphically illustrates the FDM implementation of the open-boundary truncation on lat-

Figure 6. Detail of FDM lattice near the boundary truncation surface.

tice faces aligned along the xz plane. On this plane, the normal is in the y direction, for which Eq. (31) is the FDM equivalent of the first-order absorbing boundary operator in Cartesian coordinates. Similarly, Eqs. (32) and (30) are used to simulate the open boundary on xy and yz faces of the lattice, respectively.

When reduced to two dimensions, the absorption operator, B_1 , in Cartesian coordinates, takes on the form given below:

$$\frac{\partial u}{\partial x} \approx \mp \left(\frac{1}{x} + \frac{y}{x} \frac{\partial u}{\partial y} \right) \quad (33)$$

$$\frac{\partial u}{\partial y} \approx \mp \left(\frac{1}{y} + \frac{\partial u}{\partial x} \right) \quad (34)$$

The discrete versions of these equations can be written as

$$u_{i+1,j} = \mp \left\{ u_{i-1,j} - \frac{(h_i + h_{i-1})}{(x_{i,j} - x_{\text{ref}})} \left[u_{i,j} + \frac{(y_{i,j} - y_{\text{ref}})(u_{i,j+1} - u_{i,j-1})}{(h_j + h_{j-1})} \right] \right\} \quad (35a)$$

$$u_{i,j+1} = \mp \left\{ u_{i,j-1} - \frac{(h_j + h_{j-1})}{(y_{i,j} - y_{\text{ref}})} \left[u_{i,j} + \frac{(x_{i,j} - x_{\text{ref}})(u_{i+1,j} - u_{i-1,j})}{(h_i + h_{i-1})} \right] \right\} \quad (35b)$$

where, as before, \mp correspond to the outward pointing unit normal vectors $\hat{n} = \pm(\hat{x}, \hat{y})$ for operators in Eqs. (33) and (34) or (35a) and (35b), respectively. The points $x_{i,j}$ and $y_{i,j}$ denote those points in the grid that are located one cell away from the truncation boundary, while x_{ref} and y_{ref} correspond to the center of the cylinder in Figs. 2 and 4.

Finally, another approach to open-boundary truncation, which is worth mentioning, involves the regular finite-difference scheme supplemented by the use of electrostatic surface equivalence [26]. A virtual surface S_v is defined near the actual grid truncation boundary. The electrostatic potential due to charged objects, enclosed within S_v , is computed using the regular FDM algorithm. Subsequently, it is used to calculate the surface charge density and surface magnetic current, which are proportional to the normal and tangential components of the electric field on S_v .

Once the equivalent sources are known, the potential between the virtual surface and the grid truncation boundary can be readily calculated (for details, see Ref. 26). This procedure is repeated every iteration, and since the potential on the virtual surface is estimated correctly, it produces a physical value of the potential on the truncation boundary. As demonstrated in Ref. 26, this approach leads to very accurate results in boundary value problems with charged conductors embedded in open regions.

It is vastly superior to simply using the grounded conductor to terminate the computational space.

4.2. Inclusion of Dielectric Anisotropy

4.2.1. Network Analog Approach. Many materials such as printed-circuit board (PCB) and microwave circuit substrates, which are commonly used in electrical engineering, exhibit anisotropic behavior. The electrical properties of these materials vary with direction and have to be described by a tensor instead of a single scalar quantity. This section will examine how the anisotropy affects the FDM and how the algorithm must be changed to accommodate the solution of 3D problems containing such materials. The theoretical development presented below is a generalization of that available in Ref. 27 and is restricted to linear anisotropic dielectrics only.

In an attempt to provide a more intuitive interpretation to the abstract nature of the FDM algorithm, an equivalent-circuit model will be used for linear inhomogeneous, anisotropic regions. This approach is called *resistance network analog* [6]. It was initially proposed for approximating the solution of the Laplace equation in two dimensions experimentally, with a network of physical resistors whose values could be adjusted to correspond to the weighting factors [e.g., the Y s in Eq. (7)] that appear in the FDM algorithm. Since its introduction, the resistance network approach has been implemented numerically in the analysis of (1) homogeneous dielectrics in 3D (28) and (2) simple biaxial anisotropic materials (described by diagonal permittivity tensors) in 2D [29].

Since the resistance network analog gives a physical interpretation to FDM, the discretized versions of the Laplace equations for anisotropic media will be recast into this form. As the details of FDM were described earlier, only the key steps in developing the two-dimensional model are summarized below. Moreover, for the sake of brevity, the discussion of the three-dimensional case will be limited to the final equations and their pictorial interpretation.

The Laplace equation for boundary value problems involving inhomogeneous and anisotropic dielectrics in three dimensions is given by

$$\nabla \cdot (\epsilon_0 [\epsilon_r(x, y, z)] \cdot \nabla \phi(x, y, z)) = 0 \tag{36}$$

In this equation, $[\epsilon_r]$ stands for the relative dielectric tensor and is defined as

$$[\epsilon] = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} & \epsilon_{xz} \\ \epsilon_{yx} & \epsilon_{yy} & \epsilon_{yz} \\ \epsilon_{zx} & \epsilon_{zy} & \epsilon_{zz} \end{bmatrix} \tag{37}$$

Since the material properties need not be homogeneous in the region of interest, the elements of $[\epsilon_r]$ are assumed to be functions of position. The dielectric is assumed to occupy only part of the modeling (computational) space, and its properties may vary from point to point. When Eq. (37) is substituted into Eq. (36) and rewritten in a

matrix form as

$$\begin{bmatrix} \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \end{bmatrix} \cdot \begin{bmatrix} \epsilon_{xx} \frac{\partial \phi}{\partial x} + \epsilon_{xy} \frac{\partial \phi}{\partial y} + \epsilon_{xz} \frac{\partial \phi}{\partial z} \\ \epsilon_{yx} \frac{\partial \phi}{\partial x} + \epsilon_{yy} \frac{\partial \phi}{\partial y} + \epsilon_{yz} \frac{\partial \phi}{\partial z} \\ \epsilon_{zx} \frac{\partial \phi}{\partial x} + \epsilon_{zy} \frac{\partial \phi}{\partial y} + \epsilon_{zz} \frac{\partial \phi}{\partial z} \end{bmatrix} = 0 \tag{38}$$

it provides the starting point for developing the corresponding FDM algorithm.

After eliminating the z -dependent terms and fully expanding the equation above by following the notation used throughout this article, the finite-difference approximation for the potential at every nodal point in a 2D grid is given by

$$\phi_{i,j}^{p+1} = (1 - \Omega) \phi_{i,j}^p + \frac{\Omega}{Y_{i,j}} \times \left\{ \begin{aligned} &(\phi_{i+1,j}^p Y_{i+1} + \phi_{i-1,j}^{p+1} Y_{i-1}) \\ &+ (\phi_{i,j+1}^p Y_{j+1} + \phi_{i,j-1}^{p+1} Y_{j-1}) \\ &+ (\phi_{i+1,j+1}^p Y_{i+1,j+1} + \phi_{i-1,j-1}^{p+1} Y_{i-1,j-1}) \\ &- (\phi_{i-1,j+1}^p Y_{i-1,j+1} + \phi_{i+1,j-1}^{p+1} Y_{i+1,j-1}) \end{aligned} \right\} \tag{39}$$

where

$$Y_{i\pm 1} = \left(\begin{array}{c} (\epsilon_{i,j-1}^{yy} + \epsilon_{i,j}^{yy}) \\ (\epsilon_{i-1,j-1}^{yy} + \epsilon_{i-1,j}^{yy}) \end{array} \right) \left(\frac{1}{h_i} + \frac{2}{h_i + h_{i-1}} \right) + \left(\frac{2}{h_i + h_{i-1}} \right) \left(\frac{2}{h_j + h_{j-1}} \right) [(\epsilon_{i,j}^{zy} + \epsilon_{i-1,j}^{zy}) - (\epsilon_{i-1,j-1}^{zy} + \epsilon_{i,j-1}^{zy})] \tag{40}$$

$$Y_{j\pm 1} = \left(\begin{array}{c} (\epsilon_{i-1,j}^{zz} + \epsilon_{i,j}^{zz}) \\ (\epsilon_{i-1,j-1}^{zz} + \epsilon_{i,j-1}^{zz}) \end{array} \right) \left(\frac{1}{h_j} + \frac{2}{h_j + h_{j-1}} \right) + \left(\frac{2}{h_i + h_{i-1}} \right) \left(\frac{2}{h_j + h_{j-1}} \right) [(\epsilon_{i,j-1}^{yz} + \epsilon_{i,j}^{yz}) - (\epsilon_{i-1,j-1}^{yz} + \epsilon_{i-1,j}^{yz})] \tag{41}$$

$$Y_{i\pm 1, j\pm 1} = Y_{i\pm 1, j} + Y_{i, j\pm 1} = \left(\frac{2}{h_i + h_{i-1}} \right) \left(\frac{2}{h_j + h_{j-1}} \right) [(\epsilon_{i,j}^{yz} + \epsilon_{i-1,j}^{yz} + \epsilon_{i,j-1}^{yz} + \epsilon_{i-1,j-1}^{yz}) + (\epsilon_{i-1,j}^{zy} + \epsilon_{i-1,j-1}^{zy} + \epsilon_{i,j-1}^{zy} + \epsilon_{i-1,j-1}^{zy})] \tag{42}$$

$$Y_{i,j} = Y_{i+1} + Y_{i-1} + Y_{j+1} + Y_{j-1} \tag{43}$$

Note that, unlike the treatment of isotropic dielectrics, the permittivity of each cell is now described by a tensor

Figure 7. Detail with FDM cell for anisotropic medium in two dimensions.

Figure 8. Network analog for 2D FDM algorithm at gridpoint i, j for arbitrary anisotropic medium.

(see Fig. 7). In addition, the presence of the anisotropy is responsible for added coupling between the voltage $\phi_{i,j}$ and voltages $\phi_{i\pm 1, j\pm 1}$ (actually all four combinations of the subscripts).

The symbols Y in Eq. (39) can be interpreted as admittances representing the “electrical link” between the gridpoint voltages. The resulting equivalent network for Eq. (39) can thus be represented pictorially as shown in Fig. 8.

Similarly, after fully expanding Eq. (36) in three dimensions, the following finite-difference approximation for the potential at every nodal point in a 3D lattice can be obtained:

$$\phi_{i,j,k}^{p+1} = (1 - \Omega)\phi_{i,j,k}^p + \frac{\Omega\phi_{\text{new}}}{Y_{i,j,k}} \quad (44)$$

where ϕ_{new} is defined as

$$\begin{aligned} \phi_{\text{new}} = & \phi_{i+1,j,k}^p(Y_{i+1} + Y_1^A) + \phi_{i-1,j,k}^{p-1}(Y_{i-1} - Y_1^A) \\ & + \phi_{i,j+1,k}^p(Y_{j+1} + Y_2^A) + \phi_{i,j-1,k}^{p-1}(Y_{j-1} - Y_2^A) \\ & + \phi_{i,j,k+1}^p(Y_{k+1} + Y_3^A) + \phi_{i,j,k-1}^{p-1}(Y_{k-1} - Y_3^A) \\ & + Y_4^A[(\phi_{i+1,j+1,k}^p - \phi_{i-1,j-1,k}^{p-1}) - (\phi_{i-1,j+1,k}^p + \phi_{i+1,j-1,k}^p)] \\ & + Y_5^A[(\phi_{i+1,j,k+1}^p + \phi_{i-1,j,k-1}^{p-1}) - (\phi_{i-1,j,k+1}^p + \phi_{i+1,j,k-1}^p)] \\ & + Y_6^A[(\phi_{i,j+1,k+1}^p + \phi_{i,j-1,k-1}^{p-1}) - (\phi_{i,j+1,k-1}^p + \phi_{i,j-1,k+1}^p)] \end{aligned} \quad (45)$$

and

$$Y_{i,j,k} = Y_{i+1} + Y_{i-1} + Y_{j+1} + Y_{j-1} + Y_{k+1} + Y_{k-1}$$

The Y terms appearing in Eqs. (44) and (45) are given by

$$\begin{aligned} Y_{i-1} = & \frac{2}{h_i + h_{i-1}} \left[T_{1,xx} \left(\frac{1}{h_{i-1}} - \frac{2}{h_i + h_{i-1}} \right) \right. \\ & \left. + T_{2,xx} \left(\frac{1}{h_{i-1}} - \frac{2}{h_i + h_{i-1}} \right) \right] \end{aligned} \quad (46)$$

$$\begin{aligned} Y_{i+1} = & \frac{2}{h_i + h_{i-1}} \left[T_{1,xx} \left(\frac{1}{h_i} + \frac{2}{h_i + h_{i-1}} \right) \right. \\ & \left. + T_{2,xx} \left(\frac{1}{h_i} + \frac{2}{h_i + h_{i-1}} \right) \right] \end{aligned} \quad (47)$$

$$\begin{aligned} Y_{j-1} = & \frac{2}{h_j + h_{j-1}} \left[T_{1,yy} \left(\frac{1}{h_{j-1}} - \frac{2}{h_j + h_{j-1}} \right) \right. \\ & \left. + T_{2,yy} \left(\frac{1}{h_{j-1}} + \frac{2}{h_j + h_{j-1}} \right) \right] \end{aligned} \quad (48)$$

$$\begin{aligned} Y_{j+1} = & \frac{2}{h_j + h_{j-1}} \left[T_{1,yy} \left(\frac{1}{h_j} + \frac{2}{h_j + h_{j-1}} \right) \right. \\ & \left. + T_{2,yy} \left(\frac{1}{h_j} - \frac{2}{h_j + h_{j-1}} \right) \right] \end{aligned} \quad (49)$$

$$\begin{aligned} Y_{k-1} = & \frac{2}{h_k + h_{k-1}} \left[T_{1,zz} \left(\frac{1}{h_{k-1}} - \frac{2}{h_k + h_{k-1}} \right) \right. \\ & \left. + T_{2,zz} \left(\frac{1}{h_{k-1}} + \frac{2}{h_k + h_{k-1}} \right) \right] \end{aligned} \quad (50)$$

$$\begin{aligned} Y_1^A = & \left(\frac{2}{h_j + h_{j-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) (T_{1,yx} - T_{2,yx}) \\ & + \left(\frac{2}{h_k + h_{k-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) (T_{1,zx} - T_{2,zx}) \end{aligned} \quad (51)$$

$$\begin{aligned} Y_2^A = & \left(\frac{2}{h_j + h_{j-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) (T_{1,xy} - T_{2,xy}) \\ & + \left(\frac{2}{h_k + h_{k-1}} \right) \left(\frac{2}{h_j + h_{j-1}} \right) (T_{1,zy} - T_{2,zy}) \end{aligned} \quad (52)$$

$$\begin{aligned} Y_3^A = & \left(\frac{2}{h_k + h_{k-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) (T_{1,xz} - T_{2,xz}) \\ & + \left(\frac{2}{h_k + h_{k-1}} \right) \left(\frac{2}{h_j + h_{j-1}} \right) (T_{1,yz} - T_{2,yz}) \end{aligned} \quad (53)$$

$$Y_4^A = 2 \left(\frac{2}{h_j + h_{j-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) \times \left(\frac{T_{1,xy} + T_{2,xy}}{8} + \frac{T_{1,yx} + T_{2,yx}}{8} \right) \quad (54)$$

$$Y_5^A = 2 \left(\frac{2}{h_k + h_{k-1}} \right) \left(\frac{2}{h_i + h_{i-1}} \right) \times \left(\frac{T_{1,xz} + T_{2,xz}}{8} + \frac{T_{1,zx} + T_{2,zx}}{8} \right) \quad (55)$$

$$Y_6^A = 2 \left(\frac{2}{h_j + h_{j-1}} \right) \left(\frac{2}{h_k + h_{k-1}} \right) \times \left(\frac{T_{1,yz} + T_{2,yz}}{8} + \frac{T_{1,zy} + T_{2,zy}}{8} \right) \quad (56)$$

Figure 9. Network analog for 3D FDM algorithm at gridpoint i, j for anisotropic dielectric with diagonal permittivity tensor.

with the T terms having the following forms:

$$T_{1,xx} = \varepsilon_{i,j-1,k-1}^{xx} + \varepsilon_{i,j,k-1}^{xx} + \varepsilon_{i,j-1,k}^{xx} + \varepsilon_{i,j,k}^{xx} \quad (57a)$$

$$T_{2,xx} = \varepsilon_{i-1,j-1,k-1}^{xx} + \varepsilon_{i-1,j,k-1}^{xx} + \varepsilon_{i-1,j-1,k}^{xx} + \varepsilon_{i-1,j,k}^{xx} \quad (57b)$$

$$T_{1,yy} = \varepsilon_{i-1,j,k-1}^{yy} + \varepsilon_{i,j,k-1}^{yy} + \varepsilon_{i-1,j,k}^{yy} + \varepsilon_{i,j,k}^{yy} \quad (58a)$$

$$T_{2,yy} = \varepsilon_{i-1,j-1,k-1}^{yy} + \varepsilon_{i,j-1,k-1}^{yy} + \varepsilon_{i-1,j-1,k}^{yy} + \varepsilon_{i,j-1,k}^{yy} \quad (58b)$$

$$T_{1,zz} = \varepsilon_{i-1,j-1,k}^{zz} + \varepsilon_{i,j-1,k}^{zz} + \varepsilon_{i-1,j,k}^{zz} + \varepsilon_{i,j,k}^{zz} \quad (59a)$$

$$T_{2,zz} = \varepsilon_{i-1,j-1,k-1}^{zz} + \varepsilon_{i,j-1,k-1}^{zz} + \varepsilon_{i-1,j,k-1}^{zz} + \varepsilon_{i,j,k-1}^{zz} \quad (59b)$$

$$T_{1,xy} = \varepsilon_{i,j-1,k-1}^{xy} + \varepsilon_{i,j,k-1}^{xy} + \varepsilon_{i,j-1,k}^{xy} + \varepsilon_{i,j,k}^{xy} \quad (60a)$$

$$T_{2,xy} = \varepsilon_{i-1,j-1,k-1}^{xy} + \varepsilon_{i-1,j,k-1}^{xy} + \varepsilon_{i-1,j-1,k}^{xy} + \varepsilon_{i-1,j,k}^{xy} \quad (60b)$$

$$T_{1,xz} = \varepsilon_{i,j-1,k-1}^{xz} + \varepsilon_{i,j,k-1}^{xz} + \varepsilon_{i,j-1,k}^{xz} + \varepsilon_{i,j,k}^{xz} \quad (61a)$$

$$T_{2,xz} = \varepsilon_{i-1,j-1,k-1}^{xz} + \varepsilon_{i-1,j,k-1}^{xz} + \varepsilon_{i-1,j-1,k}^{xz} + \varepsilon_{i-1,j,k}^{xz} \quad (61b)$$

$$T_{1,yx} = \varepsilon_{i-1,j,k-1}^{yx} + \varepsilon_{i,j,k-1}^{yx} + \varepsilon_{i-1,j,k}^{yx} + \varepsilon_{i,j,k}^{yx} \quad (62a)$$

$$T_{2,yx} = \varepsilon_{i-1,j-1,k-1}^{yx} + \varepsilon_{i,j-1,k-1}^{yx} + \varepsilon_{i-1,j-1,k}^{yx} + \varepsilon_{i,j-1,k}^{yx} \quad (62b)$$

$$T_{1,yz} = \varepsilon_{i-1,j,k-1}^{yz} + \varepsilon_{i,j,k-1}^{yz} + \varepsilon_{i-1,j,k}^{yz} + \varepsilon_{i,j,k}^{yz} \quad (63a)$$

$$T_{2,yz} = \varepsilon_{i-1,j-1,k-1}^{yz} + \varepsilon_{i,j-1,k-1}^{yz} + \varepsilon_{i-1,j-1,k}^{yz} + \varepsilon_{i,j-1,k}^{yz} \quad (63b)$$

$$T_{1,zx} = \varepsilon_{i-1,j-1,k}^{zx} + \varepsilon_{i,j-1,k}^{zx} + \varepsilon_{i-1,j,k}^{zx} + \varepsilon_{i,j,k}^{zx} \quad (64a)$$

$$T_{2,zx} = \varepsilon_{i-1,j-1,k-1}^{zx} + \varepsilon_{i,j-1,k-1}^{zx} + \varepsilon_{i-1,j,k-1}^{zx} + \varepsilon_{i,j,k-1}^{zx} \quad (64b)$$

$$T_{1,zy} = \varepsilon_{i-1,j-1,k}^{zy} + \varepsilon_{i,j-1,k}^{zy} + \varepsilon_{i-1,j,k}^{zy} + \varepsilon_{i,j,k}^{zy} \quad (65a)$$

$$T_{2,zy} = \varepsilon_{i-1,j-1,k-1}^{zy} + \varepsilon_{i,j-1,k-1}^{zy} + \varepsilon_{i-1,j,k-1}^{zy} + \varepsilon_{i,j,k-1}^{zy} \quad (65b)$$

Note that Eq. (45) has a similar interpretation as its 2D counterpart Eq. (39). It can also be represented by an equivalent network, whose diagonal terms are shown in

Fig. 9. For clarity, the off-diagonal terms, which provide the connections of $\phi_{i,j,k}$ to the voltages at the remaining nodes in Eq. (45), are shown separately in Fig. 10.

4.2.2. Coordinate Transformation Approach. Coordinate transformations can be used to simplify the solution to electrostatic boundary value problems. Such transformations can reduce the complexity arising from complicated geometry or from the presence of anisotropic materials. In general, these methods utilize coordinate transformation to map complex geometries or material properties into simpler ones, through a specific relationship that links each point in the original and transformed problems, respectively.

One class of coordinate transformations, known as *conformal mapping*, is based on modifying the original complex geometry to one for which an analytic solution is available. This technique requires extensive mathematical expertise in order to identify an appropriate coordinate transformation function. Its applications are limited to a few specific geometrical shapes for which such functions exist. Furthermore, the applications are restricted to two-dimensional problems. Even though this technique can be very powerful, it is usually rather tedious and thus it is considered beyond the scope of this article. The interested reader can refer to Ref. 30, among others, for further details.

Figure 10. Network analog for 3D FDM algorithm at gridpoint i, j for arbitrary anisotropic dielectric.

The second class of coordinate transformations reduces the complexity of the FDM formulation in problems involving anisotropic materials. As described in the previous section, the discretization of the Laplace equation in anisotropic regions [Eq. (36)] is considerably more complicated than the corresponding procedure for isotropic media [Eq. (7)]. However, it can be shown that a sequence of rotation and scaling transformations can convert any symmetric permittivity tensor into an identity matrix (i.e., free space). As a result, the FDM solution of the Laplace equation in the transformed coordinate system is considerably simplified, since the anisotropic dielectric is eliminated.

To illustrate the concept, this technique will be demonstrated with two-dimensional examples. In 2D (no z dependence is assumed) the Laplace equation can be written as

$$\nabla \cdot ([\epsilon_r(x,y)]\nabla\phi) = 0 \tag{66}$$

where

$$[\epsilon_r] = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} \\ \epsilon_{yx} & \epsilon_{yy} \end{bmatrix} \tag{67}$$

If the principal (crystal or major) axes of the dielectric are aligned with the coordinate system of the geometry, then the off-diagonal terms vanish. Otherwise, $[\epsilon_r]$ is a full symmetric matrix. In this case, any linear coordinate transformation of the form

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = [A] \begin{bmatrix} x \\ y \end{bmatrix} \tag{68}$$

(where $[A]$ is a 2×2 nonsingular matrix of constant coefficients) also transforms the permittivity tensor as follows:

$$[\epsilon'] = [A]^{-1}[\epsilon_r][A] \tag{69}$$

Next, consider the structure shown in Fig. 11a. It consists of a perfect conductor (metal) embedded in an anisotropic dielectric, all enclosed within a rectangular conducting shell. The field within the rectangular shell must be determined given the potentials on all conductors. In this example, $[\epsilon_r]$ is assumed to be diagonal:

$$[\epsilon_r] = \begin{bmatrix} \epsilon_{xx} & 0 \\ 0 & \epsilon_{yy} \end{bmatrix} \tag{70}$$

By scaling the coordinates with

$$[A] = \begin{bmatrix} 1/\sqrt{\epsilon_{xx}} & 0 \\ 0 & 1/\sqrt{\epsilon_{yy}} \end{bmatrix} \tag{71}$$

the permittivity can be transformed into an identity matrix. The geometry of the structure is deformed as shown in Fig. 11b, with the corresponding rectangular

Figure 11. Graphical representation of coordinate transformation for homogeneous anisotropic dielectric with diagonal permittivity tensor.

discretization grid depicted in Fig. 11c. Note that the locations of the unknown potential variables are marked by white dots, while the conducting boundaries are represented by known potentials and their locations are denoted by black dots. The potential in the transformed boundary value problem can now be computed by applying the FDM algorithm, which is specialized for free space, since $[\epsilon_r]$ is an identity matrix.

Once the potential is computed everywhere, other quantities of interest, such as the E field and charge, can be calculated next. However, to correctly evaluate the

required space derivatives, transformation back to original coordinates is required, as illustrated in Fig. 11d. Note that in spite of the resulting simplifications, this method is limited to cases where the entire computational space is occupied by a single homogeneous anisotropic dielectric.

In general, when the principal (or major) axes of the permittivity are arbitrarily orientated with respect to the coordinate axes of the geometry, $[\epsilon_r]$ is a full symmetric matrix. In this case, $[\epsilon_r]$ can be diagonalized by an orthonormal coordinate transformation. Specifically, there exists a rotation matrix of the form

$$[A] = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \tag{72}$$

such that the product

$$[\epsilon'] = [A]^T [\epsilon_r] [A] \tag{73}$$

is a diagonal matrix. The angle θ is defined as the angle by which the coordinate system should be rotated to align it with the major axes of the dielectric.

Consider the structure shown in Fig. 12a, which is enclosed in a metallic shell. However, in this example the nonconducting region of interest includes both free space and an anisotropic dielectric. Furthermore, the major axis of $[\epsilon_r]$ is at 30° with respect to that of the structure. The effect of rotating the coordinates by $\theta = -30^\circ$ leads to a geometry shown in Fig. 12b. In the transformed coordinate system, the major axis of the permittivity is horizontal and $[\epsilon_r]$ is a diagonal matrix. Observe that this

transformation does not affect the dielectric properties of the free-space region (or of any other isotropic dielectrics, if present). However, the subsequent scaling operation for transforming the properties of the anisotropic region to free space is not useful. Such transformation also changes the properties of the original free-space region to those exhibiting anisotropic characteristics. Regardless of this limitation, the coordinate rotation alone considerably simplifies the FDM algorithm of Eq. (45) to

$$\begin{aligned} \phi_{\text{new}} = & \phi_{i+1,j,k}^p (Y_{i+1} + Y_1^A) + \phi_{i-1,j,k}^{p-1} (Y_{i-1} - Y_1^A) \\ & + \phi_{i,j+1,k}^p (Y_{j+1} + Y_2^A) + \phi_{i,j-1,k}^{p-1} (Y_{j-1} - Y_2^A) \end{aligned} \tag{74}$$

where all z -dependent (or k) terms have been removed.

Without the rotation, the permittivity is characterized by Eq. (67). Under such conditions, the corresponding FDM update equation includes four additional potential variables, as shown below:

$$\begin{aligned} \phi_{\text{new}} = & \phi_{i+1,j,k}^p (Y_{i+1} + Y_1^A) + \phi_{i-1,j,k}^{p-1} (Y_{i-1} - Y_1^A) \\ & + \phi_{i,j+1,k}^p (Y_{j+1} + Y_2^A) + \phi_{i,j-1,k}^{p-1} (Y_{j-1} - Y_2^A) \\ & + Y_4^A [(\phi_{i+1,j+1,k}^p - \phi_{i-1,j-1,k}^{p-1}) \\ & - (\phi_{i-1,j+1,k}^p + \phi_{i+1,j-1,k}^{p-1})] \end{aligned} \tag{75}$$

The simplification resulting from coordinate rotation in three dimensions is even more significant. In the general

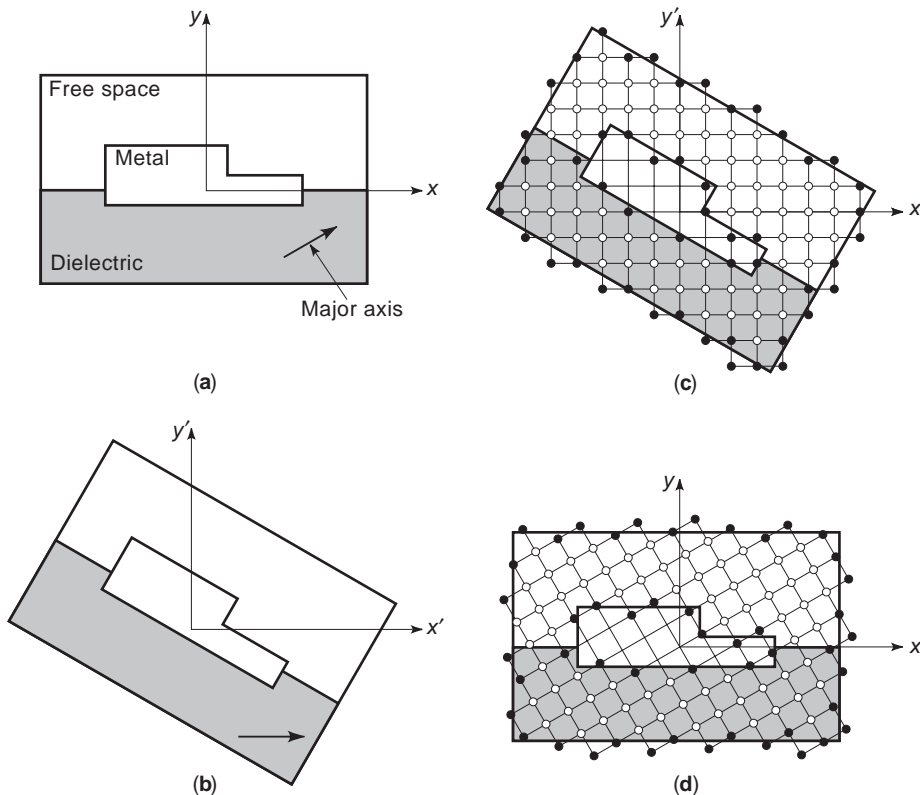

Figure 12. Graphical representation of coordinate transformation for inhomogeneous anisotropic dielectric with diagonal permittivity tensor.

case, the full FDM algorithm [Eq. (45)] contains 18 terms, while in the rotated coordinates the new equation has only 6.

Next, a rectangular discretization grid is constructed for the transformed geometry as shown in Fig. 12c, with the unknown potential represented by white dots and conducting boundaries denoted by black dots. As can be seen, the rotation complicates the assignment (or definition) of the boundary nodes. In general, a finer discretization may be required to approximate the metal boundaries more accurately.

Once the potential field is computed, the transformation back to the original coordinates is performed by applying the inverse rotation $[A]^T$, as illustrated in Fig. 11d. Note that in the original coordinate system, the grid is rotated and, as such, complicates the computation of electric field. In addition to the required coordinate mapping, this method is also limited to boundary value problems containing only one type of anisotropic dielectric, though any number of isotropic dielectric regions may be present.

The examples above illustrate that coordinate transformations are beneficial in solving a narrow class of electrostatic problems. Undoubtedly, considerable computational savings can be achieved in the calculation of the potential using FDM. However, the computational overhead associated with the pre- and postprocessing can be significant, since the geometry is usually complicated by such transformations.

5. SAMPLE NUMERICAL RESULTS

To illustrate the versatility of FDM in solving engineering problems that involve arbitrary geometries and inhomogeneous materials, consider the cross section of the microwave field-effect transistor (FET) shown in Fig. 13. Note that this device is composed of many different materials, each of different thickness and cross-sectional profile. The FET is drawn to scale, with the $1\ \mu\text{m}$ thickness of the

buffer layer serving as a reference. FDM can be used to calculate the potential and field distribution throughout the entire cross section of the FET. This information can be used by the designer to investigate such effect as material breakdown near the metallic electrodes. In addition, the computed field information can be used to determine the parasitic capacitance matrix of the structure, which can be used to improve the circuit model of this device and is very important in digital circuit design. Finally, it should be noted that the losses associated with the silicon can also be computed using FDM as shown in Eq. (25).

It should be added that in addition to displaying the potential distribution over the cross section of the FET, Fig. 13 also illustrates the implementation of open-boundary truncation operators. Since the device is located in an open boundary environment, it was necessary to artificially truncate the computation space (or 2D grid). Note that, as demonstrated in Ref. 25, only the first-order operator was sufficient to obtain accurate representation of the potential in the vicinity of the electrodes as well as near the boundary truncation surface.

A sample with three-dimensional geometry that can be easily analyzed with the FDM is shown in Fig. 14. The insulator in the multilayer ceramic capacitor is assumed to be anisotropic barium titanate dielectric, which is commonly used in such components. The permittivity tensor is diagonal and its elements are $\epsilon_{xx} = 1540$, $\epsilon_{yy} = 290$, and $\epsilon_{zz} = 1640$. To demonstrate the effect of anisotropy on this passive electrical component, its capacitance was calculated as a function of the misalignment angle between the crystal axes of the insulator and the geometry of the structure (see Fig. 15).

For the misalignment angle (or rotation of axes) in the yz plane, the capacitance of this structure was computed. The results of the computations are plotted in Fig. 16. Note that the capacitance varies considerably with the rotation angle. Such information is invaluable to a designer, since the goal of the design is to maximize the capacitance for the given dimensions of the structure.

Figure 14. Geometry of a multilayer ceramic chip capacitor. All dimensions are in millimeters.

The preceding examples are intended to demonstrate the applicability of FDM to the solution of practical engineering boundary value problems. FDM has been used extensively in analysis of other practical problems. The interested reader can find additional examples where FDM was used in Refs. 31–37.

6. SUMMARY

Since the strengths and weaknesses of FDM were mentioned throughout this article, as were the details dealing with the derivation and numerical implementation of this method, they need not be repeated. However, the reader should realize that FDM is best suited for boundary value problems with complex geometries and arbitrary material composition. The complexity of the problem is the primary motivating factor for investing the effort into developing a general-purpose volumetric analysis tool.

Acknowledgments

The authors wish to express their sincere thanks to many members of the technical staff at AVX Corporation for initiating, supporting, and critiquing the development and implementation of many concepts presented in this arti-

BURIED OBJECT DETECTION

AHMET SERDAR TÜRK
 ALI KÖKSAL HOCAGLU
 Information Technologies
 Research Institute
 Gebze, Kocaeli, Turkey

1. INTRODUCTION

The subsurface detection and identification of buried geologic and synthetic (human-produced) structures is currently an important research area and a progressive technological concept on the global scale. The scope of the problem is very complex, and aspects of the topic depend on wide-area demands from the military to the commercial necessities. Some examples are the localization of the underground pipes, buried mines, and archeological or anthropological artifacts. The variety of unknown false and undesired targets under the ground complicates the object identification task. In addition, the medium involved is usually lossy and inhomogeneous. The size, geometry, constitution (dielectric, metallic, explosive, etc.), and depth of the target object and the characteristics of the medium (wet soil, sand, etc.) are the principal parameters for the detector designs. As yet, there is unfortunately still no single method or unique system that can detect all kinds of objects at arbitrary size, structure, depth, and soil. Therefore, a few numbers of the convenient sensor technologies are considered regarding to the specific situations. These sensors may have common, similar, or different capabilities for the detection of the desired targets.

This article is an introduction to buried-object detection and attempts to compile and present the available methods to readers who are potentially involved in physics, geophysics, civil engineering, archeology, or electrical engineering, regardless of their educational or academic background levels. On this scope, different sensor technologies and radar systems mainly based on the electromagnetic, acoustic, infrared, or chemical methods are examined with the cons and pros such as operating principles, strengths, limitations, and feasibilities. Furthermore, some convenient multisensor approaches for wide-range applications are discussed to attain the best detection performance level in each specific case.

2. SENSOR TYPES

The main sensors for buried-object detection are based on the electromagnetic, acoustic, seismic, and optical technologies. The electromagnetic sensors are divided into two groups: electromagnetic induction (EMI) and ground penetrating radar (GPR). The EMI or metal detector uses low-frequency electromagnetic fields to induce the eddy currents in metal components of buried objects. It is a very mature, popular, and relatively inexpensive sensor technology performed in a wide range of environments for conducting target detection. The main limitation of the EMI sensor is the possible metallic clutter of the medium, especially for the low-conductivity or small-metallic-content objects. The GPR is another widely used and established electromagnetic sensor type. The operating principle is the reflection and backscattering of the radiofrequency (RF) waves from buried metallic or dielectric objects. GPR detects all anomalies under the ground, even if nonmetal. The most important problems are the clutter due to the unwanted objects in soil and the buried targets that have constitutive parameters similar to those of soil. The acoustic and seismic sensors benefit from the sound or seismic wave reflection from the object principles. Although they are not completely established sensor technologies, such detector systems can have low false-alarm rates. Nevertheless, deep buried objects, rough surfaces, and vegetation/mineral-covered or frozen ground present the main difficulties in detection. Optical sensors use the infrared and hyper spectral band to distinguish the target from the temperature and light reflectance differences. If the heat absorbing capacity of the object is much more different from that of the soil, the sensor performance will be very satisfactory. The infrared detector can quickly scan wide areas from high altitudes. However, this is not a suitable sensor for deep-buried-object detection.

Beyond the main sensor technologies mentioned above, a few additional detector systems can be examined either for main sensor performance improvement or some specific applications such as explosive-materials detection. For instance, subsurface microwave tomography uses operating principles similar to those of GPR and achieves the high-resolution imaging of shallow buried objects, electrical impedance tomography determines the electrical conductivity distribution of the surface, and the X-ray sensor images the buried objects with X-ray radiation. Moreover, the systems based on electrochemical, piezo-

electric, nucleonic, and biological methods have proved useful just for the explosive vapor detection. Detailed discussions of all sensor types are presented in the following sections.

3. GROUND-PENETRATING RADAR

3.1. Overview

The terms *ground probing*, *subsurface detecting*, and *surface penetrating* refer to a wide range of electromagnetic methods designed for the detection and identification of buried artifacts or structures beneath the surface, generally termed *ground penetrating radar* (GPR). GPR uses the electromagnetic wave propagation and scattering principles to locate, quantitatively identify, and image the variations in electrical and magnetic properties under the ground. It may be performed from Earth's surface, from a land vehicle, or from an aircraft and has high-resolution in subsurface imaging equal to that of any geophysical method, approaching the centimeter range under the right conditions. Since GPR senses subsurface electrical inhomogeneities, the detection performance of the subsurface features such as depth, orientation, water density, size, and shape are related to the contrast in electrical and magnetic properties. The detection performance can be further improved by quantitative feature interpretation through modeling. The GPR technology is largely application-oriented. Implementation of its hardware and software determines the overall system performance characteristics. The detection range can vary from a few centimeters to tens meters. Metallic or dielectric structures can be detected. Identification of small objects even in the centimetric range is possible. Any metallic object and dielectric discontinuity can be detected by the GPR system in principle. The target may be a long, thin, cylindrical, or spherical object or a planar soil layer and can be classified according to its physical geometry and electrical constitution. All these performances strongly depend on the soil properties and the radar parameters, which are mainly operational frequency, transmitter power, system dynamic range, and electromagnetic wave polarization [1,4,7,13].

Two kinds of GPR systems—the impulse GPR and swept-frequency GPR—are employed in most current applications. The impulse GPR uses time-domain electromagnetic pulse radiation and scattering principles.

Table 1. Radar Cross Section Formulas of Basic Target Geometries

Object	Aspect Direction	RCS (dBsm)	Shape Parameters
Sphere	Omnidirectional	πR^2	Sphere radius R (m)
Cylinder	Broadside	$\frac{2\pi a d^2}{\lambda}$	Cylinder radius a (m) Cylinder length d (m)
Flat plate	Normal	$\frac{4\pi w^2 h^2}{\lambda^2}$	Plate width w (m) Plate length h (m)
Corner reflector, dihedral	Symmetry axis	$\frac{8\pi A^2}{\lambda^2}$	Reflector plate area A (m ²) Wavelength λ (m)
Corner reflector, rectangular trihedral	Symmetry axis	$\frac{4\pi L^4}{3\lambda^2}$	Sidelength L (m)

The shape of the impulse signal determines the frequency bandwidth. The object detection is done by means of the amplitude and time delay of the received pulse. In the case of the swept-frequency GPR, the operational band is clearly defined by the designer. The electromagnetic wave scattering problem is solved in the frequency domain. The target information is obtained from the amplitude and the phase of the received signal [1].

The GPR is not very different from conventional radar. The main differences are the short-range concept, near-field analysis, and lossy inhomogeneous propagation medium. The detection technique is usually based on the backscattered radiation signal from the underground object, but forward scattering can also be employed to yield target information in specific cases. Since this is a short-range radar, the clutter is the main problem for target detection and identification. The sources of the clutter are the antenna ringing, transmitter/receiver (T/R) coupling, the ground surface reflection, and unwanted (spurious) backscattering from other buried structures or soil inhomogeneities. The preventive measures such as proper antenna matching, shielding enclosure design, and adaptive methods for processing the signal should be taken to improve radar performance.

Selection of the center frequency, the bandwidth, and the power of the GPR system are the key factors in design. The electromagnetic wave reflection from the ground surface and the attenuation under the ground dramatically increase with the increasing frequency and the soil conductivity as given in Table 2. As a rule, material that has a high conductivity will have a large attenuation. Thus GPR object probing in sand, gravel, dry soil, and freshwater is much easier than in clay, wet, mineral soils, and salty water. Since the ground attenuation and reflection parameters indicate power loss and clutter, lower frequencies are used to detect deeply buried objects. Nevertheless, higher frequencies are needed for better resolution and detailed echo to determine small objects [4]. Thus, the ultrawideband (UWB) GPR is mostly preferred in order to benefit from both low and high frequencies. UWB antenna design is a significant area in terms of GPR performance. Transmitter and receiver antennas are designed to comply with the

existing hardware to radiate and couple the signal into the ground efficiently [3].

The object-oriented design procedure and critical parameters for GPR systems are discussed in Section 3.2. More specifically, suitable broadband antennas, appropriate continuous-wave (CW) or impulse signal generator design, low-noise RF receiver units, and signal processing techniques are discussed.

3.2. System Design Procedure

Ground penetrating radar has an enormously wide application area from underground structure exploration to small-object detection just beneath the surface. The operational principle consists in generation of impulse or radiofrequency (RF) power by the signal source, radiation of the electromagnetic wave by the transmitter antenna, characterization of the soil and air-Earth interface, reception of the backscattered electromagnetic wave from the target object by the receiver antenna, and finally, sensing, digitizing, and processing the received RF signal by the receiver (see Fig. 1). The critical parameters such as soil type and target properties strongly affect the detection performance. The main goal of the design is to provide application-oriented information and to illustrate the technical options available for the operator or designer. To operate the GPR successfully, the following requirements must be satisfied:

1. Sufficiently high power RF or impulse signal generator to attain the required penetration depth
2. Suitable antenna to couple the electromagnetic wave into the ground efficiently with sufficient bandwidth, high-gain, narrowbeam, and low-input reflection
3. Proper frequency bandwidth to obtain a sufficiently large scattered signal from the smallest buried object
4. Appropriate receiver hardware to achieve an adequate signal-to-noise (S/N) and signal to clutter ratios for the best target detection performance
5. Adaptive signal processing techniques to distinguish and classify the buried objects

Table 2. Propagation Losses at 100 MHz and 1 GHz in Different Soils

Material	Relative Dielectric Constant	Conductivity (mS/m)	Loss at 100 MHz (dB/m)	Loss at 1 GHz (dB/m)
Air	1	0	0	0
Asphalt, dry	2–4	1–10	2–15	20–150
Asphalt, wet	6–12	10–100	5–20	50–200
Clay	2–40	1–1000	5–300	50–3000
Concrete	4–20	1–100	1–25	10–250
Freshwater	81	0.1	0.1	1
Rock	4–10	0.1–1	0.01–1	0.1–10
Sand, dry	4–6	0.0001–1	0.01–2	0.1–20
Seawater	81	4	1000	10000
Snow	8–12	0.001–0.01	0.1–2	1–20
Sandy soil	4–30	0.1–10	0.1–5	1–50
Loamy soil	4–20	0.1–100	0.5–60	5–600
Clayey soil	4–15	0.1–1000	0.3–100	3–1000

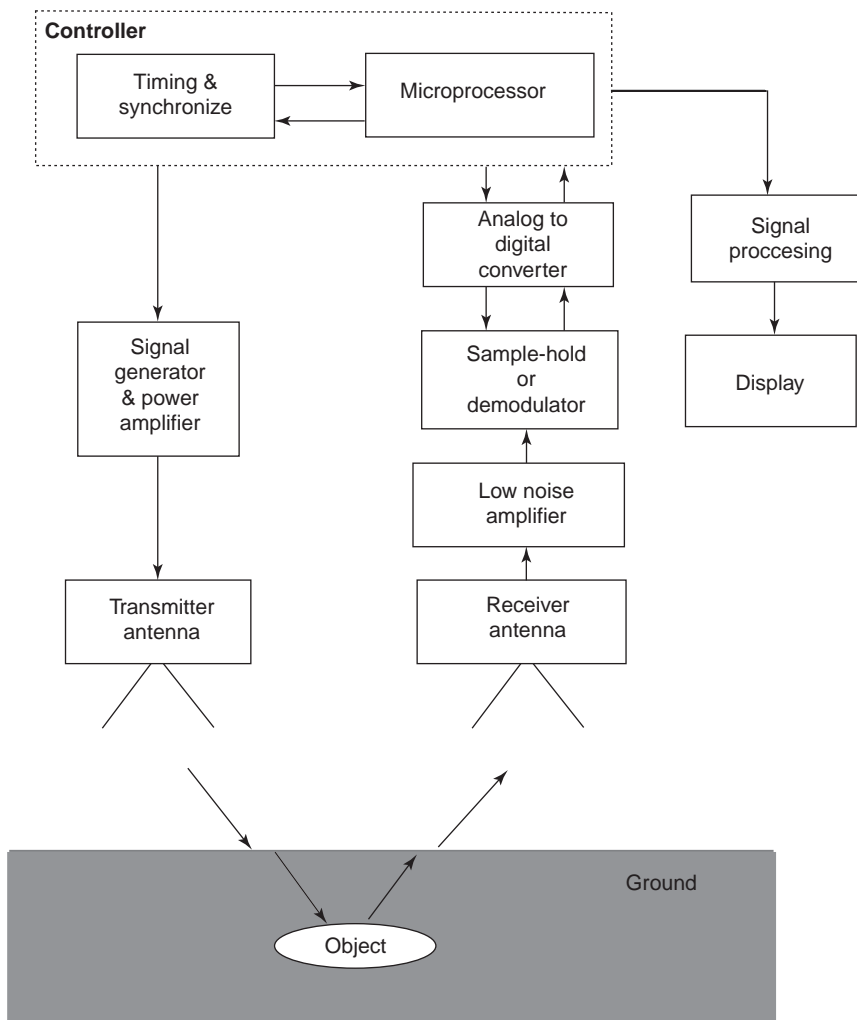

Figure 1. Block diagram of GPR operating system.

The electrical properties of the medium (soil) are important parameters in GPR design. The soil in concept is quasihomogeneous, and its electrical behavior may be defined by its constitutional parameters, namely, dielectric permittivity (ϵ), magnetic permeability (μ), and electrical conductivity (σ). Here, the relative dielectric and the magnetic constants (ϵ_r, μ_r) designate the effective wavelength, and the soil conductivity determines the propagation loss. The variability of both material parameters and local geologic conditions cause great difficulty in accurate prediction of propagation behavior. All of these parameters are generally the functions of frequency as well. For instance, RF propagation and ground surface reflectivity losses sharply increases after 3 GHz and in many cases, this fact physically limits the operational bandwidth. Nevertheless, when the buried objects decrease in size, the simulation results show that the radar cross section (RCS) values are insufficient before the resonance frequency region (see Fig. 3). As is well known, the RCS of a target object represents the object's electromagnetic wave backscattering level. Since the RCS depends on the electrical sizes (measurements with respect to wavelength) of the object and the effective wavelength is inversely proportional to the square root

of the soil dielectric constant, the GPR frequency can be shifted downward in high dielectric mediums (e.g., in wet soils). For example, the operating frequency must be at least 2 GHz to obtain sufficiently powerful backscattered signal from a 5-cm-diameter cylindrical target buried in dry soil. However, if this object were buried in wet soil, the frequency bandwidth about 1 GHz would be enough for the desired backscattering level. The range resolution in depth (ΔR_z) is another important performance parameter for GPR design. The thickness of the depth-range layers on the GPR screen is directly related to the range resolution (see Fig. 14). For impulse radars, the bandwidth (BW) expressed in (1) is inverse proportional to the downrange resolution

$$BW = \frac{c}{2 \cdot \Delta R_z \cdot \sqrt{\epsilon_r}} \quad (1)$$

where c is the free-space speed of light and ϵ_r is the relative permittivity of the soil. If it is presumed that $\epsilon_r = 9$ and $\Delta R_z = 2$ cm, the required bandwidth will be 2.5 GHz.

The radar equation given in (2) determines the detection range for a given target RCS in different parametric

cases, such as power, frequency, soil type, and antenna structure (see configuration in Fig. 2)

$$P_r = \frac{P_t G_t A_e RCS}{(4\pi R^2)^2 L} \quad (2)$$

$$L(\text{dB}) = L_a(\text{dB}) + L_{r1}(\text{dB}) + L_{s1}(\text{dB}) + L_{s2}(\text{dB}) + L_{r2}(\text{dB}) \quad (3)$$

where

- P_r = received power (W)
- P_t = transmitter power (W)
- G_t = transmitter antenna gain
- R = target detection range (m)
- A_e = receiver antenna effective area (m^2)
- RCS = radar cross-section of buried object (m^2)
- L = total propagation loss (except free space loss)
- L_a = transmitter and receiver antenna efficiency loss
- L_{r1} = surface reflectivity loss (air to ground)
- L_{r2} = surface reflectivity loss (ground to air)
- $L_{s1,2}$ = soil attenuation losses

The transmitter antenna gain (G_t) depends on the antenna type, geometry, and frequency. The gain at given frequency band is taken for stepped frequency GPR, while the peak gain (or the average gain) must be considered for an impulse GPR. Typical gains can be from minus a few decibels over isotropic to >10 dBi. The receiver effective area is expressed in terms of the antenna gain (4). The antenna efficiencies are generally related to the radiation losses due to the resistive loadings and impedance mismatching at the structures. Such losses are typically expressed in a few decibels:

$$A_e = \frac{G_r \lambda^2}{4\pi} \quad (4)$$

The RCS of the target depends on the object geometry and structure. However, the model formulas for canonical geometries given at Table 1 and the numerical simulation

plots for 5-cm-diameter cylindrical dielectric target shown in Fig. 3 are presented to express an author's opinion [18].

The reflectivity losses between air-ground and ground-air layers are subject to the problem of electromagnetic wave scattering from a dielectric surface. Too many parameters, such as antenna-ground surface and target-ground surface distances, dielectric constant of soil, antenna and target geometries, antenna radiation and target scattering waveshapes at surface, and tilt angles of antenna and object, are included in this formulation. In this case, some useful approximations are usually proposed for easy-to-calculate coherent estimations [1]. For example, the air-ground reflection loss is given by (5) presuming that the radiated wave on the surface is a uniformly distributed plane wave. Another generic method based on the transmission-line approach in Eq. (6) that uses the characteristic impedances of the air (Z_{air}) and the soil (Z_{soil}) is expressed as

$$L_{r1} = 20 \log_{10} \left(\frac{\sqrt{\epsilon_0} \cos \theta_1 - \sqrt{\epsilon_r} \cos \theta_2}{\sqrt{\epsilon_0} \cos \theta_1 + \sqrt{\epsilon_r} \cos \theta_2} \right) \quad (5)$$

(dB); (see Fig. 2)

$$L_{r1} = 20 \log_{10} \left(\frac{2Z_{\text{soil}}}{Z_{\text{soil}} + Z_{\text{air}}} \right) \quad (6)$$

(dB)

where

$$Z_{\text{air}} = 377 \Omega \quad \text{and} \quad Z_{\text{soil}} = \left(\sqrt{\frac{\mu_0 \mu_r}{\epsilon_0 \epsilon_r}} \right) \frac{\left(\cos \frac{\delta}{2} + j \sin \frac{\delta}{2} \right)}{(1 + \tan^2 \delta)^{1/4}} \quad (7)$$

Typical values for many soil materials, Z_{soil} is about 100Ω , hence $L_{r1} \approx 8$ – 10 dB and $L_{r2} \approx 5$ dB. Finally, soil attenuation losses are defined as

$$L_{s1,2} = 8.686 \cdot 2\pi f R \sqrt{\frac{\mu_0 \mu_r \epsilon_0 \epsilon_r}{2}} \left\{ \sqrt{(1 + \tan^2 \delta) - 1} \right\} \quad (8)$$

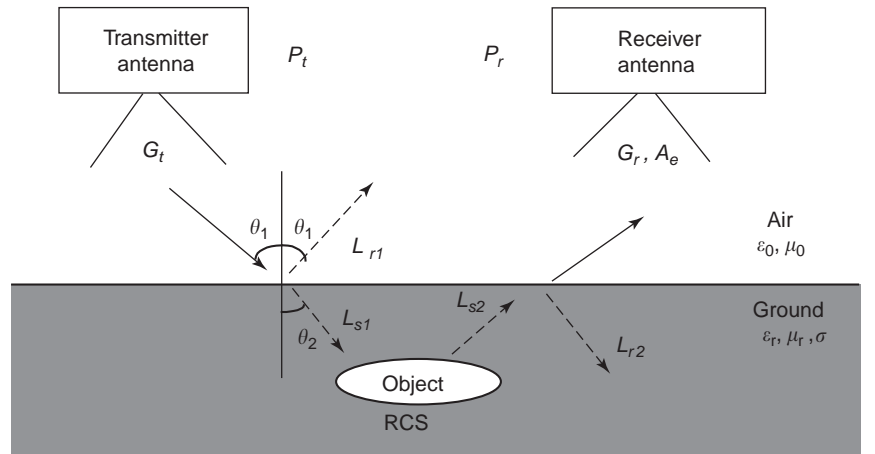

Figure 2. Propagation modeling of GPR system.

Figure 3. RCS behaviour of different cylindrical objects in air.

where δ is the soil propagation path loss in nepers per meter ($1 \text{ N} = 8.686 \text{ dB}$) in soil, f is the operating frequency, and R' is the pathlength in the soil. Table 2 exhibits the RF propagation losses in some soils at 100 MHz and 1 GHz.

As a general rule, the system noise threshold determines the minimum detectable signal (MDS) level. Detection of the target is possible if the received power backscattered from the object is sufficiently higher than both noise and clutter. The MDS can be calculated by (9) using the system frequency bandwidth (BW), the receiver noise figure (NF), and the required signal-to-noise ratio (SNR)

$$\text{MDS} = k \cdot T_0 \cdot \text{BW} \cdot \text{NF} \cdot \text{SNR} \quad (9)$$

where k is Boltzmann's constant and T_0 is room temperature in kelvins ($kT_0 \cong 4 \times 10^{-21} \text{ W/Hz}$). To obtain a received power, Pr , that exceeds this value, the MDS will not suffice for detection when clutter dominates the signal. The sources of the clutter are mostly the undesired cou-

pling signals from transmitter to receiver, the unwanted backscattering from other buried objects, and the reflection from the ground surface. For this reason, minimum SNR requirement of the system should be accurately estimated on the design to guarantee the physical radar detection range.

Design Example. Suppose that we want to detect a dielectric cylindrical object of 10 cm diameter that is buried up to $R = 100 \text{ cm}$. The system operating frequency is chosen 1 GHz. The soil is dry and loamy ($\epsilon_r = 4$). The transmitter antenna has 3 dBi gain, and the receiver antenna effective area is $A_e = 0.0012 \text{ m}^2$. Using (2)–(9), Table 2, and Fig. 3, we find that the two-way reflection losses are totally taken as 15 dB, the soil attenuation loss is 10 dB, the target has an RCS of -10 dBm^2 , and the overall power loss (dynamic range) is calculated as $\sim 94 \text{ dB}$. If we assume that the amplifier of the GPR receiver has a noise figure (NF) of 3 dB over 1 GHz bandwidth (BW), the MDS for the specified receiver characteristics yields $8 \times 10^{-10} \text{ W}$ or -91 dBW , considering a signal-to-noise ratio (SNR) of 20. Under the circumstances, the peak power of the transmitter must be at least 3 dBW or approximately 2 W. For a 50- Ω -impulse GPR system, this corresponds to 10 V peak voltage of the transmitter output.

3.3. Signal Sources and Modulation Methods

Many kinds of the modulation techniques can be employed for ground penetrating radar systems. The most frequently used GPR systems are the impulse radar that generates short pulses or impulses in the category of amplitude modulation (AM) and the swept or stepped-frequency radar that uses frequency modulation (FM) followed by a synthesized pulse.

Impulse GPR is commercially the most popular system preferred for a wide range of applications. The operational principle is based on the impulse signal generation at required peak power and frequency bandwidth. The signal sources generate monocycle or monopulse waveforms that can last for a few hundred picoseconds to a few nanoseconds. The impulse waveforms are generally Gaussian in shape and their frequency bandwidths start from a few hundred MHz up to a few GHz depending on the application (Fig. 6). The main difference between the monocycle and monopulse is in the frequency-domain behavior. The monopulse signal highly contains DC or low-frequency components. Nevertheless, the monopulse waveform has some physical advantages for time-domain radar signal transmission and radiation.

Frequency-modulated continuous-wave (FMCW) and stepped-frequency GPR systems are used when the targets of interest are shallow and an operational frequency of $\geq 1 \text{ GHz}$ has to be maintained. These systems are easier to design compared to the wideband impulse radars. Such swept- and stepped-frequency radars have the advantage of greater selection and control of the operational frequency bandwidth. This feature provides better radiation efficiency with high-power generators and high-gain antennas, lower noise level at narrower bands, and con-

sequently wider dynamic range in comparison to the impulse radar.

3.3.1. Impulse Generator Design. There are two major concerns in an impulse generator used in GPR applications: (1) the pulshape and plusewidth and (2) pulse amplitude. In many cases, both of these parameters are highly critical. The pulshape and plusewidth imply broadband characteristics, conducive to the detection of buried small objects. On the other hand, pulse amplitude implies system power related to the operational detection depth of the target in soil.

The shape of the pulse signal rigorously affects the operational frequency bandwidth of the GPR system. For example, a steplike pulse has a large amount of spectral energy at lower frequencies with the spectrum falling off as inverse frequency ($1/f$), while an impulselike pulse has a flat spectrum over the bandwidth. In every case, the high-frequency content of the pulse signal is limited by either the step risetime (T_s) or the impulse duration (T_d). For ideal impulse waveforms, the first null (f_0) in the spectrum occurs at $1/T_d$. The spectral power distribution of the impulse decreases rapidly beyond f_0 and typically follows an equation of the sinc function form. A monocycle signal can be analyzed as a pulse AM modulation of a RF sine-wave carrier. Thus, the spectrum of the monocycle impulse is shifted upward in the frequency domain with respect to the risetime and centered on the carrier frequency that corresponds to $1/T_d$. Generation of these various waveforms normally begins with a very fast-risetime-edge, steplike pulse. Then one takes the first derivative of the step risetime to obtain an impulse signal. To obtain a monocycle, the first derivative of an impulse or the second derivative of a step pulse is taken. In practice, this process can be implemented by adding a proper short-circuit-terminated transmission line to the impulse generator output. The UWB antenna and the wideband amplifier must be appropriately designed to avoid bandpass filtering, which can cause multicycling [4].

Various high-power switching transistors or FETs can be used to acquire the typical GPR pulses of a few hundred picoseconds to a few nanoseconds in duration. Avalanche transistors are often used to generate peak power levels from 50 W to several kilowatts. For the 3–10-GHz UWB band, selection of available devices is much smaller. Step recovery diodes (SRDs) can generate 50–200 ps edges with amplitudes of several volts [2].

The following is given as a monocycle impulse circuit design procedure especially for high-frequency and high-amplitude GPR applications:

- A fast risetime and high-amplitude square-wave generator
- Impulse generator with step recovery diodes
- Wideband impedance matching with resistors and high-speed Schottky diodes
- Impulse bandwidth improvement by short-circuit shunt stubs
- Wideband MMIC amplifier (if the signal power is insufficient)

The monocycle pulse generator shown in Fig. 4 is developed using transmission-line stubs realized by rigid cables, SRDs, and a Schottky diode, a MESFET and a monolithic microwave integrated circuit (MMIC) amplifier. At the input, a square-wave signal with a repetition frequency of 400 kHz is applied by a microprocessor. The risetime of the signal is shortened with a comparator circuit. The signal proceeds to the impulse generator, composed of SRDs in active mode [8]. Operating in active mode enable the designer to shape the impulse by adjusting the DC bias current drawing from the DC source. The MESFET is used particularly for the circuit isolation and wideband impedance matching. Finally, the first stub, which is at the gate of the MESFET, is used to generate a very short impulse. It is noted that, due to the MESFET buffer, the antenna cannot load back the circuit in an undesirable way. Figures 5 and 6 show the measured output monocycle pulse in time domain and in frequency domain, respectively. The measured waveform has less than 1.5 ns pulse duration in time domain, and its frequency domain bandwidth is approximately 2 GHz.

The design procedure of the avalanche-mode monocycle impulse generator is similar to that of the SRD circuit. The main difference is that an avalanche transistor is used instead of the short recovery diodes. The transistor is operated in avalanche breakdown mode used with switching by discharging the stored energy into the short transmission lines. These are output loads, which also include the transmitter antenna input impedance. The time-domain impulse signal output and its frequency-domain transformation of an avalanche-mode impulse generator are presented in Figs. 7 and 8.

3.3.2. FMCW and Stepped-Frequency Radar. The FMCW radar system transmits a sweeping RF carrier signal controlled by a voltage-controlled oscillator (VCO) over a selected frequency bandwidth. The operational frequency band can be selected by considering mainly the maximum depth and the minimum size of the buried object. The backscattered signal from the target object is mixed with a sample of the transmitted waveform and the results in a difference frequency, called the *intermediate frequency* (IF), is derived from an I/Q (in-phase/quadrature) mixer pair. The IF output contains the amplitude and phase data of the received signal. The phase information yields the range of the target since it is correlated with time delay. Only if there is a target on the scope will the IF signal be produced. If the variation in transmitter frequency is a linear function of time, then a target return will occur at a time T_r given by

$$T_r = \frac{2R}{u} \quad (10)$$

where R is the range in meters and u is the velocity of electromagnetic wave on the propagation path (air, ground, or both) in meters per second.

Since the FMCW radar essentially measures the phase of the IF signal, which is directly related to target range, it

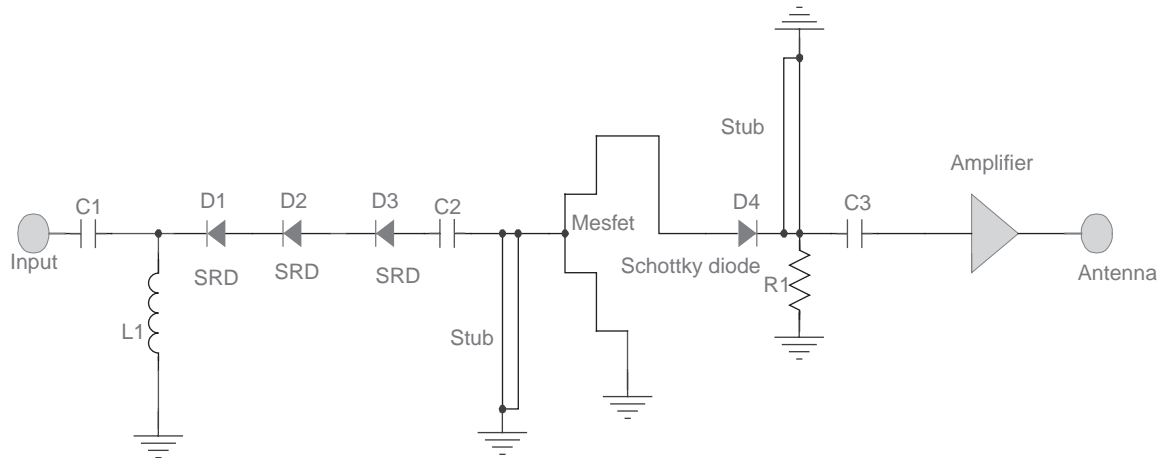

Figure 4. Schematic of the monocycle pulse generator.

requires a high degree of linearity of frequency sweep with time to avoid spectral widening of the IF, which indicates the system range resolution degradation. In practice, the sweeping nonlinearity levels should keep below 0.1% [1]. The amplifier and the antenna gain responses over the frequency band must also be linear for an appropriate system design. A time-domain equivalent to the impulse radar can be acquired by the inverse Fourier transformation.

Stepped-frequency radar is a continuous wave system that is sequentially repetitive at different frequencies as shown in Fig. 9. This kind of radar radiates a sequence of N number of carrier frequency steps and the amplitude and the phase of the received signal is stored. Downconversion to IF signal is similar in principle to that for FMCW radar. The complex Fourier transformation is applied to obtain the time-domain response of the reflected or backscattered target signal. The range resolution is defined as

$$\Delta R = \frac{u}{2N\Delta f} \quad (11)$$

where ΔR is the range resolution and Δf is the frequency increment of every step.

For both FMCW and stepped-frequency radar, it is evident that the thermal noise level is much lower than that of the receiver of the time-domain impulse radar. Nevertheless, the discrimination of the target backscattering signal from the ambiguous clutter at the receiver unit is a more difficult problem due to the futility of simple anti-aliasing filters. Therefore, some calibrating methods such as iterative range gating are usually employed for such systems.

3.4. GPR Antennas

The performance of GPR is highly dependent on the proper design of the transmitter and receiver (T/R) antenna pair. In practice, the transmitted GPR signal has broadband characteristics, which may vary from 10 MHz to 5 GHz for impulse system and from 1 to 8 GHz for stepped/swept-frequency systems. Therefore, wideband T/R antennas must be designed to reach the largest dynamic range, best focused illumination area, lowest T/R antenna coupling, reduced clutter, and uniformly shaped impulse

Figure 5. Measured output monocycle pulse in time domain.

Figure 7. Time-domain signal output of the avalanche-mode impulse generator.

radiation [3]. These antennas should satisfy the following electrical characteristics over the operational frequency band such as high directivity gain, low input reflection level, suppressed side/backlobes, convenient polarization with respect to the target shape, high T/R shielding, and linear phase response (for impulse GPR). Moreover, some physical restrictions, such as lightweight requirements for movable handheld GPR, can also rigorously restrict the convenient antenna types. A useful reference to the general case of antennas in matter is given by King and Smith [9]. Further considerations in the selection of the suitable antenna types are subject to the types of targets and radar systems. On this scope, most popular ultrawideband (UWB) antenna models, such as dipole, bowtie, spiral, and TEM horn, are proposed for the impulse GPR system. For FMCW and stepped-frequency GPR, wideband-selective octave horns, dielectric filled open-ended waveguides, cavity-backed planar spirals, and pencil-beam dish antennas (only in certain specific cases) may be preferred because of their higher gain characteristics [1,6,11,12,18].

Figure 8. Frequency-domain behavior of the avalanche-mode impulse generator signal.

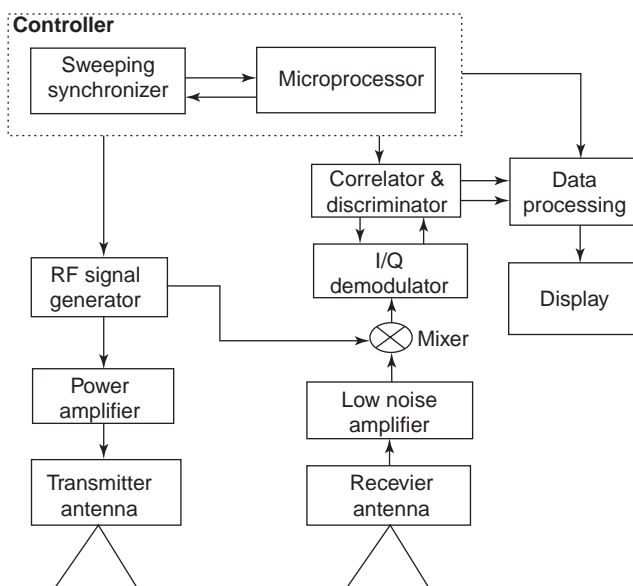

Figure 9. Block diagram of swept/stepped-frequency radar.

The simplest GPR antenna is an electrically small dipole element. It is a linearly polarized antenna that has far-field intensity proportional to its electrical length. Thus, the antenna gain and the radiation efficiency can be very small at lower frequencies. In order to avoid performance degradation, resonance dipoles such as half-wave are usually preferred for impulse GPR. Although the dipoles have a physical advantage especially for handheld GPR systems because of their small size, lightweight and easy-to-fabricate structures, and their frequency-dependent input impedance and radiation gain characteristics. Some dielectric and absorber loading techniques are usually employed to improve antenna frequency bandwidth [10]. The bowtie configuration is similar to the dipole wideband antenna frequently used for pulse radiation (Fig. 10c). The bowtie exhibit shows higher gain and wider band performance than does the simple dipole. For a circular object, the bowtie is a suitable antenna type since it produces linear polarization and has relatively good linear phase response over the wideband [3,10]. If the target is noncircular, with respect to electromagnetic wave scattering principles, circularly polarized planar antennas such as spirals may be preferred. The spiral is based on which Archimedian and logarithmic models, is theoretically a frequency-independent antenna (see Fig. 10). But in practice, both are bandlimited with respect to the feed radius for the upper frequency and the armlength for the lower frequency [3]. The frequency-domain responses of bowtie and spiral antennas are presented in Fig. 11.

When a wider band, lower-voltage standing-wave ratio (VSWR), higher gain, and narrower beamwidth are required, the TEM horn is one of the most promising antenna types for impulse GPR systems. Such a structure consists of a pair of triangular or circular slice-shaped conductors forming a V-dipole structure. It is characterized by L , d , α , and θ parameters, which correspond to the length of the antenna, the feedpoint gap, the conductor plate angle, and the elevation angle, respectively

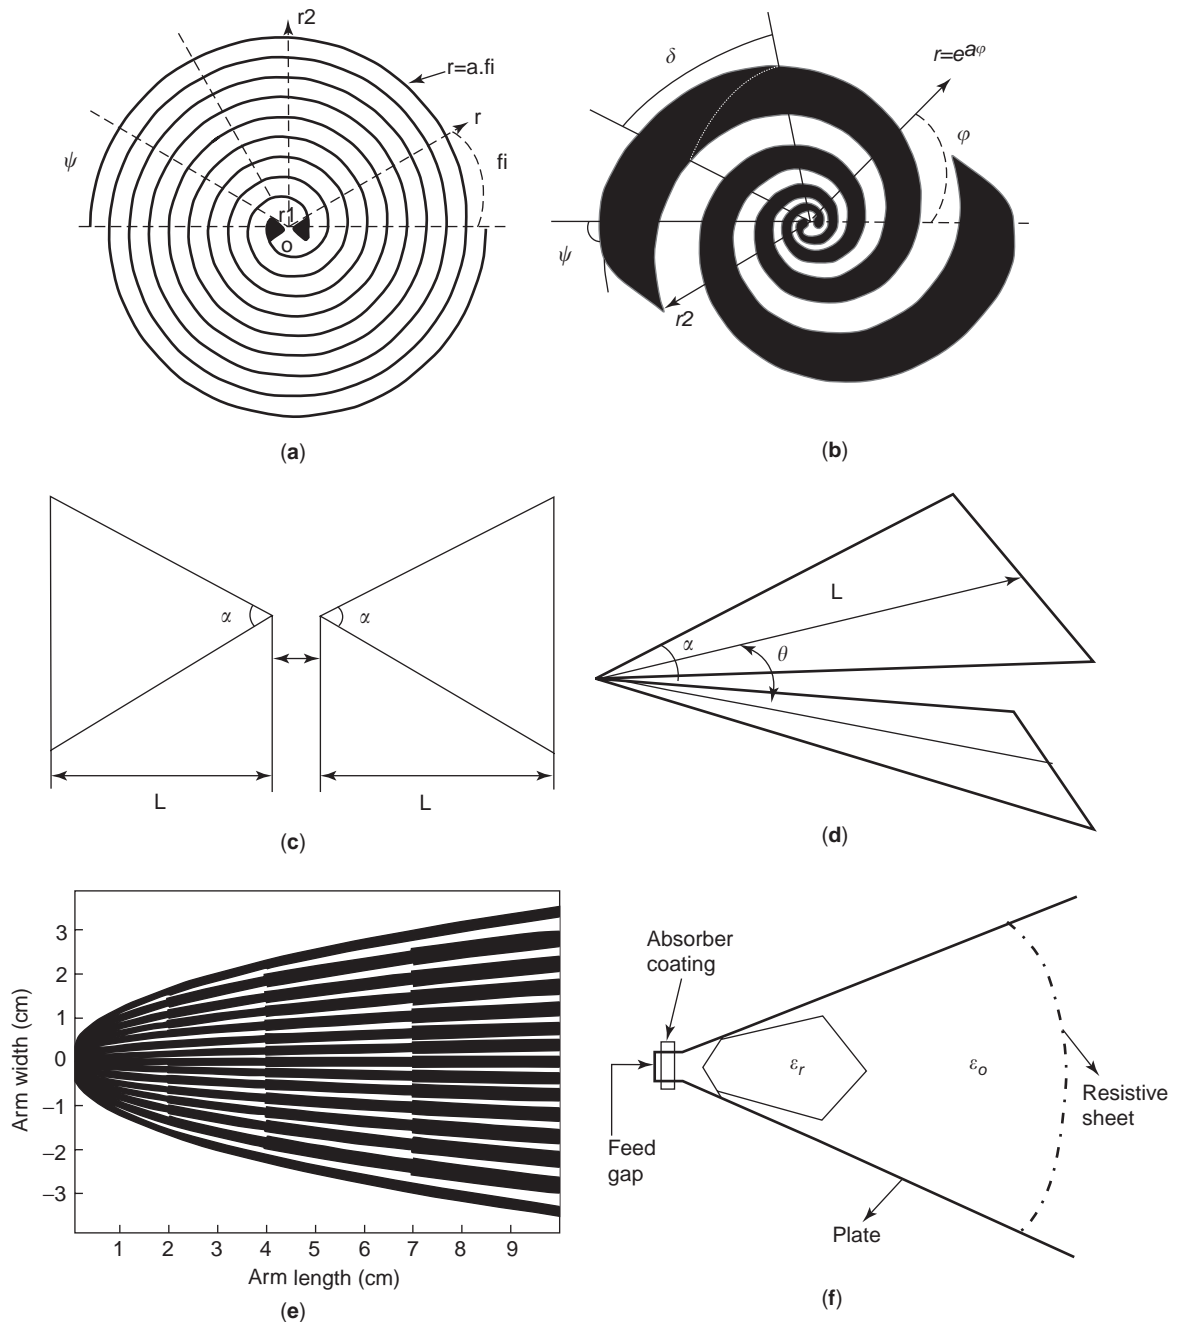

Figure 10. Wideband GPR antenna types: (a) Two-armed Archimedean spiral; (b) two-armed logarithmic spiral; (c) triangular plate bowtie; (d) triangular plate TEM horn; (e) grating model TEM horn arm (top view); (f) PDTEM horn geometry (side view).

(Fig. 10d). A TEM horn generally shows bandpass filter-like antenna gain behavior over a large bandwidth. In practice, its electrical dimensions strongly limit the lower operation frequency. Thus, dielectric-filling techniques are applied mostly to decrease the lower cutoff frequency due to certain physical restrictions in GPR applications [11]. In this case, the operational band of the antenna can be shifted downward in the frequency domain but the frequency bandwidth probably cannot be broadened. The partial-dielectric-loaded TEM (PDTEM) horn structure is proposed by Turk to achieve low VSWR (voltage stand-

ing-wave ratio) and high directivity gain with stable performance over the wideband [6]. The PDTEM structure is modeled as a microstrip line, and its geometry is designed to match the antenna output impedance to the feed source impedance (nominal, 50Ω) by decreasing the segment characteristic impedances along the antenna line. For this purpose, using multiangular dielectric profile loading and arranging the segment widths of the plate wings properly, one can implement an efficient geometric design for the TEM horn (see Fig. 10f). This approach is quite effective for higher frequencies where the electrical length

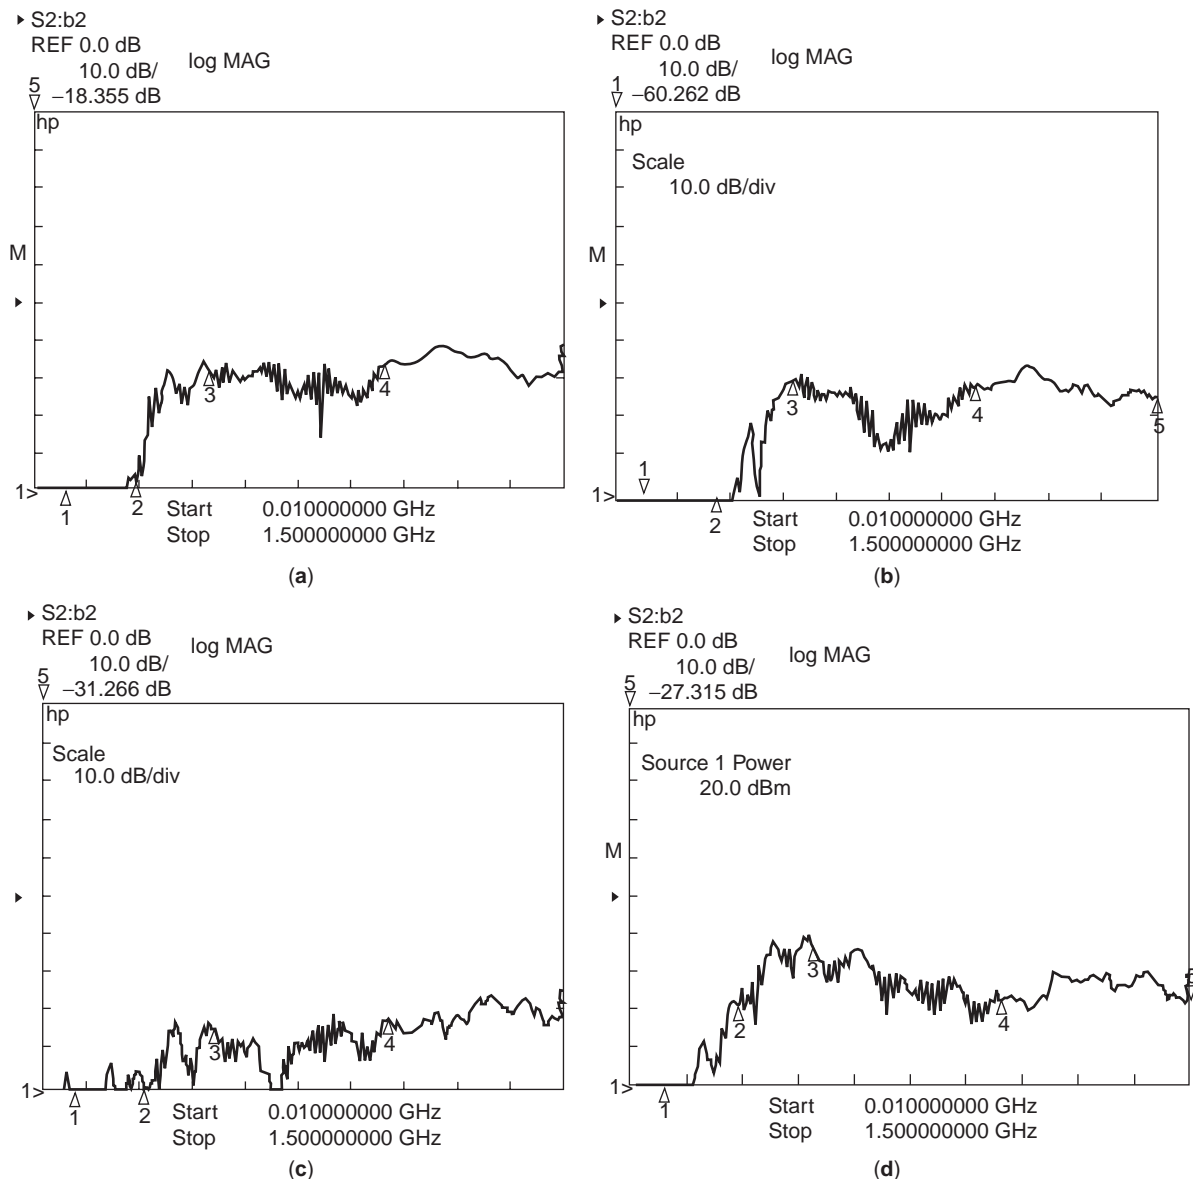

Figure 11. Measured frequency-domain S_{21} responses of the planar antennas for 60 cm dry soil: (a) logarithmic spiral ($r_1 = 0.5$ cm, $r_{2h} = 5.5$ cm, $r_{2v} = 7.3$ cm); (b) Archimedean spiral ($r_1 = 0.5$ cm, $r_2 = 8$ cm); (c) bowtie ($\alpha = 60^\circ$, $d = 0.5$ cm, $L = 7.3$ cm)—cross-polarization; (d) bowtie—copolarization.

of the antenna line is sufficiently long to transform output impedance. Nevertheless, the antenna output impedance strongly determines the matching performance rather than the characteristic impedance. An extensional resistive aperture loading is used to keep VSWR levels reasonable at lower frequencies. Finally, the feed gap is coated by a piece of low-conductivity absorber to improve the overall VSWR performance. The grating model arm structure is the metal-reduced version of the PDTEM horn antenna, which is recommended for multisensor (GPR combined with metal detector) systems (see Fig. 10e). Typical input reflection and antenna gain behaviors of TEM, PDTEM, and rigid horns are shown in Figs. 12 and 13.

Impedance matching is a critical step to improve the antenna gain and to reduce time-domain ringing effects.

Since most of the GPR impulse signals are generated by avalanche-mode transistors that produce impedance-dependent pulseshapes, the variability of the antenna impedance over the wide operational band must be stabilized by a matching circuit design. In addition, the antenna structure should be balanced to avoid structural imbalances using a wideband balun (balanced-to-unbalanced) transformer that has a sufficiently short risetime [3].

Standard-gain-horn, rigid-horn, dielectric-loaded waveguide, and dish antennas can also be considered for FMCW and stepped-frequency GPR systems. All of these models are high-gain and narrowbeam band-selective antennas that are used from L band to X band (from ~ 1 to ~ 10 GHz). The typical gain of the standard horn antenna is ~ 15 dBi over a 2–1 frequency bandwidth. To increase

Figure 12. VSWR plot of PDTEM horn ($L=10$ cm, $\alpha=30^\circ$, $\theta=80^\circ$).

the antenna directivity gain with a narrower beamwidth, a model using proper dielectric loadings is available [12]. For multiband GPR operations, the rigid horn that yields ~ 10 dBi gain over 10–1 frequency bandwidth can be chosen (Fig. 13). When the highest gain and the narrowest beamwidth are highly necessary and the physical size of the antenna is not restricted (i.e., as in vehicle-mounted forward-looking systems), the dish antenna is an appropriate solution because of its high gain up to 30 dBi and pencil-beam characteristics. The electrical size of the dish aperture is directly related with the directivity gain and HPBW as follows [18]

$$G = 20 \log\left(\frac{D}{\lambda}\right) + 9.94 \text{ dBi} \quad (12)$$

$$\text{HPBW} = \frac{180\lambda}{\pi D} \text{ degrees} \quad (13)$$

Figure 13. UWB antenna gain performances of GPR antennas.

where G is the antenna gain for 100% efficiency and D is the diameter of the circular dish.

3.5. Signal Processing Techniques

The development of advanced processing algorithms for GPR data is very important to achieve high performance for the detection and identification of objects. The signal processing methods are based on interpreting the backscattered signal parameters; these are the amplitude and the phase of the received signal for continuous or stepped-frequency GPR, and the time-domain shape of the received signal for impulse GPR. In both cases, the amplitude represents how much power is returned back from the target. The impulsive oscillations or the change in phase indicates the depth range of the target. For CW GPR, the phase difference between the transmitted and received signals indicates the depth of the target. The phase of the electromagnetic wave changes when propagating over the path proportional to its effective wavelength. Thus, every wavelength distance corresponds to 360° phase difference, but it is not easy to find the target range if the medium is inhomogeneous and cluttered. At this stage, advanced signal processing algorithms are needed to estimate the parameters adaptively from the raw data collected from inhomogeneous regions [1].

In the case of impulse radar, the received pulse signals are collected in the scanning direction. The *A*-scan and *B*-scan raw data series are obtained as shown in Fig. 14. *A*-scan data represent the received impulse signals for any scanning step. The *B*-scan plot is simply a two-dimensional (2D) representation of consecutive *A* scans in the scanning direction. Here, the x and y axes correspond to the scanning direction and the propagation time, respectively. Time also means the range, since the electromagnetic

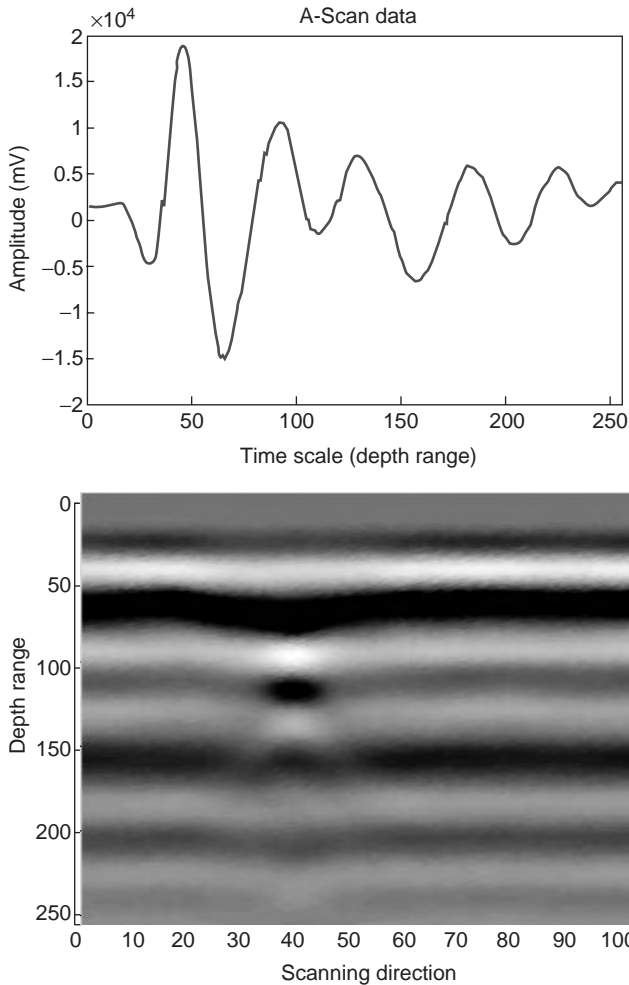

Figure 14. Measured A-scan and B-scan impulse GPR raw data.

wave has a velocity of

$$u = \frac{3 \times 10^8}{\sqrt{\epsilon_r \mu_r}} \text{ (m/s)} \tag{14}$$

where ϵ_r and μ_r respectively are the relative constitutional dielectric and magnetic coefficients of the propagation medium. Thus, if any anomaly occurs under the ground, the signal amplitude changes at the timescale to express the related depth range. When the soil structure is not well known, inhomogeneous and there are many unwanted buried objects, detection and discrimination of the target will be a difficult problem. Most of the GPR processing algorithms are based on background estimation, differentiated power density analysis, and subband processing of GPR data [1,5]. The main goal is to find the target emphasizing the anomalies under the ground. For background estimation and removal, an average A-scan dataset is calculated from multiple A-scan data that do not contain any signal from a target, and then this average is taken as a reference. The other A-scan data are calculated relatively. The magnitude of the GPR data after the background removal process is computed (see Fig. 15). Further processing can be done in several frequency

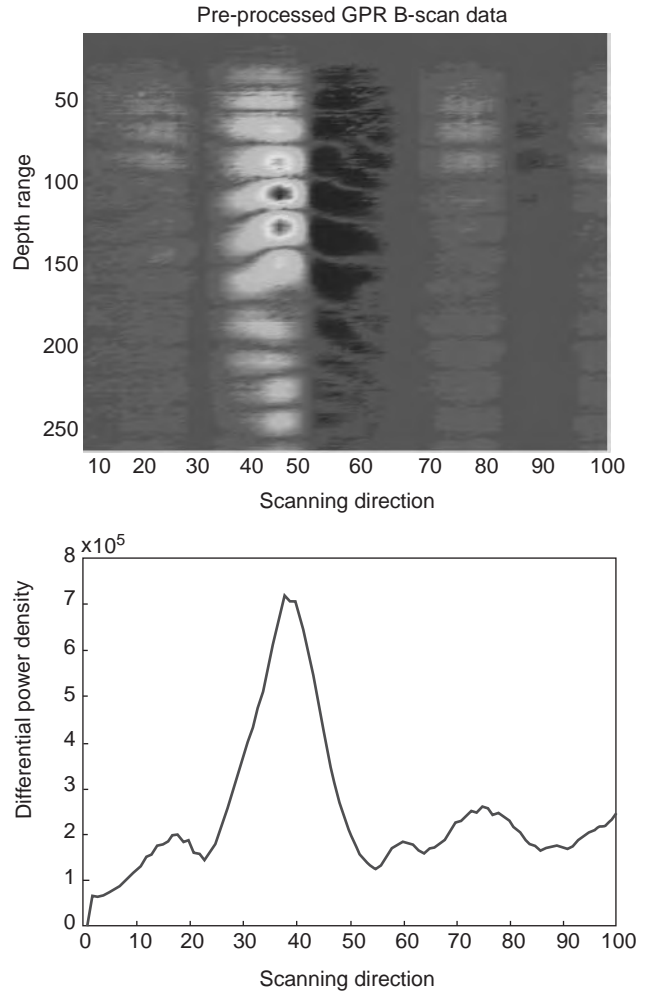

Figure 15. Processed A-scan and B-scan impulse GPR data.

bands separately. The advantage of subband processing is that it allows one to take into account the different target responses and clutter behaviors in different frequency regions. For example, the average RCS values of the probable target objects can be calculated for every subband, and some correlation algorithms can be estimated to discriminate and classify the detected objects.

4. ELECTROMAGNETIC INDUCTION (EMI) SENSOR

4.1. Overview

Electromagnetic induction (EMI), which is the basis for the metal detectors, is one of several sensor modalities widely deployed for subsurface buried-object detection and identification. The basic technology is very mature. The EMI sensors have been used for landmine detection in World War I, and EMI metal detectors were further developed during World War II. Afterward, usage of EMI sensors was also directed to detect conducting objects in other application areas such as mineral exploration, non-destructive body testing, archeological investigation, and security enforcement.

The operating principle of the EMI sensor is to transmit a time-varying primary electromagnetic field that induces currents in any metallic object that the primary field penetrates. When the primary field is abruptly turned off, eddy currents in the metallic object produce a secondary electromagnetic field that is measured by the receiver. The employed frequency range is generally limited to a few tens of kHz [13]. EMI sensors usually consist of a pair of transmitter and receiver coils (see Fig. 16). An electrical current flowing in the transmitter coil of the wire produces the primary field, and the electromagnetic waveform is often either a broadband pulse or a continuous wideband. The transmitted field induces a secondary current in the earth (ground) as well as in any buried conducting objects. This secondary current is usually detected by sensing the voltage induced in the same or another coil of wire, called the *receiver coil*. In the case of pulsed excitation, the transmit waveform is quenched quickly and the receiving coil measures the decaying secondary field that has been induced in the earth (ground) and subsurface objects. In the case of wideband excitation, the receiving coil is placed within the magnetic cavity so that it senses only the weak secondary field radiated by the earth and buried objects [14,16,17].

4.2. Operational Theory

The detection performance of the EMI sensor depends mainly on the system parameters, namely, the primary magnetic field level created by the transmitter coil, the target range, the eddy-current induction capability of the target object, and the receiver coil probe characteristics. Assuming that the fields are time-dependent and the coil position is stationary ($\partial S / \partial t = 0$), the electrical current/magnetic field and the magnetic field/electrical voltage transformation ratios of the transmitter and receiver coils are calculated by the related Maxwell equations given in (15) and (16):

$$\begin{aligned} \nabla \times \mathbf{E} &= -\mu \frac{\partial \mathbf{H}}{\partial t} \Rightarrow \oint_c \mathbf{E} d\mathbf{l} = -\mu \int_S \frac{\partial \mathbf{H}}{\partial t} d\mathbf{S} \\ &\Rightarrow V_{AB} = i2\pi f \mu N H S \cos \varphi \end{aligned} \quad (15)$$

$$\begin{aligned} \nabla \times \mathbf{H} &= \mathbf{J} + \varepsilon \frac{\partial \mathbf{E}}{\partial t} \Rightarrow \oint_c \mathbf{H} d\mathbf{l} = \int_S \mathbf{J} d\mathbf{S} + \varepsilon \int_S \frac{\partial \mathbf{E}}{\partial t} d\mathbf{S} \\ &\Rightarrow \oint_c \mathbf{H} d\mathbf{l} = I \end{aligned} \quad (16)$$

Figure 16. Electromagnetic induction system.

Figure 17. Schematic representations of operational theories of the receiver (a) and transmitter (b) coils.

where E is the electric field, H is the magnetic field, f is the frequency, N is the number of turns, S is the coil surface area of the coil, J is the current density, I is the coil current, φ is the angle between the magnetic field and the coil surface normal vectors, (ε, μ) is the dielectric permittivity and magnetic permeability of the coil material and V_{AB} is the induced voltage (see Fig. 17).

Equation (15) denotes that the coil probe sensitivity increases with the operation frequency, the number of coil turns, the magnetic permeability of the coil ferrite, and the effective area of the coil. The physical shapes of the coils are also important for the sensitivity in terms of the coil's effective area and the field pattern. The field amplitude is inverse proportional to the range. Since EMI sensors use very low frequencies, the ground surface reflectivity and the soil conductivity losses are very slight values. Nevertheless, the specific soil types that contain high conductive and magnetic molecules or particulars can cause some attenuation, and remarkable clutter levels can occur. The eddy currents set up in an object, and hence the induced field, depend on the size, shape, and composition of the object. Because of this, different objects generally have different EMI responses. The basic issues are then how much information about an object can be inferred from its EMI response, and whether that information can be used to distinguish between target and clutter. The objects that contain much more metallic elements will naturally produce more powerful eddy currents and secondary fields on the receiver coil, but the shape of the metallic part in the sense of the angular position with respect to the primary electromagnetic field vector will be an important parameter for detection sensitivity, as well.

4.3. System Performance

The system detection capability of buried metallic objects is generally a well-known parametric problem as mentioned above. It is possible to detect any small amount of metallic or metal-like object under the dynamic range limitations of the system. The range equation is not as complicated as that of a GPR. For instance, the soil attenuation and reflection loss parameters are not strong enough to affect system performance; even in most cases, the size of the metallic content of the object is the most effective system parameter. The experimental results presented in Ref. 14 show that the measured voltages (the receiver voltage, after eliminating from the transmitter–receiver coupling voltage) at the receiver

coil are 3000, 450, and 50 mV for the 15-mm-, 8-mm-, and 5-mm-diameter spherical aluminum objects, respectively. These figures decrease by half for the same size of iron objects.

The concept of EMI sensor capability involves not only detection of metal objects, but also discrimination of the targets of interest from clutter. The traditional detection technique is made based on the secondary field energy calculation method for the decision regarding the presence or absence of an object. In some physical applications, this approach can lead to excessively high false-alarm rates due to the presence of the other metal pieces or granules in soil. Several modifications of traditional EMI sensors are considered in order to facilitate the target discrimination and classification. Wideband sensor operation is one of the most promising methods. In this way, the frequency-dependent response of the induced field by a buried conducting object is used to distinguish the target from the clutter [15]. Another way is to use a simple phenomenological model that describes the measured time-domain waveform as a weighted sum of decaying exponentials to provide an accurate discrimination model for EMI sensors [17]. The measured EMI response can be modeled as a sum of decaying exponential signals whose characteristic decay rates are intrinsic to the interrogated target. Since the decay rates are not dependent on target/sensor orientation, decay rate estimation has been proposed as an effective and robust method for target identification by Ho et al. [17]. In general, the decay rates associated with metallic objects are slower than that of the earth (ground), so there is more energy in the received signal when a metallic object is present under the surface of the earth. This simple phenomenology allows very basic signal processing to be employed; for example, either an energy detector or the overall amplitude of the signal in a given time gate may be used when the goal is to detect any metallic subsurface object. Nevertheless, such processing can be the source of many false alarms in highly cluttered media.

5. ACOUSTIC AND SEISMIC SENSOR

5.1. Overview

Most technologies for the detection of shallow buried objects are electromagnetic methods. They measure the contrast in ferrous content, electrical conductivity, or dielectric constant between the object and the soil in which they are buried. Plastic objects have no or little such contrast because of their nonconductive constitutions. They have dielectric constants that are low, very close to the dielectric constant of dry soil. This makes them very difficult to detect by these technologies. Their acoustic compliance, on the other hand, makes them easier to detect by seismic and acoustic technologies. These methods search for buried objects by causing them to vibrate by introducing sound or seismic waves into the ground. As the materials with different properties vibrate differently, the pattern of ground motion leads to the detection and possibly the identification of the buried object.

Seismic sensors provide a means of sensing the mechanical properties of buried objects remotely. Seismic

technologies are commonly employed in exploration of oil. The equipment used in such applications is designed to find layered geology or use field techniques too expensive to apply. Geophones provide an inexpensive solution to record seismic data and thus sense buried objects. The main difficulty of this approach is to generate clean Rayleigh waves. Also, the geophones have to contact the ground to perform the measurements. This is not desirable for detecting objects containing explosives.

Seismic motion can also be generated by an airborne acoustic wave. A loudspeaker above the ground can be used for this purpose. A phenomenon called *acoustic-to-seismic coupling* occurs when an airborne acoustic wave is incident at the ground surface. This term refers to the coupling of acoustic energy into the ground as seismic motion. Acoustic-to-seismic coupling causes particles to vibrate on the soil surface. More recent techniques use a laser Doppler vibrometer (LDV) to measure and study the spatial pattern of particle velocity amplitude of the surface. A variety of sensors such as radars, microphones, and ultrasonic devices have also been tried to detect the vibrations and the backscattered sound.

There are three main approaches for buried-object detection using acoustics:

1. *The Linear Acoustic Technique.* This technique has proved to be an extremely accurate technology for locating buried landmines [19]. In this technique, loudspeakers insonify broadband acoustical noise over the soil and a laser Doppler velocimeter (LDV) equipped with X-Y scanning mirrors is used to detect increased soil vibration across a scan region.
2. *The Nonlinear Acoustic Technique.* This technique uses a single speaker to drive two tonal excitations to provide the airborne sound to produce A/S coupling [20]. An accelerometer is used to measure the surface acceleration.
3. *Excitation of Elastic Waves and Surface Displacement Measurement.* The main objective of this approach is to excite elastic waves in the soil and then measure the surface displacements [21]. It uses an electrodynamic shaker to excite elastic waves. As the waves propagate through a scan region, the surface displacements are measured using radar.

5.2. Linear Acoustic Techniques

Acoustic–seismic systems proposed by Sabatier et al. have shown great promise in detecting low metal mines [19,22]. In these systems, a loudspeaker above the ground surface insonifies the target region at the surface. Acoustic energy is coupled into the ground, producing vibrations. The velocity of the ground surface resulting from these vibrations is measured with a laser Doppler vibrometer (LDV) at several positions over a rectangular grid. The output of the system at a single spatial position is a collection of complex velocities at a set of frequencies, typically within the range from ~ 100 to 300 Hz for large objects and within 100–1000 Hz for small objects. The data collected over a

region form a three-dimensional (3D) complex image. This 3D image can be regarded as a stack of two-dimensional (2D) images, referred to as *spectral images*. These spectral images can be viewed as the displacement energy of the soil above the buried object at various frequencies. The analysis of these images leads to detection and identification of the buried object [23,24].

There are three different versions of the linear acoustic systems proposed by Sabatier et al:

1. The first version uses a stop-and-stare data collection scheme [19,22]. The LDV collects data staring at a single spatial position and then stares at a position close to the previous one. A region of interest is thus scanned by stopping and staring. The data are collected with some predefined spatial resolution, which obviously depends on the size of the object to be detected. As a rule, the spatial resolution is selected such that a minimum of three equally spaced positions is scanned along the major axis of the object to increase detection rate. The scantime of this type of data collection scheme may be too slow for some applications such as mine detection, where a faster scanning speed is always desirable.

2. A faster version of the linear acoustic system scans a region without stopping [25]. A laser beam continuously sweeps over an area by moving back and forth as shown in Fig. 18. The spatial resolution in downtrack can be adjusted by factoring in the size of the buried object. However, the cross-track resolution depends on the imaging techniques employed as well as the sweeping speed. Unlike the previous systems, spectral images are not readily available. Transforming the time-domain data into spectral images is a critical step in this second approach. The scanning speed of an area by the sweeping beam approach is faster than that of the stop-and-stare approach.

3. A much faster scanning speed is achieved using an array of LDVs placed on a moving platform [26]. Scanning of the area is performed by moving the platform. The LDVs on the platform are positioned such that they point to uniquely spaced positions in cross-track direction (see Fig. 19). When the platform is moved in the downtrack direction, each LDV scan the region along the path. Since this system uses more than one LDV, a normalization

Figure 19. LDV array on a moving platform.

problem is likely to occur due to nonuniqueness of the LDVs.

5.3. Nonlinear Acoustic Techniques

Nonlinear acoustic technique proposed by Donskoy employs dual-frequency (f_1 and f_2) acoustic signal transmitted toward a buried object [20]. It relies on reception of a signal generated on the soil–buried object interface. This signal has frequencies different from the initially radiated signal. The dual-frequency sound causes an object to radiate a signal at the intermodulation frequencies ($f_1 \pm f_2$). Thus, the presence of the difference frequency in the radiated signal leads to detection of the object. Some solid object such as bricks, steel disks, tree roots, and rocks do not radiate this new signal with the difference frequency. This makes it easier to differentiate certain objects from debris.

Dynamic behavior of the buried object is strongly dependent on the stiffness of the soil and the buried object. The stiffness of solid objects such as rocks and shrapnel is usually much higher than that of the soil in which they are buried. Their burial of depth also affects their stiffness. The stiffness increases as the depth of the object increases. When the stiffness of the object is much higher than that of the soil, the nonlinear motion is not observable; rather, it is a linear motion. Therefore, the nonlinear acoustic technique is not sensitive to such solid objects and deeply buried objects. Donskoy explains this by modeling the buried object as a mass–spring system [20]. This model is discussed in Section 5.5.1.

5.4. Simultaneous Use of Elastic and Electromagnetic Waves

The detection system proposed by Scott et al. simultaneously uses elastic and electromagnetic waves [21]. Elastic surface waves are generated using an elastic wave transducer, which is an electrodynamic shaker in direct contact with the soil (see Fig. 20). The shaker is excited

Figure 18. Sweeping scheme for laser measurement of the velocity of ground vibration.

Figure 20. Use of elastic and electromagnetic waves for object detection.

with a differentiated Gaussian pulse with a center frequency of 400 Hz. The waves propagate through the scan region. A radar-based sensor is used to measure the surface displacements of the soil throughout the scan region. The displacements of the surface are measured as a function of time and position. The sensitivity of the radar is typically around 1 nm. As in the linear and nonlinear acoustic techniques, the technique relies on the flexible mechanical structure of the object to be detected. If the object is solid and inflexible, it will not exhibit resonant response. The surface displacements of the soil are then will not likely yield to the detection of the object. Flexible objects such as plastic pipes can be detected using this technology. The main advantage of this method is that it can be used even if the surface is covered with some vegetation. Electrical arc source and air acoustic source have also been investigated in place of the electrodynamic shaker.

5.5. Detection Algorithms

An important step in object detection by acoustic/seismic technology is to process the acquired data. The processing steps for detecting an object are dependent on the acquired data, sensor type, soil type, target type, and environmental conditions. For example, the acquired data can be in either time or frequency domain, and this may require applying different processing steps to prepare for further processing. Figure 21 shows a sensor output in the time domain. Each row represents the time-domain signals acquired by sweeping a region on the ground along the scan direction. The location of the buried object is shown by the dotted line in the same figure. A number of imaging techniques, such as short-time fast Fourier transform (FFT) and the Yule–Walker method, can be applied to obtain spectral images. In some cases, on the other hand, the sensor readily provides the spectral images as shown in Fig. 22. In the sample spectral images shown in the figure, the buried object is located at the lower left of the 8 × 12 grid with a spatial resolution of 2 cm. If multiple sensors are used to collect the signals at each row in Figs. 21 and 22, a processing step to equalize the channels may be necessary if the sensors are not unique. This step is

Figure 21. LDV measurements of an acoustic/seismic object detection system producing time-domain signals.

skipped if a single sensor is used to scan the same region by stopping and staring, as shown in Fig. 18. It is, therefore, necessary to design detection algorithms specific to the detection technique. Some examples of automated methods for detecting and discriminating buried objects from clutter objects are discussed below.

5.5.1. Model-Based Detection Techniques. Mathematical models are often used for detection and identification of objects. For buried objects, the depth and the physical properties of the objects and the soil are the common parameters of the models. Unfortunately, some of these parameters such as the depths of the objects are not known or sometimes their estimation is too time-consuming and impractical. These problems render the model useless even if a perfect model is available. Also, it is obvious that a general model for any type of buried object cannot

Figure 22. LDV measurements of an acoustic/seismic object detection system producing spectral images.

be given. Therefore, each model must be specific to each problem.

A mathematical model for a buried mine using coupled damped harmonic oscillators was developed by Donskoy to interpret acoustic measurements taken on the soil surface [20]. On the basis of this model, it can be shown that the transfer function of a buried mine is in the following form:

$$H(s) = \frac{V(s)}{F(s)} = K \frac{s^3 + n_1 s^2 + n_2 s}{s^4 + p_1 s^3 + p_2 s^2 + p_3 s + p_4} \quad (17)$$

where V is the velocity of the vibration on the surface of the ground and F is the driving acoustic force at a particular spatial location [27]. The coefficients are somewhat complicated functions of the model parameters. They are very difficult to estimate and are not given here. Assuming that $F(s)$ is nearly constant over all frequencies, the frequency spectrum of the velocity of the ground surface vibration is proportional to $|H(j\omega)|$ and it is what is actually measured by the LDV:

$$|V(j\omega)| \approx \left| \frac{(j\omega)^3 + n_1(j\omega)^2 + n_2(j\omega)}{(j\omega)^4 + p_1(j\omega)^3 + p_2(j\omega)^2 + p_3(j\omega) + p_4} \right| \quad (18)$$

A sample Bode diagram of the transfer function in (17) is shown in Fig. 23. This system has four poles and three transmission zeros. As the depth of the mine increases, the leftmost peak shifts to the left and the rightmost peak shifts to the right.

It can be easily verified that an autoregressive moving-average (ARMA) process with order (4,4) has the same form as shown in (17). This suggests that the acoustic measurements, namely, the velocity of the vibration of the ground surface, have frequency spectra that can be modeled by an ARMA process with order (4,4). This leads to pole analysis for detection of the buried objects [27].

Figure 23. A sample Bode diagram of the transfer function in Eq. (17).

Observe that the change in the phase is dramatic at the same frequency of the leftmost peak of the magnitude plot in the Bode diagram in Fig. 23. Another approach uses this property to extract feature based on the phase information [28]. It significantly lowers false-alarm rates at given detection probabilities.

5.5.2. Shape-Based Detection. A common approach for object detection is to use shape information [23,24]. For buried objects, the spectral images usually provide good shape information. In Fig. 24, for example, the shape of the object shown in the spectral images at various bands is quite round. Thus, the *roundness* can be used as a feature.

Shape-based detection algorithms usually have a pre-processing step that may include background subtraction, normalization, and thresholding. Connected component analysis usually follows this step. Features such as eccentricity, minor-axis length, major-axis length, area, and compactness are found useful for discriminating different objects [23]. Hocaoglu et al. used independent component analysis to extract additional features to enhance the detection rate [24]. Similar features can also be applicable to the images representing the basis vectors of independent components.

6. OPTICAL DETECTORS

Detection of buried objects by optical sensing is regarded as one of the most promising techniques [29,30]. Its main advantage is that passive sensors are employed, which is very important especially in military applications. A common practice is to use several sensors (cameras) sensitive at different wavelengths. The spectrally reach reflection region (from 0.4 to 2.5 μm) is available for only daylight detection. The detection concepts using the midwave infrared (3–5 μm) and the longwave infrared (8–12 μm) are usually emphasized for a day/night system.

There are two main approaches for optical detection; the sensor can detect either (1) the thermal signature of the buried object itself or (2) a disturbance to the surface soil caused by the process of burying an object. The first approach uses the thermal contrast governed by the alternation of temperature over day and night and it is referred as the *thermal detection method*. As buried objects heat up at a rate different from that for soil, a thermal signature can be obtained to detect them. The latter is referred as the *nonthermal detection method*. The principal rationale behind the nonthermal detection method is that the spectral properties of the surface layer are different from those of the subsurface soil. The act of burying an object will bring some subsurface materials such as SiO_2 content of rocks and soils to the surface. Thus, the spectral properties of the soil above the buried object will be different from the spectral properties of the soil around the same region. The contrast between the spectral properties will lead to the detection of a freshly buried object exploiting the 8–9.4 μm Reststrahlen feature, which refers to absorption of energy as a function of silica content. The emissivity decreases more

Figure 24. IR imagery taken at different times of day: (a) 8:00 A.M.; (b) 2:00 P.M.; (c) 3:00 P.M.

and also shifts as wavelengths become longer and as silica content increases.

Soil contains both large and small particles. In fact, many of the larger particles are usually coated with smaller particles. The smaller particles in the surface layer, on the other hand, tend to be cleared from the larger particles by wind and rain. This weathering process over time causes the clean large particle to dominate the surface layer, and thus changing the spectral property of the soil at the surface layer. When the soil is disturbed, the chemical composition of the surface will change. The weathering process over time will bring the surface to its original state. Therefore, this technique may not be suitable to detect objects that were buried a long time ago.

Both of these methods have extreme variability in performance. Their performances depend heavily on environmental conditions such as the humidity and the temperature. Figure 24 shows images of two buried objects in the thermal band, obtained by a thermal camera with an operating wavelength of 7.5–13 μm . The objects are 10 cm deep and they have circular shape with a diameter of 15 cm. The best contrast between the areas near the objects and the surrounding areas is obtained at the warmest time of the day. But, the objects lose heat more quickly at night. Thus, they show up as dark spots in the imagery, instead of the bright spots. Laser illumination or microwave radiation can be used to induce these differential temperature profiles.

7. OTHER SENSORS

In this section, the auxiliary sensor types generally used for the specific application areas or to improve detector performance, will briefly be presented with their operating principles, current capabilities, limitations, and further improvement potentials. Most of these sensor technologies, such as electrical impedance tomography, X-ray imaging, and explosive-material detectors, are still at the stage of prototyping or technical research [13].

Electrical impedance tomography (EIT) is a low-cost and basic measurement technique employed to obtain the conductivity distribution of the ground surface. The detection principle is based on the discrimination of the shallow buried objects that have electrical resistance different from that of soil. The ground surface is probed by many numbers of low-current electrodes to image the surface resistivity with a required resolution [31]. The detection capability of EIT is limited to the probing depth, which is usually less than 20 cm. It is also not convenient for quick-time wide-area scanning operations.

X-ray scattering is one of the highest-resolution buried-object detector technologies. The pencil beam of the X rays is emitted to the scanning area, and the backscattered rays are detected by the sensor [32]. The performance depends essentially on the X-ray absorbing characteristics of the target object. For instance, organic materials, soil layers, and explosives have less absorbing and more scattering characteristics than do metals. Solid objects are more easily distinguished than are clutters. Since higher X-ray energy sources are needed to penetrate deeper, these sensors are usually suitable for shallow buried targets.

Subsurface microwave tomography is actually a type of electromagnetic sensor. The operating principle and hardware units of the diffraction tomography system are similar to those of stepped-frequency GPR. However, such systems generally use higher frequencies up to millimeter bands and their detection process is based on solution of the inverse scattering problem. The sweeping microwave signal is radiated to the buried object, and the diffracted wave from the target is received. Wideband antennas, mostly dielectric-loaded horns, are employed for wave transmitting and receiving. Then, I/Q data signatures of the buried target are processed using some image reconstruction algorithms such as Born–Kirchhoff approximations. The diffraction tomography sensor can yield high-resolution subsurface mapping and target imaging [33]. Nevertheless, the detection depth is less than 10 cm, due to the strong soil attenuation at high frequencies, and they are not still convenient for real-time detection since the scanning time is usually very long.

In addition to these detector types, some biological, electrochemical, and piezoelectric sensor systems are employed for specific applications such as explosive-material detection, which may be very important especially for military applications (i.e., mine detection). Biological smell sensors can detect the vapors or the gases produced by the explosive components of objects. The electrochemical detector measures the changes in polymer electrical resistance of the explosive vapors. The piezoelectric sensor uses the resonant frequency shifting of various materials when exposed to the explosive vapors [13].

CALIBRATION OF A CIRCULAR LOOP ANTENNA *

AYDIN AYKAN
Tutzing, Germany

A time-varying magnetic field at a defined area S can be determined with a calibrated circular loop connected to the input of an appropriate measuring receiver (Fig. 5). There may be a passive or an active network between the loop and the output port. The measuring loop can also include a shielding over its circumference against any perturbation of strong and unwanted electric fields. The shielding must be interrupted at a point on the loop circumference.

Generally in the far field the streamlines of magnetic flux are uniform, but at near field, in the vicinity of the generator of a magnetic field, they depend on the source and its periphery. Figure 4 shows the streamlines of the electromagnetic vectors generated by the transmitting loop L1. In the near field, the spatial distribution of the magnetic flux $B = \mu_0 H$ over the measuring loop area is not known. Only the normal components of the magnetic flux, averaged over the closed-loop area, can induce a current through the loop conductor. The measuring loop must have a calibration (conversion) factor or set of factors that, at each frequency, expresses the relationship between the field strength impinging on the loop and indication of the measuring receiver. The calibration of a measuring loop requires the generation of a well-defined standard magnetic field on its effective receiving surface. Such a magnetic field is generated by a circular transmitting loop when a defined root-mean-square (RMS) current is passed through its conductor. The unit of the generated or measured magnetic field strength H_{av} is A/m (amperes per meter) and therefore is also an RMS value. The subscript "av" strictly indicates the average value of the spatial distribution, not the average over a period of T of a periodic function. This statement is important for near-field calibration and measuring purposes. For far-field measurements the result indicates the RMS value of the magnitude of the uniform field. The traceability of the calibration must be established for the calibration process, through linking the assigned value of any components to the International System of Units (SI). In the following we discuss the requirements for the near-zone calibration of a measuring loop.

1. CALCULATION OF STANDARD MAGNETIC FIELDS

To generate a standard magnetic field, a transmitting loop L1 is positioned coaxial and plane-parallel at a separation distance d from the loop L2 to be calibrated, as in Fig. 1. The analytical formula for the calculation of the average

Figure 1. Configuration of two circular loops.

magnetic field strength H_{av} in A/m generated by a circular filamentary loop at an axial distance d including the retardation due to the finite propagation time was obtained earlier by Greene [1]. The average value of field strength H_{av} was derived from the retarded vector potential A_φ as a tangential component on the point P of the periphery of loop L2:

$$H_{av} = \frac{I r_1}{\pi r_2} \int_0^\pi \frac{e^{-j\beta R(\varphi)}}{R(\varphi)} \cos(\varphi) d\varphi \quad (1a)$$

$$R(\varphi) = \sqrt{d^2 + r_1^2 + r_2^2 - 2r_1 r_2 \cos(\varphi)} \quad (1b)$$

In these equations for thin circular loops, I is the transmitting loop RMS current in amperes, d is the distance between the planes of the two coaxial loop antennas in meters, r_1 and r_2 are filamentary loop radii of transmitting and receiving loops in meters, respectively, β is wavelength constant, $\beta = 2\pi/\lambda$, and λ is wavelength in meters.

Equations (1) give the exact results for the separation distances even from $d=0$. For $d=0$ the radii of the loops must be $r_1 \neq r_2$, otherwise the integral gives a singularity for $\varphi = \pi$, because for $r_1 = r_2$ the root in Eq. (1b) being zero.

The use of any approximate formula (Eq. 25 in Ref. 1 and Eqs. (2) in Ref. 2) is not suitable, because it imposes restrictions on the range applicability for the approximate equations. Using the expressions of maximum magnetic field H_{max} would also not be suitable for purposes of near-field calibration purpose (see Fig. 2 in Ref. 2).

Generally the Eqs. (1) can be determined by numerical integration. To this end we separate the real and imaginary parts of the integrand using Euler's formula

*This article is based on "Calibration of Circular Loop Antennas," by Aydin Aykan, which appeared in *IEEE Transactions on Instrumentation and Measurement*, Vol. 7, No. 2, © 1998 IEEE.

Figure 2. Current distribution on a circular loop.

$e^{-j\varphi} = \cos(\varphi) - j \sin(\varphi)$ and rewrite Eq. (1a) as

$$H_{av} = \frac{I r_1}{\pi r_2} (F - jG) \quad (2a)$$

where

$$F = \int_0^\pi \frac{\cos(\beta R(\varphi))}{R(\varphi)} \cos(\varphi) d\varphi \quad (2b)$$

$$G = \int_0^\pi \frac{\sin(\beta R(\varphi))}{R(\varphi)} \cos(\varphi) d\varphi \quad (2c)$$

and the magnitude of H_{av} is then obtained as

$$|H_{av}| = \frac{I r_1}{\pi r_2} \sqrt{F^2 + G^2} \quad (2d)$$

It is possible to evaluate the integrals in Eqs. (2) numerically with an appropriate mathematics software on a personal computer. Some mathematics software can directly calculate the complex integral of Eqs. (1). Hence, some of the following equations are written in complex form for convenience.

2. ELECTRICAL PROPERTIES OF CIRCULAR LOOPS

2.1. Current Distribution around a Loop

The current distribution around the transmitting loop is not constant in amplitude and in phase. A standing wave of current exists on the circumference of the loop. This current distribution along the loop circumference is discussed by Greene [1, pp. 323–324]. He has assumed the loop circumference $2\pi r_1$ to be electrically smaller than the

Figure 3. Deviation of I_{av}/I_1 for a loop radius 0.1 m as $20 \log(I_{av}/I)$ in decibels versus frequency.

wavelength λ and the loop current to be constant in phase around the loop and the loop proper to be sufficiently loss-free. The single-turn thin loop was considered as a circular balanced transmission line fed at points A and D and short-circuited at points E and F (Fig. 2).

In an actual calibration setup the loop current I_1 is specified at the terminals A and D. The average current was given as a function of input current I_1 of the loop [2]:

$$I_{av} = I_1 \frac{\tan(\beta \pi r_1)}{\beta \pi r_1} \quad (3)$$

The fraction of I_{av}/I_1 from Eq. (3) expressed in decibels gives the conditions for determining of the highest frequency f and the radius of the loop r_1 . The deviation of this fractions is plotted in Fig. 3.

The current I in Eq. (1a) must be substituted with I_{av} from Eq. (3). Since Eq. (3) is an approximate expression, it is recommended to keep the radius of the transmitting loop small enough for the highest frequency of calibration to minimize the errors. For the dimensioning of the radius of the receiving loop, these conditions are not very important, because the receiving loop is calibrated with an accurately defined standard magnetic field, but the resonance of the loop at higher frequencies must be taken into account.

2.2. Circular Loops with Finite Conductor Radii

A measuring loop can be constructed with one or more windings. The form of the loop is chosen as a circle because of the simplicity of the theoretical calculation and calibration. The loop conductor has a finite radius. At high frequencies the loop current flows on the conductor surface and shows the same proximity effect as two parallel, infinitely long cylindrical conductors. Figure 4 shows the cross section of two loops in intentionally exaggerated dimensions. The streamlines of the electric field are orthogonal to the conductor surface of the transmitting loop L1 and they intersect at points A and A'. The total conductor current is assumed to flow through a fictive thin filamentary loop with the radius $a_1 = \sqrt{r_1^2 - c_1^2}$, where $a_1 = \overline{OA} = \overline{QP} = \sqrt{\overline{OQ}^2 - \overline{QP}^2}$. The streamlines of the magnetic field are orthogonal to the streamlines of electric field. The receiving loop L2 with the finite conductor

Figure 4. Filamentary loops of two loops with finite conductor radii and orthogonal streamlines of the electromagnetic vectors, produced from transmitting loop L1.

radius c_2 can encircle a part of magnetic field with its effective circular radius $b_2 = r_2 - c_2$.

The sum of the normal component of vectors H acting on the effective receive area $S_2 = \pi b_2^2$ induces a current in the conductor of the receiving loop L2. This current flows through the filamentary loop with the radius a_2 . The average magnetic field vector H_{av} is defined as the integral of vectors H_n over effective receiving area S_2 , divided by S_2 . The magnetic streamlines, which flow through the conductor and outside of loop L2, cannot induce a current through the conductor along the filamentary loop Ar, Ar' of L2. The equivalent filamentary loop radii a_1, a_2 and effective circular surface radii b_1, b_2 can be seen directly from Fig. 4.

The equivalent thin current filament radius a_1 of the transmitting loop L1:

$$a_1 = \sqrt{r_1^2 - c_1^2} \quad (4a)$$

The equivalent thin current filament radius a_2 of the receiving loop L2 is

$$a_2 = \sqrt{r_2^2 - c_2^2} \quad (4b)$$

The radius b_1 of the effective transmitting circular area of the transmitting loop L1 is

$$b_1 = r_1 - c_1 \quad (4c)$$

The radius b_2 of the effective receiving circular area of the receiving loop L2 is

$$b_2 = r_2 - c_2 \quad (4d)$$

2.3. Impedance of a Circular Loop

The impedance of a loop can be defined at chosen terminals Q, D as $Z = V/I_1$ (Fig. 2). Using Maxwell's equation with Faraday's law $\text{curl}(\mathbf{E}) = -j\omega\Phi_m$, we can write the line integrals of the electric intensity \mathbf{E} along the loop conductor through its cross section, along the path joining points D, Q and the load impedance Z_L between the terminals Q, A :

$$\int_{(AEFD)} \mathbf{E}_s ds + \int_{(DQ)} \mathbf{E}_s ds + \int_{(QA)} \mathbf{E}_s ds = -j\omega\Phi_m \quad (5a)$$

Here Φ_m is the magnetic flux. The impressed emf (electromotive force) V acting along the path joining points D and Q is equal and opposite to the second term of Eq. (5a):

$$V = - \int_{(DQ)} \mathbf{E}_s ds \quad (5b)$$

The impedance of the loop at the terminals D, Q can be written from Eqs. (5) dividing with I_1 as

$$Z = \frac{V}{I_1} = \frac{\int_{(AEFD)} \mathbf{E}_s ds}{I_1} + \frac{\int_{(QA)} \mathbf{E}_s ds}{I_1} + \frac{j\omega\Phi_m}{I_1} = Z_i + Z_L + Z_e \quad (6)$$

where Z_i indicates the internal impedance of the loop conductor. Because of the skin effect, the internal impedance at high frequencies is not resistive. For the calculation of the Z_i , we refer to Schelkunoff, [3, p. 263] and Ramo et al. [4, p. 185]. Z_L is a known load or a source impedance on Fig. 2. Z_e is the external impedance of the loop:

$$Z_e = j\omega \frac{\Phi_m}{I_1} = j\omega \frac{\mu_0 H_{av} S}{I_1} \quad (7a)$$

We can consider that the loop consists of two coaxial and coplanar filamentary loops (i.e., separation distance $d = 0$). The radii a_1 and b_1 are defined in Eqs. (4). The average current I_{av} flows through the filamentary loop with the radius a_1 and generates an average magnetic field strength H_{av} on the effective circular surface $S_1 = \pi b_1^2$ of the filamentary loop with the radius b_1 . From Eqs. (1) and (3) we can rewrite Eq. (7a), for the loop L1:

$$Z_e = j \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (7b)$$

$$R_0(\varphi) = \sqrt{a_1^2 + b_1^2 - 2a_1 b_1 \cos(\varphi)} \quad (7c)$$

The real and imaginary parts of Z_e are the radiation resistance and the external inductance of loops,

respectively:

$$\operatorname{Re}(Z_e) = \left| \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \right| \mu_0 \omega a_1 b_1 \int_0^\pi \frac{\sin(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (7d)$$

$$\operatorname{Im}(Z_e) = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_1 \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (7e)$$

From Eq. (7e) we obtain the external self-inductance:

$$L_e = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 a_1 b_1 \int_0^\pi \frac{\cos(\beta R_0(\varphi))}{R_0(\varphi)} \cos(\varphi) d\varphi \quad (7f)$$

Equations (7) include the effect of current distribution on the loop with finite conductor radii.

2.4. Mutual Impedance between Two Circular Loops

The mutual impedance Z_{12} between two loops is defined as

$$Z_{12} = \frac{V_2}{I_1} = \frac{Z_2 I_2}{I_1} \quad (8)$$

The impedance of Z_2 in Eq. (8) can be defined as in Eqs. (6):

$$Z_2 = \frac{V_2}{I_2} = Z_{2i} + Z_L + Z_{2e} \quad (9)$$

here Z_{2i} is the internal impedance, Z_L is the load impedance, and Z_{2e} is the external impedance of the second loop L2.

The current ratio I_2 to I_1 in Eq. (8) can be calculated from Eqs. (1), (3), and (4). The current I_1 of the transmit loop with separation distance d

$$I_1 = \frac{H_{av} \pi b_2}{\frac{\tan(\beta\pi a_1)}{\beta\pi a_1} a_1 \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi} \quad (10a)$$

$$R_d(\varphi) = \sqrt{d^2 + a_1^2 + b_2^2 - 2a_1 b_2 \cos(\varphi)} \quad (10b)$$

and the current I_2 of the receive loop for the same H_{av} (here $d = 0$) is

$$I_2 = \frac{H_{av} \pi b_2}{\frac{\tan(\beta\pi a_2)}{\beta\pi a_2} a_2 \int_0^\pi \frac{e^{-j\beta R_0(\varphi)}}{R_0(\varphi)} \cos(\varphi) d\varphi} \quad (10c)$$

$$R_0(\varphi) = \sqrt{a_2^2 + b_2^2 - 2a_2 b_2 \cos(\varphi)} \quad (10d)$$

The general mutual impedance between two loops from Eqs. (8) and (9) is

$$Z_{12} = (Z_{2i} + Z_L + Z_{2e}) \frac{I_2}{I_1} = Z_{12i} + Z_{12L} + Z_{12e} \quad (11a)$$

here Z_{12i} is the mutual internal impedance, Z_{12L} denotes the mutual load impedance, and Z_{12e} is the external mutual impedance.

Arranging Eq. (7b) for Z_{2e} and the current ratio I_2/I_1 from Eqs. (10), we obtain the external mutual impedance:

$$Z_{12e} = j \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 \omega a_1 b_2 \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (11b)$$

The real part of Z_{12e} may be described as mutual radiation resistance between two loops.

The imaginary part of Z_{12e} divided by ω gives the mutual inductance

$$M_{12e} = \frac{\tan(\beta\pi a_1)}{\beta\pi a_1} \mu_0 a_1 b_2 \int_0^\pi \frac{\cos(\beta R_d(\varphi))}{R_d(\varphi)} \cos(\varphi) d\varphi \quad (11c)$$

Equations (11b) and (11c) include the effect of current distribution on the loop with finite conductor radii.

3. DETERMINATION OF THE ANTENNA FACTOR

The antenna factor K_H is defined as a proportionality constant with necessary conversion of units. K_H is the ratio of the average magnetic field strength H_{av} bounded by the loop to the measured output voltage V_L on the input impedance R_i of the measuring receiver.

$$K_H = \frac{H_{av}}{V_L} \text{ in } (\text{A/m}) \cdot \text{V}^{-1} \quad (12a)$$

Equation (12a) can also be expressed logarithmically:

$$k_H = 20 \log(K_H) \text{ in } \text{dB}(\text{A/m}) \cdot \text{V}^{-1} \quad (12b)$$

For evaluation of the antenna factor there are two methods. The first is by calculation of the loop impedances, and the second is with the well-defined standard magnetic field calibration.

3.1. Determination of the Antenna Factor by Computing from the Loop Impedances

If a measurement loop, (e.g., L2), has a simple geometric shape and a simple connection to a voltage measuring device with a known input impedance R_i , we can determine the antenna factor by calculation. In the case of the unloaded loop from Fig. 2, the open-circuit voltage is

$$V_0 = j\omega \mu_0 H_{av} S_2 \quad (13a)$$

For the case of the loaded loop the current is

$$I = \frac{V_0}{Z} = \frac{V_0}{R_L + Z_i + Z_e} \quad (13b)$$

The antenna factor from Eq. (12a) can be written with $V_L = Z_i I$ and Eqs. (13) and (1) as

$$K_H = \left| \frac{1}{j\omega \mu_0 S_2} \left(1 + \frac{Z_e}{R_L} + \frac{Z_i}{R_L} \right) \right| \text{ in } (\text{A/m}) \cdot \text{V}^{-1} \quad (14)$$

The effective loop area is $S_2 = \pi b_2^2$. The external loop impedance Z_e can be calculated with Eqs. (7). The internal

impedance Z_i is in general small in respect to external impedance Z_e , and can be neglected. For a more precise calculation of the internal impedance Z_i due to the skin effect, refer to Refs. 3 and 4.

3.2. Standard Magnetic Field Method

In the calibration setup in Fig. 5 we measure the voltages with standard laboratory measuring instrumentation with the 50Ω interface impedances. The device to be calibrated consists at least of a loop and a cable with an output connector. The measuring loop can also include a passive or active network between the terminals C, D and a coaxial shield on the circular loop conductor against unwanted electric fields, depending on its development and construction. The impedance Z_{CD} and the voltage V_{CD} at the terminals C, D is not accurately measurable. The behavior of the attenuation and/or the gain between the interfaces D, C and F cannot be accurately defined. Such a complex measuring loop must be calibrated with the standard magnetic field method through the calibration setup in Fig. 5. To prevent the deterioration of the magnetic field, produced by L1, we must place the attenuators sufficiently far from the transmitting loop using a twisted-pair balanced line. The attenuators (e.g., nominal 10 dB) must have the calibrated attenuations m for attenuator 1 and n for attenuator 2, and the calibrated interface resistances (nominal 50Ω). The shielding of the attenuators must be electrically connected at the points x . The ferrite pads on the twisted-pair line and on the coaxial cable attenuate the magnetic field scattering from the measuring transmission lines. The electrical length Le of the twisted transmission line must be taken into account and the equation (3) must be redefined for the average current I_{av} :

$$I_{av} = I_1 \frac{\tan(\beta(\pi a_1 + Le))}{\beta(\pi a_1 + Le)} \quad (15)$$

The usable highest frequency of the loop L1 decreases with the additional electrical length of the twisted-pair line. This consideration is used to define an appropriate length of the twisted-pair transmission line.

The antenna factor in Eqs. (12) can be fully defined for each frequency through the measurement of the transmitting loop current I_1 at the interface M' and voltage V_L at the interface F :

$$K_H = \frac{\left| \frac{I_1 \tan(\beta(\pi a_1 + Le))}{\pi a_1 + Le} \frac{a_1}{\pi b_2} \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \right|}{V_L} \quad (16a)$$

Here $r_1 = a_1, r_2 = b_2, Le$ is the electrical length of the twisted-pair transmission line and R_d defined with Eq. (10b). Attenuator 1 attenuates the current I_1 with the ratio m and hence the current through the interface M' becomes $m \cdot I_1$. The transmitting loop current is $I_1 = V_2/m \cdot R_2$. Consequently, the current flowing through the interface N' is $I_1/(n \cdot m)$. With the measuring receiver we can measure first the voltage V_2 at the interface M' to obtain the transmitting loop current I_1 , which produces the magnetic field H_{av} in the receiving loop L2. We then measure the voltage V_L at the interface F , which is produced by the same magnetic field H_{av} . With setting $\alpha = V_2/V_L$, we can write Eq. (16a) as

$$K_H = \left| \frac{\alpha \tan(\beta(\pi a_1 + Le))}{m} \frac{a_1}{R_2(\beta\pi a_1 + Le)} \frac{a_1}{\pi b_2} \int_0^\pi \frac{e^{-j\beta R_d(\varphi)}}{R_d(\varphi)} \cos(\varphi) d\varphi \right| \quad (16b)$$

Equation (16b) is expressed in SI units $[(A/m)V^{-1}]$ and can also be expressed logarithmically as

$$k_H = 20 \log(K_H) \text{ in dB}[(A/m) \cdot V^{-1}] \quad (16c)$$

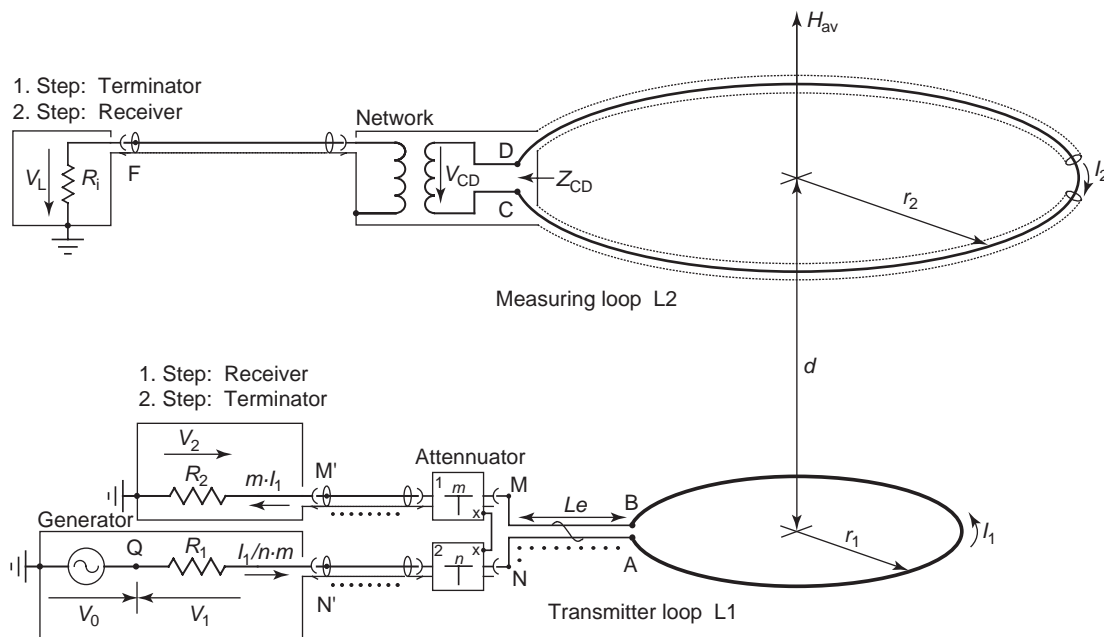

Figure 5. Calibration setup for circular loop antennas.

The ratio of the measured voltages is an attenuation and with an appropriate measuring setup the calibration is realized as an attenuation measurement. A network analyzer is generally used for this purpose instead of discrete measurements at each individual frequency with a signal generator and a measuring receiver. A network analyzer can normalize the frequency characteristic of the transmit loop current I_1 and gives a quick overview of the measured attenuation for the frequency band under consideration.

Equation (16b) reduces the calibration process of the loop to an accurate measurement of attenuation α for each frequency. The other terms of Eq. (16a) can be calculated depending on the geometric configuration of the calibration setup at the working frequency band of the measuring loop. The calibration uncertainties are also calculable with the given expressions. The uncertainty of the separation distance d between two loops must be taken into consideration as well. At a separation distance $d < a_1$, the change in the magnetic field is high (see Fig. 2 in Ref. 2).

For a calibration setup the separation distance d can be defined as small as possible. However, the effect of the mutual impedance must be taken into account in the calibration process, and a condition for definition of the separation distance d must be given (Fig. 5). If the second loop is open-circuited, that is, if the current $I_2 = 0$, the current I_1 is defined only from the impedances of the transmitting loop L1. In the case of a short-circuited second loop L2, I_2 is maximum and the value of I_1 will change depending on the supply circuit and loading of the transmitting loop. A current ratio q between these two cases can be defined as the condition of the separation distance d between the two loops.

It is assumed that the generator voltage V_0 is constant. The measuring loop L2 is terminated by Z_L . For $Z_L = 0$ and $V_{CD} = 0$, one obtains the current I_1 in the transmitting loop as

$$I_{1(Z_L=0)} = \frac{V_0}{R_1 + R_2 + Z_{AB} - \frac{Z_{12}^2}{Z_{CD}}} \quad (17a)$$

and for $Z_L = \infty$, that is, $I_2 = 0$

$$I_{1(Z_L=\infty)} = \frac{V_0}{R_1 + R_2 + Z_{AB}} \quad (17b)$$

The ratio of Eq. (17a) to Eq. (17b) is

$$q \equiv \left| \frac{I_{1(Z_L=0)}}{I_{1(Z_L=\infty)}} \right| = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB} \left(1 - \frac{Z_{12}^2}{Z_{AB}Z_{CD}} \right)} \right| \quad (18a)$$

here with the coupling factor $k = Z_{12}/\sqrt{Z_{AB}Z_{CD}}$ between two loops:

$$q = \left| \frac{R_1 + R_2 + Z_{AB}}{R_1 + R_2 + Z_{AB}(1 - k^2)} \right| \quad (18b)$$

where $R_1 = R_2 = 50 \Omega$ and Z_{AB} , Z_{CD} , and Z_{12} can be calculated from Eqs. (7) and (11). For greater accuracy one must try to keep the ratio q close to unity (e.g., $q = 1.001$).

The influence of the loading of the second loop on the transmitting loop can also be found experimentally. The change of voltage V_2 at R_2 in Fig. 5 must be considerably small (e.g., < 0.05 dB) when the measuring loop is short-circuited at the chosen separation distance d .

4. CONCLUSION

All equations in this article are written in their original exact form without approximations, which usually restrict their range of validity in applications regarding frequency range, distance, and other quantities. Also, no simplifications of the equations are made. All equations deliver the results directly in units of SI with an appropriate mathematical software on a personal computer. The electrical properties of the loops are calculable without approximation. The necessary conditions are given for the choice of dimensions of the measuring and transmitting circular loops and the separation distance d .

For calibration of circular loop antennas, the standard magnetic field method is recommended with the calibration setup in Fig. 5 and also for determination of the antenna factor K_H and k_H in Eqs. (16b) and (16c). The calibration process is based on the measurement of attenuation at each frequency on the same impedance level of 50Ω , using the standard laboratory equipment. The measurement can also be accelerated by using a network analyzer.

1. INTRODUCTION

Since the early 1950s, microwave circuits have evolved from discrete circuits to planar integrated circuits, then to multilayered and three-dimensional integrated circuits. With the increased circuit density, the multiconductor line in multilayered dielectric media has become the major form of the transmission line or interconnect. Multilayered routing reduces the area as well as the volume of the

circuit. However, as a result, electromagnetic coupling among conductors greatly influences circuit performance. In some microwave integrated circuits, this coupling effect is utilized to construct compact circuit components. But under most circumstances, it is regarded as a parasitic effect that must be modeled accurately for verification of the circuit's validity and performance.

In the related field of very-large-scale integration (VLSI) circuits, electromagnetic coupling among interconnects is also becoming increasingly important. With the introduction of deep-sub-micrometer (DSM) semiconductor technologies, the on-chip interconnect wire can no longer be considered equipotential jointing. The parasitic effects introduced by the wires display a scaling behavior that differs from that of active devices such as transistors, and these effects tend to gain importance as device dimensions are reduced and circuit speed is increased. In fact, they begin to dominate some of the relevant metrics of digital integrated circuits such as speed, energy consumption, and reliability. A typical recursive design flowchart of a state-of-the-art integrated circuit (IC) is shown in Fig. 1, where a postlayout step termed *parasitic extraction* precedes *gate-level simulation*. The task of parasitic extraction is to model the electromagnetic effects of the wire with parasitic components of capacitance, resistance, and inductance, so that a more accurate circuit simulation can be performed.

With the increase in working frequency and development of silicon technologies, the discrepancy between the microwave IC and the common VLSI circuit becomes marginal. Therefore, the electromagnetic modeling and accurate extraction of the interconnect parasitics have become a subject of advanced research in both fields to date. Among the three parasitic parameters, capacitance has attracted the most attention because it greatly influences time delay, power consumption, and the signal integrity and its calculation becomes complicated under DSM technologies.

In the following sections, the fundamental theory and contemporary methodology and algorithms of capacitance extraction will be discussed.

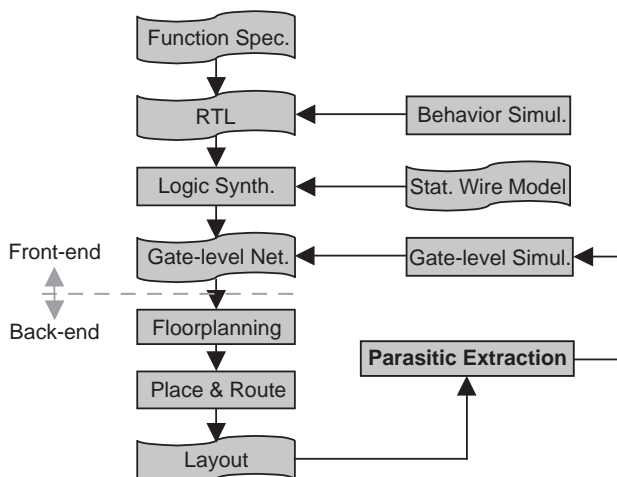

Figure 1. A typical flowchart of IC design.

2. PROBLEM FORMULATION

As is well known, the capacitor is a commonly used component in electric or electronic equipment. It is usually composed of two conductors insulated from each other. When charged, the two surfaces of the conductor facing each other carry equal and opposite charges Q and $-Q$, respectively (see Fig. 2). The electric potential difference between the two conductors $\phi_1 - \phi_2$ is called the *voltage* of the capacitor and is always denoted by V . Experiments and theoretical analyses show that, for a capacitor, Q is always proportional to V and thus the ratio Q/V is a constant determined by the structure of the capacitor. This ratio is called the *capacitance* of the capacitor and is denoted by C : $C = (Q/V)$.

In the International System of Units (SI), the unit of capacitance is the faraday (F). It expresses the capacitance of a capacitor that has one coulomb on one of its poles when the potential difference is 1 V. Other commonly used units of capacitance are μF (10^{-6} F), pF (10^{-12} F), and fF (10^{-15} F).

The capacitance of some simple capacitor can be calculated easily. For example, for the parallel-plate capacitor shown in Fig. 2, we have

$$C = \frac{\epsilon_0 \epsilon_r S}{d} \quad (1)$$

where ϵ_0 is the dielectric constant of free space and in SI, is expressed as

$$\epsilon_0 = \frac{1}{4\pi \times 9 \times 10^9} = 8.85 \times 10^{-12} \text{ C}^2/\text{N} \cdot \text{m}^2$$

where ϵ_r is the relative permittivity of the insulating material, S is the area of the plate, and d is the distance between two parallel plates.

Specific capacitors widely used in the design of microwave circuits include the interdigital capacitor and the metal-insulator-metal (MIM) capacitor. Figure 3 shows the physical layout of an interdigital capacitor with nine fingers, and Fig. 4 shows the cross-sectional view of an MIM capacitor with the GaAs process. The interdigital capacitor works with the electrostatic coupling between the intercrossed fingers, and has a very high Q value. So, it is widely used in the high-frequency microwave circuits.

Figure 2. A parallel-plate capacitor.

Figure 3. An interdigital capacitor.

The MIM capacitor has simple geometry and is easily fabricated, and its capacitance is controlled by the dimensions of the polar planes. Since the interdigital capacitor and the MIM capacitor are widely used, calculation of the parameters of their structures within given the working frequency and corresponding capacitor value becomes an important issue for both design and optimization. This can be regarded as the reverse procedure of capacitance extraction. For further discussion of this issue, please refer to the literature [39,40].

Actually, the capacitor has more generalized forms than that described above, which consists of two insulated conductors. The *capacitance* of a single conductor (conductor 1) is defined as if another conductor (conductor 2) were located at an infinite distance away to form a joint capacitor (conductors 1 + 2). For example, the capacitance of an isolated conductor sphere with radius of R can be calculated as $C = 4\pi\epsilon_0 R$.

Many conductor interconnect wires are involved in the microwave IC and the common VLSI circuit, and they are insulated by some dielectric such as oxide SiO_2 . The capacitance between any two wires reflects the electrostatic coupling effect between these wires, and calculating these capacitances with high accuracy is very important for analysis of the circuit's performance.

For an N -conductor system, such as the interconnect wires in an IC, an $N \times N$ capacitance matrix $[C_{ij}]_{N \times N}$ is defined by

$$Q_i = \sum_{j=1}^N C_{ij} U_j, \quad i = 1, 2, \dots, N, \quad (2)$$

where C_{ij} ($i \neq j$) is the coupling capacitance between conductors i and j , and C_{ii} is the self-capacitance or total capacitance of conductor i . Q_i is the induced charge on

Figure 4. An MIM capacitor (cross-sectional view).

Figure 5. A structure involving 2×2 crossover interconnect wires.

conductor i , and U_j is the electric potential of conductor j (usually the known bias voltage).

Figure 5 shows a typical crossover wires in the VLSI system, where the coupling capacitances between any two conductors need to be calculated.

Accurate modeling of the wire capacitances in a state-of-the-art integrated circuit is not a trivial task. It is further complicated by the fact that the interconnect structure of contemporary integrated circuits is three-dimensional (see Fig. 5). The capacitance of such a wire is a function of its shape, environment, distance from the substrate, and distance to surrounding wires. Generally SiO_2 is the insulating material among interconnect wires in integrated circuits, although some materials with lower permittivity, and thus lower capacitance, are coming into use. The relative permittivity ϵ_r of several dielectrics commonly used in integrated circuits is presented in Table 1. It should also be pointed out that ϵ_r of air or vacuum is 1.

3. METHODOLOGY AND ALGORITHMS

With the advances in IC technology, the methodology of capacitance extraction has evolved from one-dimensional (1D), two-dimensional (2D), 2.5-dimensional (2.5D), to three-dimensional (3D) to meet the required accuracy. In this section, the 1D and 2D methods are briefly introduced. Then, the 2.5-D method and the mechanism of the modern commercial capacitance extraction tools that employ the 3D capacitance extractor are presented. Finally, we will discuss some details of algorithms of the 3D field solver for capacitance extraction.

3.1. 1D and 2D Methods

From the formula for calculation of parallel-plate capacitance [Eq. (1)], we can infer that the capacitance is proportional to the overlapping area between the conductors and inversely proportional to their separation distance. This is very important for capacitance extraction without a high degree of precision.

Table 1. Relative Permittivity of Several Commonly used Dielectric Materials

Dielectric Material	Silicon	Alumina (Package)	Silicon Nitride (Si ₃ N ₄)	Glassepoxy (PCB)	Silicon Dioxide	Polyimides (Organic)	Aerogels
Relative permittivity (ϵ_r)	11.7	9.5	7.5	5	3.9	3–4	~1.5

Figure 6 shows a typical microstrip structure, where there is only a single rectangular conductor over a ground plane. This structure is very different from the above parallel-plate model discussed because of the existence of the capacitance between the sidewalls of the wire and the substrate, called the *fringing capacitance*. To avoid the time-consuming numerical modeling of this geometry, an approximate 1D method can be used as a good engineering practice. The capacitance is assumed to be the sum of two components: (1) a parallel-plate capacitance determined by the vertical field between a wire of width w and the ground plane and (2) the fringing capacitance modeled by a cylindrical wire with radius equal to the conductor thickness H . So, this simple and practical 1D formula becomes

$$C = C_{\text{area}} + C_{\text{fringe}} = \frac{\epsilon \cdot w}{d} + \frac{2\pi\epsilon}{\log(d/H)}$$

where $w = W - H/2$ is a good approximation for the width of the parallel-plate capacitor (W is the width of the wire), d is the distance between the ground plane and the bottom of wire, and ϵ is the permittivity of the insulating material. With this formula, we obtain the approximate capacitance per unit length.

In another kind of 1D capacitance extraction, the area and perimeter parameters of interconnect geometries are first obtained. Then, a fine-tuned set of area and perimeter weights per routing layer can be used to calculate capacitance values as an inner product [1]:

$$C = (\text{area amount, perimeter amount}) \\ \cdot (\text{area weight, perimeter weight})$$

Such area and perimeter weights can be obtained by pre-characterization of an “average” environment of a wire. The area can be that from single layer or a combination of layer overlaps.

Usually, the 1D extraction method works well when the number of interconnect layers is restricted to only one or two. However, the current process technology often involves many more interconnect layers, and they are also of high density. So, several capacitance components of a wire embedded in the multilayered interconnect system may

Figure 6. A conductor above a ground plane (cross-sectional view).

exist, other than the only capacitive coupling to the ground plane (see Fig. 7). Each wire is coupled not only to the grounded substrate but also to the neighboring wires on the same layer and on adjacent layers. Not all capacitive components terminate at the grounded substrate; actually a large number of them connect to other wires. These (fringing, lateral, parallel, etc.) capacitors between wires not only form a source of noise (crosstalk among signal lines) but also can have a negative impact on the circuit performance.

To model the capacitance in the multilayered interconnect system with higher accuracy, 2D capacitance extraction methodology was developed. In 2D capacitance extraction, accurate geometry modeling and numerical techniques are implemented for the cross section of simulated structure (as in Fig. 7). For the 2D region of dielectrics, the electric field equation is solved with numerical techniques. 2D extraction ignores all three dimensional details and assumes that the geometries being modeled are uniform in one dimension, usually the signal propagation direction. Therefore, 2D capacitance extraction is only suitable only for some special cases, such as like the transmission line.

The details of numerical techniques for solving the electric field will be introduced in Section 3.3, albeit in a 3D manner.

3.2. 2.5D Method and Commercial Capacitance Extraction Tool

The 2.5D (also called *quasi-3D*) method goes a step further than 2D extraction. Its main idea is to calculate the capacitance of several cross sections (using the 2D method) and combine the 2-D results into the final capacitance value.

A typical 2.5D capacitance extraction method is also called the “(2 × 2)D method”, in which any 3D structure is swept in two perpendicular directions and by considering the geometry overlapping, 3D structure can be modeled more accurately (see Fig. 8).

In Fig. 8, an m_2 wire crosses an m_1 wire. Along direction A, a 2D cross-sectional view is shown in the middle. Along direction B, the other 2D cross section is shown to

Figure 7. Capacitive coupling between wires in a multilayered interconnect system.

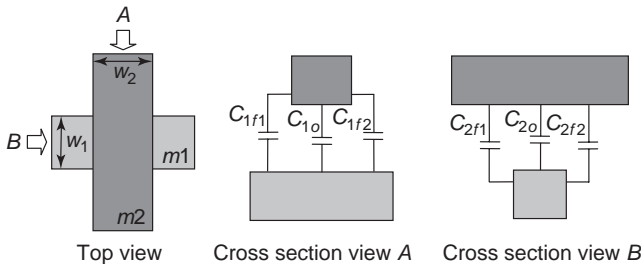

Figure 8. 2.5D capacitance for a crossover structure.

the right. Solving the two orthogonal strictly 2D problems numerically, we obtain $C_A = C_{1f1} + C_{1o} + C_{1f2}$, $C_B = C_{2f1} + C_{2o} + C_{2f2}$ (see Fig. 8). Then, $C_{m1,m2} = C_A \times w_1 + (C_B - C_{2o}) \times w_2$, where w_1, w_2 are the widths of wires m_1 and m_2 , respectively. However, this method is still not very accurate. The error could be more than 10%, especially for coupling capacitance, which is very important for signal integrity analysis.

Obviously, true 3D extraction is a straightforward method to achieve high precision. However, the 3D electrostatic Laplace equation must be solved numerically within a complicated 3D structure. This consumes extensive computational effort. 3D capacitance extraction (usually called the “field solver”) is actually not a trivial extension of the 2D case. This aspect is discussed further in Section 3.3.

For the current task of capacitance extraction in modern IC design, using the 3D extraction method directly is impossible because of its huge expense of memory and CPU time. To obtain a good tradeoff between accuracy and efficiency, modern capacitance extraction tools utilize special techniques for the full-chip extraction task, which is usually divided into three major steps [1]:

1. *Technology Precharacterization.* Given a description of the process cross sections, tens of thousands of test structures are enumerated and simulated with 2D and/or 3D field solvers. These structures are of medium dimensions. The resulting data are collected either to fit some empirical formulas or to build lookup tables (either type is called a “pattern library”). In Ref. 3, analytical equations are used for model fitting. A good fit would require fewer simulation points. The number of patterns can be reduced by pattern reduction techniques. Arora et al. [4] present a pattern compression technique that reduces the total number of precharacterization patterns. With this technology, the capacitance in some layout pattern can be extrapolated from the capacitance values in two simpler precharacterization patterns, without losing much accuracy. Capacitance field solvers employ different numerical algorithms, and they may give different answers for certain special layout structures depending on the problem setup and boundary conditions. Therefore, the precharacterization software should have the flexibility to incorporate any third-party field solvers. This first step should be performed only

Figure 9. A realistic vertical cross section of IC interconnect. We see that conductors on layers 1–5 are trapezoidal, and there is a conformal dielectric on top of the top layer metal (passivation). (SEM photograph courtesy of IBM Corp. © Copyright IBM Corp. 1994, 1996.)

once per process technology. The challenge in this area includes the handling of increasingly complex processing technology, such as low- k dielectric, air-bubble dielectric, nonvertical conductor cross sections, conformal dielectric (see Fig. 9), and shallow trench isolations.

2. *Geometric Parameter Extraction.* This is also an integral part of precharacterization. If a geometric pattern requires 10 parameters to describe, there is a corresponding precharacterization of 1×5^{10} ($\sim 10,000,000$) patterns to simulate. This is assuming that five sample points are taken in each of the 10 parameters, resulting in a 10-dimensional (10D) table of the dimensions given above. This is clearly not feasible. On the other hand, if a geometric pattern can be described by very few parameters, then it is difficult for it to be accurate. In a full-chip situation, the runtime of geometric parameter extraction can be very time/space-consuming, with millions of interconnect polygons to analyze. Time/space-efficient geometric processing algorithms are very important. Habitz and Wemple [5] present a geometric parameter reduction technique in which geometric parameters can be dramatically reduced by taking advantage of the shielding effect. Conductors two layers away from the main conductor of interest do not require a precise description. This is particularly useful for the very-deep-sub-micrometer geometry, where a very distant conductor mesh behaves like a large airplane.
3. *Calculation of Capacitance from Geometric Parameters.* Here, the geometric parameters are matched to some entries in the pattern library. Usually a full-chip or full-path extraction task involves at least thousands of conductors. The whole structure is chopped into medium-size pieces first, which are then calculated with the pattern-matching approach described above. Finally, the capacitance values must be combined to get the desired result.

One major source of error is called the *pattern mismatch*, where extracted geometry parameters do not have an exact match in the pattern library. At this time, there are two remedies to perform the capacitance calculations. One method is to enhance the pattern library by running field solvers at the full-chip extraction time. The other method is to employ heuristics to synthesize a solution from closely matched precharacterization patterns. Even if all the geometric patterns match the library completely, there could still be discontinuities in the layout pattern decomposition, which is another source of error. This error is analyzed in Ref. 6, where the error bound was obtained by utilizing the “empty” and “full” boundary conditions.

3.3. Algorithms for 3D Field Solver

The 3D method can be used model the actual geometry accurately, so it behaves with the highest precision. 3D capacitance extraction becomes increasingly important under the DSM technology of VLSI circuit, although presently it is used widely only as a library-building tool in the industry. More recently, much research work has been devoted to improve the efficiency of the 3D extraction method. Related papers are published on the annually held conferences (*Design Automation Conf.*, *Int. Conf. Computer-Aided Design*, etc.) and many academic journals (*IEEE Trans. Microwave Theory Tech.*, *IEEE Trans. Comput. Aided Design*, etc.). To date, some 3D extraction algorithms have been developed to integrate with the commercial software of some electronic design automation (EDA) companies in the Silicon Valley (in California). Research on 3D capacitance extraction is still advancing very rapidly.

In this section, the principles and mainstream techniques of the 3D field solver are introduced. More cutting-edge techniques are mentioned with related references.

3.3.1. Overview. For a system involving multiple conductors (see Fig. 5), with one conductor setting 1V and others 0V, the electrostatic equation (called the *Laplace equation*) need to be solved with a homogenous dielectric region [7]:

$$\nabla^2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0 \quad (3)$$

where u is the electric potential. This equation can be transformed into different mathematical formulations. Then, various numerical methods are employed to solve it with different levels of efficiency.

According to the domain of the above Laplace equation (3), there are two models for capacitance extraction: (1) *the infinite-domain model*, in which the electrostatic field spreads to the infinite, resulting in an infinite problem space; and (2) *the finite-domain model*, where the electrostatic field is restricted within a finite domain, with the Neumann condition on the outer boundary [8]: $(\partial u / \partial n) = 0$. This means that electric field is not able to spread out of the finite problem domain. The Neumann condition is also called the *reflective boundary condition*, and is introduced as the “magnetic wall” in Ref. 9. It

should be pointed out that the infinite-domain model is ideal for simulating isolated structures, but for the on-chip application it is not accurate because of the influence of neighboring conductors. On the other hand, the finite-domain model considers a part cut from actual layout of VLSI circuit; it is suitable for the realistic capacitance extraction of VLSI interconnects [8]. Now, both models of capacitance extraction are used in different applications, and accordingly the numerical methods are also different. The problems a numerical algorithm usually encountered in modeling are discussed below.

Classifications of the 3D field solver methods include the domain discretization method, the boundary integral equation method, semianalytical approaches, and the stochastic method. The domain discretization method includes the finite-difference method (FDM) [10], finite-element method (FEM) [11], and the method of the measured equation of invariance (MEI) [13,14]. The boundary integral equation method includes the method of moment [15], indirect boundary element method (BEM) [8,17–27], and direct boundary element method [28–34]. The semianalytical approaches combine the analytical formulas and some traditional numerical methods [9,35–37]. The stochastic method is based on statistical theory [38].

FDM and FEM discretize the entire 3D domain, thus producing a linear algebra system with large order; hence the computational speed of these methods is greatly limited. However, since both methods are relatively well established, they are still used in the industry as a reference tool with accurate values calculated under fine grids. For example, the famous software of 2/3D capacitance extraction “Raphael” utilizes FDM, and the “SpiceLink” of Ansoft Corp. is based on FEM.

Since the mid-1990s, the boundary integral equation method has begun to replace the domain discretization method because of its high performance. In both indirect and direct BEM, only the boundary of 3D domain is discretized, and a smaller system of linear equations is obtained. Problems encountered with the complex boundary can be effectively handled with BEM, whose accuracy is superior to that of FEM as well. Thus, the BEM with rapid computing techniques has become the focus of research on the 3D field solver.

3.3.2. Indirect Boundary-Element Method. The indirect boundary method can be regarded as a variation of the method of moments (MoM). Because only the domain boundary needs to be discretized, the indirect BEM involves much fewer unknowns than does FDM or FEM. However, it leads to a dense coefficient matrix, whose formation and solution introduce many difficulties. The innovation of the multipole acceleration method, the singular-value decomposition (SVD) method, and the hierarchical method has made the indirect BEM more applicable. Now, indirect BEM combined with a fast computational technique has become a main choice for the 3D field solver.

The indirect BEM method is also called the *equivalent charge method*, whose boundary integral equation involves the surface charge density $\sigma(x')$ as an unknown

function

$$u(\mathbf{x}) = \int_{\Gamma} G(\mathbf{x}, \mathbf{x}') \sigma(\mathbf{x}') d\mathbf{a}' \quad (\mathbf{x} \in \Gamma) \quad (4)$$

where $G(\mathbf{x}, \mathbf{x}')$ is Green's function. For free space, $G(\mathbf{x}, \mathbf{x}') = 1/|\mathbf{x} - \mathbf{x}'|$; Γ is the boundary surface. After solving the surface charge density $\sigma(\mathbf{x}')$, the charge on conductor i can be calculated with

$$Q_i = \int_{S_d(i)} \sigma(\mathbf{x}') d\mathbf{a}' \quad (5)$$

where $S_d(i)$ is the surface of conductor i . We discretize the surfaces of m conductors into n constant elements (or panels); then the potential at the center of the k th panel \mathbf{x}_k can be expressed as a sum of the contributions of all the panels

$$u_k = \sum_{j=1}^n \int_{\Gamma_j} \frac{\sigma_j(\mathbf{x}')}{\|\mathbf{x}' - \mathbf{x}_k\|} d\mathbf{a}'$$

where $\sigma_j(\mathbf{x}')$ is the surface charge density of panel j (Γ_j). Substituting the known boundary conditions, we obtain a dense linear algebra equation.

$$\mathbf{P}q = b \quad (6)$$

where the coefficient matrix \mathbf{P} is dense and nonsymmetric. The Krylov subspace iterative method, such as the generalized minimal residual algorithm (GMRES) [2], is usually used to solve this equation.

For a problem involving multiple dielectrics, the polarization charge density on the dielectric interface needs to be introduced, which contributes to the potential distribution together with the free charge density on conductor surfaces. Therefore, the problem becomes equivalent to that in the free space and the simple free-space Green function is used to form Eq. (4). Except for Eq. (4) on each conductor panel, the normal derivative of the potential satisfies

$$\varepsilon_a \frac{\partial u_+(x)}{\partial \mathbf{n}_a} = \varepsilon_b \frac{\partial u_-(x)}{\partial \mathbf{n}_a} \quad (7)$$

with $\mathbf{x} \in$ interface of ε_a and ε_b at any point \mathbf{x} on a dielectric interface. Here \mathbf{n}_a is the normal to the dielectric interface at \mathbf{x} that points into dielectric a and ε_a and ε_b are the permittivities of the corresponding homogenous dielectric region; $u_+(x)$ is the potential at x approached from the side of the interface ε_a , and $u_-(x)$ is the analogous potential for the b side.

For the multielectric problem, the so-called total-charge Green function approach presented above involves more unknowns at the interfaces. Another choice to deal with the problem is to employ the multilayered Green function. Then, only the free charge density on the conductor surfaces needs to be considered as an unknown function. However, to evaluate the Green function for the multilayered medium, infinite summations are involved,

which is very time-consuming. Oh et al. [20] derived a closed-form expression of Green's function for the multilayered medium by approximating the Green function using a finite number of images in the spectral domain. This greatly reduces the computational task. Li et al. [22] presented for the first time the general analytical formulas for the static Green functions for shielded and open arbitrarily multilayered media. Zhao et al. [21] an efficient scheme for the generation of multilayered Green functions using a generalized image method presented. The multilayered Green function is much more complicated than the free-space Green function; it is applicable only to the simple stratified structure of multiple dielectrics, while for more complex structures, such as the conformal dielectric, the deduction of Green's function may be impossible.

More research work has been undertaken to accelerate the capacitance extraction using the total-charge Green's function approach. In 1991, Nabors et al. applied the multipole accelerated (MPA) method successfully, proposed earlier by Greengard and Rokhlin [16], to 3D capacitance extraction with the indirect BEM. In the MPA method, calculation of the interaction between charges [i.e., the coefficients in (6)] is divided into two parts: the near-field computation and the far-field computation. For the near-field computation, the coefficients are calculated directly; for the far-field computation, the multipole expansion and local expansion are used to expedite the computation. Therefore, the CPU time of forming and solving (6) with the iterative equation solver is greatly reduced. Figure 10 illustrates of the multipole expansion. Nabors and White [18], developed the adaptive, preconditioned MPA method. The corresponding software prototype FastCap is shared on the MIT Website, and has become a popular tool of capacitance extraction for relevant researchers. To date, the capacitance extraction using the MPA indirect BEM is still undergoing research [25].

In 1998, a fast hierarchical algorithm for 3D capacitance extraction was proposed at the *Design Automation Conference*, and was reprinted in a journal article [24]. Similar to the multipole algorithm, it is also based on fast computation of the "N-body" problem. For the singular integral kernel of $1/|\mathbf{x} - \mathbf{x}'|$, it can achieve high acceleration of computation, and only $O(N)$ operations are needed

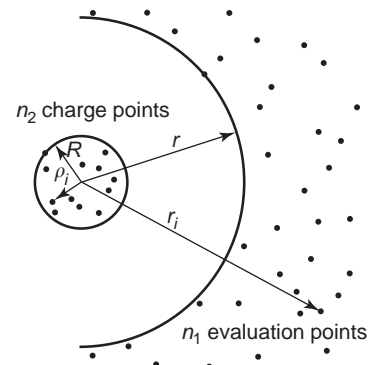

Figure 10. Evaluation point potentials are approximated with a multipole expansion [17].

for each iteration. For other weaker-singular kernels, the efficiency of this method may be reduced. In 1997, Kapur et al. and Long [19] proposed an accelerated method based on the singular-value decomposition (SVD) method that is independent of the kernel and based on the Galerkin method using the pulse function as the basis function. It requires an $O(N)$ times operation to construct the coefficient matrix and $O(N \log N)$ operations to perform an iteration. The precorrected fast Fourier transform (FFT) algorithm [23] has the same computational complexity, while it is based on the collocation method for discretization.

These studies on capacitance extraction with indirect BEM all handle the infinite-domain model. In 1996, Wang et al. [8] improved the multipole accelerated indirect BEM, enabling it to handle the finite-domain problem and also proposed a parallel multipole accelerated 3D capacitance simulation method based on nonuniformed cube partition.

Other fast computational methods for indirect BEM include those based on wavelets [26] and the multiscale method [27].

3.3.3. Direct Boundary-Element Method. The direct BEM is based on the direct boundary integral equation (BIE), and is suitable for solving the 3D Laplace equation with varied boundary conditions [12]. However, the direct BEM method is generally used to deal with the finite-domain model of capacitance extraction.

Within the finite domain that is involved in capacitance extraction (see Fig. 11), the electric potential u satisfies the following Laplace equation with mixed boundary conditions [32]

$$\begin{cases} \epsilon_i \nabla^2 u = 0, & \text{in } \Omega_i (i = 1, \dots, M) \\ u = u_0, & \text{on } \Gamma_u \\ q = \partial u / \partial \mathbf{n} = q_0 = 0, & \text{on } \Gamma_q \end{cases} \quad (8)$$

where the whole domain $\Omega = \bigcup \Omega_i$, where Ω_i stands for the space possessed by the i th dielectric. Γ_u represents the Dirichlet boundary (conductor surfaces), where u is known as the bias voltages; Γ_q represents the Neumann boundary (outer boundary of the simulated region), where the electric flux q is supposed to be zero. Here \mathbf{n} denotes the unit vector outward normal to the boundary. At the dielectric interface, the compatibility equation (7) holds.

With the fundamental solution as the weighting function, the Laplace equations in (8) are transformed into the

following direct BIEs by the Green identity [12]

$$c_s u_s^i + \int_{\partial \Omega_i} q^* u^i d\Gamma = \int_{\partial \Omega_i} u^* q^i d\Gamma \quad (i = 1, \dots, M)$$

where u_s^i is the electric potential at collocation point s (in dielectric region i) and c_s is a constant dependent on the boundary geometry near to the point s . $u^* = 1/4\pi r$ is the fundamental solution of the 3D Laplace equation, whose derivative along the outward normal direction \mathbf{n} is $q^* = \partial u^* / \partial \mathbf{n} = -(\mathbf{r}, \mathbf{n})/4\pi r^3$, r is the distance from the collocation point to the point on Γ , and $\partial \Omega_i$ is the boundary that surrounds dielectric region i .

Employing the collocation method after discretizing the boundary, such as that in the indirect BEM, we obtain system of linear equations [32]:

$$\mathbf{A}\mathbf{x} = \mathbf{f} \quad (9)$$

Finally, with the preconditioned Krylov iterative equation solver, such as the GMRES algorithm [2], the normal electric field intensity on the conductor surface is obtained [32].

In direct BEM, variables of both potential and field intensity are involved; thus two kinds of integral kernels are found. Although this is more complex than the indirect BEM method, direct BEM has its own advantages: (1) it is suitable for capacitance extraction within the finite domain since two variables are included, and (2) because the variables in each BIE are within the same dielectric region, it has a “localization” characteristic, which leads to a sparse linear system for problem with multiple dielectrics.

In direct BEM, a great deal of time and memory are consumed in forming and solving the system of discretized BEM equations. Wang et al. continued the research work of Fukuda [28] on 2D capacitance extraction using direct BEM, extending it to the 3D structure of VLSI interconnects [32]. An efficient analytical/semianalytical integration scheme was used to accurately calculate the boundary integrals under the VLSI planar process. This method achieves high computational speed and accuracy when forming Eq. (9) [32]. In 1996, Bachtold et al. [29] extended the multipole method to handle the “potential boundary integral” (whose kernel is $1/r^3$) in the direct BEM. They discussed the model of multiple dielectrics within the infinite domain. In 1999, Gu et al. extended the fast hierarchical method used in the indirect BEM and made it feasible to apply it for direct-BEM-based capacitance extraction [30].

In 2000, Yu et al. proposed a quasi-multiple medium (QMM) method, based on the localization characteristic of direct BEM [32]. The QMM method exploits the sparsity of the resulting coefficient matrix when handling the multi-dielectric problem. Together with the efficient equation organization and iterative solving technology, the QMM accelerated method has greatly reduced the computing time and memory usage. Figure 12 shows that a typical 3D interconnect capacitor with five dielectric layers is cut into $5 \times 3 \times 2$ fictitious medium regions. The QMM method has been successfully applied to actual 3D multidielectric

Figure 11. A structure with three dielectrics (cross-sectional view).

Figure 12. A typical 3D interconnect capacitor with five dielectric layers is cut into 3×2 structure.

capacitance extraction [32,34]. For the finite-domain multidielctric problem, the QMM-based method has shown a $10 \times$ higher computation speed and memory saving over the multipole approach (FastCap 2.0) with comparable accuracy [34].

Another kind of field solver, called the “global approach,” does not solve the resulting linear system in the usual way. The global approach discretizes the field equations and converts them to a circuit network of resistors or capacitors. Finally, with circuit reduction or matrix computation, the whole resistance or capacitance matrix can be obtained directly. In 1997, Dengi of Carnegie Mellon University proposed a global approach (called “macromodel” method) for 2D interconnect capacitance extraction based on direct BEM [31]. More recently, Lu et al. successfully extended the concept of boundary element macromodel to the 3D case, and developed a rapid hierarchical block boundary element method (HBBEM) for interconnect capacitance extraction [33].

3.3.4. Semianalytical Approaches. Semianalytical approaches have been proposed as a solution for 3D capacitance extraction. Basically, they take certain special procedures and reduce the original problem by one dimension, such as using domain decomposition. Since some subdomains with specific geometry symmetry can be handled using the analytical formula, these approaches have very high computational speed as well as much less memory usage. Another characteristic of these approaches is that the FDM is often used for the general and complicated subdomain. That is why these approaches are sometimes considered as improvements over the finite-difference method.

The semianalytical approaches include the dimension-reduction technique (DRT) [9] and techniques based on the domain decomposition method [35–37]. The principles of the latter two techniques will be briefly discussed as follows.

3.3.4.1. Dimension Reduction Technique. The DRT attempts to solve problems within the finite domain. Most VLSI interconnects have stratified structures, and every layer is homogeneous along the direction perpendicular to the interfaces of the layers (denoted as the z direction; see Fig. 13). The DRT takes full advantage of this fact. It first

Figure 13. A 3D interconnect capacitor and the stratified layers.

partitions the whole structure according to these homogeneous layers. Then, for each layer the 3D Laplace equation can be reduced to a 2D Helmholtz equation, which is solved with the most efficient method (including the analytical formula) according to the arrangement of the conductors. Finally, the solutions for these cascading 2D problems are combined together to yield the final result.

For the finite-domain problem of the i th layer with Eq. (8), denote $W^{(i)}(x, y, V_c)$ as a linear function of x, y and the bias voltage setting on conductors (denoted by vector V_c), and let

$$u^{(i)} = v^{(i)} + W^{(i)}(x, y, V_c).$$

If there exists a function such as $W^{(i)}(x, y, V_c)$, that function $v^{(i)}$ satisfies

$$\begin{cases} \nabla^2 v^{(i)}(x, y, z) = 0 \\ v^{(i)}(x, y, z) = 0, & (x, y) \in \Gamma_u^{(i)} \\ \partial v^{(i)}(x, y, z) / \partial \mathbf{n} = 0, & (x, y) \in \Gamma_q^{(i)} \end{cases}$$

then from the method of separation of variables, the general solution of $v^{(i)}$ is

$$v^{(i)}(x, y, z) = \sum_{m=1} T_m^{(i)}(x, y) L_m^{(i)}(z)$$

where $T_m^{(i)}$ is the mode function fulfilling the Helmholtz equation and $L_m^{(i)}$ can be solved analytically [9].

According to the conductor arrangement in the layer and the preceding analysis, the layer slices are classified as follows:

1. An Empty layer or a layer containing some simple conductors (such as that involving straight lines penetrating the structure) for which the linear function W and the analytical solution of the Helmholtz equation both exist.
2. The layer for which the linear function W exists, allowing the corresponding 3D problem to be transferred into the 2D Helmholtz equation.
3. A complex layer for which the W function does not exist. The 3D Laplace equation must be solved, but

only the 2D finite-difference grid is utilized because of the geometry symmetry along the z direction.

The main drawback of the DRT is that the geometry it employs has some limitations; For instance, it is difficult to apply DRT to nonplanarized structures. So, for generalized and complicated interconnect structures using the DSM technology, the efficiency of DRT is not guaranteed.

3.3.4.2. Domain Decomposition Method. The domain decomposition method (DDM) is a newly developed numerical method. It can be subgrouped into the overlapping domain decomposition method (ODDM) and the nonoverlapping domain decomposition method (NDDM). The former is also called the *Schwarz alternating method* and the latter, the *Dirichlet–Neumann alternating method*. ODDM partitions the whole structures into some overlapped subdomains. Then, a global iteration is used for the solution. Its principles are discussed below [35].

Consider a 3D finite domain Laplace problem with the Dirichlet boundary condition

$$\begin{cases} \nabla^2 u = 0, & (x, y, z) \in \Omega \\ u|_{\Gamma} = g(x, y, z) \end{cases}$$

Assume that the problem domain Ω involves two overlapping subdomains Ω_1 and Ω_2 (see Fig. 14), and denote Γ_j and Λ_j as the outer boundary and fictitious boundary of Ω_j ($j=1, 2$), respectively. Then, the Schwarz alternating method is represented as

$$\begin{cases} \nabla^2 u_1^{i+1} = 0, & (x, y, z) \in \Omega_1 \\ u_1^{i+1} = u_2^i, & (x, y, z) \in \Lambda_1 \\ u_1^{i+1} = g(x, y, z), & (x, y, z) \in \Gamma_1 - \Lambda_1 \end{cases}$$

$$\begin{cases} \nabla^2 u_2^{i+1} = 0, & (x, y, z) \in \Omega_2 \\ u_2^{i+1} = u_1^{i+1}, & (x, y, z) \in \Lambda_2 \\ u_2^{i+1} = g(x, y, z), & (x, y, z) \in \Gamma_2 - \Lambda_2 \end{cases}$$

with $i=0, 1, 2, \dots$, where u^0 is the initial value for iteration. In each iterative step, the known values of u on Λ_1 are used to solve the field of subdomain Ω_1 . Then, the field of subdomain Ω_2 is resolved with the u obtained on Λ_2 . The discrepancy of u on Λ_1 between two adjacent iterative steps is used as the criterion of convergence. A relaxation factor ω can be introduced to these formulas to accelerate the convergence. It is also obvious that the convergence rate of the Schwarz alternating method is closely related to the size of the overlapping region. Usually the iteration

Figure 14. Two overlapping subregions.

Figure 15. Four conductors embedded in nine dielectric layers.

error decreases exponentially with increase in the ratio of the overlapping domain over the subdomain [35].

It is straightforward to extend the preceding formulas of two subdomains to the generalized case with more subdomains. In each iterative step an analysis similar to that used in DRT can be employed to achieve high efficiency. In the actual application to capacitance extraction, the iteration sequence and selection of relaxation factor need to be considered. Figure 15 shows a cross-sectional view of an interconnect capacitor with nine layers, and the domain partition scheme is illustrated.

In the NDDM technique, the decomposed subdomains do not overlap each other, while the iteration algorithm is similar to that in ODDM; the difference is that in the adjacent subdomains the problem is solved with the Dirichlet boundary condition and the Neumann boundary condition, respectively, in the NDDM. In NDDM, there are fewer unknowns in the subdomain, and sometimes only 2D discretization is needed for a simple subdomain with homogeneous structure. However, the convergence rate of NDDM is slower than that of ODDM [36].

Research on capacitance extraction based on the domain decomposition method is still underway. More recent progress can be found in Ref. 37.

3.3.5. Other Methods. The measured equation of invariance (MEI) method can be considered as a variation of FDM. To solve the infinite-domain model of capacitance extraction, the MEI method terminates the meshes very close to the object conductors and still preserves the sparsity of the finite-difference (FD) equations. The geometry-independent measured equation of invariance (GIMEI) is proposed for the capacitance extraction of the general 2D and 3D interconnects by using the free-space Green function only [13]. The MEI method has now been developed to the on-surface level, where a surface mesh is used to minimize the number of unknowns [14]. The stochastic method is based on the random-walk theory and can effectively handle complex 3D structures. Its most recent progress can be found in Ref. 38.

4. PERSPECTIVE

In this article, we reviewed the state of the art in capacitance extraction techniques. These methods are discussed

mainly for the accurate analysis of VLSI interconnects. However, they can also be easily applied to computer-aided design of microwave ICs. With the development of IC technologies, the following issues related to capacitance extraction are important:

1. 3D capacitance extraction (i.e., 3D field solution) has the highest computational accuracy, and is suitable for complex interconnect structure under the DSM technologies. Many accelerating techniques have been developed to improve its speed. However, it is yet not feasible to use the 3D field solver directly in the full-chip extraction task. More effort should be devoted to improving the computational speed of the 3D field solver, or to develop special techniques for the full-chip task. The full-chip extraction method employing the 3D field solver would give both high computational speed and high accuracy.
2. Currently, few 3D capacitance extraction methods can be “tuned” for performance versus accuracy. The error estimation of the boundary-element method is also not established for practice. To make the 3D field solver suitable for various applications, its flexibility in tradeoff of accuracy versus computational performance must be improved. The adaptive algorithm and stable element partition scheme will be the focus of research in the future.
3. Mixed-signal integrated circuits have been demonstrated to provide high-performance system solutions for various applications such as wireless communications. Also, the silicon-based CMOS technology is increasingly widely used because of the fabrication cost advantage. To consider the significant impact of the lossy nature of the silicon substrate on the on-chip interconnects of the mixed-signal ICs, the frequency-dependent parameters of interconnects in high-speed circuits must be extracted accurately. Defining the complex permittivity of a material, the parasitic capacitance and conductance in a frequency-dependent model can be extracted using methods similar to that employed for traditional capacitance extraction. The most efficient algorithms for frequency-dependent capacitance extraction should be considered.

CAVITY RESONATORS

ARVIND K. SHARMA
TRW
Redondo Beach, California

1. RESONANT STRUCTURES

Resonant structures are network elements that are used extensively in the development of various microwave components [1]. At low frequencies, resonant structures are invariably composed of lumped elements. As frequencies increase, lumped-element resonant circuits are attained by using transmission lines. Microwave resonant structures are almost invariably understood as cavity resonators. Conventional resonators consist of a bounded electromagnetic field in a volume enclosed by metallic walls. The electric and magnetic energies are stored in the electric and magnetic fields, respectively, of the electromagnetic fields inside the cavity and the equivalent lumped inductance and capacitance of the structure can be determined from the respective stored energy. It is important to note that cavity resonators, in contrast to lumped resonators, have an infinite number of resonant frequencies (or modes). In the vicinity of each resonant frequency, the cavity can be approximated by an associated lumped equivalent circuit.

Some energy is dissipated as finite conductivity of the metallic walls, and the equivalent resistance can therefore be determined from the currents flowing on the walls of the cavity resonator [2,3]. In this article, a brief description of the cavity resonators most commonly employed in various microwave components is presented. As far as possible, simple expressions have been provided for design applications. Basic parameters of microwave resonators are first presented because they describe a cavity. Then, various coaxial and waveguide resonators are described. Fabrication, coupling, measurements, and applications of cavity resonators are also included.

2. RESONATOR PARAMETERS

2.1. Resonant Frequency

The parameters of a resonator at microwave frequencies are essentially similar to those of a lumped-element resonator circuit at low frequencies. They can easily be described using an *RLC* series or parallel network. Consider, for instance, an *RLC* parallel network as shown in Fig. 1a. The input impedance of such a network as a function of frequency has both real and imaginary parts. At resonance, the input impedance is real and is equal to the resistance of the circuit. The electric and magnetic stored energies are also equal, leading to the expression for the resonant frequency as

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad (1)$$

Figure 1. Lumped-element (a) parallel and (b) series resonant circuits.

2.2. Quality Factor

The performance of a resonant circuit is described in terms of the quality factor Q , and such features as frequency selectivity, bandwidth, and damping factors can be deduced from this. The quality factor is defined as

$$Q = \omega \frac{\text{time-averaged stored energy}}{\text{energy lost per second}} \quad (2)$$

for the lumped resonant circuits

$$Q = \omega RC = \frac{R}{\omega L} \quad (3)$$

for the parallel network in Fig. 1a, and

$$Q = \frac{1}{\omega CR} = \frac{\omega L}{R} \quad (4)$$

for the series network in Fig. 1b.

2.3. Fractional Bandwidth

The input impedance of the parallel resonant circuit of Fig. 1 is given by

$$Z_{\text{in}} = \left[\frac{1}{R} + \frac{1}{j\omega L} + j\omega C \right]^{-1} \quad (5)$$

At a frequency $\omega_0 \pm \Delta\omega$ in the vicinity of the resonant frequency, Eq. (5) reduces to

$$Z_{\text{in}} = \frac{R}{1 \pm j2Q(\Delta\omega/\omega_0)} \quad (6)$$

From Eq. (6), it is clear that at $\omega = \omega_0$ the input impedance is only resistive. However, when

$$\Delta\omega = \frac{\omega_0}{2Q} \quad (7)$$

the magnitude of the input impedance decreases to $R\sqrt{2}$ of its maximum value R , and the phase angle is $\pi/4$ for $\omega < \omega_0$ and $-\pi/4$ for $\omega > \omega_0$. From Eq. (7), the fractional band-

width BW is defined as

$$\text{BW} = \frac{2\Delta\omega}{\omega_0} = \frac{1}{Q} \quad (8)$$

2.4. Loaded Quality Factor

In practical situations, the resonant circuit is coupled to an external load R_L that also dissipates power, and the loaded quality factor Q_L is given by

$$\frac{1}{Q_L} = \frac{1}{Q} + \frac{1}{Q_e} \quad (9)$$

where Q_e is the external quality factor for a lossless resonator in the presence of the load.

2.5. Damping Factor

Another important parameter associated with a resonant circuit is the damping factor δ_d . It is a measure of the rate of decay of the oscillations in the absence of an exciting source. For high- Q resonant circuits, the rate at which the stored energy decays is proportional to the average energy stored. Consequently, the stored energy as a function of time is given by

$$W = W_0 e^{-2\delta_d t} = W_0 e^{-\omega_0 t/Q} \quad (10)$$

which implies that

$$\delta_d = \frac{\omega_0}{2Q} \quad (11)$$

Thus, we see that the damping factor is inversely proportional to the Q of the resonant circuit. In the presence of an external load, the Q should be replaced by Q_L .

Alternately, the input impedance in the vicinity of resonance Z_{in} given by Eq. (6) can be rewritten to take into account the effect of losses in terms of the complex resonant frequency

$$\omega_c = \omega_0 + j\delta_d = \omega_0 \left(1 + j\frac{1}{2Q} \right) \quad (12)$$

so that

$$Z_{\text{in}} = \frac{\omega_0 R / (2Q)}{j(\omega - \omega_c)} \quad (13)$$

In Eq. (13) the parameter R/Q is called the *figure of merit* and describes the effect of the cavity on the gain-bandwidth product. In terms of the lumped elements of the resonant circuit, we obtain

$$\frac{R}{Q} = \sqrt{\frac{L}{C}} \quad (14)$$

3. COAXIAL CAVITY RESONATORS

At microwave frequencies, the dimensions of lumped resonator circuits become comparable to the wavelength, and

this may cause energy loss by radiation. Therefore, resonant circuits at these frequencies are shielded to prevent radiation. Perfectly conducting enclosures, or cavities, provide a means of confining energy. Usually, cavities with the largest possible surface area for the current path are preferred for low-loss operation, and the energy is coupled to them by the various means described later in this article.

3.1. Coaxial Resonators

A coaxial cavity resonator (Fig. 2) supporting TEM (transverse electromagnetic) waves can easily be formed by a short section of coaxial line. Resonances appear whenever the length d of the cavity is an integral number of half-wavelengths. The resonance modes occur at

$$f = \frac{nc}{2d}, \quad n = 1, 2, \dots \quad (15)$$

where c is the speed of light. The lowest resonant frequency corresponds to $n = 1$, and the Q of the cavity for this mode is given by [4]

$$Q \frac{\delta}{\lambda_0} = \frac{1}{4 + 2(d/b)(1 + b/a) / \ln(b/a)} \quad (16)$$

where δ is the skin depth and a and b are inner and outer radii, respectively. It is also possible to have higher-order resonance modes, depending on the structural parameters of the coaxial line. The first higher-order mode appears when the average circumference is equal to the wavelength in the dielectric medium of the line. The cutoff frequency of this mode is

$$f_c = \frac{c}{\pi\sqrt{\epsilon_r}(a + b)} \quad (17)$$

where ϵ_r is the dielectric constant of the medium. Other higher-order modes correspond to TE (transverse electric) and TM (transverse magnetic) waves that exist in a circular waveguide with the radius of the center conductor approaching zero. The resonance condition is

$$k_{nml} = \left[p_{nm}^2 + \left(\frac{l\pi}{2d} \right)^2 \right]^{1/2} \quad (18)$$

where $k_{nml} = 2\pi f_{nml}/c$ and p_{nm} is the cutoff wavenumber that is obtained as the m th root of the transcendental

Figure 2. Coaxial cavity resonator and its cross section.

equations

$$J'_n(ka)N'_n(kb) - J'_n(kb)N'_n(ka) = 0 \quad (19)$$

for TE modes and

$$J_n(ka)N_n(kb) - J_n(kb)N_n(ka) = 0 \quad (20)$$

for TM modes. Here J_n and N_n are the n th-order Bessel functions of the first and second kinds, respectively, and the prime denotes their derivatives with respect to their arguments.

3.2. Reentrant Coaxial Resonators

Another coaxial cavity configuration consists of a short section of coaxial line with a gap in the center conductor. Figure 3a shows a capacitively loaded coaxial cavity. Radial cavity as shown in Fig. 3b is another possible variation. They are also referred to as *reentrant coaxial cavities* because the metallic boundaries extend into the interior of the cavity. They are widely used in microwave tubes. The resonant frequency of such a structure can be evaluated from the solution of the transcendental equation

$$\tan \beta l = \frac{dc}{\omega a^2 \ln(b/a)} \quad (21)$$

where d is the gap in the center conductor, and $2l + d$ is the length of the cavity. From Eq. (21), it is obvious that the capacitively loaded coaxial cavity can have an infinite number of modes. For the radial reentrant cavity of Fig. 3b, the resonant frequency can be evaluated by calculating the inductance and capacitance of the structure. The expression for the resonant frequency is

$$f = \frac{c}{2\pi\sqrt{\epsilon_r}} \left[al \left(\frac{a}{2d} - \frac{2}{l} \ln \frac{0.765}{\sqrt{l^2 + (b-a)^2}} \right) \ln \frac{b}{a} \right]^{-1/2} \quad (22)$$

Figure 3. Reentrant coaxial cavity resonators: (a) capacitively loaded coaxial cavity resonator; (b) radial cavity resonators.

An approximate expression for the Q of the cavity is

$$Q \frac{\delta}{\lambda_0} = \frac{2l}{\lambda} \frac{\ln(b/a)}{2 \ln(b/a) + l[(1/a) + (1/b)]} \quad (23)$$

for a tunable reentrant cavity, d is large, and $(l - d)$ is also large compared with b . The resonances occur whenever the length of the center conductor is approximately a quarter-wavelength.

3.3. Annular Coaxial Resonator

An annular coaxial resonator is formed by a figure of revolution of a coaxial radial cavity resonator (refer to Fig. 3) about an axis that is offset from and parallel to the center conductor [5]. As shown in Fig. 4, the electric field in the plane containing the axis is similar to that of the radial cavity resonator. The electric field in the plane normal to the axis is radial and is same along the circumference. In effect, the annular resonator is equivalent to a half wavelength coaxial resonator with a small shunt capacitance in the middle. One of the important application of this type of resonator is that it can be coupled simultaneously with several sources. The electric field at the gap is quite high and results in good coupling to external sources.

4. WAVEGUIDE CAVITIES

4.1. Rectangular Waveguide Resonators

Rectangular resonant cavities are formed by a section of rectangular waveguide of length d . This cavity can also support an infinite number of modes. The field configura-

tion of the standing-wave pattern for the incident and reflected waves is not unique, that is, it depends on the assumed direction of propagation of the wave. In order to be consistent, we shall assume that wave propagation is in the positive z direction. The standing-wave pattern is then formed by the incident and reflected waves traveling in $+z$ and $-z$ directions, respectively. The cutoff wavenumber k_{cmn} is given by

$$k_{cmn}^2 = \left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2, \quad m=0, 1, 2, \dots, \quad n=0, 1, 2, \dots \quad (24)$$

where a and b are waveguide dimensions. The resonant wavenumber is then expressed as

$$k_{mnp} = \left[\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 + \left(\frac{p\pi}{d}\right)^2 \right]^{1/2}, \quad p=1, 2, \dots \quad (25)$$

and the resonant frequency is defined as

$$f_{mnp} = \frac{k_{mnp}c}{2\pi} \quad (26)$$

From the preceding discussion, we see that the resonant frequency is the same for TE and TM modes. Therefore, they are referred to as *degenerate modes*. The field configuration of the dominant TE_{101} mode is shown in Fig. 5b. The quality factor Q of the dominant TE_{101} mode in the rectangular resonant cavity having surface resistance R_s can be evaluated using the expression

$$Q = \frac{120\pi^2}{4R_s} \left[\frac{2b(a^2 + d^2)^{3/2}}{ad(a^2 + d^2) + 2b(a^3 + b^3)} \right] \quad (27)$$

Figure 4. Two views of annular coaxial resonator structure.

Figure 5. (a) Rectangular waveguide cavity resonator; (b) field configuration of the dominant TE_{101} mode.

In rectangular cavities, the resonant frequency increases for higher-order modes, as does the Q at a given frequency. Higher-order mode cavity or “echo boxes” are useful in applications where a slow rate of decay of the energy stored in the cavity after it has been excited is required.

4.2. Circular Waveguide Resonators

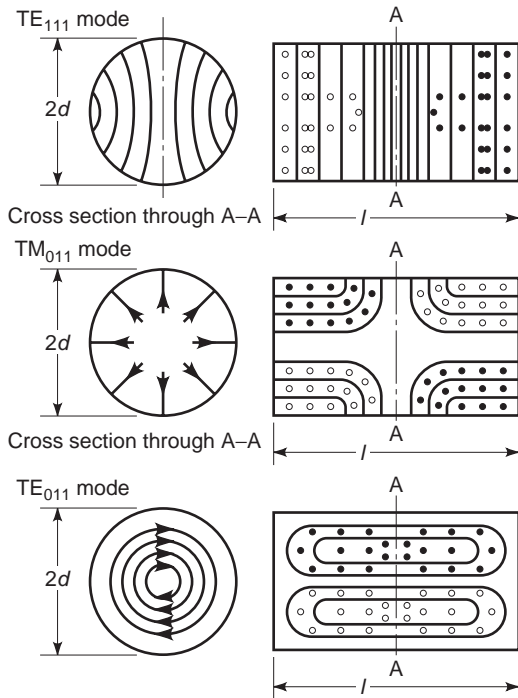

Circular waveguide cavities are most useful in various microwave applications. Most commonly, they are used in wavemeters to measure frequency, have a high Q factor, and provide greater resolution. These consist of a section of circular waveguides of radius a and length d as shown in Fig. 6.

The resonance wavenumber of the circular waveguide cavity is given by

$$k_{nml} = \left[\left(\frac{x_{nm}}{a} \right)^2 + \left(\frac{l\pi}{d} \right)^2 \right]^{1/2}, \quad l = 0, 1, 2, \dots \quad (28)$$

(a)

(b)

Figure 6. (a) Circular cylindrical waveguide cavity resonator; (b) field configurations for TE_{111} , TM_{011} , and TE_{011} modes in cylindrical cavities.

Table 1. Roots of the Transcendental Equation $J'_n(ka) = 0$

Modes		
n	m	p'_{nm}
0	1	0.0
1	1	1.841
2	1	3.054
0	2	3.832
3	1	4.201
4	1	5.318

where

$$x_{nm} = \begin{cases} p'_{nm} & \text{for TE modes} \\ p_{nm} & \text{for TM modes} \end{cases} \quad (29)$$

Values for p'_{nm} for various modes are given in Table 1. Field lines for TE_{111} , TM_{011} , and TE_{011} modes are shown in Fig. 6. Simplifying Eq. (28) yields

$$(2af_{nml})^2 = \left(\frac{cx_{nm}}{\pi} \right)^2 + \left(\frac{cl}{2} \right)^2 \left(\frac{2a}{d} \right)^2 \quad (30)$$

The Q of the circular cavity for TE_{nml} modes can be evaluated from

$$Q \frac{\delta}{\lambda_0} = \frac{[1 - (n/p'_{nm})^2][(p'_{nm})^2 + (l\pi a/d)^2]^{3/2}}{2\pi[(p'^2_{nm} + 2a/d(l\pi a/d)^2 + (1 - 2a/d)(nl\pi a/p'_{nm}d)^2]} \quad (31)$$

and for the dominant TE_{111} mode, Q can be obtained by substituting $n = m = l = 1$ in the preceding equation. Using Eq. (30), plots of $(2af)^2$ versus $(2a/d)^2$ can be used to construct mode charts, as shown in Fig. 7. From this it can be seen that, for the TE_{011} mode operation, the safe value of $(2a/d)^2$ is between 2 and 3. For TM model operation, the Q is given by

$$Q \frac{\delta}{\lambda_0} = \begin{cases} \frac{[p'^2_{nm} + (l\pi a/d)^2]^{1/2}}{2\pi(1 + 2a/d)} & \text{for } l > 0 \\ \frac{p_{nm}}{2\pi(1 + a/d)} & \text{for } l = 0 \end{cases} \quad (32)$$

As with rectangular cavity resonators, the Q is higher for higher-order modes.

4.3. Elliptic Waveguide Resonators

Elliptic resonant cavities that are formed using a section of an elliptic waveguide offer several advantages. There is no mode splitting caused by slight deformations in the cavity surface, and the electric field configuration in the transverse plane is fixed with respect to its axes. Also, the longitudinal electric field of the TM_{111} mode in an elliptic cavity with semi-major axis a is always greater than the circular cavity with radius a . This feature may be useful in the dielectric material characterization that uses perturbation techniques [6].

Figure 7. Mode chart of a circular cylindrical cavity resonator.

The elliptic waveguide supports four different types of modes, namely, even TE and TM modes and odd TE and TM modes. The TE modes have $E_z = 0$ and the TM modes have $H_z = 0$. From the solution of wave equations, there exist four different modes. The modes having cosine-type variation are called *even modes*, and modes having sine-type variation are called *odd modes*. The subscripts *c* and *s* are added to the mode designation to describe this variation.

The elliptic waveguide in Fig. 8a is shown along with the orthogonal elliptic coordinate system. As can be seen, the confocal elliptic cylinders are formed with constant ξ , and confocal hyperbolic cylinders are formed with constant η . The distance between the two foci, F and F' is $2h$. The outer wall of the elliptic waveguide is formed with $\xi = \xi_0$. The semi-major axis is then

$$2a = 2h \cosh \xi_0 \quad (33)$$

and, the semi-minor axis is

$$2b = 2h \sinh \xi_0 \quad (34)$$

Alternatively, the eccentricity e is

$$e = 1 / \cosh \xi_0 = \sqrt{1 - (b/a)^2} \quad (35)$$

The resonance wavenumber for elliptic cavity is given by

$$k_{rml} = \left[\left(\frac{2\sqrt{x_{rml}}}{ae} \right)^2 + \left(\frac{l\pi}{d} \right)^2 \right]^{1/2}, \quad l = 0, 1, 2, \dots \quad (36)$$

(a)

TE_{C111}

(b)

Figure 8. (a) Elliptic waveguide cavity resonator; (b) field configuration for some modes in elliptical cavities.

where

$$x_{rml} = \begin{cases} q'_{rml} & \text{for TE}_{rml} \text{ modes} \\ q_{rml} & \text{for TM}_{rml} \text{ modes} \end{cases} \quad (37)$$

In Eq. (37), r can be substituted with c and s to obtain even and odd modes, respectively. The parameter $q_{cmn}(q_{smn})$ is the n th parametric zero of the even (odd) modified Mathieu function of order m with argument ξ_0 and is used to calculate $\text{TM}_{cmn}(\text{TM}_{smn})$ modes. Similarly, for a $\text{TE}_{cmn}(\text{TE}_{smn})$ mode, the parameter $q'_{cmn}(q'_{smn})$ is the n th parametric zero of the first derivative of the even (odd)

modified Mathieu function of order m with argument ξ_0 and is used to calculate $TE_{cmn}(TE_{smn})$ modes. The equations used to find the parametric zeros are given next [7]:

$$\begin{aligned}
 \text{TM modes : } & Ce_m(\xi_0, q) = 0 \text{ even} \\
 & Se_m(\xi_0, q) = 0 \text{ odd} \\
 \text{TE modes : } & Ce'_m(\xi_0, q) = 0 \text{ even} \\
 & Se'_m(\xi_0, q) = 0 \text{ odd}
 \end{aligned}
 \tag{38}$$

Field lines for some modes are shown in Fig. 8b.

4.4. Annular Elliptic Resonator

The annular elliptic waveguide in Fig. 9a is shown along with the orthogonal elliptic coordinate system. The outer ellipse with eccentricity e_0 and the inner ellipse with eccentricity e_1 form a confocal annular elliptic waveguide. The distance between the two foci F and F' is $2h$ and is related to the other structural parameters via the relation

$$2h = 2a_0e_0 = 2a_1e_1 \tag{39}$$

where a_0 and a_1 are the semi-major axes of the outer and inner ellipses, respectively. Alternatively, the eccentricities e_0 and e_1 are also expressed as

$$e_0 = 1/\cosh \xi_0 = \sqrt{1 - (b_0/a_0)^2} \tag{40}$$

and

$$e_1 = 1/\cosh \xi_1 = \sqrt{1 - (b_1/a_1)^2} \tag{41}$$

where b_0 and b_1 are the semi-minor axes of the outer and inner ellipses, respectively. The axial coordinates of the outer and inner ellipses are ξ_0 and ξ_1 .

In a manner similar to the elliptic waveguide, the eigenvalue equation for annular elliptic waveguide was solved by Bräckelmann [8]. The relevant equations for TM and TE modes follow.

Even modes, TE_{cmn} :

$$\begin{aligned}
 Ce'_m(\xi_0, q_{cmn})Fe'y'_m(\xi_1, q_{cmn}) \\
 - Ce'_m(\xi_1, q_{cmn})Fe'y'_m(\xi_0, q_{cmn}) = 0
 \end{aligned}
 \tag{42}$$

Figure 9. (a) Annular elliptic cavity resonator; (b) field configuration for some modes in annular elliptic cavities.

Odd modes, TE_{smn} :

$$\begin{aligned} Se'_m(\xi_0, q_{smn})Ge y'_m(\xi_1, q_{smn}) \\ - Se'_m(\xi_1, q_{smn})Fe y'_m(\xi_0, q_{smn}) = 0 \end{aligned} \quad (43)$$

Even modes, TM_{cmn} :

$$\begin{aligned} Ce_m(\xi_0, q_{cmn})Fe y_m(\xi_1, q_{cmn}) \\ - Ce_m(\xi_1, q_{cmn})Fe y_m(\xi_0, q_{cmn}) = 0 \end{aligned} \quad (44)$$

Odd modes, TM_{smn} :

$$\begin{aligned} Se_m(\xi_0, q_{smn})Ge y_m(\xi_1, q_{smn}) \\ - Se_m(\xi_1, q_{smn})Fe y_m(\xi_0, q_{smn}) = 0 \end{aligned} \quad (45)$$

In Eqs. (42)–(45), $Ce_m(\xi, q)$ and $Se_m(\xi, q)$ are the even and odd modified Mathieu functions of the first kind and order m . $Fe y_m(\xi, q)$ and $Ge y_m(\xi, q)$ are the even and odd modified Mathieu functions of the second kind and order m [9]. The primes in Eqs. (42)–(45) denote the derivative with respect to the argument ξ . The parameter q'_{cmn} is the n th parametric zero of Eq. (42), and q_{cmn} is the n th parametric zero of Eq. (44). Similar explanation applies for Eqs. (43) and (45) for the odd TE and TM modes.

The resonance wavenumber for annular elliptic cavity is given by

$$k_{rml} = \left[\left(\frac{2\sqrt{x_{rml}}}{ae} \right)^2 + \left(\frac{l\pi}{d} \right)^2 \right]^{1/2}, \quad l = 0, 1, 2, \dots \quad (46)$$

where

$$x_{rml} = \begin{cases} q'_{rml} & \text{for } TE_{rml} \text{ modes} \\ q_{rml} & \text{for } TM_{rml} \text{ modes} \end{cases} \quad (47)$$

The annular elliptic resonators also supports four different types of modes, namely, even TE and TM modes and odd TE and TM modes. Field lines for some modes are shown in Fig. 9b.

4.5. Spherical Resonators

Another cavity resonator shape is the spherical resonator. Based on the solution of Maxwell's equations in the spherical coordinate system, the axial symmetry results in TM modes containing E_r , E_θ , H_ϕ , and TE modes containing H_r , H_θ , E_ϕ . Because the origin is included inside the hollow spherical cavity, the resonance condition is easily obtained by setting $E_\theta = 0$ at $r = a$, where a is the radius of the sphere.

Solution of the transcendental equation

$$\tan ka = \frac{ka}{1 - (ka)^2} \quad (48)$$

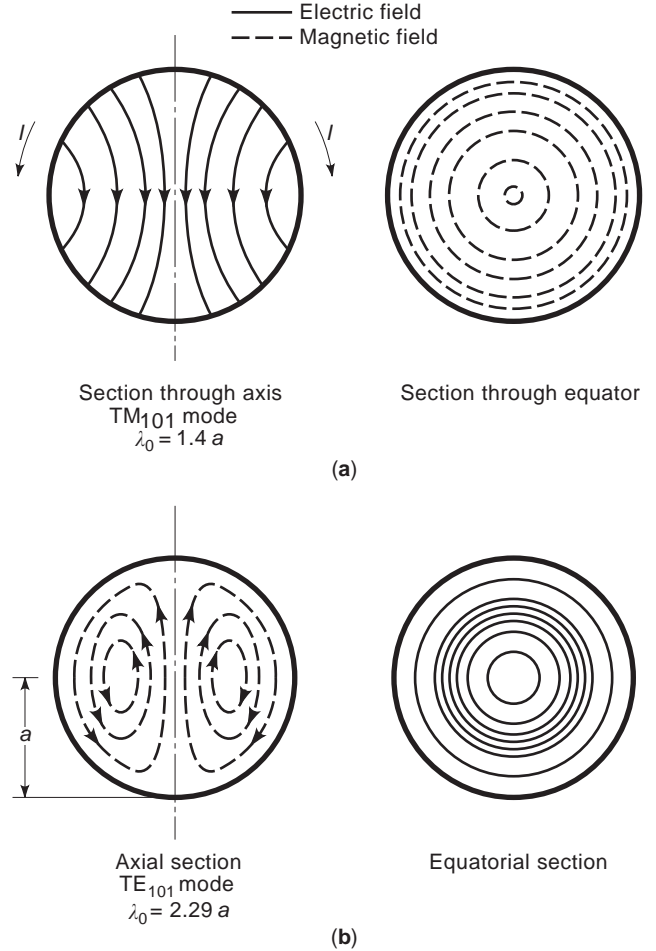

Figure 10. Fields in a spherical cavity resonator at the first and second resonant frequencies.

results in dominant TM_{101} resonance at

$$\lambda_0 = 2.29a \quad (49)$$

and the second TM_{102} resonance at a wavelength of

$$\lambda_0 = 1.4a \quad (50)$$

The modes in a spherical cavity are shown graphically in Fig. 10.

The Q of a spherical cavity operating in the dominant mode is

$$Q \frac{\delta}{\lambda_0} = 0.318 \quad (51)$$

and the equivalent shunt resistance is simply

$$R \frac{\delta}{\lambda_0} = 104.4 \quad (52)$$

4.5.1. Spherical Resonators with Reentrant Cones. Spherical resonators with reentrant cones were found to be suitable for realizing oscillators for klystrons [10].

Figure 11. Spherical resonator with reentrant cones and fields in the fundamental modes.

It consists of a hollow conducting sphere of radius a and two cones whose apex is at the center of the sphere and subtends an angle of $2\theta_0$. Its structure and fundamental mode fields are shown in Fig. 11.

The resonant wavelength is not a function of θ , as is the case in spherical resonators. The resonant wavelength is

$$\lambda_0 = 4a \tag{53}$$

However, Q and R of the resonator are functions of the angle θ . The plots of $Q(\delta/\lambda_0)$ and $R(\delta/\lambda_0)$ [4] are given in Figs. 12 and 13, respectively.

As can be seen, the maximum Q is obtained at $\theta = 34^\circ$ and is given by

$$Q \frac{\delta}{\lambda_0} = 0.1095 \tag{54}$$

and the maximum R occurs at $\theta = 9^\circ$ and is given by

$$R \frac{\delta}{\lambda_0} = 32.04 \tag{55}$$

4.6. Ellipsoid–Hyperbolic Waveguide Resonators

Another cavity resonator suitable for klystrons is of ellipsoid–hyperboloid shape. This shape is a figure of revolution about the axis passing through its foci, as shown in

Figure 12. $Q(\delta/\lambda_0)$ for a spherical resonator with reentrant cones.

Figure 13. $R(\delta/\lambda_0)$ of a spherical resonator with reentrant cones.

Fig. 14. The distance between foci a as well as the hyperboloid that determines part of the resonator is held constant. The normalized resonant wavelength λ_0/b , where b is the equatorial radius, is plotted as a function of the shape factor $\sigma_0 = 2b/a$. Interestingly, the shape of the resonators vary widely as the shape factor is increased. Both the Q as well as the R are functions of the shape factor. The $Q(\delta/\lambda_0)$ and $R(\delta/\lambda_0)$ (given in Ref. 4) are plotted as a function of shape factor in Figs. 15 and 16, respectively.

Figure 14. Ellipsoid–hyperboloid resonator and normalized resonant wavelength λ_0/b as a function of shape factor $\sigma_0 = 2b/a$.

Figure 15. $Q(\delta/\lambda_0)$ of an ellipsoid–hyperboloid resonator as a function of shape factor $\sigma_0 = 2b/a$.

4.7. Arbitrarily Shaped Resonators

The early work in microwaves focused on analytical and numerical solutions of hollow waveguide problems. Most of the attempts were to solve them for TE and TM modes, either exactly or approximately. Ng [11] compiled the methods used to calculate the cutoff wavenumbers of hollow waveguides. As pointed out there, three basic cross-sectional shapes can be distinguished:

1. Convex shape
2. Nonconvex with smooth reentrant portion
3. Nonconvex with sharp reentrant portion

A resonant structure can be formed using any of these shapes by closing the hollow waveguide with endwalls. The cutoff wavenumbers can be found using references given in Table II of Ref. 11. The resonant frequency can be easily calculated. The basic equation to use is

$$k = \frac{2\pi f_0}{c} = \left[(k_c)^2 + \left(\frac{l\pi}{d} \right)^2 \right]^{1/2}, \quad l = 0, 1, 2, \dots \quad (56)$$

Figure 16. $R(\delta/\lambda_0)$ of an ellipsoid–hyperboloid resonator as a function of shape factor $\sigma_0 = 2b/a$.

5. FABRICATION

5.1. Materials

Microwave and millimeter-wave cavities are usually made from the same material used for the waveguide such as copper, brass, or aluminum. In order to provide low-loss characteristics, the interior (and exterior) is plated with low-loss materials such as silver and gold.

There exists a wide range of waveguide sizes to cover frequencies from as low as 400 MHz–200 GHz. The operating bandwidth of the waveguide increases as the frequency increases. Therefore, the method of fabrication is very important in realizing low-loss or high- Q cavities.

Cavities are formed using short sections of waveguides. There are various approaches used in their fabrication. The waveguide tubing formed using extrusion process generally provides various dimensional tolerances varying from 0.008 in. (0.2 mm) to 0.001 in. (0.025 mm). In order to realize accurate waveguide dimensions, particularly at millimeter wavelengths, the process of electroforming is generally used. A conducting or nonconducting mandrel is used as a starting material in the electroforming process. The mandrel is later removed to leave the electroformed waveguide. Special-grade stainless-steel mandrels with high surface finish can be used to electroform the waveguide. They are removed by heating and applying uniform force. Nonconducting mandrels formed using plastics or highly compressed wax can be used to form complicated cross sections. Such mandrels can be chemically dissolved to retain the final form of the electroformed waveguide.

In most applications, the waveguide must interact with cavities to realize the prescribed description of the component. Fabrication from a solid metal block using a milling process is preferred because it provides an integrated component for some complicated waveguide assemblies. This approach reduces reflections and spurious transmission by minimizing interfaces or flanges.

5.2. Cavity Perturbation

At resonance the cavity contains equal amounts of average electric and magnetic energy. Any perturbation in the structural dimensions or imperfections in the cavity wall will require readjustment in resonant frequency such that the electric and magnetic energies are equal. It is possible to measure accurately the frequency shift $\Delta\omega/\omega$, which can be used to determine other parameters of the cavity [2].

5.3. Effects of Temperature and Humidity

The resonant frequencies of a cavity resonator depend on the dimensional variations of the material used in the construction as well as on the variations in the dielectric constant.

As temperature changes, the dimensions of the cavity change in accordance with the thermal expansion coefficient of the material used in its construction. The change in the resonant frequency can be easily determined using the equation for the resonant frequency for a given cavity

structure. This change can be minimized by bimetals with a lower coefficient of thermal expansion.

Furthermore, the dielectric constant of the air within an unsealed cavity also varies depending on the temperature, atmospheric pressure, and humidity level.

5.4. Tunable Cavities

Various microwave and millimeter-wave applications require resonators that can be tuned frequently and at high speeds. Both contacting as well as noncontacting plungers are used to tune cavity resonators.

5.4.1. Contacting Plunger. A movable short circuit is provided by the direct contact between the plunger and the cavity walls. The plunger is typically a quarter wavelength long at the center frequency. In order to provide good electrical contact, the contacting plungers, as shown in Fig. 17, have axial serrations. These serrated fingers maintain sufficient pressure to scratch off any insulating film formed inside the cavity walls. Because the contact is made at or near a current node, the losses are minimized. In some cases, particularly for millimeter-wave applications, a metal shoulder is also added to move the short circuit reference plane forward. In this case, the actual contact is not at or near a current node.

Contacting resonators have several disadvantages, such as

- They provide erratic contact due to small metal particles and nonsmooth cavity interior walls.
- They are not repeatable because of the backlash in the mechanical driving mechanism as well as the friction between the contacting surfaces.
- The contact causes wear and produces an insulating film, which results in increased contact resistance. The increases losses will result in lower Q of the cavity.

5.4.2. Noncontacting Plunger. The disadvantages of the contacting plungers can be eliminated by using noncontacting plungers. These plungers provide a near short

Figure 17. Contacting plunger.

Figure 18. Noncontacting plunger.

circuit over a wider frequency range. The impedance at the face of the plunger is a complex impedance with a low value of resistance. The capacitive, choke, or bucket-type plungers, as shown in Fig. 18, provide reasonable performance [5]. Multisection plungers are formed by quarter-wavelength low-high-low impedance sections. The leakage through these sections may cause parasitic resonance; therefore, the back of the plunger section must be terminated in the characteristic impedance of the transmission line used to realize the cavity.

6. COUPLING INTO AND OUT OF CAVITIES

As we have seen, the cavities are essentially enclosed structures. In order to use them, we must couple them to transmission lines. We can use the coaxial line or any form of waveguide to couple power into and out of the cavities. In this sense, the input and output coupling structures act as a load on the cavity. The cavity parameters, such as resonant frequency and Q , are invariably affected by the presence of these structures. The resonant behavior of the cavities is exploited extensively in the realization of filters with prescribed functional forms.

6.1. General Coupling

Coupling structures provide a means of coupling energy into and/or out of the cavity. The excitation of the cavity can be accomplished by electric or magnetic coupling. In case of electric coupling, the electric field of the coupling structure is parallel to the electric field of the cavity. The magnetic coupling is provided when the magnetic field of the coupling structure is parallel to the magnetic field of the cavity.

The coaxial line can be used to provide either electric or magnetic coupling.

1. *Electric Probes.* The center conductor of the coaxial line acts as a probe. Its direction is parallel to the direction of the electric field in the cavity.
2. *Current Loops.* The center conductor of the coaxial line is terminated in a short circuit to form a loop. The loop produces a magnetic field perpendicular to the plane of the probe and in the same direction as the magnetic field in the cavity.

Figure 19. Cavity excitation using (a) loop coupling, (b) electric probe coupling, and (c) aperture coupling.

Cavities are also excited by waveguides through apertures formed by holes and slits (Fig. 19). The coupling mechanism can be of electric or magnetic type.

1. *Magnetic Coupling Apertures.* The aperture is located between the cavity and input waveguide such that the magnetic field in the waveguide is parallel to the magnetic field in the cavity. Round holes in the wall separating the waveguide and cavity provide magnetic coupling.
2. *Electric Coupling Apertures.* The aperture is located between the cavity and input waveguide such that the electric field in the waveguide is normal to the electric field in the cavity. A narrow slot in the wall separating the waveguide and cavity can provide electric coupling.

6.2. Coupling through Probes

One popular approach used to transfer energy from a coaxial line to a waveguide is by electric probes. In a typical configuration, the axis of the coaxial line is perpendicular to the broadside of the rectangular waveguide. The center conductor of the coaxial line protrudes through the waveguide wall and extends into the waveguide. The outer conductor of the coaxial line is terminated at the waveguide wall. The electric fields from the end of the center conductor terminate on the other broadside wall parallel to the dominant E field of the waveguide. They are, therefore, called electric probes. If the probe is shaped to form a circular loop and the end of the probe is terminated on the broad wall of the waveguide, the current flow through this loop will induce a magnetic field parallel to the dominant H field of the waveguide. In this case, the probe is a magnetic current loop.

In an electric probe, the center conductor of the coaxial line forms a radiating antenna. Depending on the length or depth of this section, the input impedance

at the interface can be inductive or capacitive. For optimum performance, the antenna should present a matched load at the interface. The probe excites waveguide modes that propagate in both directions; therefore, the energy is divided equally in both directions. In order to redirect the energy in the preferred direction, the other side is terminated in a short circuit. In the case of rectangular waveguide cavities, the placement of the probe is determined from one of the short-circuited ends. Invariably, a tunable short circuit will be required for optimum transfer of power. The probe can be constructed with various lengths and diameters. The distance between the probe and the short circuit is determined experimentally.

The bandwidth of the probe can be improved by providing a broadband match at the interface. This can be achieved by changing the length and diameter of the probe. Other approaches include making the end round, attaching a metal sphere at the end, or flaring the center conductor. If direct current (DC) return is desired, the probe can be terminated on the other broadwall, or it can rest on a crossbar across the waveguide broad dimension. Sometimes the probe is extended through the opposite side of the waveguide to form another section of shorted coaxial line. The position of the short circuit in this case provides an additional variable.

The input impedance of a short-diameter coaxial antenna is given by

$$Z_{\text{in}} \cong l^2 \cos^2 \frac{\pi x_0}{a} \sin^2 \frac{2\pi x_1}{\lambda_g} - jX \quad (57)$$

where l is length of the probe, x_0 is the distance from the center of the waveguide, and x_1 is the distance from the probe to the short circuit. The value of the reactance is large, implying that the input impedance has a large capacitive component.

6.3. Coupling Holes in Waveguides

The coupling from a waveguide to a cavity can be provided by apertures consisting of holes and slits. The aperture can be infinitesimally thin or with finite thickness. The insertion loss caused by a hole of finite thickness t is given by

$$\alpha_T = \alpha_b + \alpha_t \quad (58)$$

where α_b is the attenuation resulting from the susceptance of the hole and α_t is the attenuation in the below cutoff waveguide hole.

6.3.1. Holes in a Rectangular Waveguide. For a hole of diameter d in a rectangular waveguide normal to the direction of propagation, the normalized susceptance B is given by

$$\frac{B}{Y_0} \cong \frac{3}{2\pi} \frac{ab\lambda_g}{d^3} \quad (59)$$

where Y_0 is the characteristic admittance of the dominant waveguide mode and λ_g is the guide wavelength of a

waveguide having broadside dimension a and smaller dimension b .

The attenuation α_b resulting from the hole is

$$\alpha_b = 20 \log \frac{B}{2Y_0} \quad (60)$$

and the attenuation resulting from the finite thickness α_t is

$$\alpha_t = 32 \sqrt{1 - \left(1.706 \frac{d}{\lambda}\right)^2} \frac{t}{d} \cong 32 \frac{t}{d} \text{ dB} \quad (61)$$

where λ is the operating wavelength.

6.3.2. Holes in a Circular Waveguide. For a hole of diameter d normal to the direction of propagation in a circular waveguide of diameter $2a$, the normalized susceptance B is given by

$$\frac{B}{Y_0} = \frac{\lambda_g}{4a} \left(5.71 \frac{a^3}{d^3} - 2.344\right) \quad (62)$$

where Y_0 is the characteristic admittance of the dominant waveguide mode, and λ_g is the guide wavelength of the dominant mode.

The attenuation α_b resulting from the hole is

$$\alpha_b = 10 \log \left[\frac{(B/Y_0)^2}{4} - 1 \right] \text{ dB} \quad (63)$$

and the attenuation α_t resulting from the finite thickness is given by Eq. (61), and the total attenuation is calculated using Eq. (58).

7. RESONATOR MEASUREMENTS

As described earlier, the resonator is described fully in terms of the resonant frequency f_0 , the coupling coefficient, and the quality factors. The unloaded quality factor Q_u , loaded quality factor Q_L , and external quality factor Q_e are useful in various circuit analyses containing microwave cavities.

Experimental determination of the parameters is straightforward using modern microwave network analyzers. In Fig. 20, single-port and two-port cavity measurement setups are shown. The magnitude and phase of the reflection and transmission coefficients are measured to determine the resonator parameters.

7.1. Single-Port Resonator

The equivalent circuit of a single-port cavity resonator is shown in Fig. 1, where R , L , and C are the equivalent lumped resistance, inductance, and capacitance. The equivalent parallel and series circuits of Figs. 1a and 1b are also known as the detuned short and open configurations, respectively. The equivalence between series and

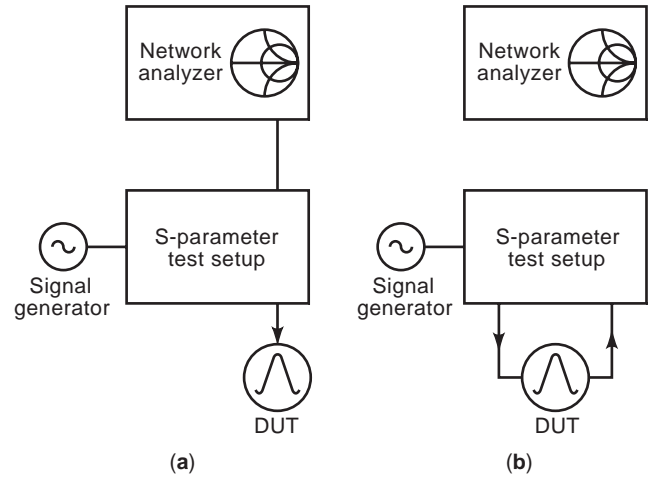

Figure 20. Measurement setup for (a) reflection and (b) transmission resonator.

shunt parameters of these resonant circuits is as shown in the following table:

Parameter	Series Tuned	Parallel Tuned
f_0	$\frac{1}{\sqrt{LC}}$	$\frac{1}{\sqrt{LC}}$
Q_u	$\frac{\omega L}{R}$	$\frac{R}{\omega L}$
β	$\frac{Z_0}{R}$	$\frac{R}{Z_0}$
Q_L	$\frac{Q_u}{1 + \beta}$	$\frac{Q_u}{1 + \beta}$

The input impedance of the circuit in Fig. 1a can be rewritten as

$$Z_{in} = \frac{R}{1 + j2Q_u\delta} \quad (64)$$

where $\delta = (\omega - \omega_0)/\omega_0$ represents the frequency detuning parameter [12]. By varying δ , the locus of the impedance given by Eq. (64) is determined. On a Smith chart, a circular locus, as shown in Fig. 21 is obtained depending on the coupling coefficient. For circle A, $R = Z_0$ and the locus passes through the origin. This condition is called *critical coupling* and corresponds to $\beta = 1$, implying that it provides a perfect match to the transmission line at resonance. The circle B with $R < Z_0$ is called undercoupled condition and $\beta < 1$. Finally, the circle C with $R > Z_0$ is an overcoupled condition with $\beta > 1$ [13].

The coupling coefficient for any cavity is calculated using the measurement of reflection coefficient S_{11,ω_0} at resonance. For the undercoupled case, we obtain

$$\beta = \frac{1 - S_{11,\omega_0}}{1 + S_{11,\omega_0}} \quad (65)$$

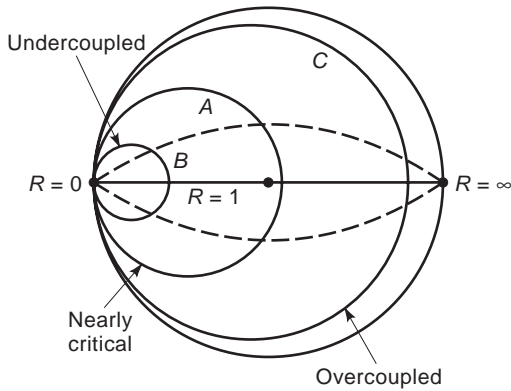

Figure 21. Input impedance of a single-port resonant cavity on the Smith chart for 3 degrees of coupling.

and for the overcoupled case, we obtain

$$\beta = \frac{1 + S_{11, \omega_0}}{1 - S_{11, \omega_0}} \quad (66)$$

The intersection of the impedance locus with the real axis provides the value of β as shown in Fig. 22.

Other quality factors can be determined from Eq. (64), which can be rewritten as

$$\begin{aligned} \bar{Z}_{in} = \frac{Z_{in}}{Z_0} &= \frac{\beta}{1 + j2Q_u \delta} \\ &= \frac{\beta}{1 + j2Q_L(1 + \beta)} = \frac{\beta}{1 + j2Q_e \beta} \end{aligned} \quad (67)$$

The Q_u , Q_L , and Q_e are related as

$$Q_u = Q_L(1 + \beta) = Q_e \beta \quad (68)$$

Figure 22. Determination of β and the half-power points from the Smith chart. Q_0 locus is given by $X=R(B=G)$; Q_L by $X=R+1$; Q_{ext} by $X=1$.

The normalized frequency deviations for unloaded, loaded, and external quality factors are given by

$$\delta_u = \pm \frac{1}{2Q_u}, \quad \delta_L = \pm \frac{1}{2Q_L}, \quad \delta_e = \pm \frac{1}{2Q_e} \quad (69)$$

From Eqs. (69) and (67), the impedance locus of Q_u is determined and is given by

$$(Z_{in})_u = \frac{\beta}{1 \pm j} \quad (70)$$

Equation (70) represents the points on the impedance locus where the real and imaginary parts of the impedance are the same. Figure 22 represents the locus of these points (corresponding to $R=X$) for all possible values of β . This locus is an arc whose center is at $Z=0 \pm j$, and the radius is the distance to the point $0 \pm j$. The intersection of this arc with the impedance locus determines the Q_u measurement points:

$$Q_u = \frac{f_0}{f_1 - f_2} \quad (71)$$

The frequencies f_1 and f_2 are called half-power points because these points correspond to $R=X$ on the impedance locus. The loaded and external Q values can be determined in a similar way. Equations (67) and (69), the impedances corresponding to Q_e and Q_L , are given by

$$(Z_{in})_e = \frac{\beta}{1 \pm j\beta} \quad (72)$$

and

$$(Z_{in})_L = \frac{\beta}{1 \pm j(1 + \beta)} \quad (73)$$

By using Eqs. (72) and (73), the Q_e and Q_L loci are easily determined. These loci are shown in Fig. 22.

7.2. Two-Port Resonator

The equivalent circuit of a two-port cavity resonator is shown in Fig. 23. In this case, the input and output coupling are represented as β_1 and β_2 . They are determined from

$$\beta_1 = \frac{Y_{01}}{n_1^2 G} \quad \text{and} \quad \beta_2 = \frac{Y_{02}}{n_2^2 G} \quad (74)$$

where Y_{01} and Y_{02} are the admittances seen at the input and output ports. The coupling coefficients are directly determined by measuring the VSWR at the input and output ports with the other port open-circuited.

The transmission response of such a resonant circuit measured using the setup of Fig. 20, is shown in Fig. 23. The coupling coefficients and the quality factors for two-port resonators determined from the measurement of the insertion loss T at resonant frequency and the 3 dB

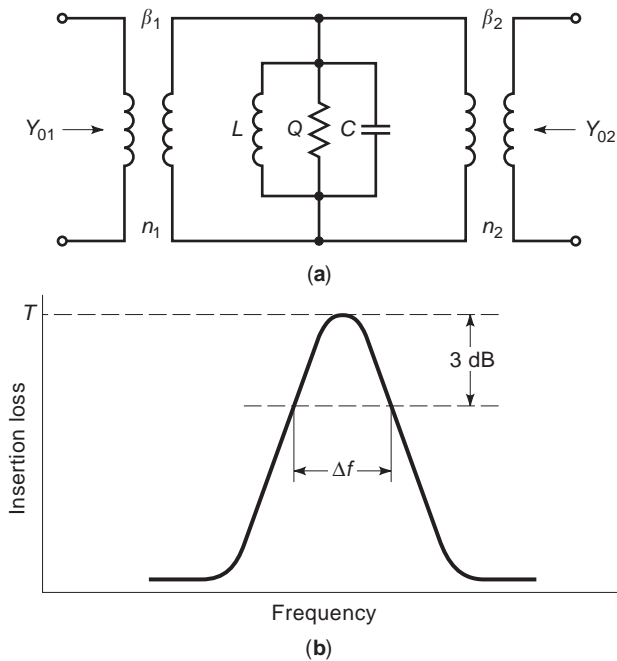

Figure 23. (a) Equivalent circuit of a two-port resonator with input and output transformers; (b) transmission response of a two-port resonator.

bandwidth Δf using the following well-known relations [14]

$$T = \frac{2\sqrt{\beta_1\beta_2}}{1 + \beta_1 + \beta_2} \tag{75}$$

$$Q_L = \frac{f_0}{\Delta f} \tag{76}$$

$$Q_u = Q_L(1 + \beta_1 + \beta_2) \tag{77}$$

8. APPLICATIONS

A development of the cavity resonators was an important milestone in microwave technology. Early work on cavity resonators focused on cavities of regular shapes. But the development of microwave oscillators and amplifiers required complex shapes to achieve the performance required in the development of klystrons, magnetrons, and traveling-wave tubes. Some of those shapes were covered in this article to illustrate the fact that different cavity structures are required to achieve the desired results.

Cavity resonators are also used extensively to measure frequency or wavelength. Tunable cavities are made to resonate at different frequencies by varying size and then calibrating size against frequency.

Cavity resonators are now most widely used to develop filters. Depending on the characteristics of the cavity, it can be used for narrowband as well as wideband filters. The applications of cavity resonators are concomitant with those of filters. In that sense, cavity resonators have

applications in lowpass, bandpass, bandstop, and high-pass filters. They are also used in duplexers, multiplexers, and directional filters.

In the following sections, the preceding applications will be reviewed and their key aspects will be highlighted. Additional information can be found in other relevant articles of this encyclopedia.

8.1. Applications in Microwave Tubes

There were many problems in the early development of microwave valves that were caused by circuit elements and their interconnections. The development of resonant cavities led to the invention of klystron. The cavity resonators were able to reduce the transit time. The capacitance between the cathode and grid was used to resonate with the low inductance provided by the cavity.

In klystron amplifiers, multiple cavities are used to allow bunching of electrons. Because the electromagnetic fields in a cavity are changing as a function of time, the alternating electric fields at the grid cause bunching of electrons. By using another cavity at an optimum distance, the electrons are further bunched to build up oscillations. The first “buncher” resonator is excited into resonance through external means, and the second “catcher” resonator takes out the power. In klystron amplifiers, internal feedback is also provided via openings in the cavities.

In the reflex klystron, the electron beam is bunched by passing through a single resonator. The reflector returns the electron beam to this cavity at an optimum bunched condition. At this time, the energy is extracted from the cavity.

Magnetrons use various shapes of cavities to build oscillations and power. The power is extracted from one of the resonators through a coupling loop or an iris.

In traveling wave tubes, cavities are used as part of the slow wave structure. For additional information, refer to the appropriate article in this encyclopedia.

8.2. Filters

In order to use cavity resonators in filter applications, a reactance or susceptance slope parameter is generally required. The reactance slope parameter for a series resonant structure is defined as

$$\chi = \left. \frac{\omega_0 dX}{2 d\omega} \right|_{\omega=\omega_0} \text{ ohms} \tag{78}$$

Similarly, the susceptance slope parameter for the parallel resonant structure is defined as

$$B = \left. \frac{\omega_0 dG}{2 d\omega} \right|_{\omega=\omega_0} \text{ siemens} \tag{79}$$

From Eqs. (78) and (79), it is straightforward to see that for a series resonant circuit at resonance

$$\chi = \omega_0 L = \frac{1}{\omega_0 C} \tag{80}$$

and

$$Q = \frac{\lambda}{R} \quad (81)$$

Similarly, for a parallel resonant circuit at resonance

$$B = \omega_0 C = \frac{1}{\omega_0 L} \quad (82)$$

and

$$Q = \frac{B}{G} \quad (83)$$

In a bandpass filter design, impedance or admittance inverters can be used with series or shunt-type resonant structures. The reactance or admittance slope parameter is related to filter prototype element values. The external Q and coupling coefficients are also expressed in terms of the reactance or admittance slope parameter. Inductive posts or irises with impedance inverters can be used to construct a bandpass filter. For details on waveguide filters, refer to the appropriate section in this encyclopedia.

8.3. Frequency Measurement

Both coaxial and waveguide resonators have been used in commercially available wavemeters. The main requirement in selecting cavity dimensions is to ensure that the cavity resonates in the fundamental mode, that there are no degenerate modes, and that they are easy to manufacture and calibrate.

These wavemeters are basically tunable cavities, and when the length is $\lambda_g/2$, the cavity resonates by taking in some energy from the transmission line, coaxial, or waveguide. This action will produce a dip in the transmitted power. When the length of the cavity is calibrated, the frequency or wavelength can be read off directly from the dial. The extent of the dip depends on the amount of coupling. The Q of wavemeter cavities is quite high, on the order of 5000–10,000 depending on the desired accuracy.

In a coaxial-line wavemeter, as shown in Fig. 24, the center conductor is used as a probe to couple energy to the resonator. Noncontacting plungers with chokes are used

Figure 24. Coaxial cavity wavemeter.

Figure 25. Cylindrical cavity wavemeter: (a) end view; (b) top view.

to provide a variable short position. The coaxial resonator will resonate whenever the cavity length is a half-wavelength. Measuring the change in plunger positions between two successive minima and multiplying by 2 will give the wavelength of operation. Because of the large surface area of the coaxial outer wall, the cavity Q is not very high.

Cylindrical cavities are generally used for wavemeters, as shown in Fig. 25. The currents in the TM_{01} mode flow circumferential to the cavity cross section. Therefore, the short-circuiting plunger does not need to have a good contact and provides easy manufacturability. Furthermore, other higher-order modes that require current flow in the endplates are not supported. In order to prevent other modes from being excited, two coupling holes in the side wall of a waveguide, which are a half-wavelength apart, are used. The bandwidth of the coupling structures can be increased by selecting an elongated hole.

CELLULAR RADIO

WILLIAM C. Y. LEE
AirTouch Communication

The cellular radio system is sometimes called a *mobile phone system* or a *car phone system*. Due to the daily needs of subscribers, cellular systems have expanded considerably all over the world. This article discusses the history of cellular systems and the difficulty of deploying them in the mobile radio environment, elaborating on employing digital cellular systems, Personal Communication Services (PCS) mobile satellite systems, and the future IMT-2000 system.

1. HISTORY OF CELLULAR RADIO SYSTEMS

1.1. Analog System

1.1.1. Startup Period (1964–1987). In 1964, AT&T Bell Labs actively developed a high-capacity mobile radio phone system called Advanced Mobile Phone Service (AMPS) [1], which is an analog frequency modulation (FM) system. The system consists of many so-called cells.

Each cell has one or multiple transceivers. Because of the cell formation, the system is referred to as a cellular system. In the analog AMPS system, mobile units are compatible with all the cellular systems operating in the United States, Canada, and Mexico. A spectrum of 50 MHz (limited to 825–849 MHz for mobile transmissions and 869–896 MHz for base-station transmissions) is shared by two cellular system providers in each market (city). Each one provider operates over a bandwidth of 25 MHz in a duplex fashion (using 12.5 MHz in each direction between cell sites and mobile units). There are 416 channels, comprising 21 setup channels and 395 voice channels. The channel bandwidth is 30 kHz. Mobile cellular telecommunications systems [2] have two unique features:

1. First, they invoke the concept of frequency reuse for increasing spectrum efficiency. The same set of frequency channels can be assigned to many cells. These cells are called *cochannel cells*. The separation between two cochannel cells is engineered by the D/R ratio (see Fig. 1), where D is the cochannel cell separation and R is the cell radius. A 4-mi cell implies $R = 4$ mi. The D/R ratio is characteristic of a cellular system. If the D/R ratio is high, the voice quality is improved by reducing the system's user capacity.
2. A second feature, handing off communications from one frequency to another, occurs when a mobile unit enters a new cell. The scheme is called a handoff in North America and a handover in Europe. The system handles this operation automatically, and the users do not need to intervene. A good handoff

Figure 1. Hexagonal coils in an AMPS system: R = radius of cells, D = minimum separation of cochannel cells, $q = D/R = 4.6$, K = number of cells in a cluster = 7. Clusters are indicated, and the six cells that effectively interfere with cell 1 are numbered 2 through 7. The shaded cells are cochannel cells.

algorithm can reduce both the call drop rates and interference. In general, there are two kinds of handoffs: (1) soft handoffs, which implies making a new connection before breaking the old one; and (2) hard handoffs, which involves breaking the old connection before making the new one.

The first installation of a cellular system occurred in Tokyo in 1979, using a minor modification of AMPS. The first AMPS cellular system installed in the United States took place in Chicago in 1983. Analog cellular systems are in use over most of the world, employing different versions of AMPS: in Japan, the Nippon Telephone and Telegraph (NTT) AMPS system; in the UK, the Total Access Communications System (TACS); and in northern Europe, the Nordic Mobile Telephone (NMT). The major difference is their reduced channel bandwidths of 25 kHz instead of 30 kHz as in AMPS.

1.1.2. Mature Period (1987–1992). From 1987 to 1992, the 90 MSA (metropolitan statistical area) markets, as well as most of the 417 RSA (rural service area) markets, had cellular operations in the United States. The number of subscribers reached 1 million. The cell split (reducing the size of cells) technique and dynamic frequency assignment were applied to increase the user capacity.

When the cell radius R is less than half a kilometer, the cell is called a *microcell*. In such small cells it is harder to reduce the so-called cochannel interference in order to increase capacity, requiring special technological approaches called *microcell technology*. The world was also becoming more aware of the potential future markets. Suddenly, finding the means to increase capacity became urgent.

1.2. Digital System

1.2.1. Introduction Period. In 1987, the capacity of the AMPS cellular system started to show its limitations. The growth rate of cellular subscribers far exceeded expectations. In 1987, the Cellular Telecommunication Industry Association (CTIA) formed a Subcommittee for Advanced Radio Technology to study the use of a digital cellular system [3] to increase capacity. At that time, the Federal Communications Commission (FCC) had clearly stated that no additional spectrum would be allocated to cellular telecommunications in the foreseeable future. Therefore, the existing analog and forthcoming digital systems would have to share the same frequency band. In December 1989, a group formed by the Telecommunication Industry Association (TIA) completed a draft of a digital cellular standard.

The digital AMPS, which must share the existing spectrum with the analog AMPS, is a duplex time-division multiple-access (TDMA) system. The channel bandwidth is 30 kHz. There are 50 TDMA frames per second in each channel. Three or six timeslots per frame can serve three calls or six calls at the same time in one channel. The

speech coding rate is 8 kbps (kilobits) per second. An equalizer is needed in the receiver to reduce the intersymbol interference that is due to the spread in time delay caused by the dispersed time arrival of multipath waves. The North American TDMA system was first called IS-54 by the TIA. Later, the system was modified and renamed IS-136.

During this period, not all mobile telephone systems in Europe were compatible. A mobile phone unit working in one country could not operate in another country. In 1983, in response to the need for compatibility, a special taskforce, the Special Mobile Group [4], was formed among European countries to develop a digital cellular system called GSM (group of special mobile systems) in 1994, then renamed to stand for global system for mobile communications. The operating principles of the GSM system resemble those of the AMPS in radio operation, but the system parameters are different; this will be described later.

In the United States, in addition to the TDMA being considered above, another particularly promising technology is code-division multiple access (CDMA) [3]. It is a spread-spectrum technique with a bandwidth of 1.25 MHz. The maximum number of traffic channels is 55. This CDMA system is called IS-95 or cdmaone.

There are three mobile data systems in the United States: Ardis, operated by IBM/Motorola; Ram, operated by Ericsson; and CDPD (Cellular Digital Packet Data) system. The transmission rates for all data systems are around 8 kbps. Only CDPD operates in the cellular spectrum band.

1.2.2. The Future. Starting in 1996, the so-called PCS systems were deployed. They were cellular-like systems, but operated in the 1.8 GHz band in Europe and the 1.9 GHz range in North America. In Europe, the so-called DCS-1800 PCS systems were endorsed, which are based on the GSM system. In the United States, the PCS had three versions: DCS-1800 (a GSM version), TDMA-1900 (IS-136 version), and CDMA-1900 (IS-95 version). The PCS could have six operational licenses (A, B, C, D, E, F) in each city. Therefore, more competitors would be in the mobile phone services business.

In addition, the mobile satellite systems that use the LEO concept (low-Earth orbit) were deployed. Iridium (66 satellites) and Globalstar (48 satellites) were launched at 900 km and 400 km altitudes, respectively. These systems can integrate with cellular systems and enhance cellular coverage domestically and roam internationally as a global system. Other LEO systems are also in the development stage. There is a special LEO system called Teledesic that will be operating at 26 GHz with 840 satellites in orbit. This system is used for wideband data and video channels to serve subscribers in a high capacity network.

A future cellular system, called the International Mobile Telephone (IMT-2000) system, is now in the planning stage. A universal cellular standard (or PCS) system with high capacity and high transmission rate was realized by the year 2002.

2. MOBILE RADIO ENVIRONMENT: A DIFFICULT ENVIRONMENT FOR CELLULAR RADIO SYSTEMS

2.1. Understanding the Mobile Radio Environment

2.1.1. The Limitations of Nature. In the mobile radio environment, there are many attributes that limit the system performance for wireless communication. In the past, there were attempts to adapt digital equipment such as data modems and fax (facsimile) machines used for wireline to cellular systems. The data engineers at that time only realized the blanking and burst interruption in the voice channel as a unique feature of handoffs and power control. They modified data signaling by overcoming the impairments caused by blanking and burst signaling interruption. This modified data modem did not work as expected in the cellular system. Actually, the blanking and burst interruption scheme was not the sole cause of the inadequate data transmission and would have been relatively easy to handle. But without entirely understanding the impairments, the unexpected poor performance could not be offset by merely overcoming the blanking and burst signaling impairment.

2.1.2. Choosing the Right Technologies. In designing radiocommunication systems, there are many different technologies, and among them no single technology is superior to the others. Choosing a technology depends on real conditions in the environment of a particular communication. In satellite communication or microwave link transmission, the radio environments are different from that of the mobile radio environment. There are many good technologies that work in satellite communication and microwave link transmission, but they may not be suitable for the terrestrial mobile radio environment. Therefore, choosing the right technology must depend on the transmission environment.

2.2. Description of the Mobile Radio Environment

The mobile radio environment is one of the most complex ones among the various communication environments.

2.2.1. Nature Terrain Configuration. Because the antenna height of a mobile unit or a portable unit is very close to the ground, the ground-reflected wave affects the reception of the signal from the transmitting site via the direct path. The free-space loss is 20 dB/dec (dec stands for decade, a period of 10) or, in other words, it is inversely proportional to the distance d^{-2} . However, in the mobile radio environment, due to the existing ground-reflected wave and the small incident angle θ , as shown in Fig. 2, the total energy of the ground-reflected wave is reflected back to space. Due to the nature of electromagnetic waves, when the wave hits the ground, the phase of the wave changes by 180° . Therefore, at the mobile, the direct wave and reflected wave cancel each other instead of adding constructively. As a result, the signal that is received becomes very weak. A simple explanation is as follows. If the pathlength of the direct wave is d , the pathlength of the reflected wave is $d + \Delta d$. Then the received power of the two combined waves is proportional to d^{-4} as

Figure 2. Two-wave propagation model.

demonstrated below

$$P_r \propto \left(\frac{1}{d} - \frac{1}{d + \Delta d} \right)^2 = \left(\frac{\Delta d}{d(d + \Delta d)} \right)^2 = \frac{(\Delta d)^2}{d^4} \quad (1)$$

where Δd is assumed to be much less than d and Δd is a function of the antenna height h_1 at the base station. From Eq. (1), the mobile radio path loss follows the inverse fourth-power rule or 40 dB/dec, and the antenna height gain follows the second-power rule or 6 dB/oct. In the mobile radio environment, the average signal strength at the mobile unit varies due to the effective antenna height h_e at the base station measured from the mobile unit location. Since the mobile unit is traveling, the effective antenna height is always changing as a function of terrain undulations, and so is the average signal strength. This phenomenon is shown in Fig. 3.

This two-wave (direct wave and ground-reflected wave) model is only used to explain the propagation loss of 40 dB/dec in the mobile radio environment, not the multipath fading.

2.2.2. Humanmade Effects

2.2.2.1. Humanmade Communities. These can be classified as metropolitan areas, urban areas, suburban areas, open areas, and so on. The distribution of buildings and homes depends on the population size. The reception of the signal is affected by the differences in humanmade communities and results in different propagation path loss.

2.2.2.2. Humanmade Structures. Different geographic areas use different construction materials, different types of construction frames, and different sizes of buildings.

Cities such as Los Angeles, San Francisco, and Tokyo are in earthquake zones and follow earthquake construction codes. The signal reception in those cities is different from that in others. Humanmade structures will affect the propagation path loss and multipath fading due

Figure 3. Effective antenna heights at base station based on different locations of mobile stations.

to reflection and the signal penetration through the buildings.

2.2.2.3. Humanmade Noise. This can be classified into two categories: industrial noise or automotive ignition noise. The high spikes in automotive ignition or in machines are like impulses in the time domain; their power spectrum density will cover a wide spectrum in the industrial frequency domain. At 800 MHz, automotive ignition noise is determined by the number of vehicles. For a traffic volume from 100 cars/h to 1000 cars/h, the noise figure increases 7 dB. As the application of ultra-high-frequency (UHF) devices and microwave systems increase, so does the noise pollution for cellular systems. As we will mention later, a communication system is designed to maintain the minimum required carrier-to-interference ratio (C/I_s). The interference I may, under certain circumstances, be included in noise the N . If the interference level is higher, the level of the carrier, C should also be higher in order to meet the $(C/I)_s$ requirement. This means that when the humanmade noise level is high, either the transmission power at the base station should be increased or the cell size must be reduced.

2.2.3. Moving Medium. If the mobile unit is in motion, the resulting signal from multipath waves at one location is not the same at another; thus the mobile receiver observes an instantaneous fluctuation in amplitude and phase. The amplitude change is called *Rayleigh phase*, and the phase change is a uniformly distributed process, or random FM in FM systems. The signal fading can be fast or slow depending on the speed of the vehicle. When the vehicle speed is slow, the average duration of fading is long. This average fading duration can be, for example, 7 ms at -10 dB below the average level when the vehicle speed is 24 km/h at a propagation frequency of 850 MHz. In an analog system, a fade duration of 7 ms does not affect the analog voice; the ear cannot detect these short fades. However, the fade duration of 7 ms is long enough to corrupt the digital (voice and data) transmissions. At a transmission rate of 20 kbps, 140 bits will sink in the fade. Furthermore, the vehicle speed of all the users is not constant, and the use of interleaving and channel coding to protect the information bits is very difficult. Furthermore, voice communication is operating in real time unlike data transmission which can be in any time-delay fashion. Many schemes used by data communication cannot be used for digital voice communication.

2.2.4. Dispersive Medium. Because of humanmade structures, the medium becomes dispersive. In a dispersive medium, two phenomena occur. One is time delay spread and the other is selective fading. The time delay spread is caused by a signal transmission from the base station reflected from different scatterers and arriving at the mobile unit at different times. In urban areas, the mean time-delay spread Δ is typically 3 μ s; in suburban areas, Δ is typically 0.5 μ s. In an open area, Δ is typically 0.2 μ s, and in an in-building floor, Δ is around 0.1 μ s or less. These time delay spreads do not affect the analog signal because the ear cannot detect the short delay

Figure 4. Time delay spread Δ at the receiving end when transmitting one bit in a dispersive medium.

spread. However, in a digital system when a symbol (bit) is sent, many echoes arrive at the receiver at different times. If the next symbol is sent out before the first one dies down, intersymbol interference occurs. The dispersive medium also causes frequency selective fading (Fig. 4).

The selective fading will not harm the moving receiver because when the mobile unit is moving, only the average power is considered. Then, in order to make a mobile phone call when the mobile unit is at a standstill, it usually requires that all the signal strengths from four frequencies have two strong setup channels and two strong voice channels. A pair of frequencies is formed by a channel carrying a call on both a forward link and a reverse link. When the mobile unit is moving, the average power of the four frequencies is the same. Then we base our quality estimates on one $(C/I)_s$ value. But when the mobile unit is still, the signals of four frequencies at one location are different due to frequency selective fading. Unless all four frequencies are above the acceptable threshold level, the call cannot be connected.

2.3. Concept of C/I

In designing high-capacity wireless systems, the most important parameter is the carrier-to-interference ratio (C/I). The C/I ratio and the D/R ratio are directly related. The D/R ratio is determined by the C/I ratio. Usually, with a given received signal level C , the lower the interference level, the higher the C/I ratio and hence the quality improves. There is a specific C/I level, namely $(C/I)_s$, that the system design criterion is based on. We may derive the relationship between C/I and D/R as follows. Assume that the first tier of six cochannel interference cells is the major cause for the interference I . Based on the 40 dB/dec propagation rule, we obtain

$$\frac{C}{I} = \frac{C}{\sum_{i=1}^6 I_i} \approx \frac{C}{6 \cdot I_i} = \frac{R^{-4}}{6 \cdot D^{-4}} = \frac{(D/R)^4}{6} \quad (2)$$

A general equation of the cochannel interference reduction factor q can be expressed, from Eq. (2), as

$$q = (D/R)_s = (6(C/I)_s)^{1/4} \quad (3)$$

where $(C/I)_s$ is obtained from a subjective test corresponding to the required voice (or data) quality level, as mentioned

Figure 5. Relationship between q and $(C/I)_s$ [Eq. (3)].

previously. Equation (3) is plotted in Fig. 5. The $(C/I)_s$ ratio is chosen according to either the required voice or data channel quality.

2.4. The Predicted Signal Strength Models

Since the $(C/I)_s$ is a system design parameter, system planning engineers would like to use an effective model to predict both C and I in a given area. There are two different prediction models. One predicts the average signal strength along the radio path based on the path loss slope. The Okumura and Hata models [5,6] represent these types of models. The other predicts the local mean signal strength along a particular mobile path (street or road) based on the particular terrain contour. Lee's model [7] represents these types of models.

3. REASONS FOR DIGITAL CELLULAR

3.1. Compatibility in Europe

Again, due to the lack of a standard mobile radio system in Europe during the early 1980s, the mobile phone unit used in each country could not be used in other countries. Starting in 1982, ETSI (European Telecomms Standard Institute) formed a group called the Group of Special Mobile to construct an international mobile radio system called GSM for Europe. The system chosen was to be a digital system using TDMA for the access scheme. The GSM advanced intelligent network (AIN) was adopted from the wireline telephone network. GSM was the first digital mobile phone system in the world.

3.2. Capacity in North America

The frequency spectrum is a very limited resource commonly shared by all wireless communications. Among the wireless communications systems, cellular is the most spectral efficient system where the so-called spectral efficiency is related to the number of traffic channels per cell. From this number, we can derive the erlang/cell ratio, which translates to erlangs/km², or the number of traffic channels/km² based on the traffic model and the size of the cells.

However, a spectrum of only 50 MHz has been allocated to cellular operators in the United States. Furthermore, since two operators are licensed in each market, the spec-

trum of 50 MHz must be split in two. Therefore, system trunking efficiency is reduced and interference caused by an operator in one market often contaminates the other operator's allocated spectrum. Furthermore, manufacturing companies were always considering lowering the cost of cellular units and increasing sales volume. As a result, the specification of cellular units could not be kept tight, and thus more interference prevailed. Once interference increased and could not be controlled by cellular operators, both voice quality and system capacity decreased.

In 1987, the top 10 U.S. markets were already feeling the constraints of channel capacity; they would not be able to meet the market demand in the future. The solution for this increasing need for high capacity was to go digital [1-3]. Going digital was the best solution because of the nature of the digital waveform. If system compatibility is not an issue, the top 10 U.S. markets might and could go digital by themselves. However, for the sake of compatibility the United States needed one standard for the entire North American cellular industry.

3.3. The Advantages of a Digital System

Digital systems offer the following advantages:

1. The digital waveform is discrete in nature. Therefore, the digital waveform can be regrouped easily for transmission needs.
2. Digital transmission is less susceptible to noise and interference.
3. Digital modulation can confine the transmitted energy within the channel bandwidth.
4. Digital equipment may consume less battery power, and hence may reduce equipment weight.
5. Digital systems can provide reliable authentication and privacy (encryption).

4. REQUIREMENT FOR CELLULAR AND PCS

In 1996, the Telecommunications Act Bill was passed by the U.S. Congress and stated, in simple terms, that everyone could get into everyone's business. Cellular service is moving toward digital and is trying to compete with PCS. The PCS spectrum was auctioned in early 1996. There are wideband PCSs and narrowband PCSs (see Fig. 6). The spectrum of wideband PCS is allocated at 1900 MHz in order to operate the same technology as the cellular system. The spectrum of narrowband PCS is allocated at 900 MHz and is used for two-way paging. The joint requirements of both cellular and PCS are as follows:

From the end user's perspective—the PCS and cellular units should be light in weight and small in size, and have long talk-time capabilities without battery recharging and good quality in voice and data. The unit should be employable for initiating and receiving calls anywhere using any telephone feature. The important requirement of PCS and cellular is to please the vast majority of subscribers who always prefer to carry a single unit, not many units. This

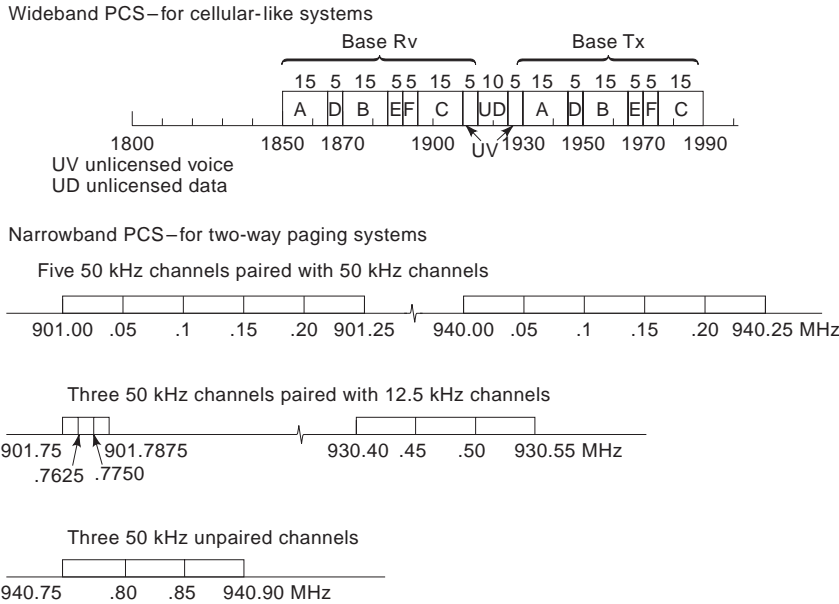

Figure 6. Spectrum allocated for wideband PCS and narrowband PCS.

unit can be classified according to the different grades of service.

From the system provider’s perspective—the PCS should provide full coverage and large system capacity to serve end users. An end user unit ideally should be serviced by one system with different grades of service and unless there are natural limitations by the various personal communication environments (such as mobile vehicle, pedestrian, and indoor public communication). Then one end user unit should be capable of accessing more than one system.

5. DIGITAL MODULATIONS AND MULTIPLE ACCESS

5.1. Digital Modulation Schemes

Digital modulation schemes can be selected to confine the transmitted energy of a digital voice signal in a given frequency bandwidth while transmitting in a mobile radio environment. The information may have to be modulated by signal phases or frequencies, rather than amplitudes, because the multipath fading impairs the signal amplitude.

5.2. Multiple Access

Digital transmission can use time-division multiple access (TDMA), frequency-division multiple access (FDMA), or code-division multiple access (CDMA), but in analog transmission only FDMA can be used. FDMA provides many different frequency channels, where each is assigned to support a call. TDMA means chopping a relatively broadband channel over time into many timeslots. Each timeslot is assigned to support a call. CDMA means generating many different code signatures over a long code-bitstream channel, where each code signature is assigned to convey a call. FDMA is a narrowband system. It

is a low-risk system to develop but was voted down by the industry in 1987. FDMA is not suitable for high-speed data transmission. TDMA was first developed in Europe and is called GSM. TDMA has been developed in North America. For the ADC (American Digital Cellular system), CDMA needs more advanced technology and is relatively harder to implement than the other two multiple-access schemes, especially in the mobile radio environment. However, the improved user capacity of CDMA has given the cellular industry the incentive to develop this system. Therefore, digital transmission in the mobile radio environment has only two competing multiple accesses. The North America selected TDMA based on the influence from the European GSM.

6. SPECIFICATIONS FOR DIFFERENT CELLULAR/PCS SYSTEMS

6.1. Analog Systems

Each traffic channel in an analog system uses two frequencies, one receiving and one transmitting frequency. In general, we often refer to “a 30-kHz channel” when we really mean a bandwidth of 30 kHz on one of two frequencies. Therefore, the total occupied spectrum for each traffic channel is 60 kHz. There are three analog systems: The AMPS from North America, the NTT system from Japan, and the TACS system from the UK. Their specifications are listed in Table 1.

6.2. TDMA Systems

The following TDMA systems can be grouped into two different duplexing techniques, FDD and TDD:

FDD. Frequency-division duplexing, where each traffic channel consists of two operational frequencies. The analog system can use only a FDD system, whereas the digital system has a choice.

Table 1. Large-Capacity Analog Cellular Telephones Used in the World

	Japan	North America	United Kingdom
System transmission frequency (MHz)			
Base station	870–885	869–894	917–950
Mobile station	925–940	824–849	872–905
Spacing between transmission and receiving frequencies (MHz)	55	45	45
Spacing between channels (kHz)	25, 12.5	30	25
Number of channels	600	832 (control channel 21 × 2)	1320 (control channel 21 × 2)
Coverage radius (km)	5 (urban area) 10 (suburbs)	2–20	2–20
Audio signal: type of modulation	FM	FM	FM
Frequency deviation (kHz)	±5	±12	±9.5
Data transmission rate (kbps)	0.3	10	8
Message protection	Transmitted signal is checked when it is sent back to the sender by the receiver.	Principle of majority decision is employed.	Principle of majority decision is employed.

GSM. The term GSM often implies DCS-1800 and DCS-1900 services. They are in the same family, only the carrier frequencies are different. We list the physical layer parameters in Table 2.

NA-TDMA (North American-TDMA). NA-TDMA, sometimes called ADC, is North America's standard system. It incorporates both 800 MHz and 1900 MHz system versions. The network follows philosophy of the GSM intelligent network. The physical layer is shown in Table 3.

The PDC (personal digital cellular) system. This system was developed in Japan and is very similar to the NA-TDMA system, but its radio carrier bandwidth is 25 kHz.

IDEN (integrated digital enhanced network). This system was developed by Motorola. It was called MIRS (mobile integrated radio system); then Motorola mod-

ified the system and renamed it IDEN. This system uses the SMR (Special Mobile Radio) band, which is specified by Part 90 of FCC CER (*Code of Federal Regulations*) in the private sector. The system now can be used cellularlike commercial services. The physical parameter system is as follows:

1. Full-duplex communication system
2. Frequency: 806–824 MHz (mobile transmitter), 851 MHz
3. Channel bandwidth: 25 kHz
4. Multiple access: TDMA
5. Number of timeslots: 6
6. Rate of speech coder: VSELP (vector sum excitation linear predicted)
7. No equalizer implemented
8. Handoff
9. Transmission rate: 6.5 kbps/slot
10. Forward error correction: 3 kbps
11. Dispatch capability

Table 2. Physical-Layer Parameters of GSM

Parameter	Specifications
Radio carrier bandwidth	200 kHz
TDMA structure	8 timeslots per radio carrier
Timeslot	0.577 ms
Frame interval	8 timeslots = 4.615 ms
Radio carrier number	124 radio carriers (935–960 MHz downlink, 890–915 MHz uplink)
Modulation scheme	Gaussian minimum shift keying with $BT^a = 0.3$
Frequency hopping	Slow frequency hopping (217 hops/s)
Equalizer	Equalization up to 16 μs time dispersion
Frequency hop rate	217 hops/s
Handover	Hard handover

^aBT = bandwidth × time.

Table 3. Physical Layer of NA-TDMA

Parameter	Specifications
Radio carrier bandwidth	30 kHz
TDMA structure	3 timeslots per radio carrier
Timeslot	6.66 ms
Frame interval	20 ms
Radio carrier number	2 × 416 (824–849 MHz reverse link, 869–894 MHz forward link)
Modulation scheme	$\frac{\pi}{4}$ -DQPSK
Equalizer	Equalization up to 60 μs time dispersion

TDD. Time-division duplexing, where transmission and reception are shared by one frequency. Certain timeslots are for transmission and certain timeslots are for reception.

CT-2 (Cordless Phone Two). CT-2 was developed by GPT Ltd. in the UK for so-called telepoint applications. Phone calls can be dialed out but cannot be received. The transmission parameters for CT-2 are as follows:

1. Full-duplex system
2. Voicocoder: 32 kbps adaptive differential pulse-code modulation (ADPCM).
3. Duplexing: TDD, where portable and base units transmit and receive on the same frequency but different timeslots
4. Multiple access: TDMA-TDD, up to four multiplexed circuits
5. Modulation: $\pi/4$ DQPSK differential QPSK, rolloff rate = 0.5
6. Data rate: 192 ksym/s (192 kilosymbols per second or 384 kbps)
7. Spectrum allocation: 1895–1918.1 MHz (this spectrum has been allocated for private and public use)
8. Carrier frequency spacing: 300 kHz

PHS (personal handy-phone system). It was developed in Japan. Now there are three operators: NTT, STEL, and DDI. The system serves for the low-tier subscribers, such as teenagers. There are around 7 million customers. The specifications for transmission parameters are as follows:

1. Full-duplex system
2. Voicocoder: 32 kbps adaptive differential pulse-code modulation (ADPCM)
3. Duplexing: TDD, where portable and base units transmit and receive on the same frequency but different timeslots
4. Multiple access: TDMA-TDD, up to four multiplexed circuits
5. Modulation: $\pi/4$ DQPSK, rolloff rate = 0.5
6. Data rate: 192 ksym/s (or 384 kbps)
7. Spectrum allocation: 1895–1918.1 MHz (this spectrum has been allocated for private and public use)
8. Carrier frequency spacing: 300 kHz.

Another system called PACS (personal access communication systems) [3] is in the same system family as PHS.

DECT (Digital European Cordless Telephone) [3]. DECT is a European standard system for slow-motion or in-building communications. Its system structure is as follows:

1. Duplex method: TDD
2. Access method: TDMA

3. RF (radiofrequency) power of handset: 10 mW
4. Channel bandwidth: 1.728 MHz/channel
5. Number of carriers: five (a multiple-carrier system)
6. Frequency: 1800–1900 MHz

DECT's characteristics are as follows:

1. Frame: 10 ms
2. Timeslots: 12
3. Bit rate: 38.8 kb/slot
4. Modulation: GFSK (Gaussian filtered FSK)
5. Handoff: yes

6.3. CDMA Systems

CDMA is another multiple-access scheme using different orthogonal code sequences to provide different call connections. It is a broadband system and can be classified by two approaches: (1) frequency-hopping system approach [3] and (2) direct-sequence system approach [3]. The commercial CDMA system applies the direct-sequence approach. Developed in the United States, it is called the IS-95 Standard System. The first CDMA system was deployed in Hong Kong and then in Los Angeles in 1995. CDMA is a high-capacity system. It has been proved, theoretically, that CDMA system capacity can be 20 times higher than analog capacity. In a CDMA system, all the cells share the same radio carrier in an operating system. The handoff from cell to cell is soft (i.e., not only is the frequency kept unchanged, but the cell is connected in both the old cell and the new cell in the handoff region). The IS-95 CDMA is now called cdmaone. The CDMA radio specifications are as follows:

1. CDMA shares the spectrum band with AMPS
2. Total number of CDMA radio carriers is 18.
3. Radio carrier bandwidth is 1.2288 MHz.
4. Pseudo noise (PN) chip rate is 1.2288 Mchips/s
5. Pilot channel is one per radio carrier.
6. Power control step is 1 dB in 1 ms.
7. Soft handoffs are used.
8. Traffic channels are 55 per each radio carrier.
9. Vocoder is qualcomm (quadrature) code-excited linear prediction (QCELP) at a variable rate.
10. Modulation is quaternary (quadrature) phase shift keying (QPSK).
11. Data frame size is 20 ms.
12. Orthogonal spreading is 64 Walsh functions.
13. Long PN code length is $2^{42} - 1$ chips.
14. Short PN code length is $2^{15} - 1$ chips.

6.4. Mobile Satellite Systems

Mobile satellite systems (MSSs) are used to enhance terrestrial radiocommunication, either in rural areas or in terms of global coverage. Therefore, MSS becomes, in a

Table 4. Comparative Low-Earth-Orbiting Mobile Satellite Service Applications

System Characteristics	Loral/ QUALCOMM	Motorola Iridium	TRW Odyssey	Constellation ARIES (b)	Ellipsat ELLIPSO
Number of satellites	48	66	12	48	24
Constellation altitude (North Meridian)	750	421	5600	550	1767 × 230
Unique feature	Transponder	Onboard processing	Transponder	Transponder	Transponder
Circuit capacity (U.S.)	6500	3835	4600	100	1210
Signal modulation	CDMA	TDMA	CDMA	FDMA/CDMA	CDMA
Gateways in USA	6	2	2	5	6
Gateway spectrum band	C band existing	New Ka band	New Ka band	Unknown	Unknown
Coverage	Global	Global	Global	Global	Northern Hemisphere

broad sense, a PCS system. By taking advantage of reduced transmitting power and short time delays, the low-Earth orbit (LEO) systems are being developed. However, there is a drawback. Each LEO system needs many satellites to cover the planet. There are many LEO systems, as shown in Table 4. There is also another LEO referred to as the *Teledesic system*, which will operate at 24 GHz with a spectrum band of 500 MHz. This LEO system is not just for enhancing cellular or PCS coverage, but also can replace the terrestrial long-distance telephone network in the future.

6.5. IMT-2000

Since the CDMA One system has been successfully deployed in Korea and the United States, in mid-1997 the European countries under the auspices of the so-called (ETSI) European Telecommunications Standard Institute, Japan (ARIB) Association of Radio Industrial and Business, and the United States (TIA) Telecom Industrial Assoc. began planning a universal single-standard system for the so-called IMT-2000 (International Mobile Telephone—Year 2000). There are three general proposals. The proposals disagree on many issues, but they do agree on the following general guideline principles:

1. Use wideband CDMA (WCDMA).
2. Use direct sequence as spread-spectrum modulation.
3. There should be a multiband, single mobile unit.
4. The standard band should be 5 MHz.
5. There is a need for international roaming.
6. There should be IPR (intellectual property right) issues in developing the new global system among all the international vendors.

The IMT-2000 system will require a great deal of compromise in selecting technologies due to the political differences in the international standards bodies. The formal IMT-2000 system will be adapted by the ITU (International Telecommunication Union). A single universal IMT-2000 was established by the year 2000.

Janeiro
Rio de Janeiro, Brazil

1. INTRODUCTION

Any signal can be considered to be composed of several sinusoidal components with different frequencies, amplitudes, and phases. *Filtering* is one of the fundamental methods in signal processing, where the signal is processed by a linear system that changes the amplitudes and

phases of these components, but not their frequencies. In the most usual form, filtering can be used to let pass or to reject selected frequency bands, ideally with no attenuation at the passbands and infinite attenuation at the stopbands. This article discusses a class of approximations to this kind of ideal filter, known as *Chebyshev filters*. It starts with a discussion on a technique for the derivation of optimal *magnitude filters*, then discusses the direct and inverse Chebyshev approximations for the ideal filtering operator, continuing with comments on extensions of the technique. Explicit formulas for *LC* ladder realizations for some cases, and tables with example filters that can be used to verify the properties of the filters and the formulas in the article, are listed at the end.

The magnitude approximation problem in *filter design* consists essentially in finding a convenient transfer function with the magnitude satisfying given attenuation specifications. Other restrictions can exist, such as structure for implementation, maximum order, and maximum Q of the poles, but in most cases the problem can be reduced to the design of a normalized continuous-time low-pass filter that can be described by a transfer function in Laplace transform. This filter must present a given maximum passband attenuation (A_{\max}), between $\omega = 0$ and $\omega = \omega_p = 1$ rad/s, and a given minimum stopband attenuation (A_{\min}) in frequencies above a given limit ω_r rad/s. From this prototype filter, the final transfer function can be obtained by frequency transformations [3,6,7], by continuous-time to discrete-time transformations in the case of a digital filter [1], or by a convenient transformation for realization by microwave structures [6].

A convenient procedure for the derivation of optimal magnitude filters is to start with the *transducer function* $H(s)$ and the *characteristic function* $K(s)$ [6]. $H(s)$ can also be called the *attenuation function*, which is the inverse of the filter transfer function, scaled to have the minimum of $|H(j\omega)|$ equal to 1. $K(s)$ is related to $H(s)$ by the equation, due to *FeldtKeller* [6]:

$$|H(j\omega)|^2 = 1 + |K(j\omega)|^2 \quad (1)$$

This greatly simplifies the problem, because $K(j\omega)$ can be a ratio of two real polynomials in ω , both with roots located symmetrically on both sides of the real axis, while $H(j\omega)$ is a complex function. $K(s)$ is obtained by replacing ω by s/j in $K(j\omega)$, and ignoring possible $\pm j$ or -1 multiplying terms resulting from the operation. The complex frequencies where $K(s) = 0$ are the attenuation zeros, and $K(s) = \infty$ corresponds to the transmission zeros. If $K(s)$ is a ratio of real polynomials in s , then $K(s) = F(s)/P(s)$, $H(s)$ is also a ratio of real polynomials, with the same denominator, $H(s) = E(s)/P(s)$, and $E(s)$ can be obtained by observing that for $s = j\omega$, Eq. (1) is equivalent to

$$\begin{aligned} H(s)H(-s) &= 1 + K(s)K(-s) \\ \therefore E(s)E(-s) &= P(s)P(-s) + F(s)F(-s) \end{aligned} \quad (2)$$

Because $E(s)$ is the denominator of the filter transfer function, which must be stable, $E(s)$ is constructed from the roots of the polynomial $P(s)P(-s) + F(s)F(-s)$ with nega-

tive real parts. The desired transfer function is then $T(s) = P(s)/E(s)$.

2. CHEBYSHEV POLYNOMIALS

Two important classes of approximations, the direct and inverse Chebyshev approximations, can be derived from a class of polynomials known as *Chebyshev polynomials*. These polynomials were first described by P. L. Chebyshev [2]. The Chebyshev polynomial of order n can be obtained from the following expression:

$$C_n(x) = \cos(n \cos^{-1} x) \quad (3)$$

It is simple to verify that this expression corresponds, for $-1 \leq x \leq 1$, to a polynomial in x . Using the trigonometric identity $\cos(a+b) = \cos a \cos b - \sin a \sin b$, we obtain

$$\begin{aligned} C_{n+1}(x) &= \cos[(n+1) \cos^{-1} x] \\ &= xC_n(x) - \sin(n \cos^{-1} x) \sin(\cos^{-1} x) \end{aligned} \quad (4)$$

Now applying the identity $\sin a \sin b = \frac{1}{2}[\cos(a-b) - \cos(a+b)]$ and rearranging, we obtain a recursion formula:

$$C_{n+1}(x) = 2xC_n(x) - C_{n-1}(x) \quad (5)$$

For $n = 0$ and $n = 1$, we have $C_0(x) = 1$ and $C_1(x) = x$. Using Eq. (5), the series of Chebyshev polynomials shown in Table 1 is obtained.

The values of these polynomials oscillate between -1 and $+1$ for x between -1 and $+1$, in a pattern identical to a stationary Lissajous figure [3]. For x out of this range, $\cos^{-1} x = j \cosh^{-1} x$, an imaginary value, but Eq. (3) is still real, in the form

$$C_n(x) = \cos(nj \cosh^{-1} x) = \cosh(n \cosh^{-1} x) \quad (6)$$

For high values of x , looking at the polynomials in Table 1, we see that $C_n(x) \approx 2^n x^n$, growing monotonically. The plots of some Chebyshev polynomials for $-1 \leq x \leq 1$ are shown in Fig. 1.

Table 1. Chebyshev Polynomials

n	$C_n(x)$
0	1
1	x
2	$2x-1$
3	$4x^3-3x$
4	$8x^4-8x^2+1$
5	$16x^5-20x^3+5x$
6	$32x^6-48x^4+18x-1$
7	$64x^7-112x^5+56x^3-7x$
8	$128x^8-256x^6+160x^4-32x^2+1$
9	$256x^9-576x^7+432x^5-120x^3+9x$
10	$512x^{10}-1280x^8+1120x^6-400x^4+50x^2-1$
11	$1024x^{11}-2816x^9+2816x^7-1232x^5+220x^3-11x$
12	$2048x^{12}-6144x^{10}+6912x^8-3584x^6+840x^4-72x^2+1$

Figure 1. Plots of the first six Chebyshev polynomials $C_n(x)$. The squares limit the region $-1 \leq x \leq 1$, $-1 \leq C_n(x) \leq 1$, where the polynomial value oscillates.

3. THE CHEBYSHEV LOWPASS APPROXIMATION

The normalized *Chebyshev approximation* for lowpass filters is obtained by using

$$K(j\omega) = \epsilon C_n(\omega) \tag{7}$$

The result is a transducer function with the magnitude given by [from Eq. (1)]

$$|H(j\omega)|^2 = 1 + [\epsilon C_n(\omega)]^2 \tag{8}$$

The corresponding attenuation in decibels is

$$A(\omega) = 10 \log\{1 + [\epsilon C_n(\omega)]^2\} \tag{9}$$

The parameter ϵ controls the maximum passband attenuation, or the passband ripple. Considering that when $C_n(\omega) = \pm 1$ the attenuation $A(\omega) = A_{\max}$, Eq. (9) gives

$$\epsilon = (10^{0.1A_{\max}} - 1)^{1/2} \tag{10}$$

Figure 2 shows examples of the magnitude function $|T(j\omega)|$ in the passband and in the stopband obtained for some normalized Chebyshev lowpass approximations, with $A_{\max} = 1$ dB. The magnitude of the Chebyshev approximations presents uniform ripple in the passband, with the gain departing from 0 dB at $\omega = 0$ for odd orders and from $-A_{\max}$ dB for even orders.

The stopband attenuation is the maximum possible among filters derived from polynomial characteristic functions, with the same A_{\max} and degree [4]. This can be proved by assuming that there exists a polynomial $P_n(x)$ that is also bounded between -1 and 1 for $-1 \leq x \leq 1$, with $P_n(x) = \pm P_n(-x)$ and $P_n(+\infty) = +\infty$, but that exceeds the value of $C_n(x)$ for some value of $x > 1$. An approximation using this polynomial instead of $C_n(x)$ in Eq. (7) would be more selective. The curves of $P_n(x)$ and $C_n(x)$ will always cross n times for $-1 \leq x \leq 1$, due to the maximum oscillations of $C_n(x)$, but if $P_n(x)$ grows faster, they will

Figure 2. Passband gain (a) and stopband gain (b) for the first normalized Chebyshev approximations with 1 dB passband ripple. Observe the uniform passband ripple and the monotonic stopband gain decrease.

cross another 2 times for $x \geq 1$ and $x \leq -1$. This makes $P_n(x) - C_n(x)$ a polynomial of degree $n + 2$, because it presents $n + 2$ roots, what is impossible since both are of degree n .

The required approximation degree for given A_{\max} and A_{\min} can be obtained by substituting Eq. (6) in Eq. (9), with $A(\omega_r) = A_{\min}$ and solving for n . The result, including a denormalization for any ω_p is

$$n \geq \frac{\cosh^{-1} \gamma}{\cosh^{-1}(\omega_r/\omega_p)} \tag{11}$$

where it is convenient to define the following constant:

$$\gamma = \left(\frac{10^{0.1A_{\min}} - 1}{10^{0.1A_{\max}} - 1} \right)^{1/2} \tag{12}$$

The transfer functions for the normalized Chebyshev filters can be obtained by solving Eq. (2). For a polynomial

approximation, using $P(s) = 1$, from Eq. (7), it follows that

$$E(s)E(-s) = 1 + \left[\varepsilon C_n \left(\frac{s}{j} \right) \right]^2 \quad (13)$$

The roots of this polynomial are the solutions for s in

$$C_n \left(\frac{s}{j} \right) = \cos \left(n \cos^{-1} \frac{s}{j} \right) = \pm \frac{j}{\varepsilon} \quad (14)$$

Identifying

$$n \cos^{-1} \frac{s}{j} = a + jb \quad (15)$$

it follows that $\pm(j/\varepsilon) = \cos(a + jb) = \cos a \cos jb - \sin a \sin jb = \cos a \cosh b - j \sin a \sinh b$. Equating real and imaginary parts, we have $\cos a \cosh b = 0$ and $\sin a \sinh b = \mp(1/\varepsilon)$. Since $\cosh x \geq 1$, the equation of the real parts gives

$$a = \frac{\pi}{2}(1 + 2k) \quad k = 0, 1, \dots, 2n - 1 \quad (16)$$

and as for these values of a , $\sin a = \pm 1$, the equation of the imaginary parts gives

$$b = \mp \sinh^{-1} \frac{1}{\varepsilon} \quad (17)$$

Applying these results in Eq. (15), it follows that the roots of $E(s)E(-s)$ are

$$s_k = \sigma_k + j\omega_k \quad k = 0, 1, \dots, 2n - 1$$

$$\sigma_k = \sin \frac{\pi}{2} \frac{1 + 2k}{n} \sinh \left(\frac{1}{n} \sinh^{-1} \frac{1}{\varepsilon} \right) \quad (18)$$

$$\omega_k = \cos \frac{\pi}{2} \frac{1 + 2k}{n} \cosh \left(\frac{1}{n} \sinh^{-1} \frac{1}{\varepsilon} \right)$$

The roots s_k with negative real parts ($k \geq n$) are the roots of $E(s)$. By the expressions in Eq. (18), it is easy to see that the roots s_k are located in an ellipse with vertical semiaxis $\cosh[(1/n) \sinh^{-1}(1/\varepsilon)]$, horizontal semiaxis $\sinh[(1/n) \sinh^{-1}(1/\varepsilon)]$, and foci at $\pm j$. The location of the roots can be best visualized with the diagram shown in Fig. 3 [3].

4. REALIZATION OF CHEBYSHEV FILTERS

These approximations were originally developed for realization in passive form, and the best realizations were obtained as *LC* doubly terminated structures designed for maximum power transfer at the passband gain maxima [3,6,7]. These structures are still important today in high-frequency filters and as prototypes for active and digital realizations, due to the low sensitivity to errors in element values. At each attenuation zero, and the Chebyshev approximations have the maximum possible number of them distributed in the passband, maximum power

Figure 3. Localization of the poles in a normalized Chebyshev lowpass approximation (seventh order in this case). The pole locations can be obtained as shown.

transfer occurs between the terminations. In this condition, errors in the capacitors and inductors can only decrease the gain [5]. This causes zeros in the derivatives of $|T(j\omega)|$ in relation to all reactive element values at the attenuation zeros, and reduces the error throughout the passband. Table 2 lists polynomials, poles, frequency and Q of the poles, and *LC* doubly terminated ladder structures, with the structure shown in Fig. 4a, for some normalized Chebyshev lowpass filters. Note in the realizations that odd-order filters have identical terminations, but even-order filters require different terminations, because there is no maximum power transfer at $\omega = 0$, since the gain is not maximum there. With the impedance normalization shown, it is clear that the even-order realizations have antimetrical structure (one side is the dual of the other). The odd-order structures are symmetric.

5. THE INVERSE CHEBYSHEV LOWPASS APPROXIMATION

The *inverse Chebyshev approximation* is the most important member of the inverse polynomial class of approximations. The lowpass version is conveniently obtained by using the characteristic function obtained from

$$K(j\omega) = \frac{F(j\omega)}{P(j\omega)} = \frac{\varepsilon\gamma}{C_n(1/\omega)} = \frac{\varepsilon\gamma\omega^n}{\omega^n C_n(1/\omega)} \quad (19)$$

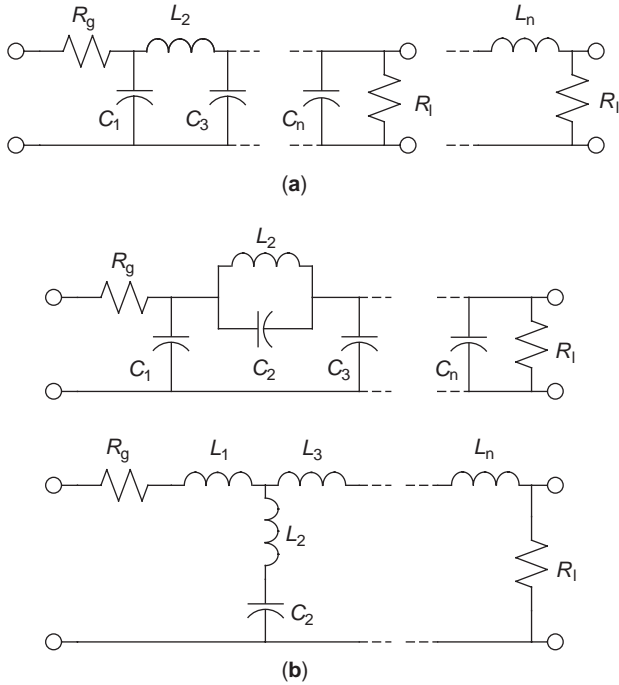

Figure 4. LC doubly terminated ladder realizations for Chebyshev filters, in the direct form (a) and in the inverse form (b). These classical realizations continue to be the best prototypes for active realizations, due to their low sensitivity to errors in the element values.

where ε and γ are as given by Eqs. (10) and (11). The polynomials $F(s)$ and $P(s)$ are then

$$F(s) = \varepsilon \gamma \left(\frac{s}{j} \right)^n \quad (20)$$

$$P(s) = \left(\frac{s}{j} \right)^n C_n \left(\frac{j}{s} \right)$$

Ignoring $\pm j$ or -1 , multiplying factors in Eq. (20), $F(s)$ reduces to $\varepsilon \gamma s^n$, and $P(s)$ reduces to a Chebyshev polynomial with all the terms positive and the coefficients in reverse order. The magnitude characteristic of this approximation is maximally flat at $\omega = 0$, due to the n attenuation zeros at $s = 0$, and thus is similar in the passband to a Butterworth approximation. In the stopband, it presents a series of transmission zeros at frequencies inverse to the roots of the corresponding Chebyshev polynomial. Between adjacent transmission zeros, there are gain maxima reaching the magnitude of $-A_{\min}$ dB. Without renormalization, the stopband starts at 1 rad/s, and the passband ends where the magnitude of the characteristic function, Eq. (19), reaches ε :

$$\omega_p = \frac{1}{C_n^{-1}(\gamma)} = \frac{1}{\cosh \left(\frac{1}{n} \cosh^{-1} \gamma \right)} \quad (21)$$

Odd-order filters present a single transmission zero at infinity, and even-order filters end with a constant gain

$-A_{\min}$ at $\omega = \infty$. From Eqs. (1) and (19), the attenuation in decibels for a normalized inverse Chebyshev approximation is

$$A(\omega) = 10 \log \left\{ 1 + \left[\frac{\varepsilon \gamma}{C_n(1/\omega)} \right]^2 \right\} \quad (22)$$

The gains for some normalized inverse Chebyshev approximations are plotted in Fig. 5. A frequency scaling by the factor given by Eq. (21) was applied, causing the passband to end at $\omega = 1$.

The selectivity of the inverse Chebyshev approximation is the same as the corresponding Chebyshev approximation, for the same A_{\max} and A_{\min} . This can be verified by calculating the ratio ω_p/ω_r for both approximations. For the normalized Chebyshev approximation, $\omega_p = 1$, and ω_r occurs when $\varepsilon C_n(\omega_r) = \gamma$. For the normalized inverse Chebyshev approximation, $\omega_r = 1$, and ω_p occurs when $(\varepsilon \gamma)/C_n(1/\omega_p) = \varepsilon$. In both cases, the resulting ratio is $\omega_r/\omega_p = C_n^{-1}(\gamma)$. Equation (11) can be used to compute the required degree.

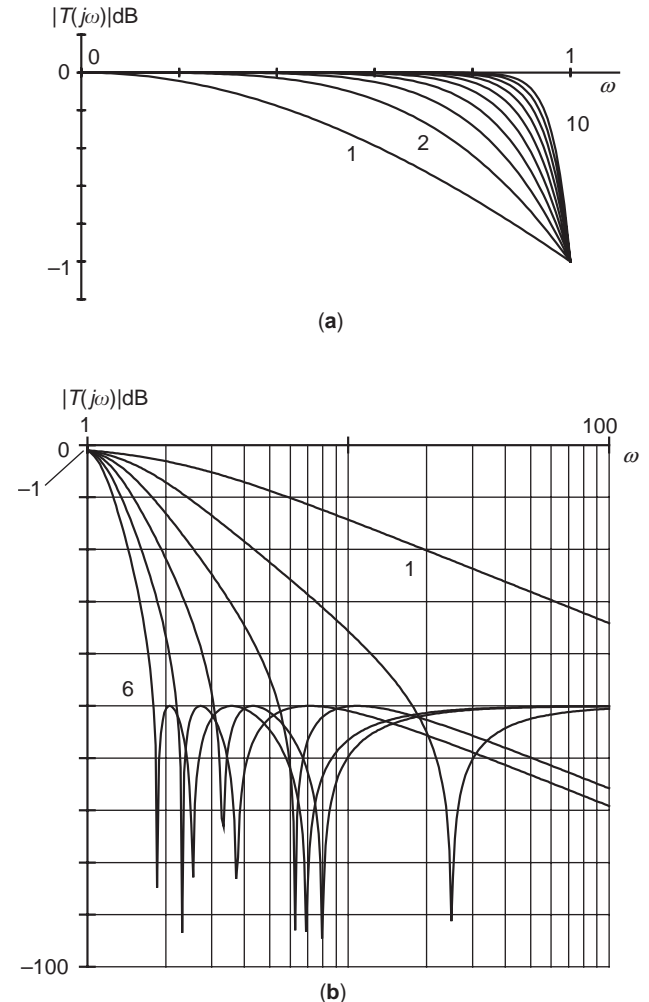

Figure 5. Passband gain (a) and stopband gain (b) for the first normalized inverse Chebyshev approximations with $A_{\max} = 1$ dB and $A_{\min} = 50$ dB. Observe the maximally flat passband and the uniform stopband ripple.

The transmission zero frequencies are the frequencies that make Eq. (19) infinite:

$$C_n\left(\frac{1}{\omega_k}\right) = \cos\left(n \cos^{-1}\left(\frac{1}{\omega_k}\right)\right) = 0$$

$$\therefore \omega_k = \frac{1}{\cos\left(\frac{\pi}{2} \frac{1+2k}{n}\right)}, \quad k=0, 1, \dots, n-1 \quad (23)$$

The pole frequencies are found by solving Eq. (2) with $F(s)$ and $P(s)$ as given by Eq. (20):

$$E(s)E(-s) = (\varepsilon\gamma)^2 \left(\frac{s}{j}\right)^{2n} + \left(\frac{s}{j}\right)^{2n} C_n\left(\frac{j}{s}\right)^2 \quad (24)$$

The roots of this equation are the solutions of

$$C_n\left(\frac{j}{s}\right) = \pm j\varepsilon\gamma \quad (25)$$

By observing the similarity of this equation to Eq. (14), the roots of $E(s)E(-s)$ can be obtained as the complex inverses of the values given by Eq. (18), with ε replaced by $1/(\varepsilon\gamma)$. They lie in a curve that is not an ellipse. $E(s)$ is constructed from the roots with negative real parts, which are distributed in a pattern that resembles a circle shifted to the left side of the origin.

Because of the similarity of the passband response to the Butterworth response, the phase characteristics of the inverse Chebyshev filters are much closer to linear than those of the direct Chebyshev filters, simplifying the task of a phase equalizer that may be cascaded with the magnitude filter. The maximum Q of the poles is also significantly lower for the same gain specifications.

6. REALIZATION OF INVERSE CHEBYSHEV FILTERS

The realization based on *LC doubly terminated ladder* structures is also convenient for inverse Chebyshev filters, by the same reasons mentioned for the direct approximation. In this case, the passband sensitivities are low because of the n th-order attenuation zero at $s=0$, which results in the nullification of the first n derivatives of the filter gain in relation to all the reactive elements at $s=0$, and keeps the gain errors small in all the passband. Stopband errors are also small, because the transmission zero frequencies depend only on simple *LC* series or parallel resonant circuits. The usual structures used are shown in Fig. 4b.

Those realizations are possible only for the odd-order cases, because those structures can't realize the constant gain at infinity that occurs in the even-order approximations (realizations with transformers or with negative elements, or with just one termination, are possible). Even-order modified approximations can be obtained by using, instead of the Chebyshev polynomials, polynomials obtained by the application, to the Chebyshev polynomials,

of the *Moebius transformation* [4,6]

$$x^2 \rightarrow \frac{x^2 - x_{z1}^2}{1 - x_{z1}^2}; \quad x_{z1} = \cos \frac{k_{\max}\pi}{2n} \quad (26)$$

where k_{\max} is the greatest odd integer that is less than the filter order n . This transformation moves the pair of roots closer to the origin of an even-order Chebyshev polynomial to the origin. If the resulting polynomials are used to generate polynomial approximations, starting from Eq. (7), the results are filters with two attenuation zeros at the origin that are realizable as a doubly terminated ladder filter with equal terminations, a convenience in passive realizations. If the same polynomials are used in inverse polynomial approximations, starting from Eq. (19), the results are filters with two transmission zeros at the infinity, which are now realizable by doubly terminated *LC* structures. The direct and inverse approximations obtained in this way have the same selectivity, slightly smaller than in the original case.

Table 3 lists polynomials, poles, zeros, frequency and Q of the poles, and *LC* doubly terminated realizations for some inverse Chebyshev filters. The filters were scaled in frequency to make the passband end at 1 rad/s instead of ω_p [Eq. (21)]. The even-order realizations were obtained from modified approximations with two transmission zeros at infinity, and are listed separately in Table 4. The structures are a mix of the two forms in Fig. 4b. Note that some realizations are missing. These are cases where the network would require negative elements, or transformers. For inverse Chebyshev filters, and other inverse polynomial filters, there is a minimum value of A_{\min} for each order that turns a pure *LC* doubly terminated realization possible [7].

7. OTHER SIMILAR APPROXIMATIONS

Different approximations with uniform passband or stopband ripple, somewhat less selective, can be generated by reducing the number or the amplitude of the oscillations in a Chebyshev-like polynomial, and generating the approximations starting from Eq. (7) or (19), numerically [8].

A particularly interesting case results if the last oscillations of the polynomial value end in 0 instead of ± 1 . This creates double roots close to $x = \pm 1$ in the polynomial. In a polynomial approximation, the higher-frequency passband minimum disappears, replaced by a second-order maximum close to the passband border. In an *LC* doubly terminated realization, the maximum power transfer at this frequency causes nullification of the first two derivatives of the gain in relation to the reactive elements, substantially reducing the gain error at the passband border. In an inverse polynomial approximation, this causes the joining of the first two transmission zeros, as a double transmission zero, which increases the attenuation and reduces the error at the stopband beginning, also allowing a symmetric realization for orders 5 and 7.

Other variations arise from the shifting of roots to the origin. This is also best done numerically. Odd- (even-) order polynomial approximations with any odd (even)

number of attenuation zeros at $\omega=0$, up to the approximation's order (in the last case resulting a Butterworth approximation), can be generated. The same polynomials generate inverse polynomial approximations with any odd (even) number of transmission zeros at infinity.

In all cases, the maximum Q of the poles is reduced and the phase is closer to linear. Similar techniques can also be applied to elliptic approximations. For example, a lowpass elliptical approximation can be transformed into a Chebyshev approximation by the shifting all the transmission zeros to infinity, or into an inverse Chebyshev approximation by shifting all the attenuation zeros to the origin. There are many possibilities between these extremes.

8. EXPLICIT FORMULAS

The design of filter structures is simplified when *explicit formulas* for the element values are available. They also allow the design of very high-order filters (usually for digital implementation) without serious numerical problems. Explicit formulas for the element values of direct Chebyshev filters have been known since the 1950s, and are given below, in the version due to *Takahasi*, adapted for the notation used here. Their proof can be found in Ref. 7. The formulas apply to the structure in Fig. 4a, and solve not only the case where there is maximum power transfer, but also the mismatched cases where the terminations are

arbitrarily chosen. We start by redefining Eq. (8) to allow for mismatched terminations as

$$|H(j\omega)| = \frac{1 + [\varepsilon C_n(\omega)]^2}{A} \quad (27)$$

where $A \leq 1$. For degree n , with arbitrarily chosen terminations R_g and $R_1 \leq R_g$, the constant A is obtained (from the definition: $H(s)$ = actual attenuation/minimum possible attenuation) as

$$A = \frac{4R_g R_1}{(R_g + R_1)^2}, \quad \text{for odd } n \quad (28)$$

$$A = (1 + \varepsilon^2) \frac{4R_g R_1}{(R_g + R_1)^2}, \quad \text{for even } n$$

The matched case is obtained when $R_g = R_1$ for odd orders and, or for even orders, when

$$\frac{R_1}{R_g} = \frac{(1 + \varepsilon^2)^{1/2} - \varepsilon}{(1 + \varepsilon^2)^{1/2} + \varepsilon} \quad (29)$$

We then compute the two constants

$$k = \left[\left(\frac{1}{\varepsilon^2} + 1 \right)^{1/2} + \frac{1}{\varepsilon} \right]^{1/n} \quad (30)$$

$$h = \left[\left(\frac{1-A}{\varepsilon^2} + 1 \right)^{1/2} + \left(\frac{1-A}{\varepsilon^2} \right)^{1/2} \right]^{1/n} \quad (31)$$

The first capacitor C_1 is given by

$$C_1 = \frac{2s_1}{R_g[(k - k^{-1}) - (h - h^{-1})]} \quad (32)$$

and the other elements can be calculated by the recursion formulas

$$C_{2m-1}L_{2m} = \frac{4s_{4m-3}s_{4m-1}}{b_{2m-1}(k - k^{-1}, h - h^{-1})} \quad (33)$$

$$C_{2m+1}L_{2m} = \frac{4s_{4m-1}s_{4m+1}}{b_{2m}(k - k^{-1}, h - h^{-1})}$$

where $m = 1, 2, \dots$, to the last integer $\leq n/2$. The network ends at C_n for odd n , and in L_n for even n , which can be directly calculated, if convenient, as

$$C_n = \frac{2s_1}{R_1[(k - k^{-1}) + (h - h^{-1})]} \quad (34)$$

$$L_n = \frac{2R_1s_1}{(k - k^{-1}) + (h - h^{-1})}$$

The terms that appear in the formulas are

$$b_m(\zeta, \eta) = \zeta^2 - \mathbf{c}_{2m}\zeta\eta + \eta^2 + \mathbf{s}_{2m}^2 \quad (35)$$

$$\mathbf{s}_r = 2 \sin \frac{\pi r}{2n}, \quad \mathbf{c}_r = 2 \cos \frac{\pi r}{2n}$$

If it is desired to have $R_1 > R_g$, the network can be designed with the terminations interchanged and assembled inverted. A singly terminated network can be obtained by using a large R_g in the formulas. With $R_g = \infty$, the formulas give $A = 0$, $k = h$, and a limit in Eq. (32). An exact design can be obtained starting from the output end, with Eq. (34). The solutions for the matched cases ($A = 1$, $h = 1$) and singly terminating cases are unique. The solution given by the formulas for the mismatched cases are not the only solutions possible (see Ref. 7 for details). Explicit formulas for the element values of inverse Chebyshev LC ladder filters and for the variations discussed above are not known.

9. EXAMPLE

As an example of the application of the explicit formulas and the properties of the resulting filter, consider a fifth-order filter with 1 dB passband ripple, passband edge at 10 MHz, and terminations $R_g = 100 \Omega$ and $R_1 = 50 \Omega$. From Eq. (28) $A = 0.88888$, from Eq. (30) $k = 1.33055$, and from Eq. (31) $h = 1.13099$. The frequency-normalized element values are then obtained starting from Eq. (32), with Eq. (33) applied twice. The resulting values are then divided by $2\pi \times 10^7$, to place the passband edge at 10 MHz. The results are $C_1 = 592.2$ pF, $L_2 = 1.106$ μ H, $C_3 = 755.2$ pF, $L_4 = 1.058$ μ H, and $C_5 = 476.5$ pF.

Note that when the terminations are not matched, there is no special reason for the sensitivities of the filter magnitude in relation to the element values to be low. There is a continuous degradation of the sensitivity characteristics, with the matched case being the least sensitive and singly terminated case being the most sensitive. Figure 6 shows the normalized gain (scaled to a maximum of 0 dB), with expected error margins, for the example filter and for the two extreme cases. In the singly terminated case, with $R_g = \infty$, the input was assumed to be a current source. The expected errors were computed by sensitivity analysis [6], assuming uncorrelated 5% random variations in all the elements, including the terminations, using the formula for the gain statistical deviation

$$\Delta|T(j\omega)| = \frac{20}{\ln(10)} \left(\sum_i \left(\frac{\Delta x_i}{x_i} S_{x_i}^{[T(j\omega)]} \right)^2 \right)^{1/2} \text{ dB} \quad (36)$$

where $\Delta x_i/x_i$ is the tolerance of the element x_i , set to 0.05 to all the elements. Observe that for the matched case the error returns to ± 0.307 dB at all the gain peaks, what corresponds to the expected error due to the terminations alone. The example filter produces only slightly larger errors. There is a range where the singly terminated realization is the best, but it is much worse at the critical area of the passband border. Similar relations appear also for other orders.

Figure 6. Expected passband errors for three 5th-order 1 dB Chebyshev filters, for 5% random variations on all the element values.

CHIRALITY

AKHLESH LAKHTAKIA
 Pennsylvania State University
 University Park, Pennsylvania

1. INTRODUCTION

Chiral media have the ability to discriminate between left-handed and right-handed electromagnetic (EM) fields.

These media can be classified into two types: (1) isotropic chiral media and (2) structurally chiral media. The molecules of a naturally occurring isotropic chiral medium are handed, while an artificial isotropic chiral medium can be made by randomly dispersing electrically small, handed inclusions (such as springs) in an isotropic achiral host medium. The molecules of a structurally chiral medium, such as a chiral nematic liquid crystal, are randomly positioned but have helicoidal orientational order. Structurally chiral media can also be artificially fabricated either as stacks of uniaxial laminae or using thin-film technology. Whereas considerable theoretical and experimental work on isotropic chiral media has been reported at microwave frequencies during the 1980s and the 1990s, microwave research on structurally chiral media remains in an embryonic stage at the time of this writing [1]. Therefore, the major part of this article is devoted to isotropic chiral media.

2. NATURAL OPTICAL ACTIVITY

Ordinary sunlight is split into its spectral components by a prism. A spectral component is monochromatic (i.e., it has one and only one wavelength λ_0 in vacuum). The wavelength λ_0 of one of the visible spectral components lies anywhere between 400 nm (violet) and 700 nm (red). A spectral component can be *almost* isolated from other spectral components by carefully passing sunlight through a series of filters. Although filtering yields quasi-monochromatic light, many experiments have been and continue to be performed and their results analyzed, assuming that the filtered light is monochromatic.

Light is an EM wave with spectral components to which our retinal pigments happen to be sensitive, and the consequent images, in turn, happen to be decipherable in our brains. All optical phenomena can be generalized to other electromagnetic spectral regimes.

Suppose that a monochromatic EM wave is propagating in a straight line in air, which is synonymous with vacuum (or free space) for our present purpose. Its electric field vector vibrates in some direction to which the propagation direction is perpendicular; the frequency of vibration is $f=c/\lambda_0$, where $c=3 \times 10^8$ m/s is the speed of light in vacuum. Its magnetic field vector also vibrates with the same frequency, but is always aligned perpendicular to the electric field vector as well as to the propagation direction. Suppose that we fix our attention on a certain plane that is transverse to the propagation direction. On this plane, the locus of the tip of the electric field vector is the so-called vibration ellipse, which is of the same shape as the locus of the tip of the magnetic field vector. A vibration ellipse is shown in Fig. 1. Its shape is characterized by a tilt angle as well as an axial ratio; in addition, it can be left-handed if the tip of the electric field vector rotates counterclockwise, or right-handed if otherwise. Similarly, an EM wave is said to be elliptically polarized, in general; however, the vibration ellipse can occasionally degenerate into a circle (circular polarization) or even a straight line (linear polarization).

Figure 1. The tip of the electric field vector of a plane-polarized monochromatic electromagnetic wave traces the so-called vibration ellipse in a plane transverse to the propagation direction.

The shape of the vibration ellipse of monochromatic light is altered after traversal through a certain thickness of a so-called optically active medium. This phenomenon, known as *optical activity*, was discovered around 1811 by F. Arago while experimenting with quartz. Crystals are generally anisotropic, but J.-B. Biot observed around 1817 the optical activity of turpentine vapor, definitely an isotropic medium. Isotropic organic substances were believed to have exclusively biological provenances, and in 1860 L. Pasteur argued that turpentine vapor exhibited natural optical activity, but the optical activity of crystals could not be similarly qualified. Pasteur was unduly restrictive. Isotropic optically active media, of biological or other origin, are nowadays called *isotropic chiral media*, because EM fields excited in them necessarily possess a property called handedness (Greek *cheir* = hand). Facsimile reproductions of several early papers are available [2].

3. CHIRAL MEDIA: NATURAL AND ARTIFICIAL

The molecules of an isotropic chiral medium are mirror asymmetric (i.e., they are noncongruent with their mirror images). A chiral molecule and its mirror image are called *enantiomers* [3]. As examples, the two enantiomers of 2-butanol are shown in Fig. 2. Enantiomers can have different properties, although they contain identical atoms in identical numbers. One enantiomer of the chiral compound thalidomide may be used to cure morning sickness, during pregnancy, but its mirror image induces fetal malformation. Aspartame, a common artificial sweetener, is one of the four enantiomers of a dipeptide derivative. Of these four, one (i.e., aspartame) is sweet, another is bitter, while the remaining two are tasteless. Of the approxi-

Figure 2. The two enantiomers of 2-butanol are mirror images of each other, as shown by the directed circular arrangements of the $-\text{OH}$, $-\text{CH}_2\text{CH}_3$, and $-\text{CH}_3$ groups.

mately 1850 natural, semisynthetic, and synthetic drugs marketed these days, no less than 1045 can exist as two or more enantiomers; but only 570 were being marketed in the late 1980s as single enantiomers, of which 61 were totally synthetic. But since 1992, the U.S. Food and Drug Administration (FDA) has insisted that only one enantiomer of a chiral drug be brought into the market. Biological chiroselectivity, once the subject of speculations by Pasteur on the nature of the life force (*vis viva*), is now the topic of conferences on the origin of life [4].

An isotropic chiral medium is circularly birefringent (i.e., both left-handed and right-handed circularly polarized light can propagate in a region filled with a homogeneous isotropic chiral medium, with different phase velocities and attenuation rates). Therefore, when monochromatic, elliptically polarized light irradiates an isotropic chiral slab, the tilt angle and the axial ratio of the transmitted light are different from those of the incident light. The change in the tilt angle is quantified as *optical rotation* (OR) and alteration of the axial ratio as *circular dichroism* (CD). Both OR and CD depend on the wavelength λ_0 , and the dependences are reasonably material-specific that spectroscopies based on their measurements have long had industrial importance. Biot himself had pioneered these attempts by cataloging the OR spectra of a large number of syrups and oils, and went on to found the science of saccharimetry for which he was awarded the Rumford Medal in 1840 by the Royal Society of London. The first edition of Landolt's tables on optical activity appeared in the German language in 1879; the English translation of the second edition of 1898 appeared in 1902.

Although Maxwell's unification of light with electromagnetism during the third quarter of the nineteenth century came to mean that natural optical activity is an EM phenomenon, the term *optical rotation* persisted. By the end of the nineteenth century, several empirical rules had evolved on OR spectrums of isotropic chiral mediums. Then, in the late 1890s, two accomplishments of note were reported:

1. J. C. Bose constructed several artificial chiral materials by twisting jute fibers and laying them end to end, and experimentally verified OR at millimeter wavelengths. These materials were anisotropic, but

Bose went on to infer from his experiments that isotropic chiral materials could also be constructed in the same way [5]. Thus, he conclusively demonstrated the geometric microstructural basis for optical activity, and he also constructed possibly the world's first artificial anisotropic chiral medium to alter the vibration ellipses of microwaves.

2. P. Drude showed that chiral molecules can be modeled as spiral oscillators and theoretically verified a rule Biot had given regarding OR spectra [6].

Experimental verification of Drude's spiral oscillator hypothesis had to wait for another two decades. As electromagnetic propositions can be tested at lower frequencies if the lengths are correspondingly increased and other properties proportionally adjusted, K. F. Lindman made 2.5-turn, 10-mm-diameter springs from 9-cm-long copper wire pieces of 1.2 mm cross-sectional diameter. Springs are handed, as illustrated in Fig. 3. Each spring was wrapped in a cotton ball, and about 700 springs of the same handedness were randomly positioned in a $26 \times 26 \times 26$ -cm cardboard box with an eye to achieving tolerable isotropy. Then the box was irradiated with 1–3-GHz ($30 \text{ cm} \geq \lambda_0 \geq 10 \text{ cm}$) microwave radiation and the OR was measured. Lindman verified Drude's hypothesis remarkably well. He also determined that (1) the OR was proportional to the number of (identically handed) springs in the box, given that the distribution of springs was rather sparse; and (2) equal amounts of left-handed or right-handed springs brought about the same OR, but in opposite senses [7]. Lindman's experiments were extensively repeated during the 1990s by many research groups in several countries [8,9], and several patents have even been awarded on making artificial isotropic chiral mediums with miniature springs.

Figure 3. An enantiomeric pair of springs. An artificial isotropic chiral medium can be made by randomly dispersing springs in an isotropic achiral host medium, with more springs of one handedness than the springs of the other handedness.

4. CONSTITUTIVE RELATIONS OF AN ISOTROPIC CHIRAL MEDIUM

Electromagnetic fields are governed by the Maxwell postulates, in vacuum as well as in any material medium. These four postulates have a microscopic basis and are given in vacuum as follows:

$$\nabla \cdot \tilde{\mathbf{B}}(\mathbf{r}, t) = 0 \quad (1a)$$

$$\nabla \times \tilde{\mathbf{E}}(\mathbf{r}, t) = -\frac{\partial}{\partial t} \tilde{\mathbf{B}}(\mathbf{r}, t) \quad (1b)$$

$$\varepsilon_0 \nabla \cdot \tilde{\mathbf{E}}(\mathbf{r}, t) = \tilde{\rho}_{\text{tot}}(\mathbf{r}, t) \quad (1c)$$

$$\nabla \times \tilde{\mathbf{B}}(\mathbf{r}, t) = \mu_0 \varepsilon_0 \frac{\partial}{\partial t} \tilde{\mathbf{E}}(\mathbf{r}, t) + \mu_0 \tilde{\mathbf{J}}_{\text{tot}}(\mathbf{r}, t) \quad (1d)$$

Thus, $\tilde{\mathbf{E}}(\mathbf{r}, t)$ and $\tilde{\mathbf{B}}(\mathbf{r}, t)$ are the primitive or the fundamental EM fields, both functions of the three-dimensional position vector \mathbf{r} and time t ; $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m and $\mu_0 = 4\pi \times 10^{-7}$ H/m are, respectively, the permittivity and the permeability of vacuum; $\tilde{\rho}_{\text{tot}}(\mathbf{r}, t)$ is the electric charge density and $\tilde{\mathbf{J}}_{\text{tot}}(\mathbf{r}, t)$ is the electric current density.

Equations (1) apply at any length scale, whereas the charge and the current densities must be specified not continuously but over a set of isolated points. Electromagnetically speaking, matter is nothing but a collection of discrete charged particles in vacuum. As per the Heaviside–Lorentz procedure to get a macroscopic description of continuous matter, spatial averages of all fields and sources are taken, while both $\tilde{\rho}_{\text{tot}}(\mathbf{r}, t)$ and $\tilde{\mathbf{J}}_{\text{tot}}(\mathbf{r}, t)$ are partitioned into matter-derived and externally impressed components. Then the Maxwell postulates at the macroscopic level can be stated as

$$\nabla \cdot \tilde{\mathbf{D}}(\mathbf{r}, t) = 0 \quad (2a)$$

$$\nabla \times \tilde{\mathbf{E}}(\mathbf{r}, t) = -\frac{\partial}{\partial t} \tilde{\mathbf{B}}(\mathbf{r}, t) \quad (2b)$$

$$\nabla \cdot \tilde{\mathbf{D}}(\mathbf{r}, t) = \tilde{\rho}(\mathbf{r}, t) \quad (2c)$$

$$\nabla \times \tilde{\mathbf{H}}(\mathbf{r}, t) = \frac{\partial}{\partial t} \tilde{\mathbf{D}}(\mathbf{r}, t) + \tilde{\mathbf{J}}(\mathbf{r}, t) \quad (2d)$$

Here, $\tilde{\rho}(\mathbf{r}, t)$ and $\tilde{\mathbf{J}}(\mathbf{r}, t)$ are the externally impressed source densities, while the new fields

$$\tilde{\mathbf{D}}(\mathbf{r}, t) = \varepsilon_0 \tilde{\mathbf{E}}(\mathbf{r}, t) + \tilde{\mathbf{P}}(\mathbf{r}, t) \quad (3a)$$

$$\tilde{\mathbf{H}}(\mathbf{r}, t) = \frac{\tilde{\mathbf{B}}(\mathbf{r}, t) - \tilde{\mathbf{M}}(\mathbf{r}, t)}{\mu_0} \quad (3b)$$

contain two matter-derived quantities: the polarization $\tilde{\mathbf{P}}(\mathbf{r}, t)$ and the magnetization $\tilde{\mathbf{M}}(\mathbf{r}, t)$.

Constitutive relations must be prescribed to relate the matter-derived fields $\tilde{\mathbf{D}}(\mathbf{r}, t)$ and $\tilde{\mathbf{H}}(\mathbf{r}, t)$ to the basic fields $\tilde{\mathbf{E}}(\mathbf{r}, t)$ and $\tilde{\mathbf{B}}(\mathbf{r}, t)$ in any material medium. The construction of these relations is primarily phenomenological, although certain epistemologically mandated proprieties

must be adhered to. The constitutive relations appropriate for a general, linear, homogeneous, material medium with time-invariant response characteristics may be stated as

$$\begin{aligned} \tilde{\mathbf{D}}(\mathbf{r}, t) = & \varepsilon_0 \tilde{\mathbf{E}}(\mathbf{r}, t) + \varepsilon_0 \int_0^\infty \tilde{\chi}^e(\tau) \cdot \tilde{\mathbf{E}}(\mathbf{r}, t - \tau) d\tau \\ & + \int_0^\infty \tilde{\chi}^{\text{em}}(\tau) \cdot \tilde{\mathbf{B}}(\mathbf{r}, t - \tau) d\tau \end{aligned} \quad (4a)$$

$$\begin{aligned} \tilde{\mathbf{H}}(\mathbf{r}, t) = & \frac{1}{\mu_0} \tilde{\mathbf{B}}(\mathbf{r}, t) - \frac{1}{\mu_0} \int_0^\infty \tilde{\chi}^{\text{m}}(\tau) \cdot \tilde{\mathbf{B}}(\mathbf{r}, t - \tau) d\tau \\ & + \int_0^\infty \tilde{\chi}^{\text{me}}(\tau) \cdot \tilde{\mathbf{E}}(\mathbf{r}, t - \tau) d\tau \end{aligned} \quad (4b)$$

Four constitutive property kernels appear in these equations; the dyadic $\tilde{\chi}^e(t)$ is the dielectric susceptibility kernel, $\tilde{\chi}^{\text{m}}(t)$ is the magnetic susceptibility kernel, while the dyadics $\tilde{\chi}^{\text{em}}(t)$ and $\tilde{\chi}^{\text{me}}(t)$ are called the *magnetolectric kernels*. Although a dyadic may be understood as a 3×3 matrix for the purpose of this article, Chen's textbook [10] is recommended for a simple introduction to the use of dyadics in EM theory.

All four dyadic kernels in Eqs. (4) are causal [i.e., $\tilde{\chi}^e(t) \equiv \mathbf{0}$ for $t \leq 0$, etc.], because all materials must exhibit delayed response. In addition, when we substitute Eqs. (4a) and (4b) in Eqs. (2c) and (2d), respectively, a redundancy emerges with respect to Eqs. (2a) and (2b). Elimination of this redundancy leads to the constraint [11]

$$\text{Tr}[\tilde{\chi}^{\text{em}}(t) - \tilde{\chi}^{\text{me}}(t)] \equiv 0 \quad (5)$$

which has never been known to be violated by a physical material. Finally, crystallographic symmetries may also impose additional constraints on the constitutive kernels. A medium described by Eqs. (4) is said to be *bianisotropic*, since the constitutive kernels indicate anisotropy, and both $\tilde{\mathbf{D}}(\mathbf{r}, t)$ and $\tilde{\mathbf{H}}(\mathbf{r}, t)$ depend on both $\tilde{\mathbf{E}}(\mathbf{r}, t)$ and $\tilde{\mathbf{B}}(\mathbf{r}, t)$.

Suppose next that the linear medium's constitutive properties are direction-independent. Equations (4) then simplify to

$$\begin{aligned} \tilde{\mathbf{D}}(\mathbf{r}, t) = & \varepsilon_0 \tilde{\mathbf{E}}(\mathbf{r}, t) + \varepsilon_0 \int_0^\infty \tilde{\chi}^e(\tau) \tilde{\mathbf{E}}(\mathbf{r}, t - \tau) d\tau \\ & + \int_0^\infty \tilde{\chi}^{\text{chi}}(\tau) \tilde{\mathbf{B}}(\mathbf{r}, t - \tau) d\tau \end{aligned} \quad (6a)$$

$$\begin{aligned} \tilde{\mathbf{H}}(\mathbf{r}, t) = & \frac{1}{\mu_0} \tilde{\mathbf{B}}(\mathbf{r}, t) - \frac{1}{\mu_0} \int_0^\infty \tilde{\chi}^{\text{m}}(\tau) \tilde{\mathbf{B}}(\mathbf{r}, t - \tau) d\tau \\ & + \int_0^\infty \tilde{\chi}^{\text{chi}}(\tau) \tilde{\mathbf{E}}(\mathbf{r}, t - \tau) d\tau \end{aligned} \quad (6b)$$

in consequence of Eq. (5), where the scalar $\tilde{\chi}^{\text{chi}}(t)$ is the chirality kernel. Equations (6a)–(6b) describe the *isotropic chiral medium*—the most general, isotropic, linear electromagnetic material known to exist [12,13].

Most commonly, EM analysis is carried out in the frequency domain, not the time domain. Let all time-depen-

dent quantities be Fourier-transformed; thus

$$\tilde{\mathbf{D}}(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-i\omega t} \mathbf{D}(\mathbf{r}, \omega) d\omega \quad (7)$$

and so on, where $\omega = 2\pi f$ is the angular frequency. In the remainder of this article, phasors such as $\mathbf{D}(\mathbf{r}, \omega)$ are called *fields*, following normal practice. The four Maxwell postulates [Eqs. (2)] assume the form

$$\nabla \cdot \mathbf{B}(\mathbf{r}, \omega) = 0 \quad (8a)$$

$$\nabla \times \mathbf{E}(\mathbf{r}, \omega) = i\omega \mathbf{B}(\mathbf{r}, \omega) \quad (8b)$$

$$\nabla \cdot \mathbf{D}(\mathbf{r}, \omega) = \rho(\mathbf{r}, \omega) \quad (8c)$$

$$\nabla \times \mathbf{H}(\mathbf{r}, \omega) = -i\omega \mathbf{D}(\mathbf{r}, \omega) + \mathbf{J}(\mathbf{r}, \omega) \quad (8d)$$

while the constitutive equations [Eqs. 6] for an isotropic chiral medium simultaneously transform into

$$\mathbf{D}(\mathbf{r}, \omega) = \varepsilon_0 [1 + \chi^e(\omega)] \mathbf{E}(\mathbf{r}, \omega) + \chi^{\text{chi}}(\omega) \mathbf{B}(\mathbf{r}, \omega) \quad (9a)$$

$$\mathbf{H}(\mathbf{r}, \omega) = \frac{1}{\mu_0} [1 - \chi^{\text{m}}(\omega)] \mathbf{B}(\mathbf{r}, \omega) + \chi^{\text{chi}}(\omega) \mathbf{E}(\mathbf{r}, \omega) \quad (9b)$$

Using Eqs. (8b) and (8d) with $\mathbf{J}(\mathbf{r}, \omega) = \mathbf{0}$ in Eqs. (9a) and (9b), respectively, we obtain the Drude–Born–Fedorov (DBF) constitutive relations of an isotropic chiral medium:

$$\mathbf{D}(\mathbf{r}, \omega) = \varepsilon(\omega) [\mathbf{E}(\mathbf{r}, \omega) + \beta(\omega) \nabla \times \mathbf{E}(\mathbf{r}, \omega)] \quad (10a)$$

$$\mathbf{B}(\mathbf{r}, \omega) = \mu(\omega) [\mathbf{H}(\mathbf{r}, \omega) + \beta(\omega) \nabla \times \mathbf{H}(\mathbf{r}, \omega)] \quad (10b)$$

Their great merit is that the necessary mirror asymmetry is transparently reflected in them, because $\nabla \times \mathbf{E}(\mathbf{r}, \omega)$ and $\nabla \times \mathbf{H}(\mathbf{r}, \omega)$ are not true vectors but only pseudovectors. A chiral medium is thus described by three constitutive properties; the permittivity and permeability in Eqs. (10a) and (10b), respectively, may be formally defined as the ratios

$$\begin{aligned} \varepsilon(\omega) = & \frac{\mathbf{D}(\mathbf{r}, \omega) \cdot \mathbf{E}^*(\mathbf{r}, \omega)}{|\mathbf{E}(\mathbf{r}, \omega)|^2} \quad \text{if} \quad \mathbf{E}^*(\mathbf{r}, \omega) \\ & \cdot [\nabla \times \mathbf{E}(\mathbf{r}, \omega)] = 0 \end{aligned} \quad (11a)$$

$$\begin{aligned} \mu(\omega) = & \frac{\mathbf{B}(\mathbf{r}, \omega) \cdot \mathbf{H}^*(\mathbf{r}, \omega)}{|\mathbf{H}(\mathbf{r}, \omega)|^2} \quad \text{if} \quad \mathbf{H}^*(\mathbf{r}, \omega) \\ & \cdot [\nabla \times \mathbf{H}(\mathbf{r}, \omega)] = 0 \end{aligned} \quad (11b)$$

but the chirality parameter $\beta(\omega)$ can be regarded as either

$$\begin{aligned} \beta(\omega) = & \frac{\mathbf{D}(\mathbf{r}, \omega) \cdot [\nabla \times \mathbf{E}^*(\mathbf{r}, \omega)]}{\varepsilon(\omega) |\nabla \times \mathbf{E}(\mathbf{r}, \omega)|^2} \quad \text{if} \quad \mathbf{E}(\mathbf{r}, \omega) \\ & \cdot [\nabla \times \mathbf{E}^*(\mathbf{r}, \omega)] = 0 \end{aligned} \quad (11c)$$

or

$$\beta(\omega) = \frac{\mathbf{B}(\mathbf{r}, \omega) \cdot [\nabla \times \mathbf{H}^*(\mathbf{r}, \omega)]}{\mu(\omega) |\nabla \times \mathbf{H}(\mathbf{r}, \omega)|^2} \quad \text{if } \mathbf{H}(\mathbf{r}, \omega) \cdot [\nabla \times \mathbf{H}^*(\mathbf{r}, \omega)] = 0 \quad (11d)$$

where the asterisk denotes the complex conjugate. Equations (11) make it clear that while $\varepsilon(\omega)$ and $\mu(\omega)$ are true scalars, $\beta(\omega)$ has to be a pseudoscalar since the numerator in either of its two definitions contains a pseudovector. Other constitutive relations—equivalent to Eqs. (9) and Eqs. (10)—are also used in the frequency-domain EM literature, but this article is restricted to the DBF constitutive relations [Eqs. (10)], as they bring out the essence of chirality at the very first glance. An isotropic chiral medium and its mirror image share the same $\varepsilon(\omega)$ and $\mu(\omega)$, and their chirality parameters differ only in sign.

The time-averaged Poynting vector

$$\mathbf{S}(\mathbf{r}, \omega) = \frac{1}{2} \text{Re}[\mathbf{E}(\mathbf{r}, \omega) \times \mathbf{H}^*(\mathbf{r}, \omega)] \quad (12a)$$

denotes the direction of power flow. In any linear medium, the monochromatic Poynting theorem reads as

$$\begin{aligned} \nabla \cdot \mathbf{S}(\mathbf{r}, \omega) = & -\frac{1}{2} \text{Re}[\mathbf{E}(\mathbf{r}, \omega) \cdot \mathbf{J}^*(\mathbf{r}, \omega)] \\ & -\frac{1}{2} \text{Re}[i\omega[\mathbf{E}(\mathbf{r}, \omega) \cdot \mathbf{D}^*(\mathbf{r}, \omega) \\ & - \mathbf{B}(\mathbf{r}, \omega) \cdot \mathbf{H}^*(\mathbf{r}, \omega)]] \end{aligned} \quad (12b)$$

For specialization to an isotropic chiral medium, we have to substitute Eqs. (10) in Eq. (12b). The resulting expression is not particularly illuminating.

An isotropic chiral medium is Lorentz-reciprocal. Suppose that all space is occupied by a homogeneous isotropic chiral medium and all sources are confined to regions of bounded extent. Let sources labeled a radiate fields $\mathbf{E}_a(\mathbf{r}, \omega)$ and $\mathbf{H}_a(\mathbf{r}, \omega)$, while sources labeled b radiate fields $\mathbf{E}_b(\mathbf{r}, \omega)$ and $\mathbf{H}_b(\mathbf{r}, \omega)$, all at the same frequency. Then the relations [12]

$$\nabla \cdot [\mathbf{E}_a(\mathbf{r}, \omega) \times \mathbf{H}_b(\mathbf{r}, \omega) - \mathbf{E}_b(\mathbf{r}, \omega) \times \mathbf{H}_a(\mathbf{r}, \omega)] = 0 \quad (13a)$$

$$\begin{aligned} \nabla \cdot [\varepsilon(\omega)\mathbf{E}_a(\mathbf{r}, \omega) \times \mathbf{E}_b(\mathbf{r}, \omega) - \mu(\omega)\mathbf{H}_a(\mathbf{r}, \omega) \\ \times \mathbf{H}_b(\mathbf{r}, \omega)] = 0 \end{aligned} \quad (13b)$$

arise in a source-free region, in consequence of the Lorentz reciprocity of the medium.

5. ARTIFICIAL ISOTROPIC CHIRAL MEDIA

That matter is discrete has long been established. Furthermore, when we probe matter at length scales at which it appears continuous, whether the microstructure is molecular or merely comprises electrically small inclusions is of no consequence. The linear dimensions of an electrically

small inclusion are less than about a tenth of the maximum wavelength, in the media outside as well as inside the inclusion, at a particular frequency. Artificial isotropic chiral media—active at microwave frequencies—can be constructed with this thought in mind. Consider a random suspension of identical, electrically small, inclusions in a host medium, which we take here to be vacuum for simplicity. The number of inclusions per unit volume is denoted by N , and the volumetric proportion of the inclusions in the composite medium is assumed to be very small. Our objective is to *homogenize* this dilute particulate composite medium and estimate its effective constitutive properties [13]. Homogenization is much like blending apples into apple sauce or tomatoes into ketchup.

Any inclusion scatters the EM wave incident on it. Far away from the inclusion, the scattered EM field phasors can be conceptualized, equivalently, as being radiated by an ensemble of multipoles. Multipoles are necessarily frequency-domain entities; and adequate descriptions of electrically larger inclusions require higher-order multipoles, but homogenizing composite media with electrically large inclusions is fraught with conceptual perils.

The lowest-order multipoles are the electric dipole \mathbf{p} and the magnetic dipole \mathbf{m} . In formalisms for isotropic chiral media, both are accorded the same status. As all inclusions in our composite medium are electrically small, we can think that an inclusion located at position \mathbf{r}' is *equivalent* to the colocated dipoles characterized by the following relations:

$$\mathbf{p}_{\text{eqvt}}(\mathbf{r}', \omega) = \underline{\pi}_{\text{ee}}(\omega) \cdot \mathbf{E}_{\text{exc}}(\mathbf{r}', \omega) + \underline{\pi}_{\text{eh}}(\omega) \cdot \mathbf{H}_{\text{exc}}(\mathbf{r}', \omega) \quad (14a)$$

$$\mathbf{m}_{\text{eqvt}}(\mathbf{r}', \omega) = \underline{\pi}_{\text{he}}(\omega) \cdot \mathbf{E}_{\text{exc}}(\mathbf{r}', \omega) + \underline{\pi}_{\text{hh}}(\omega) \cdot \mathbf{H}_{\text{exc}}(\mathbf{r}', \omega) \quad (14b)$$

Here, $\mathbf{E}_{\text{exc}}(\mathbf{r}', \omega)$ and $\mathbf{H}_{\text{exc}}(\mathbf{r}', \omega)$ are the fields *exciting* the particular inclusion; while $\underline{\pi}_{\text{ee}}(\omega)$, $\underline{\pi}_{\text{eh}}(\omega)$, $\underline{\pi}_{\text{he}}(\omega)$, and $\underline{\pi}_{\text{hh}}(\omega)$ are the four linear polarizability dyadics that depend on the frequency, the constitution, and the dimensions of the inclusion. As the inclusions are randomly oriented and any homogenizable chunk of a composite medium contains a large number of inclusions, $\underline{\pi}_{\text{ee}}(\omega)$ and other terms in Eqs. (14) can be replaced by their orientationally averaged values. If the homogenized composite medium is isotropic chiral, this orientational averaging process *must* yield

$$\mathbf{p}_{\text{eqvt}}(\mathbf{r}', \omega) = N[\pi_{\text{ee}}(\omega)\mathbf{E}_{\text{exc}}(\mathbf{r}', \omega) + i\pi_{\text{chi}}(\omega)\mathbf{H}_{\text{exc}}(\mathbf{r}', \omega)] \quad (15a)$$

$$\mathbf{m}_{\text{eqvt}}(\mathbf{r}', \omega) = N[-i\pi_{\text{chi}}(\omega)\mathbf{E}_{\text{exc}}(\mathbf{r}', \omega) + \pi_{\text{hh}}(\omega)\mathbf{H}_{\text{exc}}(\mathbf{r}', \omega)] \quad (15b)$$

The polarizability dyadics of electrically small, handed inclusions (e.g., springs) may be computed either with standard scattering methods such as the method of moments [14] or using lumped-parameter circuit models [15]. Provided that dissipation in the composite medium can be ignored, at a certain angular frequency, $\pi_{\text{ee}}(\omega)$, $\pi_{\text{hh}}(\omega)$, and $\pi_{\text{chi}}(\omega)$ are purely real-valued.

On applying the Maxwell Garnett homogenization approach, the constitutive relations of the homogenized composite medium (HCM) are estimated as follows [12]:

$$\mathbf{D}(\mathbf{r}, \omega) = \tau_{ee}(\omega)\mathbf{E}(\mathbf{r}, \omega) + \tau_{chi}(\omega)\mathbf{H}(\mathbf{r}, \omega) \quad (16a)$$

$$\mathbf{B}(\mathbf{r}, \omega) = \tau_{hh}(\omega)\mathbf{H}(\mathbf{r}, \omega) - \tau_{chi}(\omega)\mathbf{E}(\mathbf{r}, \omega) \quad (16b)$$

where

$$\tau_{ee}(\omega) = \varepsilon_0 + \frac{[9\mu_0 N \tau_{ee} + 3N^2(\pi_{chi}^2 - \tau_{ee}\tau_{hh})]}{9\varepsilon_0\mu_0 - 3N(\varepsilon_0\pi_{hh} + \mu_0\tau_{ee}) - N^2(\pi_{chi}^2 - \tau_{ee}\tau_{hh})} \quad (16c)$$

$$\tau_{hh}(\omega) = \mu_0 + \frac{[9\varepsilon_0 N \tau_{hh} + 3N^2(\pi_{chi}^2 - \tau_{ee}\tau_{hh})]}{9\varepsilon_0\mu_0 - 3N(\varepsilon_0\pi_{hh} + \mu_0\tau_{ee}) - N^2(\pi_{chi}^2 - \tau_{ee}\tau_{hh})} \quad (16d)$$

$$\tau_{chi}(\omega) = \frac{i9\varepsilon_0\mu_0 N \pi_{chi}}{9\varepsilon_0\mu_0 - 3N(\varepsilon_0\pi_{hh} + \mu_0\tau_{ee}) - N^2(\pi_{chi}^2 - \tau_{ee}\tau_{hh})} \quad (16e)$$

Equivalently

$$\mathbf{D}(\mathbf{r}, \omega) = \varepsilon_{HCM}(\omega)[\mathbf{E}(\mathbf{r}, \omega) + \beta_{HCM}(\omega)\nabla \times \mathbf{E}(\mathbf{r}, \omega)] \quad (17a)$$

$$\mathbf{B}(\mathbf{r}, \omega) = \mu_{HCM}(\omega)[\mathbf{H}(\mathbf{r}, \omega) + \beta_{HCM}(\omega)\nabla \times \mathbf{H}(\mathbf{r}, \omega)] \quad (17b)$$

are the DBF constitutive relations of the HCM, with

$$\varepsilon_{HCM}(\omega) = \frac{\tau_{ee}(\omega)\tau_{hh}(\omega) + \tau_{chi}^2(\omega)}{\tau_{hh}(\omega)} \quad (17c)$$

$$\mu_{HCM}(\omega) = \frac{\tau_{ee}(\omega)\tau_{hh}(\omega) + \tau_{chi}^2(\omega)}{\tau_{ee}(\omega)} \quad (17d)$$

$$\beta_{HCM}(\omega) = -\frac{i}{\omega} \frac{\tau_{chi}(\omega)}{\tau_{ee}(\omega)\tau_{hh}(\omega) + \tau_{chi}^2(\omega)} \quad (17e)$$

as the constitutive parameters. Clearly, if $\pi_{chi}(\omega) \neq 0$, the composite medium has been homogenized into an isotropic chiral medium. In passing, other homogenization approaches are also possible for chiral composites [1,13].

6. BELTRAMI FIELDS IN AN ISOTROPIC CHIRAL MEDIUM

In a source-free region occupied by a homogeneous isotropic chiral medium, $\rho(\mathbf{r}, \omega) = 0$ and $\mathbf{J}(\mathbf{r}, \omega) = 0$. Equations (8a), (8c), and (10) then show that $\nabla \cdot \mathbf{E}(\mathbf{r}, \omega) = 0$ and $\nabla \cdot \mathbf{H}(\mathbf{r}, \omega) = 0$. Thus all four fields— $\mathbf{E}(\mathbf{r}, \omega)$, $\mathbf{H}(\mathbf{r}, \omega)$, $\mathbf{D}(\mathbf{r}, \omega)$, and $\mathbf{B}(\mathbf{r}, \omega)$ —are purely solenoidal. Next, Eqs. (8) and (10) together yield the following

vector Helmholtz-like equations:

$$\nabla^2 \begin{Bmatrix} \mathbf{E}(\mathbf{r}, \omega) \\ \mathbf{H}(\mathbf{r}, \omega) \\ \mathbf{D}(\mathbf{r}, \omega) \\ \mathbf{B}(\mathbf{r}, \omega) \end{Bmatrix} + 2 \frac{\omega^2 \varepsilon(\omega) \mu(\omega) \beta(\omega)}{1 - \omega^2 \varepsilon(\omega) \mu(\omega) \beta^2(\omega)} \nabla \times \begin{Bmatrix} \mathbf{E}(\mathbf{r}, \omega) \\ \mathbf{H}(\mathbf{r}, \omega) \\ \mathbf{D}(\mathbf{r}, \omega) \\ \mathbf{B}(\mathbf{r}, \omega) \end{Bmatrix} + \frac{\omega^2 \varepsilon(\omega) \mu(\omega)}{1 - \omega^2 \varepsilon(\omega) \mu(\omega) \beta^2(\omega)} \begin{Bmatrix} \mathbf{E}(\mathbf{r}, \omega) \\ \mathbf{H}(\mathbf{r}, \omega) \\ \mathbf{D}(\mathbf{r}, \omega) \\ \mathbf{B}(\mathbf{r}, \omega) \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (18)$$

In the limit $\beta(\omega) \rightarrow 0$, the medium becomes achiral and these equations reduce to the familiar vector Helmholtz equation, $\nabla^2 \mathbf{E}(\mathbf{r}, \omega) + \omega^2 \varepsilon(\omega) \mu(\omega) \mathbf{E}(\mathbf{r}, \omega) = \mathbf{0}$, and so on.

In lieu of the second-order differential equations [Eqs. (18)], first-order differential equations can be formulated. Thus, after defining the auxiliary fields

$$\mathbf{Q}_1(\mathbf{r}, \omega) = \frac{1}{2} \left[\mathbf{E}(\mathbf{r}, \omega) + i \sqrt{\frac{\mu(\omega)}{\varepsilon(\omega)}} \mathbf{H}(\mathbf{r}, \omega) \right] \quad (19a)$$

$$\mathbf{Q}_2(\mathbf{r}, \omega) = \frac{1}{2} \left[\mathbf{H}(\mathbf{r}, \omega) + i \sqrt{\frac{\varepsilon(\omega)}{\mu(\omega)}} \mathbf{E}(\mathbf{r}, \omega) \right] \quad (19b)$$

and using the wavenumbers

$$\gamma_1(\omega) = \frac{\omega \sqrt{\varepsilon(\omega) \mu(\omega)}}{1 - \omega \beta(\omega) \sqrt{\varepsilon(\omega) \mu(\omega)}} \quad (20a)$$

$$\gamma_2(\omega) = \frac{\omega \sqrt{\varepsilon(\omega) \mu(\omega)}}{1 + \omega \beta(\omega) \sqrt{\varepsilon(\omega) \mu(\omega)}} \quad (20b)$$

we get the two first-order differential equations

$$\nabla \times \mathbf{Q}_1(\mathbf{r}, \omega) = \gamma_1(\omega) \mathbf{Q}_1(\mathbf{r}, \omega) \quad (21a)$$

$$\nabla \times \mathbf{Q}_2(\mathbf{r}, \omega) = -\gamma_2(\omega) \mathbf{Q}_2(\mathbf{r}, \omega) \quad (21b)$$

which are easier to analyze than Eqs. (18). The denominators on the left sides of Eqs. (20) suggest that $\omega^2 \varepsilon(\omega) \mu(\omega) \beta^2(\omega) = 1$ is not permissible for an isotropic chiral medium, as both wavenumbers must have finite magnitudes.

According to Eqs. (21), $\mathbf{Q}_1(\mathbf{r}, \omega)$ and $\mathbf{Q}_2(\mathbf{r}, \omega)$ are Beltrami fields [12]. A Beltrami field is parallel to its own circulation. The concept arose early in the nineteenth century, and has often been rediscovered. The easiest way to think of a Beltrami field is as a spiral staircase or a tornado.

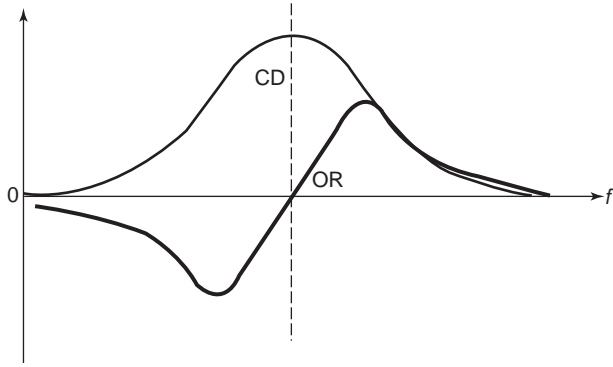

Figure 4. Optical rotation (OR) and circular dichroism (CD) spectra of a simple isotropic chiral medium. When the OR changes sign, the CD records either a maximum or a minimum, which phenomenon is called the *Cotton effect*.

While $\mathbf{Q}_1(\mathbf{r}, \omega)$ is a left-handed Beltrami field, the negative sign on the right side of Eq. (21b) means that $\mathbf{Q}_2(\mathbf{r}, \omega)$ is a right-handed Beltrami field, because the two complex-valued wavenumbers $\gamma_1(\omega)$ and $\gamma_2(\omega)$ must have positive real parts. Both wavenumbers also must have positive imaginary parts in a causal material medium, since causal materials must exhibit delayed response in the time domain and therefore must demonstrate EM loss (or attenuation) in the frequency domain.

As an isotropic chiral medium displays two distinct wavenumbers at a specific frequency, it is *birefringent*. More specifically, because $\mathbf{Q}_1(\mathbf{r}, \omega)$ and $\mathbf{Q}_2(\mathbf{r}, \omega)$ have plane-wave representations possible only in terms of circularly polarized plane waves, an isotropic chiral medium is often said to be *circularly birefringent*. The difference between $\gamma_1(\omega)$ and $\gamma_2(\omega)$ gives rise to *natural optical activity*. While OR is proportional to the *real* part of $[\gamma_1(\omega) - \gamma_2(\omega)]$, CD is proportional to the *imaginary* part of $[\gamma_1(\omega) - \gamma_2(\omega)]$. The OR and CD spectra must be consistent with the Kramers–Kronig relations [16]. The CD spectrum has a local maximum or minimum at the frequency where the sign of the OR changes; this feature is labeled as the *Cotton effect* after H. Cotton, who reported it in 1895 [2]. The OR and CD spectra of a simple chiral medium are illustrated in Fig. 4.

7. REPRESENTATION OF BELTRAMI FIELDS

A Beltrami field is represented in terms of toroidal and poloidal fields because the curl of a toroidal field is poloidal and vice versa [17]. Thus, the decomposition

$$\mathbf{Q}_v(\mathbf{r}, \omega) = \gamma_v(\omega) \nabla \times [\mathbf{r}\psi_v(\mathbf{r}, \omega)] + (-)^{v+1} \nabla \times \nabla \times [\mathbf{r}\psi_v(\mathbf{r}, \omega)]; \quad v = 1, 2 \quad (22)$$

is possible, as the first parts on the right sides of Eqs. (22) are toroidal and the second parts are poloidal. The scalar functions $\psi_v(\mathbf{r}, \omega)$ satisfy the scalar Helmholtz

equation as follows:

$$\nabla^2 \psi_v(\mathbf{r}, \omega) + \gamma_v^2(\omega) \psi_v(\mathbf{r}, \omega) = 0; \quad v = 1, 2 \quad (23)$$

Solutions of Eqs. (23) in the Cartesian, the circular cylindrical, and the spherical coordinate systems are commonplace [18].

Beltrami plane waves propagating in the $+z$ direction may be represented as

$$\mathbf{Q}_v(\mathbf{r}, \omega) = A_v 2^{-1/2} [\hat{\mathbf{x}} + (-)^{v+1} i \hat{\mathbf{y}}] \exp[i\gamma_v(\omega)z]; \quad v = 1, 2 \quad (24)$$

with A_v as the amplitudes, while $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$ are the Cartesian unit vectors.

In the circular cylindrical coordinate system (ρ, φ, z) , Beltrami fields with an $\exp(iz)$ dependence may be expressed as the sums

$$\mathbf{Q}_v(\mathbf{r}, \omega) = \sum_{n=-\infty}^{\infty} A_{vn} [\mathbf{M}_n^{(3)}(\gamma_v(\omega)|\alpha, \mathbf{r}) + (-)^{v+1} \mathbf{N}_n^{(3)}(\gamma_v(\omega)|\alpha, \mathbf{r})]; \quad v = 1, 2 \quad (25a)$$

for regular behavior as $\rho \rightarrow \infty$, while the expansions

$$\mathbf{Q}_v(\mathbf{r}, \omega) = \sum_{n=-\infty}^{\infty} B_{vn} [\mathbf{M}_n^{(1)}(\gamma_v(\omega)|\alpha, \mathbf{r}) + (-)^{v+1} \mathbf{N}_n^{(1)}(\gamma_v(\omega)|\alpha, \mathbf{r})]; \quad v = 1, 2 \quad (25b)$$

are well behaved at $\rho = 0$, with A_{vn} and B_{vn} as the coefficients of expansion. The vector cylindrical wavefunctions are given as

$$\mathbf{M}_n^{(1)}(\sigma | \alpha, \mathbf{r}) = e^{i(\alpha z + n\varphi)} \left[\hat{\rho} \left(\frac{in}{\kappa\rho} \right) J_n(\kappa\rho) - \hat{\phi} \partial J_n(\kappa\rho) \right] \quad (26a)$$

$$\mathbf{M}_n^{(3)}(\sigma | \alpha, \mathbf{r}) = e^{i(\alpha z + n\varphi)} \left[\hat{\rho} \left(\frac{in}{\kappa\rho} \right) H_n^{(1)}(\kappa\rho) - \hat{\phi} \partial H_n^{(1)}(\kappa\rho) \right] \quad (26b)$$

$$\mathbf{N}_n^{(j)}(\sigma | \alpha, \mathbf{r}) = \frac{1}{\sigma} \nabla \times \mathbf{M}_n^{(j)}(\sigma | \alpha, \mathbf{r}); \quad j = 1, 3 \quad (26c)$$

where $\kappa = +(\sigma^2 - \alpha^2)^{1/2}$; $\hat{\rho}$, $\hat{\phi}$, and $\hat{\mathbf{z}}$ are the unit vectors in the cylindrical coordinate system; $J_n(\kappa\rho)$ are the cylindrical Bessel functions of order n , and $\partial J_n(\kappa\rho)$ are the respective first derivatives with respect to the argument; while $H_n^{(1)}(\kappa\rho)$ are the cylindrical Hankel functions of the first kind and order n , and $\partial H_n^{(1)}(\kappa\rho)$ are the first derivatives with respect to the argument. For quasi-two-dimensional problems, $\alpha = 0$ because $\partial/\partial z = 0$. Parenthetically, in this paragraph ρ denotes the radial distance in the xy plane and should not be confused with the use of ρ for charge density elsewhere in this article.

Finally, with A_{vsmn} and B_{vsmn} as the coefficients of expansion, in the spherical coordinate system (r, θ, φ) , we

have

$$\begin{aligned} \mathbf{Q}_v(\mathbf{r}, \omega) &= \sum_{s=1}^2 \sum_{n=1}^{\infty} \sum_{m=0}^n A_{vsmn} [\mathbf{M}_{smn}^{(3)}(\gamma_v(\omega)\mathbf{r}) \\ &+ (-)^{v+1} \mathbf{N}_{smn}^{(3)}(\gamma_v(\omega)\mathbf{r})]; \quad v=1, 2 \end{aligned} \quad (27a)$$

for fields regular as $r \rightarrow \infty$, and

$$\begin{aligned} \mathbf{Q}_v(\mathbf{r}, \omega) &= \sum_{s=1}^2 \sum_{n=1}^{\infty} \sum_{m=0}^n B_{vsmn} [\mathbf{M}_{smn}^{(1)}(\gamma_v(\omega)\mathbf{r}) \\ &+ (-)^{v+1} \mathbf{N}_{smn}^{(1)}(\gamma_v(\omega)\mathbf{r})]; \quad v=1, 2 \end{aligned} \quad (27b)$$

for fields regular at $r=0$. The well-known vector spherical wavefunctions, $\mathbf{M}_{smn}^{(j)}(\sigma\mathbf{r})$ and $\mathbf{N}_{smn}^{(j)}(\sigma\mathbf{r})$, are stated for $j=1, 3$ as

$$\mathbf{M}_{smn}^{(1)}(\sigma\mathbf{r}) = -[n(n+1)]^{1/2} j_n(\sigma\mathbf{r}) \hat{\mathbf{r}} \times \mathbf{B}_{smn}(\theta, \varphi) \quad (28a)$$

$$\mathbf{M}_{smn}^{(3)}(\sigma\mathbf{r}) = -[n(n+1)]^{1/2} h_n^{(1)}(\sigma\mathbf{r}) \hat{\mathbf{r}} \times \mathbf{B}_{smn}(\theta, \varphi) \quad (28b)$$

$$\mathbf{N}_{smn}^{(j)}(\sigma\mathbf{r}) = \frac{1}{\sigma} \nabla \times \mathbf{M}_{smn}^{(j)}(\sigma\mathbf{r}); \quad j=1, 3 \quad (28c)$$

where the angular functions

$$\begin{aligned} \mathbf{B}_{1mn}(\theta, \varphi) &= [n(n+1)]^{-1/2} \left[\hat{\boldsymbol{\theta}} \frac{d}{d\theta} P_n^m(\cos\theta) \sin m\varphi \right. \\ &\left. + \hat{\boldsymbol{\phi}} \frac{m}{\sin\theta} P_n^m(\cos\theta) \cos m\varphi \right] \end{aligned} \quad (29a)$$

$$\begin{aligned} \mathbf{B}_{2mn}(\theta, \varphi) &= [n(n+1)]^{-1/2} \left[\hat{\boldsymbol{\theta}} \frac{d}{d\theta} P_n^m(\cos\theta) \cos m\varphi \right. \\ &\left. - \hat{\boldsymbol{\phi}} \frac{m}{\sin\theta} P_n^m(\cos\theta) \sin m\varphi \right] \end{aligned} \quad (29b)$$

have been used. In these expressions, $\hat{\mathbf{r}}$, $\hat{\boldsymbol{\theta}}$, and $\hat{\boldsymbol{\phi}}$ are the unit vectors in the spherical coordinate system; $P_n^m(\cos\theta)$ are the associated Legendre functions of order n and degree m ; $j_n(\sigma r)$ are the spherical Bessel functions of order n ; and $h_n^{(1)}(\sigma r)$ are the spherical Hankel functions of the first kind and order n .

Boundary-value problems involving scattering by isotropic chiral half-spaces, cylinders, and spheres can be analytically solved using Eqs. (24)–(29). Boundary-value problems involving more complicated geometries generally require numerical treatment, which necessitates the use of Green functions.

Isotropic chiral waveguides for use at microwave frequencies have been theoretically studied extensively, although no practical realization thereof has yet come to light. Theoretical investigations on propagation in the so-called chirowaveguides generally consist of decomposing the Beltrami fields into axial and transverse

components as

$$\begin{aligned} \mathbf{Q}_v(\mathbf{r}, \omega) &= \mathbf{Q}_{vt}(\mathbf{r}, \omega) + \hat{\mathbf{z}} \mathbf{Q}_{vz}(\mathbf{r}, \omega), \\ \hat{\mathbf{z}} \cdot \mathbf{Q}_{vt}(\mathbf{r}, \omega) &\equiv 0; \quad v=1, 2 \end{aligned} \quad (30)$$

where the z coordinate is measured on the waveguide axis while two other mutually orthogonal coordinates are specified in the transverse plane. Assuming that all fields have an $\exp(izz)$ dependence on z , and making use of Eqs. (21), we get

$$\begin{aligned} \mathbf{Q}_{vt}(\mathbf{r}, \omega) &= \frac{1}{\gamma_v^2(\omega) - \alpha^2} [i\alpha \mathbf{I} + (-)^v \gamma_v(\omega) \hat{\mathbf{z}} \times \mathbf{I} \\ &\cdot \left[\nabla - \hat{\mathbf{z}} \frac{\partial}{\partial z} \right] \mathbf{Q}_{vz}(\mathbf{r}, \omega); \quad v=1, 2 \end{aligned} \quad (31)$$

where \mathbf{I} is the identity dyadic. The axial components satisfy the reduced scalar Helmholtz equations

$$\left[\nabla^2 - \frac{\partial^2}{\partial z^2} + \gamma_v^2(\omega) - \alpha^2 \right] \mathbf{Q}_{vz}(\mathbf{r}, \omega) = 0; \quad v=1, 2 \quad (32)$$

appropriate solutions of which are commonly worked out in many different ways for waveguides of different cross-sectional geometries [18].

8. SOURCES IN AN ISOTROPIC CHIRAL MEDIUM

Let us now assume the existence of a magnetic charge density $\rho_m(\mathbf{r}, \omega)$ and a magnetic current density $\mathbf{J}_m(\mathbf{r}, \omega)$, because they assist in the solution of dual problems [19]. In addition, let us define the intrinsic impedance $\eta(\omega) = \sqrt{\mu(\omega)/\varepsilon(\omega)}$ as well as the auxiliary wavenumber $k(\omega) = \omega \sqrt{\mu(\omega)\varepsilon(\omega)}$, and drop the explicit indication of dependences on ω for notational simplicity. Now Eqs. (8) may be written as

$$\nabla \cdot \mathbf{B}(\mathbf{r}) = \rho_m(\mathbf{r}) \quad (33a)$$

$$\nabla \times \mathbf{E}(\mathbf{r}) = i\omega \mathbf{B}(\mathbf{r}) - \mathbf{J}_m(\mathbf{r}) \quad (33b)$$

$$\nabla \cdot \mathbf{D}(\mathbf{r}) = \rho(\mathbf{r}) \quad (33c)$$

$$\nabla \times \mathbf{H}(\mathbf{r}) = -i\omega \mathbf{D}(\mathbf{r}) + \mathbf{J}(\mathbf{r}) \quad (33d)$$

which yield the relations

$$\nabla \times \mathbf{Q}_v(\mathbf{r}) + (-)^v \gamma_v \mathbf{Q}_v(\mathbf{r}) = \mathbf{W}_v(\mathbf{r}); \quad v=1, 2 \quad (34)$$

for a chiral medium, where

$$\mathbf{W}_1(\mathbf{r}) = \frac{\gamma_1}{2k} [i\eta \mathbf{J}(\mathbf{r}) - \mathbf{J}_m(\mathbf{r})] \quad (35a)$$

$$\mathbf{W}_2(\mathbf{r}) = \frac{\gamma_2}{2k} [\mathbf{J}(\mathbf{r}) + \frac{1}{i\eta} \mathbf{J}_m(\mathbf{r})] \quad (35b)$$

are the Beltrami source current densities [12].

Since Eqs. (34) are linear, they can be solved using standard techniques. Their complete solution can be compactly stated for all \mathbf{r} as

$$\mathbf{Q}_v(\mathbf{r}) = \mathbf{Q}_v^{\text{cf}}(\mathbf{r}) + \mathbf{Q}_v^{\text{rad}}(\mathbf{r}); \quad v = 1, 2 \quad (36)$$

where

$$\mathbf{Q}_v^{\text{rad}}(\mathbf{r}) = (-)^{v+1} \frac{2\gamma_1\gamma_2}{k} \int_{V_s} \underline{\mathbf{G}}_v(\mathbf{r}, \mathbf{r}_0) \cdot \mathbf{W}_v(\mathbf{r}_0) d^3\mathbf{r}_0; \quad (37)$$

$$v = 1, 2$$

are the particular solutions due to the source densities $\mathbf{W}_v(\mathbf{r})$, which are wholly confined to the region V_s , and $\mathbf{Q}_v^{\text{cf}}(\mathbf{r})$ are the complementary functions satisfying the relations

$$\nabla \times \mathbf{Q}_v^{\text{cf}}(\mathbf{r}) = (-)^{v+1} \gamma_v \mathbf{Q}_v^{\text{cf}}(\mathbf{r}); \quad v = 1, 2 \quad (38)$$

identically. Substituting Eqs. (36)–(38) in Eqs. (34), we obtain the dyadic differential equations

$$\nabla \times \underline{\mathbf{G}}_v(\mathbf{r}, \mathbf{r}_0) + (-)^v \gamma_v \underline{\mathbf{G}}_v(\mathbf{r}, \mathbf{r}_0) = (-)^{v+1} \left(\frac{2\gamma_1\gamma_2}{k} \right)^{-1} \underline{\mathbf{I}} \delta(\mathbf{r} - \mathbf{r}_0); \quad v = 1, 2 \quad (39)$$

where $\delta(\cdot)$ is the Dirac delta function.

The solutions of Eqs. (39) are the Beltrami–Green dyadic functions

$$\underline{\mathbf{G}}_v(\mathbf{r}, \mathbf{r}_0) = (-)^{v+1} \left(\frac{2\gamma_1\gamma_2}{k} \right)^{-1} [\nabla \times \underline{\mathbf{I}} + (-)^{v+1} \gamma_v \underline{\mathbf{I}}] \cdot \underline{\mathbf{G}}_{\text{fs}}(\gamma_v \mathbf{r}, \mathbf{r}_0); \quad v = 1, 2 \quad (40)$$

wherein

$$\underline{\mathbf{G}}_{\text{fs}}(\sigma | \mathbf{r}, \mathbf{r}_0) = \left(\underline{\mathbf{I}} + \frac{\nabla \nabla}{\sigma^2} \right) \frac{\exp(i\sigma |\mathbf{r} - \mathbf{r}_0|)}{4\pi |\mathbf{r} - \mathbf{r}_0|} \quad (41)$$

is the familiar dyadic Green function for free space. As the properties of $\underline{\mathbf{G}}_{\text{fs}}(\sigma; \mathbf{r}, \mathbf{r}_0)$ can be found in almost any graduate-level EM textbook [20,21], those of $\underline{\mathbf{G}}_v(\mathbf{r}, \mathbf{r}_0)$ can be easily determined, as illustrated in Ref. 12.

As an example of the use of Eqs. (37), let us consider an electric dipole moment \mathbf{p} located at the origin: $\mathbf{J}(\mathbf{r}) = -i\omega \mathbf{p} \delta(\mathbf{r})$ and $\mathbf{J}_m(\mathbf{r}) = \mathbf{0}$. The radiated Beltrami fields turn out be

$$\mathbf{Q}_1^{\text{rad}}(\mathbf{r}) = \frac{\omega^2 \mu}{k} \frac{\gamma_1 \gamma_2}{k^2} \gamma_1 \underline{\mathbf{G}}_1(\mathbf{r}, \mathbf{0}) \cdot \mathbf{p}; \quad r > 0 \quad (42a)$$

$$\mathbf{Q}_2^{\text{rad}}(\mathbf{r}) = i\omega \frac{\gamma_1 \gamma_2}{k^2} \gamma_2 \underline{\mathbf{G}}_2(\mathbf{r}, \mathbf{0}) \cdot \mathbf{p}; \quad r > 0 \quad (42b)$$

which show clearly that the radiation field of a point electric dipole in an isotropic chiral medium consists of left-handed as well as right-handed components. If we have instead a point magnetic dipole \mathbf{m} located at the origin,

the source current densities are specified as $\mathbf{J}(\mathbf{r}) = \mathbf{0}$ and $\mathbf{J}_m(\mathbf{r}) = -i\omega \mathbf{m} \delta(\mathbf{r})$, so that

$$\mathbf{Q}_1^{\text{rad}}(\mathbf{r}) = i\omega \frac{\gamma_1 \gamma_2}{k^2} \gamma_1 \underline{\mathbf{G}}_1(\mathbf{r}, \mathbf{0}) \cdot \mathbf{m}; \quad r > 0 \quad (43a)$$

$$\mathbf{Q}_2^{\text{rad}}(\mathbf{r}) = \frac{\omega^2 \varepsilon}{k} \frac{\gamma_1 \gamma_2}{k^2} \gamma_2 \underline{\mathbf{G}}_2(\mathbf{r}, \mathbf{0}) \cdot \mathbf{m}; \quad r > 0 \quad (43b)$$

are the corresponding radiated Beltrami fields. A major difference between isotropic chiral and achiral media is shown by the two sets of radiated fields, Eqs. (42) and (43). Without loss of generality, let the source dipole moments be aligned parallel to the z axis. Then, if the dipole moments are radiating in an achiral medium (i.e., $\beta = 0$), there is no magnetic field due to \mathbf{p} and there is no electric field due to \mathbf{m} at any point on the z axis. On the other hand, the wavenumber difference between the left-handed and the right-handed Beltrami fields guarantees that, in an isotropic chiral medium, both $\mathbf{E}^{\text{rad}}(\mathbf{r})$ and $\mathbf{H}^{\text{rad}}(\mathbf{r})$ are not generally null-valued on the z axis, regardless of which one of the two dipole moments is radiating.

Canonical sources of Beltrami fields are possible. If there is a source distribution such that $\mathbf{J}(\mathbf{r}) \equiv -(1/i\eta) \mathbf{J}_m(\mathbf{r})$ for all \mathbf{r} , then $\mathbf{Q}_2^{\text{rad}}(\mathbf{r}) \equiv \mathbf{0}$ from Eqs. (35) and (37). Likewise, a source distribution containing electric and magnetic current densities in the simple proportion $\mathbf{J}(\mathbf{r}) = (1/i\eta) \mathbf{J}_m(\mathbf{r})$ for all \mathbf{r} radiates only a right-handed field, because $\mathbf{Q}_1^{\text{rad}}(\mathbf{r}) \equiv \mathbf{0}$ emerges from the same equations.

Radiation by complex sources has to be generally treated using integral equations. Both the Maue and the Pocklington integral equations for radiation in a homogeneous isotropic chiral medium are available [12]. Cerenkov radiation in an isotropic chiral medium has also been described using Beltrami fields [12].

The foregoing developments make it clear that a description involving differentials of only the first order suffices for monochromatic radiation and propagation in an isotropic chiral medium. True, there are $\nabla \nabla$ terms in $\underline{\mathbf{G}}_1(\mathbf{r}, \mathbf{r}_0)$ and $\underline{\mathbf{G}}_2(\mathbf{r}, \mathbf{r}_0)$, but dyadic Green functions are not fields, being instead solutions of dyadic differential equations.

Finally, although the left-handed and the right-handed Beltrami fields are capable of being independently radiated and propagated as per Eqs. (34), they do indeed couple in an isotropic chiral medium. This coupling takes place only at bimedia boundaries where conditions on the tangential components of $\mathbf{E}(\mathbf{r})$ and $\mathbf{H}(\mathbf{r})$ must be satisfied; that is, the boundary conditions are specified not on $\mathbf{Q}_1(\mathbf{r})$ or $\mathbf{Q}_2(\mathbf{r})$ singly, but on the tangential components of the combinations $\mathbf{E}(\mathbf{r}) = \mathbf{Q}_1(\mathbf{r}) - i\eta \mathbf{Q}_2(\mathbf{r})$ and $\mathbf{H}(\mathbf{r}) = \mathbf{Q}_2(\mathbf{r}) + (1/i\eta) \mathbf{Q}_1(\mathbf{r})$.

9. THEOREMS FOR SCATTERING IN AN ISOTROPIC CHIRAL MEDIUM

Equations (36)–(39) suffice to set up certain often-used principles for monochromatic scattering and radiation problems, when all space is filled with a homogeneous isotropic chiral medium.

The source–region Beltrami fields can be obtained from Eqs. (37) using the Fikioris approach [22]. Let S be the

Figure 5. For the evaluation of fields in the region V_s , when the sources are also confined to the same region and all space is occupied by a homogeneous chiral medium.

surface of the convex-shaped source region V_s , where $\hat{\mathbf{n}}_0$ is the unit outward normal at $\mathbf{r}_0 \in S$ (see Fig. 5). Then, Eqs. (37) and (40) yield the following relations:

$$\begin{aligned} \mathbf{Q}_v^{\text{rad}}(\mathbf{r}) = & (-)^{v+1} \gamma_v \left\{ \int_{V_s} [\mathbf{G}_{\text{fs}}(\gamma_v | \mathbf{r}, \mathbf{r}_0) \cdot \mathbf{W}_v(\mathbf{r}_0) \right. \\ & - \mathbf{G}_{\text{p}}(\gamma_v | \mathbf{r}, \mathbf{r}_0) \cdot \mathbf{W}_v(\mathbf{r})] d^3 \mathbf{r}_0 \\ & \left. - \gamma_v^{-2} \mathbf{L}(\mathbf{r}) \cdot \mathbf{W}_v(\mathbf{r}) \right\} \\ & + \int_{V_s} [\nabla \times \mathbf{G}_{\text{fs}}(\gamma_v | \mathbf{r}, \mathbf{r}_0)] \cdot \mathbf{W}_v(\mathbf{r}_0) d^3 \mathbf{r}_0; \\ & v = 1, 2; \quad \mathbf{r} \in V_s \end{aligned} \quad (44)$$

The depolarization dyadic

$$\mathbf{L}(\mathbf{r}) = \frac{1}{4\pi} \int_S \frac{\hat{\mathbf{n}}_0 \mathbf{r}_0 - \hat{\mathbf{n}}_0 \mathbf{r}}{|\mathbf{r} - \mathbf{r}_0|^3} d^2 \mathbf{r}_0 \quad (45)$$

in Eqs. (44) is dependent on the shape of the region V_s , while

$$\mathbf{G}_{\text{p}}(\sigma | \mathbf{r}, \mathbf{r}_0) = \frac{\nabla \nabla}{\sigma^2} \frac{1}{4\pi |\mathbf{r} - \mathbf{r}_0|} \quad (46)$$

is an auxiliary dyadic function.

If the maximum linear extent of the region V_s times the magnitude of the greater of the two wavenumbers, γ_1 and γ_2 , is much smaller than unity, we may make the quasi-static approximation: $\mathbf{W}_1(\mathbf{r}_0) \cong \mathbf{W}_1(\mathbf{r})$ and $\mathbf{W}_2(\mathbf{r}_0) \cong \mathbf{W}_2(\mathbf{r})$ for all $\mathbf{r}_0 \in V_s$. Then, Eqs. (44) simplify to

$$\begin{aligned} \mathbf{Q}_v^{\text{rad}}(\mathbf{r}) \cong & \{ (-)^{v+1} \gamma_v [\mathbf{M}(\gamma_v | \mathbf{r}) - \gamma_v^{-2} \mathbf{L}(\mathbf{r})] \\ & + \mathbf{N}(\gamma_v | \mathbf{r}) \} \cdot \mathbf{W}_v(\mathbf{r}); \quad v = 1, 2; \quad \mathbf{r} \in V_s \end{aligned} \quad (47)$$

where the dyadics

$$\mathbf{M}(\sigma | \mathbf{r}) = \int_{V_s} [\mathbf{G}_{\text{fs}}(\sigma | \mathbf{r}, \mathbf{r}_0) - \mathbf{G}_{\text{p}}(\sigma | \mathbf{r}, \mathbf{r}_0)] d^3 \mathbf{r}_0 \quad (48a)$$

$$\mathbf{N}(\sigma | \mathbf{r}) = \int_{V_s} [\nabla \times \mathbf{G}_{\text{fs}}(\sigma | \mathbf{r}, \mathbf{r}_0)] d^3 \mathbf{r}_0 \quad (48b)$$

depend on the shape as well as on the size of V_s . Finally, the Rayleigh approximation requires that we ignore the dyadics $\mathbf{M}(\sigma | \mathbf{r})$ and $\mathbf{N}(\sigma | \mathbf{r})$ completely to obtain the estimates

$$\mathbf{Q}_v^{\text{rad}}(\mathbf{r}) \cong (-)^v \gamma_v^{-1} \mathbf{L}(\mathbf{r}) \cdot \mathbf{W}_v(\mathbf{r}); \quad v = 1, 2; \quad \mathbf{r} \in V_s \quad (49)$$

when V_s is an extremely small region. The right sides of Eqs. (47) and (49) are useful in homogenizing isotropic chiral composites as well as for devising the method of moments and the coupled dipole method for scattering by bianisotropic objects in isotropic chiral environments [12,23].

Turning now to the mathematical realizations of the Huygens principle and its progeny, we suppose that all space is divided into two regions, as shown in Fig. 6. The external region V_{ext} extends to infinity in all directions but is separated from an internal region V_{int} by the convex and once-differentiable surface S . Then the Huygens principle in a homogeneous isotropic chiral medium reads as follows [12]:

$$\begin{aligned} \mathbf{Q}_v(\mathbf{r}) = & (-)^{v+1} \frac{2\gamma_1 \gamma_2}{k} \int_S \mathbf{G}_v(\mathbf{r}, \mathbf{r}_0) \cdot [\hat{\mathbf{n}}_0 \times \mathbf{Q}_v(\mathbf{r}_0)] d^2 \mathbf{r}_0; \\ & v = 1, 2; \quad \mathbf{r} \in V_{\text{ext}} \end{aligned} \quad (50a)$$

$$\mathbf{0} = \int_S \mathbf{G}_v(\mathbf{r}, \mathbf{r}_0) \cdot [\hat{\mathbf{n}}_0 \times \mathbf{Q}_v(\mathbf{r}_0)] d^2 \mathbf{r}_0; \quad v = 1, 2; \quad \mathbf{r} \notin V_{\text{ext}} \quad (50b)$$

Thus, the Cauchy data for the fields in a chiral medium comprise the components of the Beltrami fields that are tangential to a boundary. When these data are prescribed on the surface S , we can find the Beltrami fields everywhere in the region V_{ext} .

The Huygens principle allows the enunciation of the exterior surface equivalence principle. Consider a problem in which surface Beltrami current densities $\mathbf{W}_1^s(\mathbf{r})$ and $\mathbf{W}_2^s(\mathbf{r})$ exist on the exterior side of the surface S (see Fig. 6). As per Eqs. (37), these surface current densities act as

Figure 6. Relevant to the Huygens principle, the exterior surface equivalence principle, and the Ewald-Oseen extinction theorem, when all space is occupied by a homogeneous chiral medium.

sources of the radiated fields

$$\mathbf{Q}_v^{\text{rad}}(\mathbf{r}) = (-)^{v+1} \frac{2\gamma_1\gamma_2}{k} \int_S \mathbf{G}_v(\mathbf{r}, \mathbf{r}_0) \cdot \mathbf{W}_v^{\text{s}}(\mathbf{r}_0) d^2\mathbf{r}_0; \quad (51)$$

$$v = 1, 2; \quad \mathbf{r} \in V_{\text{ext}}$$

On comparing Eqs. (50a) and (51) to ensure the equivalence $\mathbf{Q}_v^{\text{rad}}(\mathbf{r}) \equiv \mathbf{Q}_v(\mathbf{r})$ for all $\mathbf{r} \in V_{\text{ext}}$, we obtain the relationships [12]

$$\mathbf{W}_v^{\text{s}}(\mathbf{r}_0) = \hat{\mathbf{n}}_0 \times \mathbf{Q}_v(\mathbf{r}_0); \quad v = 1, 2; \quad \mathbf{r}_0 \in S \quad (52)$$

as the exterior surface equivalence principle for Beltrami fields and sources, \mathbf{r}_0 in Eqs. (52) lying on the exterior side of S .

The Ewald–Oseen extinction theorem is a cornerstone of the extended-boundary-condition method [12,24]. For scattering in an isotropic chiral medium, this theorem may be stated as

$$\mathbf{0} = \mathbf{Q}_v^{\text{cf}}(\mathbf{r}) + (-)^{v+1} \frac{2\gamma_1\gamma_2}{k} \int_S \mathbf{G}_v(\mathbf{r}, \mathbf{r}_0) \cdot [\hat{\mathbf{n}}_0 \times \mathbf{Q}_v(\mathbf{r}_0)] d^2\mathbf{r}_0; \quad (53)$$

$$v = 1, 2; \quad \mathbf{r} \in V_{\text{int}}$$

where $\mathbf{Q}_v^{\text{cf}}(\mathbf{r})$ play the role of the incident Beltrami fields. Once $\mathbf{Q}_v(\mathbf{r}_0)$, $\mathbf{r}_0 \in S$, have been determined from Eqs. (53), the total fields in the exterior region may be determined as

$$\mathbf{Q}_v(\mathbf{r}) = \mathbf{Q}_v^{\text{cf}}(\mathbf{r}) + (-)^{v+1} \frac{2\gamma_1\gamma_2}{k} \int_S \mathbf{G}_v(\mathbf{r}, \mathbf{r}_0) \cdot [\hat{\mathbf{n}}_0 \times \mathbf{Q}_v(\mathbf{r}_0)] d^2\mathbf{r}_0; \quad (54)$$

$$v = 1, 2; \quad \mathbf{r} \in V_{\text{ext}}$$

From Eqs. (53) and (54), the plane-wave scattering dyadics for an object in an isotropic chiral environment can be derived, as can the forward plane-wave scattering amplitude theorems [12].

10. STRUCTURALLY CHIRAL MEDIA

The molecules of a naturally occurring isotropic chiral medium are mirror-asymmetric, and so are the inclusions in an artificial isotropic chiral medium. As a randomly dispersed and randomly oriented collection of mirror-asymmetric molecules or inclusions is also mirror-asymmetric, isotropic chiral media emerge with direction-independent constitutive properties. In contrast, the molecules or inclusions of a structurally chiral medium are not mirror-asymmetric, but their orientation is.

In chiral nematic liquid crystals (CNLCs)—also called *cholesteric liquid crystals*—needle-like molecules are randomly positioned on parallel sheets, with all molecules on any one sheet oriented parallel to one another and with the orientation rotating helicoidally as one moves across consecutive sheets. The situation is schematically depicted in Fig. 7. From 1850 to 1888, several scientists came across CNLCs but were unable to capitalize on their observations [25]. Then in 1888 the biochemist

Figure 7. Schematic depiction of the arrangement of needle-like molecules in a chiral nematic liquid crystal. The gaps between the consecutive sheets as well as the sheets are fictitious, as they are merely aids to visualization. Only half of the electromagnetic period is shown.

F. Reinitzer observed that a CNLC named *cholesteryl benzoate* has two distinct melting points—it is a solid at temperatures below 145.5°C, a clear liquid at temperatures above 178.5°C, and a cloudy liquid in between. Reinitzer’s observation of the mesophase—when positional order is absent as in a liquid, but orientational order is still strong as in a solid—opened up the area of liquid crystal research in continuum mechanics as well as in optics [26–28].

Earlier, however, (in 1869), E. Reusch had anticipated the CNLC structure as a laminate of uniaxial dielectric sheets, with the crystallographic axes of any two adjacent sheets offset in the transverse plane by a fixed small angle. At a low enough frequency, this laminate appears as a continuously nonhomogeneous medium whose constitutive properties vary helicoidally. Thus

$$\mathbf{D}(\mathbf{r}, \omega) = \varepsilon_0 \underline{\mathbf{S}}(z) \cdot \underline{\boldsymbol{\varepsilon}}_{\text{ref}}(\omega) \cdot \underline{\mathbf{S}}^{-1}(z) \cdot \mathbf{E}(\mathbf{r}, \omega) \quad (55a)$$

$$\mathbf{H}(\mathbf{r}, \omega) = \frac{1}{\mu_0} \mathbf{B}(\mathbf{r}, \omega) \quad (55b)$$

are the frequency-domain constitutive relations of a CNLC, where

$$\underline{\epsilon}_{\text{ref}}(\omega) = \epsilon_a(\omega)[\mathbf{I} - \hat{\mathbf{x}}\hat{\mathbf{x}}] + \epsilon_b(\omega)\hat{\mathbf{x}}\hat{\mathbf{x}} \quad (56)$$

is the relative permittivity dyadic in a reference plane designated as $z=0$. The rotation dyadic

$$\underline{\mathbf{S}}(z) = [\hat{\mathbf{x}}\hat{\mathbf{x}} + \hat{\mathbf{y}}\hat{\mathbf{y}}] \cos \frac{\pi z}{\Omega} \pm [\hat{\mathbf{y}}\hat{\mathbf{x}} - \hat{\mathbf{x}}\hat{\mathbf{y}}] \sin \frac{\pi z}{\Omega} + \hat{\mathbf{z}}\hat{\mathbf{z}} \quad (57)$$

denotes that the CNLC structure varies helicoidally in the axial (i.e., z) direction with a period 2Ω ; however, the electromagnetic period is Ω . The upper sign in Eq. (57) applies for structural right-handedness; the lower, for structural left-handedness.

Reusch's model of a CNLC has been often implemented with either uniaxial crystals or fibrous laminae, and appears promising for microwave and RF applications as well [29]. More recently, thin-film technology has been pressed into service to realize the CNLC structure by releasing a directed evaporant flux toward a rotating substrate [30,31]. The reference permittivity dyadic of these chiral sculptured thin films (STFs) differs from Eq. (56), being

$$\begin{aligned} \underline{\epsilon}_{\text{ref}}(\omega) = & \epsilon_a(\omega)[\mathbf{I} - (\hat{\mathbf{x}} \cos \chi + \hat{\mathbf{z}} \sin \chi)(\hat{\mathbf{x}} \cos \chi + \hat{\mathbf{z}} \sin \chi) - \hat{\mathbf{y}}\hat{\mathbf{y}}] \\ & + \epsilon_b(\omega)(\hat{\mathbf{x}} \cos \chi + \hat{\mathbf{z}} \sin \chi)(\hat{\mathbf{x}} \cos \chi + \hat{\mathbf{z}} \sin \chi) + \epsilon_c(\omega)\hat{\mathbf{y}}\hat{\mathbf{y}}; \\ & \chi > 0^\circ \end{aligned} \quad (58)$$

instead, and the electromagnetic period is 2Ω .

The reference permittivity dyadics in Eqs. (56) and (58) are uniaxial and biaxial, respectively; that is, they have either one or two crystallographic axes. Biaxial $\underline{\epsilon}_{\text{ref}}(\omega)$ is displayed by chiral smectic liquid crystals also [26,27]. Thus in general $\underline{\epsilon}_{\text{ref}}(\omega)$ displays orthorhombic symmetry [32]. Moreover, particularly with advances in thin-film technology, there is no reason for a chiral STF to be

necessarily dielectric only. These considerations led to the proposal of the helicoidal bianisotropic medium (HBM), whose frequency-domain constitutive relations may be stated as [33]

$$\begin{aligned} \mathbf{D}(\mathbf{r}, \omega) = & \epsilon_0 \underline{\mathbf{S}}(z) \cdot [\mathbf{I} + \underline{\chi}_{\text{ref}}^e(\omega)] \cdot \underline{\mathbf{S}}^{-1}(z) \cdot \mathbf{E}(\mathbf{r}, \omega) + \underline{\mathbf{S}}(z) \\ & \cdot \underline{\chi}_{\text{ref}}^{\text{em}}(\omega) \cdot \underline{\mathbf{S}}^{-1}(z) \cdot \mathbf{B}(\mathbf{r}, \omega) \end{aligned} \quad (59a)$$

$$\begin{aligned} \mathbf{H}(\mathbf{r}, \omega) = & \frac{1}{\mu_0} \underline{\mathbf{S}}(z) \cdot [\mathbf{I} - \underline{\chi}_{\text{ref}}^m(\omega)] \cdot \underline{\mathbf{S}}^{-1}(z) \cdot \mathbf{B}(\mathbf{r}, \omega) + \underline{\mathbf{S}}(z) \\ & \cdot \underline{\chi}_{\text{ref}}^{\text{me}}(\omega) \cdot \underline{\mathbf{S}}^{-1}(z) \cdot \mathbf{E}(\mathbf{r}, \omega) \end{aligned} \quad (59b)$$

subject to the constraint

$$\text{Tr}[\underline{\chi}_{\text{ref}}^{\text{em}}(\omega) - \underline{\chi}_{\text{ref}}^{\text{me}}(\omega)] = 0 \quad (60)$$

The launching and propagation of EM waves in HBMs is best studied using a 4×4 matrix differential equation formalism [31,34].

Although chiral STFs made of fluorites, and single-frequency OR measurements on them, were reported in 1959 [35], systematic experimental studies—along with scanning electron microscopic verification of the microstructural geometry—appear to have begun only in 1995 [30]. Figure 8 shows the scanning electron micrograph of a chiral STF made of silicon oxide. As typical values of Ω realized today range from 30 nm to 10 μm , microwave applications of these films are yet not feasible, but are likely to become an active area of research once films with $\Omega \sim 100 \mu\text{m}$ become available. Many possible applications have been anticipated as the concept of STFs for biological, optical, electronic, chemical, and other applications is beginning to take root, while many optical and related applications have already been implemented [30,31].

Figure 8. Scanning electron micrograph of a 10-period chiral sculptured thin film made of silicon oxide. (From Professor Russell Messier, Pennsylvania State University, with permission.)

Large-scale production appears feasible as well, with adaptation of ion-thruster technology [36].

CIRCUIT STABILITY

JAMES A. SVOBODA
Clarkson University
Potsdam, New York

Stability is a property of well-behaved circuits and systems. Typically, stability is discussed in terms of feedback systems. Well-established techniques, such as Nyquist plots, Bode diagrams, and root locus plots, are available for studying the stability of feedback systems. Electric circuits can be represented as feedback systems. Nyquist plots, Bode diagrams, and root locus plots can then be used to study the stability of electric circuits.

1. FEEDBACK SYSTEMS AND STABILITY

Consider a feedback system such as the one shown in Fig. 1. This feedback system consists of three parts: a forward block, sometimes called the “plant”; a feedback block, sometimes called the “controller”; and a summer. The signals $v_i(t)$ and $v_o(t)$ are the input and output of the

Figure 1. A feedback system.

feedback system. $A(s)$ is the transfer function of the forward block and $B(s)$ is the transfer function of the feedback block. The summer subtracts the output of the feedback block from $v_i(t)$. The transfer function of the feedback system can be expressed in terms of $A(s)$ and $B(s)$ as

$$T(s) = \frac{V_o(s)}{V_i(s)} = \frac{A(s)}{1 + A(s)B(s)} \tag{1}$$

Suppose that the transfer functions $A(s)$ and $B(s)$ can each be expressed as ratios of polynomials in s . Then

$$A(s) = \frac{N_A(s)}{D_A(s)} \quad \text{and} \quad B(s) = \frac{N_B(s)}{D_B(s)} \tag{2}$$

where $N_A(s)$, $D_A(s)$, $N_B(s)$, and $D_B(s)$ are polynomials in s . Substituting these expressions into Eq. (1) gives

$$\begin{aligned} T(s) &= \frac{\frac{N_A(s)}{D_A(s)}}{1 + \frac{N_A(s)N_B(s)}{D_A(s)D_B(s)}} = \frac{N_A(s)D_B(s)}{D_A(s)D_B(s) + N_A(s)N_B(s)} \\ &= \frac{N(s)}{D(s)} \end{aligned} \tag{3}$$

where the numerator and denominator of $T(s)$, $N(s)$, and $D(s)$ are both polynomials in s . The values of s for which $N(s) = 0$ are called the *zeros* of $T(s)$, and the values of s that satisfy $D(s) = 0$ are called the *poles* of $T(s)$.

Stability is a property of well-behaved systems. For example, a stable system will produce bounded outputs whenever its input is bounded. Stability can be determined from the poles of a system. The values of the poles of a feedback system will, in general, be complex numbers. A feedback system is stable when all of its poles have negative real parts.

The equation

$$1 + A(s)B(s) = 0 \tag{4}$$

is called the *characteristic equation* of the feedback system. The values of s that satisfy the characteristic equation are poles of the feedback system. The left-hand side of the characteristic equation, $1 + A(s)B(s)$, is called the *return difference* of the feedback system. Figure 2 shows how the return difference can be measured. First, the input, $v_i(t)$, is set to zero. Next, the forward path of the feedback system is broken. Figure 2 shows how a test signal, $V_T(s) = 1$, is applied and the response, $V_R(s) = -A(s)B(s)$, is

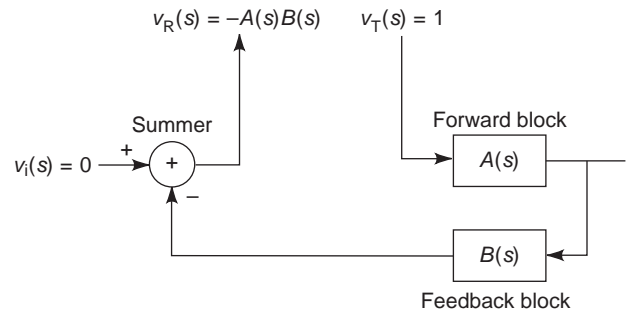

Figure 2. Measuring the return difference. The difference between the test input signal, $V_T(s)$, and the test output signal, $V_R(s)$, is the return difference.

measured. The difference between the test signal and its response is the return difference.

The calculation

$$\begin{aligned} \text{Return difference} &= 1 + A(s)B(s) = 1 + \frac{N_A(s)N_B(s)}{D_A(s)D_B(s)} \\ &= \frac{D_A(s)D_B(s) + N_A(s)N_B(s)}{D_A(s)D_B(s)} \end{aligned}$$

shows that

1. The zeros of $1 + A(s)B(s)$ are equal to the poles of $T(s)$.
2. The poles of $1 + A(s)B(s)$ are equal to the poles of $A(s)B(s)$.

Consider a feedback system of the form shown in Fig. 1 with

$$A(s) = \frac{s + 5}{s^2 - 4s + 1} \quad \text{and} \quad B(s) = \frac{3s}{s + 3} \tag{5}$$

The poles of the forward block are the values of s that satisfy $s^2 - 4s + 1 = 0$ (i.e., $s_1 = 3.73$ and $s_2 = 0.26$). In this case, both poles have real, rather than complex, values. The forward block would be stable if both poles were negative. They are not, so the forward block is itself an unstable system. To see that this unstable system is not well behaved, consider its step response [1,2]. The step response of a system is its zero state response to a step input. In other words, suppose that the input to the forward block was zero for a very long time. At some particular time, the value of input suddenly becomes equal to 1 and remains equal to 1. The response of the system is called the *step response*. The step response can be calculated by taking the inverse Laplace transform of $A(s)/s$. In this example, the step response of the forward block is

$$\text{Step response} = 5 + 0.675e^{3.73t} - 5.675e^{0.27t}$$

As time increases, the exponential terms of the step response get very, very large. Theoretically, they increase without bound. In practice, they increase until the system

saturates or breaks. This is typical of the undesirable behavior of an unstable system.

According to Eq. (3), the transfer function of the whole feedback system is

$$T(s) = \frac{\frac{s+5}{s^2-4s+1}}{1 + \frac{s+5}{s^2-4s+1} \times \frac{3s}{s+3}}$$

$$= \frac{(s+5)(s+3)}{(s^2-4s+1)(s+3) + (s+5)(3s)} = \frac{s^2+8s+15}{s^3+2s^2+4s+3}$$

The poles of the feedback system are the values of s that satisfy $s^3 + 2s^2 + 4s + 3 = 0$ —that is, $s_1 = -1$, $s_2 = -0.5 + j1.66$ and $s_3 = -0.5 - j1.66$. The real part of each of these three poles is negative. Since all of the poles of the feedback system have negative real parts, the feedback system is stable. To see that this stable system is well behaved, consider its step response. This step response can be calculated by taking the inverse Laplace transform of $T(s)/s$. In this example, the step response of the feedback system is

$$\text{Step response} = 5 - 11.09e^{-t} \cos(\sqrt{2}t + 63^\circ)$$

In contrast to the previous case, as time increases, e^{-t} becomes zero so the second term of the step response dies out. This stable system does not exhibit the undesirable behavior typical of unstable systems.

2. STABILITY CRITERIA

Frequently, the information about a feedback system that is most readily available is the transfer functions of the forward and feedback blocks, $A(s)$ and $B(s)$. Stability criteria are tools for determining whether a feedback system is stable by examining $A(s)$ and $B(s)$ directly, without first calculating $T(s)$ and then calculating its poles—that is, the roots of the denominator of $T(s)$. Two stability criteria will be discussed here: the Nyquist stability criteria and the use of Bode diagrams to determine the gain and phase margin.

The Nyquist stability criterion is based on a theorem in the theory of functions of a complex variable [1,3,4]. This stability criterion requires a contour mapping of a closed curve in the s plane using the function $A(s)B(s)$. The closed contour in the s plane must enclose the right half of the s plane and must not pass through any poles or zeros of $A(s)B(s)$. The result of this mapping is a closed contour in the $A(s)B(s)$ plane. Fortunately, the computer program MATLAB [5,6] can be used to generate an appropriate curve in the s plane and do this mapping.

Rewriting the characteristic equation, Eq. (4), as

$$A(s)B(s) = -1 \tag{6}$$

suggests that the relationship of the closed contour in the $A(s)B(s)$ plane to the point $-1 + j0$ is important. Indeed, this is the case. The Nyquist stability criterion involves

the number of encirclements of the point $-1 + j0$ by the curve in the $A(s)B(s)$ plane. Let

N = the number of encirclements, in the clockwise direction, of $-1 + j0$ by the closed curve in the $A(s)B(s)$ plane

Z = The number of poles of $T(s)$ in the right half of the s plane

P = The number of poles of $A(s)B(s)$ in the right half of the s plane

The Nyquist stability criterion states that N , Z , and P are related by

$$Z = P + N$$

A stable feedback system will not have any poles in the right half of the s plane, so $Z = 0$ indicates a stable system.

For example, suppose that the forward and feedback blocks of the feedback system shown in Fig. 1 have the transfer functions described by Eq. (5). Then

$$A(s)B(s) = \frac{3s^2 + 15s}{s^3 - s^2 - 11s + 3}$$

$$= \frac{3s^2 + 15s}{(s - 3.73)(s - 0.26)(s + 3)} \tag{7}$$

Figure 3 shows the Nyquist plot for this feedback system. This plot was obtained using the MATLAB commands

```
num = [0 3 15 0]; %Coefficients of the
              numerator of A(s) B(s)
den = [1 -1 -11 3]; %Coefficients of the
              denominator of A(s) B(s)
nyquist(num, den)
```

Since $A(s)B(s)$ has two poles in the right half of the s plane, $P = 2$. The Nyquist plot shows two counterclockwise encirclements of $-1 + j0$ so $N = -2$. Then $Z = P + N = 0$, indicating that the feedback system is stable.

Figure 3. A Nyquist plot produced using MATLAB.

Feedback systems need to be stable in spite of variations in the transfer functions of the forward and feedback blocks. The gain and phase margins of a feedback system give an indication of how much $A(s)$ and $B(s)$ can change without causing the system to become unstable. The gain and phase margins can be determined using Bode diagrams. To obtain the Bode diagrams, first let $s = j\omega$ so that Eq. (6) becomes

$$A(j\omega)B(j\omega) = -1$$

The value of $A(j\omega)B(j\omega)$ will, in general, be complex. Two Bode diagrams are used to determine the gain and phase margins. The magnitude Bode diagram is a plot of $20 \log |A(j\omega)B(j\omega)|$ versus ω . The units of $20 \log |A(j\omega)B(j\omega)|$ are decibels. The abbreviation for decibel is dB. The magnitude Bode diagram is sometimes referred to as a plot of the magnitude of $A(j\omega)B(j\omega)$, in dB, versus ω . The phase Bode diagram is a plot of the angle of $A(j\omega)B(j\omega)$ versus ω .

It is necessary to identify two frequencies: ω_g , the gain crossover frequency; and ω_p , the phase crossover frequency. To do so, first take the magnitude of both sides of Eq. (7) to obtain

$$|A(j\omega)B(j\omega)| = 1 \quad (8)$$

Converting to decibels gives

$$20 \log |A(j\omega)B(j\omega)| = 0 \quad (9)$$

Equation (8) or (9) is used to identify a frequency, ω_g , the gain crossover frequency. That is, ω_g is the frequency at which

$$|A(j\omega_g)| |B(j\omega_g)| = 1$$

Next, take the angle of both sides of Eq. (4) to

$$\angle(A(j\omega)B(j\omega)) = 180^\circ \quad (10)$$

Equation (10) is used to identify a frequency, ω_p , the phase crossover frequency. That is, ω_p is the frequency at which

$$\angle A(j\omega_p) + \angle B(j\omega_p) = 180^\circ \quad (11)$$

The gain margin of the feedback system is

$$\text{Gain margin} = \frac{1}{|A(j\omega_p)| |B(j\omega_p)|} \quad (12)$$

The phase margin is

$$\text{Phase margin} = 180^\circ - (\angle A(j\omega_g) + \angle B(j\omega_g)) \quad (13)$$

The gain and phase margins can be easily calculated using MATLAB. For example, suppose the forward and feedback blocks of the feedback system shown in Fig. 1 have the transfer functions described by Eq. (3). Figure 4 shows the

Figure 4. Bode plot used to determine the phase and gain margins. The plots were produced using MATLAB.

Bode diagrams for this feedback system. These plots were obtained using the MATLAB commands

```
num=[0 3 15 0]; %Coefficients of the
           numerator of A(s)B(s)
den=[1 -1 -11 3]; %Coefficients of the
           denominator of A(s)B(s)
margin(num,den)
```

MATLAB has labeled the Bode diagrams in Fig. 4 to show the gain and phase margins. The gain margin of -1.331 dB indicates that a decrease in $|A(s)B(s)|$ of 1.331 dB or, equivalently, a decrease in gain by a factor of 0.858 , at the frequency $\omega_p = 1.378$ rad/s, would bring the system the boundary of instability. Similarly, the phase margin of 11.6° indicates that an increase in the angle of $A(s)B(s)$ of 11.6° , at the frequency $\omega_g = 2.247$ rad/s, would bring the system the boundary of instability.

When the transfer functions $A(s)$ and $B(s)$ have no poles or zeros in the right half of the s plane, then the gain and phase margins must both be positive in order for the system to be stable. As a rule of thumb [7], the gain margin should be greater than 6 dB and the phase margin should be between 30 and 60° . These gain and phase margins provide some protection against changes in $A(s)$ or $B(s)$.

3. STABILITY OF LINEAR CIRCUITS

The Nyquist criterion and the gain and phase margin can be used to investigate the stability of linear circuits. To do so requires that the parts of the circuit corresponding to the forward block and to the feedback block be identified. After this identification is made, the transfer functions $A(s)$ and $B(s)$ can be calculated.

Figures 5–8 illustrate a procedure for finding $A(s)$ and $B(s)$ [8]. For concreteness, consider a circuit consisting of resistors, capacitors, and op amps. Suppose further that the input and outputs of this circuit are voltages. Such a circuit is shown in Fig. 5. In Fig. 6 one of the op amps has

Figure 5. A circuit that is to be represented as a feedback system.

been separated from the rest of the circuit. This is done to identify the subcircuit N_B . The op amp will correspond to the forward block of the feedback system while N_B will contain the feedback block. N_B will be used to calculate $B(s)$. In Fig. 7, the op amp has been replaced by a model of the op amp (2). This model of the op amp indicates that the op amp input and output voltages are related by

$$V_B(s) = K(s)V_A(s) \quad (14)$$

The network N_B can be represented by the equation

$$\begin{pmatrix} V_o(s) \\ V_A(s) \end{pmatrix} = \begin{pmatrix} T_{11}(s) & T_{12}(s) \\ T_{21}(s) & T_{22}(s) \end{pmatrix} \begin{pmatrix} V_i(s) \\ V_B(s) \end{pmatrix} \quad (15)$$

Combining Eqs. (14) and (15) yields the transfer function of the circuit

$$T(s) = \frac{V_o(s)}{V_i(s)} = T_{11}(s) + \frac{T_{12}(s)K(s)T_{21}(s)}{1 - K(s)T_{22}(s)} \quad (16)$$

or

$$T(s) = \frac{V_o(s)}{V_i(s)} = \frac{T_{11}(s)(1 + K(s)T_{22}(s)) + T_{12}(s)K(s)T_{21}(s)}{1 + K(s)T_{22}(s)}$$

Equation (15) suggests a procedure that can be used to measure or calculate the transfer functions $T_{11}(s)$, $T_{12}(s)$, $T_{21}(s)$, and $T_{22}(s)$. For example, Eq. (15) says that when $V_i(s) = 1$ and $V_B(s) = 0$, then $V_o(s) = T_{11}(s)$ and $V_A(s) = T_{21}(s)$. Figure 8 illustrates this procedure for determining

Figure 6. Identifying the subcircuit N_B by separating an op amp from the rest of the circuit.

Figure 7. Replacing the op amp with a model of the op amp.

$T_{11}(s)$ and $T_{21}(s)$. A short circuit is used to make $V_B(s) = 0$ and the voltage source voltage is set to 1 so that $V_i(s) = 1$. Under these conditions the voltages $V_o(s)$ and $V_A(s)$ will be equal to the transfer functions $T_{11}(s)$ and $T_{21}(s)$. Similarly, when $V_i(s) = 0$ and $V_B(s) = 1$, then $V_o(s) = T_{12}(s)$ and $V_A(s) = T_{22}(s)$. Figure 9 illustrates the procedure for determining $T_{12}(s)$ and $T_{22}(s)$. A short circuit is used to make $V_i(s) = 0$, and the voltage source voltage is set to 1 so that $V_{B1}(s) = 1$. Under these conditions the voltages $V_o(s)$ and $V_A(s)$ will be equal to the transfer functions $T_{11}(s)$ and $T_{21}(s)$.

Next, consider the feedback system shown in Fig. 10. [The feedback system shown in Fig. 1 is part, but not all, of the feedback system shown in Fig. 10. When $D(s) = 0$, $C_1(s) = 1$ and $C_2(s) = 1$; then Fig. 10 reduces to Fig. 1. Considering the system shown in Fig. 10, rather than the system shown in Fig. 1, avoids excluding circuits for which $D(s) \neq 0$, $C_1(s) \neq 1$, or $C_2(s) \neq 1$.] The transfer function of this feedback system is

$$T(s) = \frac{V_o(s)}{V_i(s)} = D(s) + \frac{C_1(s)A(s)C_2(s)}{1 + A(s)B(s)} \quad (17)$$

Figure 8. The subcircuit N_B is used to calculate $T_{12}(s)$ and $T_{22}(s)$.

Figure 9. The subcircuit N_B is used to calculate $T_{11}(s)$ and $T_{21}(s)$.

or

$$T(s) = \frac{V_o(s)}{V_i(s)} = \frac{D(s)(1 + A(s)B(s)) + C_1(s)A(s)C_2(s)}{1 + A(s)B(s)}$$

Comparing Eqs. (16) and (17) shows that

$$A(s) = -K(s) \tag{18a}$$

$$B(s) = T_{22}(s)$$

$$C_1(s) = T_{12}(s) \tag{18b}$$

$$C_2(s) = T_{21}(s)$$

$$D(s) = T_{11}(s)$$

Finally, with Eqs. (18a) and (18b), the identification of $A(s)$ and $B(s)$ is complete. In summary

1. The circuit is separated into two parts: an op amp and N_B , the rest of the circuit.
2. $A(s)$ is open-loop gain of the op amp, as shown in Fig. 7.
3. $B(s)$ is determined from the subcircuit N_B , as shown in Fig. 9.

As an example, consider the Sallen–Key bandpass filter [9] shown in Fig. 11. The transfer function of this filter is

$$T(s) = \frac{V_o(s)}{V_i(s)} = \frac{5460s}{s^2 + 199s + 4 \times 10^6} \tag{19}$$

Figure 11. A Sallen–Key bandpass filter: $R_1 = R_2 = R_3 = R_5 = 7.07 \text{ k}\Omega$, $R_4 = 20.22 \text{ k}\Omega$, and $C_1 = C_2 = 0.1 \mu\text{F}$.

The first step toward identifying $A(s)$ and $B(s)$ is to separate the op amp from the rest of the circuit, as shown in Fig. 12. Separating the op amp from the rest of the circuit identifies the subcircuit N_B . Next, N_B is used to calculate the transfer functions $T_{11}(s)$, $T_{12}(s)$, $T_{21}(s)$, and $T_{22}(s)$. Figure 13 corresponds to Fig. 8 and shows how $T_{12}(s)$ and $T_{22}(s)$ are calculated. Analysis of the circuit shown in Fig. 13 gives

$$T_{12}(s) = 1 \text{ and } T_{22}(s) = \frac{0.259s^2 + 51.6s + 1.04 \times 10^6}{s^2 + 5660s + 4 \times 10^6} \tag{20}$$

[The computer program ELab [10] provides an alternative to doing this analysis by hand. ELab will calculate the transfer function of a network in the form shown in Eq. (16)—that is, as a symbolic function of s . ELab is free and can be downloaded from <http://sunspot.ece.clarkson.edu:1050/~svoboda/software.html> on the World Wide Web.]

Figure 14 corresponds to Fig. 9 and shows how $T_{11}(s)$ and $T_{21}(s)$ are calculated. Analysis of the circuit shown in Fig. 14 gives

$$T_{11}(s) = 0 \text{ and } T_{21}(s) = \frac{-1410s}{s^2 + 5660s + 4 \times 10^6} \tag{21}$$

Substituting Eqs. (20) and (21) into Eq. (16) gives

$$T(s) = \frac{K(s) \left(\frac{-1410s}{s^2 + 5660s + 4 \times 10^6} \right)}{1 - K(s) \left(\frac{0.259s^2 + 51.6s + 1.04 \times 10^6}{s^2 + 5660s + 4 \times 10^6} \right)} \tag{22}$$

Figure 10. A feedback system that corresponds to a linear system.

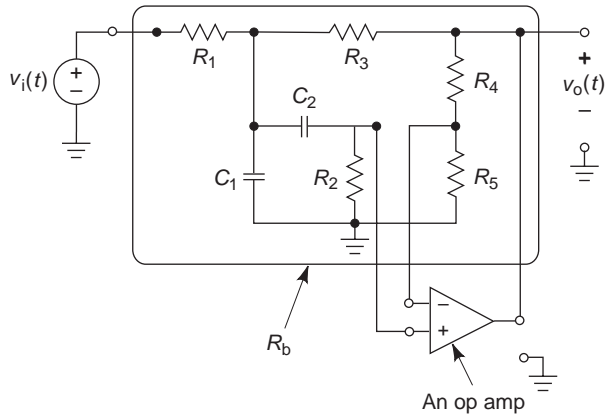

Figure 12. Identifying the subcircuit N_B by separating an op amp from the rest of the circuit.

When the op amp is modeled as an ideal op amp, $K(s) \rightarrow \infty$ and Eq. (22) reduces to Eq. (19). This is reassuring but only confirms what was already known. Suppose that a more accurate model of the op amp is used. A frequently used op amp model [2] represents the gain of the op amp as

$$K(s) = -\frac{A_o}{s + \frac{B}{A_o}} \quad (23)$$

where A_o is the DC gain of the op amp and B is the gain-bandwidth product of the op amp (2). Both A_o and B are readily available from manufacturers specifications of op amps. For example, when the op amp is a $\mu A741$ op amp, then $A_o = 200,000$ and $B = 2\pi \cdot 10^6$ rad/s, so

$$K(s) = -\frac{200,000}{s + 31.4}$$

Equation (18) indicates that $A(s) = -K(s)$ and $B(s) = T_{22}(s)$, so in this example

$$A(s) = \frac{200,000}{s + 31.4} \text{ and } B(s) = 0.259 \left(\frac{s^2 + 51.6s + 1.04 \times 10^6}{s^2 + 5600s + 4 \times 10^6} \right)$$

Figure 13. The subcircuit N_{B1} is used to calculate $T_{11}(s)$ and $T_{21}(s)$.

Figure 14. The subcircuit N_B is used to calculate $T_{12}(s)$ and $T_{22}(s)$.

To calculate the phase and gain margins of this filter, first calculate

$$A(s)B(s) = \frac{51,800(s^2 + 51.6s + 1.04 \times 10^6)}{s^3 + 5974s^2 + 5777240s + 1246 \times 10^6}$$

Next, the MATLAB commands

```
num = 20000*[0 0.259 51.6 1040000];
%Numerator Coefficients
den = [1 5974 5777240 1256*10^6];
%Denominator Coefficients
margin(num, den)
```

are used to produce the Bode diagram shown in Fig. 15. Figure 15 shows that the Sallen–Key filter will have an infinite-gain margin and a phase margin of 76.5° when a $\mu A741$ op amp is used.

4. OSCILLATORS

Oscillators are circuits that are used to generate a sinusoidal output voltage or current. Typically, oscillators have no input. The sinusoidal output is generated by the circuit itself. This section presents the requirements that a circuit must satisfy if it is to function as an oscillator and shows how these requirements can be used to design the oscillator.

To begin, recall that the characteristic equation of a circuit is

$$1 + A(s)B(s) = 0$$

Suppose that this equation is satisfied by a value of s of the form $s = 0 + j\omega_o$. Then

$$A(j\omega_o)B(j\omega_o) = -1 = 1e^{-j180^\circ} \quad (24)$$

In this case, the steady-state response of the circuit will contain a sustained sinusoid at the frequency ω_o (11). In other words, Eq. (24) indicates that the circuit will function as an oscillator with frequency ω_o when $A(j\omega_o)B(j\omega_o)$ has a magnitude equal to 1 and a phase angle of 180° .

Figure 15. The Bode diagrams used to determine the phase and gain margins of the Sallen-Key bandpass filter.

As an example, consider using Eq. (24) to design the Wienbridge oscillator, shown in Fig. 16, to oscillate at $\omega_o = 1000$ rad/s. The first step is to identify $A(s)$ and $B(s)$ using the procedure described in the previous section. In Fig. 17 the amplifier is separated from the rest of the network to identify the subcircuit N_B . Also, from Eqs. (14) and (18), we have

$$A(s) = -K$$

Next, the subcircuit N_B is used to determine $B(s) = T_{22}(s)$, as shown in Fig. 18. From Fig. 18 it is seen that

$$T_{22}(s) = \frac{\frac{1}{C_s} * R}{\frac{1}{C_s} + R} = \frac{1}{\frac{1}{C_s} * R + \left(R + \frac{1}{C_s}\right)} = \frac{1}{1 + \left(R + \frac{1}{C_s}\right) \frac{\left(R + \frac{1}{C_s}\right)}{\left(R * \frac{1}{C_s}\right)}} = \frac{1}{1 + \left(R + \frac{1}{C_s}\right) \left(C_s + \frac{1}{R}\right)} = \frac{1}{3 + RCs + \frac{1}{RCs}}$$

Figure 16. A Wien bridge oscillator.

So

$$A(s)B(s) = \frac{-K}{3 + RCs + \frac{1}{RCs}}$$

Now let $s = 0 + j\omega_o$ to get

$$A(j\omega_o)B(j\omega_o) = \frac{-K}{3 + j\omega_o RC - j\frac{1}{\omega_o RC}} \quad (25)$$

The phase angle of $A(j\omega_o)B(j\omega_o)$ must be 180° if the circuit is to function as an oscillator. That requires

$$j\omega_o RC - j\frac{1}{\omega_o RC} = 0 \Rightarrow \omega_o = \frac{1}{RC} \quad (26)$$

Figure 17. The amplifier is separated from the rest of the Wien bridge oscillator to identify the subcircuit N_B .

Figure 18. The subcircuit N_B is used to calculate $B(s) = T_{22}(s)$ for the Wien bridge oscillator.

Oscillation also requires that the magnitude of $A(j\omega_o)B(j\omega_o)$ be equal to 1. After substituting Eq. (26) into Eq. (25), this requirement reduces to

$$K = 3$$

That is, the amplifier gain must be set to 3. Design of the oscillator is completed by picking values of R and C to make $\omega_o = 1000$ rad/s (e.g., $R = 10$ k Ω and $C = 0.1$ μ F).

5. THE ROOT LOCUS

Frequently the performance of a feedback system is adjusted by changing the value of a gain. For example, consider the feedback system shown in Fig. 1 when

$$A(s) = \frac{N_A(s)}{D_A(s)} \text{ and } B(s) = K \tag{27}$$

In this case, $A(s)$ is the ratio of two polynomials in s and $B(s)$ is the gain that is used to adjust the system. The transfer function of the feedback system is

$$T(s) = \frac{N_A(s)}{D_A(s) + KN_A(s)} = \frac{N(s)}{D(s)} \tag{28}$$

The poles of feedback system are the roots of the polynomial

$$D(s) = D_A(s) + KN_A(s) \tag{29}$$

Suppose that the gain K can be adjusted to any value between 0 and ∞ . Consider the extreme values of K . When $K = 0$, $D(s) = D_A(s)$ so the roots of $D(s)$ are the same as the roots of $D_A(s)$. When $K = \infty$, $D_A(s)$ is negligible compared to $KN_A(s)$. Therefore $D(s) = KN_A(s)$ and the roots of $D(s)$ are the same as the roots of $N_A(s)$. Notice that the roots of $D_A(s)$ are the poles of $A(s)$ and the roots of $N_A(s)$ are the zeros of $A(s)$. As K varies from 0 and ∞ , the poles of $T(s)$

start at the poles of $A(s)$ and migrate to the zeros of $A(s)$. The root locus is a plot of the paths that the poles of $T(s)$ take as they move across the s plane from the poles of $A(s)$ to the zeros of $A(s)$.

A set of rules for constructing root locus plots by hand are available [1,4,7,13]. Fortunately, computer software for constructing root locus plots is also available. For example, suppose that the forward and feedback blocks in Fig. 1 are described by

$$A(s) = \frac{s(s - 2)}{(s + 1)(s + 2)(s + 3)} = \frac{s^2 - 2s}{s^3 + 6s^2 + 11s + 6} \text{ and } B(s) = K$$

The root locus plot for this system is obtained using the MATLAB [5,6] commands

```
num = ([0 1 -2 0]);
den = ([1 6 11 6]);
rlocus(num, den)
```

This root locus plot is shown in Fig. 19. After the root locus has been plotted, the MATLAB command

```
rlocfind(num, den)
```

can be used to find the value of the gain K corresponding to any point on the root locus. For example, when this command is given and the cursor is placed on the point where the locus crosses the positive imaginary axis, MATLAB indicates that gain corresponding to the point $0.0046 + j0.7214$ is $K = 5.2678$. For gains larger than 5.2678, two poles of $T(s)$ are in the right half of the s plane so the feedback system is unstable.

The bilinear theorem [12] can be used to make a connection between electric circuits and root locus plots. Consider Fig. 20, where one device has been separated from the rest of a linear circuit. The separated device could be a

Figure 19. A root locus plot produced using MATLAB. The poles of $A(s)$ are marked by x 's and the zeros of $A(s)$ are marked by o 's. As K increases from zero to infinity, the poles of $T(s)$ migrate from the poles of $A(s)$ to the zeros of $A(s)$ along the paths indicated by solid lines.

Figure 20. A single device is separated from the rest of the network. The parameter associated with this device is called x . The transfer function of the network will be a bilinear function of x .

resistor, a capacitor, an amplifier, or any two-terminal device [12]. The separated device has been labeled as x . For example, x could be the resistance of a resistor, the capacitance of a capacitor, or the gain of an amplifier. The bilinear theorem states that the transfer function of the circuit will be of the form

$$T(s) = \frac{V_o(s)}{V_i(s)} = \frac{E(s) + xF(s)}{G(s) + xH(s)} = \frac{N(s)}{D(s)} \quad (30)$$

where $E(s)$, $F(s)$, $G(s)$, and $H(s)$ are all polynomials in s . A transfer function of this form is said to be a bilinear function of the parameter x since both the numerator and denominator polynomials are linear functions of the parameter x . The poles of $T(s)$ are the roots of the denominator polynomial

$$D(s) = G(s) + xH(s) \quad (31)$$

As x varies from 0 to ∞ , the poles of $T(s)$ begin at the roots of $G(s)$ and migrate to the roots of $H(s)$. The root locus can be used to display the paths that the poles take as they move from the roots of $G(s)$ to the roots of $H(s)$. Similarly, the root locus can be used to display the paths that the zeros of $T(s)$ take as they migrate from the roots of $E(s)$ to the roots of $F(s)$.

For example, consider the Sallen–Key bandpass filter shown in Fig. 11. When

$$R_1 = R_2 = R_3 = 7.07 \text{ k}\Omega, \quad C_1 = C_2 = 0.1 \text{ }\mu\text{F}, \quad \text{and}$$

$$K = 1 + \frac{R_4}{R_5}$$

then the transfer function of this Sallen–Key filter is

$$T(s) = \frac{K(1414s)}{s^2 + (4 - K)(1414s) + 4 \times 10^6} = \frac{K(1414s)}{(s^2 + 5656s + 4 \times 10^6) + K(-1414s)} \quad (32)$$

As expected, this transfer function is a bilinear function the gain K . Comparing Eqs. (30) and (32) shows that $E(s) = 0$, $F(s) = 1414s$, $G(s) = s^2 + 5656s + 4 \times 10^6$, and

Figure 21. This root locus plot shows that the poles of the Sallen–Key bandpass filter move into the right of the s plane as the gain increases.

$H(s) = -1414s$. The root locus describing the poles of the filter is obtained using the MATLAB commands

```
G = ([1 5656 4*10^6]);
H = ([0 -1414 0]);
rlocus(H,G)
```

Figure 21 shows the resulting root locus plot. The poles move into the right half of the s plane, and the filter becomes unstable when $K > 4$.

CIRCUIT TUNING

ROLF SCHAUMANN
Portland State University
Portland, Oregon

Circuit tuning refers to the process of adjusting the values of electronic components in a circuit to ensure that the fabricated or manufactured circuit performs to specifications. In digital circuits, where signals are switched functions in the time domain and correct operation depends largely on the active devices switching all the way between their ON and OFF states, tuning in the sense discussed in this article is rarely necessary. In analog continuous-time circuits, however, signals are continuous functions of time and frequency so that circuit performance depends critically on the component values. Consequently, in all except the most undemanding applications with wide tolerances, correct circuit operation almost always requires some form of tuning. Naturally, components could be manufactured with very tight tolerances, but the resulting fabrication costs would become prohibitive. In practice, therefore, electronic components used in circuit design are never or only rarely available as accurately as the nominal design requires, so we must assume that they are affected by fabrication and manufacturing tolerances. Furthermore, regardless of whether a circuit is assembled in discrete form with discrete components on a printed circuit board (as a hybrid circuit), or in integrated form on an integrated circuit chip, the circuit will be affected by parasitic components and changing operating conditions, all of which contribute to inaccurate circuit performance. Consider, for example, the requirement of implementing as a hybrid circuit a timer of 1 s for a timer circuit via an RC time constant $\tau = RC$ with an accuracy of 0.1%. Assume that R and C are selected to have the nominal values $R = 100 \text{ k}\Omega$ and $C = 10 \text{ }\mu\text{F}$, that inexpensive chip capacitors with $\pm 20\%$ tolerances are used, and that the desired fabrication process of thin-film resistors results in components with $\pm 10\%$ tolerances. The fabricated time constant can therefore be expected to lie in the range

$$0.68 \text{ s} \leq \tau = 100 \text{ k}\Omega(1 \pm 0.1)10 \text{ }\mu\text{F}(1 \pm 0.2) \leq 1.32 \text{ s}$$

In other words, the τ error must be expected to be $\pm 32\%$, which is far above the specified 0.1%. Tuning is clearly

necessary. Because capacitors are difficult to adjust and accurate capacitors are expensive, let us assume in this simple case that the capacitor was measured with 0.05% accuracy as $C = 11.125 \text{ }\mu\text{F}$ (i.e., the measured error was $+11.25\%$). We can readily compute that the resistor should be adjusted (trimmed) to the nominal value $R = \tau/C = 1 \text{ s}/11.125 \text{ }\mu\text{F} = 89.888 \text{ k}\Omega$ within a tolerance of $\pm 45 \text{ }\Omega$ to yield the correctly implemented time constant of 1 s with $\pm 0.1\%$ tolerances. Observe that tuning generally allows the designer to construct a circuit with less expensive wide-tolerance parts because subsequent tuning of these or other components permits the errors to be corrected. Thus, C was fabricated with 20% tolerances but measured with a 0.05% error to permit the resistor with fabrication tolerances of 10% to be trimmed to a 0.05% accuracy. Note that implied in this process is the availability of measuring instruments with the necessary accuracy.

Tuning has two main purposes. Its most important function is to correct errors in circuit performance caused by such factors as fabrication tolerances such as in the preceding example. Second, it permits a circuit's function or parameters, such as the cutoff frequency of a given lowpass filter, to be changed to different values to make the circuit more useful or to be able to accommodate changing operating requirements. But even the best fabrication technology together with tuning will not normally result in a circuit operating with *zero* errors; rather, the aim of tuning is to trim the values of one or more, or in rare cases of all, components until the circuit's response is guaranteed to remain within a specified *tolerance range* when the circuit is put into operation. Figure 1 illustrates the idea for a lowpass filter. Examples are a gain error that is specified to remain within $\pm 0.05 \text{ dB}$, the cutoff frequency f_c of a filter that must not deviate from the design value of, say, $f_c = 10 \text{ kHz}$ by more than 85 Hz, or the gain of an amplifier that must settle to, say, 1% of its final value within less than $1 \text{ }\mu\text{s}$. As these examples indicate, in general, a circuit's operation can be specified in the time domain, such as a transient response with a certain highest permissible overshoot or a maximal settling time, or in the frequency (s) domain through an input-output

Figure 1. The shaded area in the gain–frequency plot shows the operating region for a lowpass filter that must be expected based on the basis of raw (untuned) fabrication tolerances; the dotted region is the acceptable tolerance range that must be maintained in operation after the filter is tuned.

transfer function with magnitude, phase, or delay specifications and certain tolerances (see Fig. 1). This article focuses on the tuning of *filters*, that is, of frequency-selective networks. Such circuits are continuous functions of components, described by transfer functions in the s domain, where tuning of design parameters (e.g., cutoff frequency, bandwidth, quality factor, gain), is particularly important in practice. The concepts discussed in connection with filters apply equally to other analog circuits. Obviously, in order to tune (adjust) a circuit, that circuit must be tunable; that is, its components must be capable of being varied in some manner (manually or electronically) by an amount sufficient to overcome the consequences of fabrication tolerances, parasitic effects, or other such factors.

An example will help to illustrate the discussion and terminology. Consider the simple second-order active bandpass circuit in Fig. 2. Its voltage transfer function, under the assumption of ideal operational amplifiers, can be derived to be

$$\begin{aligned} T(s) &= \frac{V_2}{V_1} = -\frac{b_1 s}{s^2 + a_1 s + a_0} \\ &= -\frac{\frac{1}{R_1 C_1} s}{s^2 + \frac{1}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) s + \frac{1}{R_1 R_2 C_1 C_2}} \end{aligned} \quad (1)$$

We see that $T(s)$ is a continuous function of the circuit components, as are all its coefficients that determine the circuit's behavior:

$$b_1 = \frac{1}{R_1 C_1}, \quad a_1 = \frac{C_1 + C_2}{R_2 C_1 C_2}, \quad a_0 = \frac{1}{R_1 R_2 C_1 C_2} \quad (2)$$

Just as in the earlier example of the RC time constant, the coefficients will not be implemented precisely if the component values have fabrication tolerances. If these component tolerances are “too large,” generally the coefficient errors will become “too large” as well, and the circuit will not function correctly. In that case, the circuit must be tuned. Furthermore, circuits are generally affected by parasitic components. Parasitic components, or *parasitics*, are physical effects that often can be modeled as “real components” affecting the circuit's performance but that frequently are not specified with sufficient accuracy and are not included in the nominal design. For instance, in the filter of Fig. 2, a parasitic capacitor can be assumed to

Figure 2. Active RC bandpass filter.

exist between any two nodes or between any individual node and ground; also, real “wires” are not ideal short-circuit connections with zero resistance but are resistive and, at high frequencies, even inductive. In the filter of Fig. 2, a parasitic capacitor C_p between nodes n_1 and n_2 would let the resistor R_2 look like the frequency-dependent impedance $Z_2(s) = R_2 / (1 + sC_p R_2)$. Similarly, real resistive wires would place small resistors r_w in series with C_1 and C_2 and would make these capacitors appear lossy. That is, the capacitors C_i , $i = 1, 2$, would present admittances of the form $Y_i(s) = sC_i / (1 + sC_i r_w)$. Substituting $Z_2(s)$ and $Y_i(s)$ for R_2 and C_i , respectively, into Eq. (1) shows that, depending on the frequency range of interest and the element values, the presence of these parasitics changes the coefficients of the transfer function, maybe even its type, and consequently the circuit's performance. Similarly, when changes occur in environmental operating conditions, such as bias voltages or temperature, the performance of electronic devices is altered, and as a result the fabricated circuit may not perform as specified.

As discussed by Moschytz [1, Section 4.4, pp. 394–425], and Bowron and Stevenson [2, Section 9.5, pp. 247–251], the operation of tuning can be classified into *functional* and *deterministic* tuning. In functional tuning, the designed circuit is assembled, and its performance is measured. By analyzing the circuit, we can identify which component affects the performance parameter to be tuned. These predetermined components are then adjusted in situ (i.e., with the circuit in operation), until errors in performance parameters are reduced to acceptable tolerances. The process is complicated by the fact that tuning is most often interactive, meaning that adjusting a given component will vary several circuit parameters; thus iterative routines are normally called for. As an example, consider again the active RC filter in Fig. 2. If its bandpass transfer function, Eq. (1), is expressed in the measurable terms of center frequency ω_0 , the pole quality factor $Q = \omega_0 / \Delta\omega$, the parameter that determines the filter's bandwidth $\Delta\omega$, and midband (at $s = j\omega_0$) gain K as

$$\begin{aligned} T(s) &= -\frac{\frac{1}{R_1 C_1} s}{s^2 + \frac{1}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) s + \frac{1}{R_1 R_2 C_1 C_2}} \\ &= -\frac{K \frac{\omega_0}{Q} s}{s^2 + s \frac{\omega_0}{Q} + \omega_0^2} \end{aligned} \quad (3)$$

These parameters are expressed in terms of the circuit components, and we arrive at the more meaningful and useful design equations

$$\omega_0 = \frac{1}{\sqrt{R_1 R_2 C_1 C_2}}, \quad Q = \sqrt{\frac{R_2 \sqrt{C_1 C_2}}{R_1 C_1 + C_2}}, \quad K = \frac{R_2}{R_1} \frac{C_2}{C_1 + C_2} \quad (4)$$

instead of Eq. (2). It is clear that varying any of the passive components will change all three filter parameters, so that expensive and time-consuming iterative tuning is

required. However, functional tuning has the advantage that the effects of all component and layout parasitics, losses, loading, and other hard-to-model or hard-to-predict factors are accounted for because the performance of the complete circuit is measured under actual operating conditions. In general, more accurate results are obtained by basing functional tuning on measurements of phase rather than of magnitude because phase tends to be more sensitive to component errors.

Deterministic tuning refers to calculating the needed value of a component from circuit equations and then adjusting the component to that value. We determined the resistor $R = \tau/C = 89.888 \text{ k}\Omega$ to set a time constant of 1 s at the beginning of this article in this manner. Similarly, from Eq. (4) we can derive the three equations in the four unknowns R_1 , R_2 , C_1 , and C_2

$$R_2 = \frac{Q}{\omega_0} \left(\frac{1}{C_1} + \frac{1}{C_2} \right), \quad R_1 = \frac{1}{R_2 \omega_0^2 C_1 C_2}, \quad C_1 = \frac{1}{KR_1 \omega_0} \quad (5)$$

with C_2 a free parameter. That there are more circuit components than parameters is normal, so the additional “free” elements may be used at will, for example, to achieve practical element values or element-value *spreads* (i.e., the difference between the maximum and minimum of a component type, such as $R_{\max} - R_{\min}$). Technology or cost considerations may place further constraints on tuning by removing some components from the list of tunable ones. Thus, in hybrid circuits with thin- or thick-film technology as in the preceding example, the capacitors will likely be fixed; only the two resistors will be determined as in Eq. (5) from the prescribed circuit parameters ω_0 and Q and the selected and measured capacitor values. This option leaves the midband gain fixed at the value $K = Q/(\omega_0 C_1 R_1)$. Precise deterministic tuning requires careful measurements and accurate models and design equations that, in contrast to the idealized expressions in Eq. (5), describe circuit behavior along with loss, parasitic, and environmental effects. As we saw in Eq. (5), the equations that must be solved are highly nonlinear and tend to be very complex, particularly if parasitic components also are involved. Computer tools are almost always used to find the solution. Typically, automatic laser trimming is employed to tune the resistors to the desired tolerances (e.g., 0.1%). A second tuning iteration using functional tuning may be required because the assembled circuit under power may still not meet the specifications as a result of further parasitic or loading effects that could not be accounted for in the initial deterministic tuning step.

1. SENSITIVITY

We mentioned earlier that a filter parameter P depends on the values k_i of the components used to manufacture a circuit, $P = P(k_i)$, and that real circuit components or parts can be realized only to within some tolerances $\pm \Delta k_i$; that is, the values of the parts used to assemble circuits are $k_i \pm \Delta k_i$. Clearly, the designer needs to know how much these tolerances will affect the circuit and whether the resulting errors can be corrected by adjusting (tuning) the

circuit after fabrication. Obviously, the parameter to be tuned must depend on the component to be varied. For example, Q in Eq. (4) is a function of the components R_1 , R_2 , C_1 , and C_2 , any one of which can be adjusted to correct fabrication errors in Q . In general, the questions of how large the adjustment of a component has to be, whether it should be increased or decreased, and what the best tuning sequence is are answered by considering the parameter’s *sensitivity* to component tolerances. How sensitive P is to the component-value tolerances—that is, how large the deviation ΔP of the parameter in question is—is computed for small changes via the derivative of $P(k_i)$ with respect to k_i , $\partial P/\partial k_i$, at the nominal value k_i :

$$\Delta P = \frac{\partial P(k_i)}{\partial k_i} \Delta k_i \quad (6)$$

Typically, designers are less interested in the absolute tolerances than in the relative ones

$$\frac{\Delta P}{P} = \frac{k_i}{P} \frac{\partial P}{\partial k_i} \frac{\Delta k_i}{k_i} = S_{k_i}^P \frac{\Delta k_i}{k_i} \quad (7)$$

where $S_{k_i}^P$ is the sensitivity, defined as “the relative change of the parameter divided by the relative change of the component”:

$$S_{k_i}^P = \frac{\Delta P/P}{\Delta k_i/k_i} \quad (8)$$

A detailed discussion of sensitivity issues can be found in many textbooks (see Schaumann et al. [3], Chapter 3, pp. 124–196). For example, the sensitivity of ω_0 in Eq. (4) to changes in R_1 is readily computed to be

$$\begin{aligned} S_{R_1}^{\omega_0} &= \frac{R_1}{\omega_0} \frac{\partial \omega_0}{\partial R_1} \\ &= \frac{R_1}{1/(R_1 R_2 C_1 C_2)^{1/2}} \left(-\frac{1}{2} \right) \frac{R_2 C_1 C_2}{(R_1 R_2 C_1 C_2)^{3/2}} = -\frac{1}{2} \end{aligned} \quad (9)$$

$S_{R_1}^{\omega_0} = -0.5$ means that the percentage error in the parameter ω_0 is one-half the size of the percentage error of R_1 and opposite in sign (i.e., if R_1 increases, ω_0 decreases). A large number of useful sensitivity relations that make sensitivity calculations easy can be derived (see, e.g., Moschytz [1], Section 1.6, pp. 103–105, 1.5, pp. 71–102, and 4.3, pp. 371–393, or Schaumann et al. [3], Chapter 3, pp. 124–196). Of particular use for our discussion of tuning are

$$\begin{aligned} S_k^{P(k^n)} &= n S_k^{P(k)}, \quad S_k^{P(\alpha k)} = S_k^{P(k)}, \\ S_k^{P(1/k)} &= -S_k^{P(k)}, \quad \text{and } S_k^{P(\sqrt{k})} = \frac{1}{2} S_k^{P(k)} \end{aligned} \quad (10)$$

where α is a constant, independent of k . The last two of these equations are special cases of the first one for $n = -1$ and $n = \frac{1}{2}$, respectively. The last equation generalizes the result obtained in Eq. (9). Equations (7) and (8) indicate that, for small differential changes, the

parameter deviation caused by a component error and, conversely from the point of view of tuning, the change in component value necessary to achieve a desired change in parameter can be computed if the sensitivity is known.

In Eqs. (6) and (7) we purposely used partial derivatives, $\partial P/\partial k_i$, to indicate that circuit parameters normally depend on more than one component [see Eq. (4)], all of which affect the accuracy of the parameter. To get a more complete picture of the combined effect of the tolerances and to gain insight into the operation of tuning involving several parameters, total derivatives need to be computed. Assuming P depends on n components, we find (see Schaumann et al. [3], Chapter 3, pp. 124–196)

$$\Delta P = \frac{\partial P}{\partial k_1} \Delta k_1 + \frac{\partial P}{\partial k_2} \Delta k_2 + \cdots + \frac{\partial P}{\partial k_n} \Delta k_n$$

that is

$$\begin{aligned} \frac{\Delta P}{P} &= \frac{k_1}{P} \frac{\partial P}{\partial k_1} \frac{\Delta k_1}{k_1} + \cdots + \frac{k_n}{P} \frac{\partial P}{\partial k_n} \frac{\Delta k_n}{k_n} \\ &= S_{k_1}^P \frac{\Delta k_1}{k_1} + \cdots + S_{k_n}^P \frac{\Delta k_n}{k_n} = \sum_{i=1}^n S_{k_i}^P \frac{\Delta k_i}{k_i} \end{aligned} \quad (11)$$

indicating that the sum of all relative component tolerances, weighted by their sensitivities, contributes to the parameter error. To illustrate the calculations, let us apply Eq. (11) to ω_0 in Eq. (4). Using Eqs. (9) and (10), the result is

$$\begin{aligned} \frac{\Delta \omega_0}{\omega_0} &= \frac{R_1}{\omega_0} \frac{\partial \omega_0}{\partial R_1} \frac{\Delta R_1}{R_1} + \frac{R_2}{\omega_0} \frac{\partial \omega_0}{\partial R_2} \frac{\Delta R_2}{R_2} \\ &\quad + \frac{C_1}{\omega_0} \frac{\partial \omega_0}{\partial C_1} \frac{\Delta C_1}{C_1} + \frac{C_2}{\omega_0} \frac{\partial \omega_0}{\partial C_2} \frac{\Delta C_2}{C_2} \\ &= S_{R_1}^{\omega_0} \frac{\Delta R_1}{R_1} + S_{R_2}^{\omega_0} \frac{\Delta R_2}{R_2} + S_{C_1}^{\omega_0} \frac{\Delta C_1}{C_1} + S_{C_2}^{\omega_0} \frac{\Delta C_2}{C_2} \quad (12) \\ &= -\frac{1}{2} \frac{\Delta R_1}{R_1} - \frac{1}{2} \frac{\Delta R_2}{R_2} - \frac{1}{2} \frac{\Delta C_1}{C_1} - \frac{1}{2} \frac{\Delta C_2}{C_2} \\ &= -\frac{1}{2} \left(\frac{\Delta R_1}{R_1} + \frac{\Delta R_2}{R_2} + \frac{\Delta C_1}{C_1} + \frac{\Delta C_2}{C_2} \right) \end{aligned}$$

The last expression gives insight into whether and how ω_0 can be tuned. Because the effects of the errors are additive, tuning just one component, say, R_1 , will suffice for given tolerances of R_2 , C_1 , and C_2 if ΔR_1 can be large enough. If we have measured the R_2 errors at -12% , and those of C_1 and C_2 at $+15\%$ and $+10\%$, respectively, Eq. (12) results in

$$\begin{aligned} \frac{\Delta \omega_0}{\omega_0} &= -\frac{1}{2} \left(\frac{\Delta R_1}{R_1} - 0.12 + 0.15 + 0.10 \right) \\ &= -0.5 \left(\frac{\Delta R_1}{R_1} + 0.13 \right) \end{aligned} \quad (13)$$

indicating that R_1 must be *decreased* by 13% to yield, within the linearized approximations made, $\Delta \omega_0 \approx 0$.

Inserting components with these tolerances into Eq. (4) for ω_0 confirms the result obtained.

To expand these results and gain further insight into the effects of tolerances, as well as beneficial tuning strategies and their constraints, we remember that a transfer function generally depends on more than one parameter. Returning to the example of Fig. 2 described by the function $T(s)$ in Eq. (3) with the three parameters ω_0 , Q , and K given in Eq. (4) and applying Eq. (11) leads to

$$\frac{\Delta \omega_0}{\omega_0} = S_{R_1}^{\omega_0} \frac{\Delta R_1}{R_1} + S_{R_2}^{\omega_0} \frac{\Delta R_2}{R_2} + S_{C_1}^{\omega_0} \frac{\Delta C_1}{C_1} + S_{C_2}^{\omega_0} \frac{\Delta C_2}{C_2} \quad (14a)$$

$$\frac{\Delta Q}{Q} = S_{R_1}^Q \frac{\Delta R_1}{R_1} + S_{R_2}^Q \frac{\Delta R_2}{R_2} + S_{C_1}^Q \frac{\Delta C_1}{C_1} + S_{C_2}^Q \frac{\Delta C_2}{C_2} \quad (14b)$$

$$\frac{\Delta K}{K} = S_{R_1}^K \frac{\Delta R_1}{R_1} + S_{R_2}^K \frac{\Delta R_2}{R_2} + S_{C_1}^K \frac{\Delta C_1}{C_1} + S_{C_2}^K \frac{\Delta C_2}{C_2} \quad (14c)$$

These equations can be expressed in matrix form as follows:

$$\begin{pmatrix} \frac{\Delta \omega_0}{\omega_0} \\ \frac{\Delta Q}{Q} \\ \frac{\Delta K}{K} \end{pmatrix} = \begin{pmatrix} S_{R_1}^{\omega_0} & S_{R_2}^{\omega_0} & S_{C_1}^{\omega_0} & S_{C_2}^{\omega_0} \\ S_{R_1}^Q & S_{R_2}^Q & S_{C_1}^Q & S_{C_2}^Q \\ S_{R_1}^K & S_{R_2}^K & S_{C_1}^K & S_{C_2}^K \end{pmatrix} \begin{pmatrix} \frac{\Delta R_1}{R_1} \\ \frac{\Delta R_2}{R_2} \\ \frac{\Delta C_1}{C_1} \\ \frac{\Delta C_2}{C_2} \end{pmatrix} \quad (15)$$

The *sensitivity matrix* in Eq. (15) (see Moschytz [1], Section 4.3, pp. 376–393, or Schaumann et al. [3], Section 3.3, pp. 161–188), a 3×4 matrix in this case, shows how the tolerances of all the filter parameters depend on the component tolerances. We see that adjusting any one of the circuit components will vary all filter parameters as long as *all* the sensitivities are nonzero, which is indeed the case for the circuit in Fig. 2. Thus, noninteractive tuning is not possible. To illustrate the form of the sensitivity matrix, we calculate for the circuit in Fig. 2

$$\begin{pmatrix} \frac{\Delta \omega_0}{\omega_0} \\ \frac{\Delta Q}{Q} \\ \frac{\Delta K}{K} \end{pmatrix} = \begin{pmatrix} -0.5 & -0.5 & -0.5 & -0.5 \\ -0.5 & 0.5 & -\frac{1}{2} \frac{C_1 - C_2}{C_1 + C_2} & \frac{1}{2} \frac{C_1 - C_2}{C_1 + C_2} \\ -1 & 1 & -\frac{C_1}{C_1 + C_2} & \frac{C_1}{C_1 + C_2} \end{pmatrix} \begin{pmatrix} \frac{\Delta R_1}{R_1} \\ \frac{\Delta R_2}{R_2} \\ \frac{\Delta C_1}{C_1} \\ \frac{\Delta C_2}{C_2} \end{pmatrix} \quad (16)$$

Note that the first line of Eq. (16) is equal to the last part of Eq. (12).

The tuning situation is simpler if the matrix elements above the main diagonal are zero as was assumed for an

arbitrary different circuit in Eq. (17a):

$$\begin{pmatrix} \frac{\Delta\omega_0}{\omega_0} \\ \frac{\Delta Q}{Q} \\ \frac{\Delta K}{K} \end{pmatrix} = \begin{pmatrix} S_{R_1}^{\omega_0} & 0 & 0 & S_{C_2}^{\omega_0} \\ S_{R_1}^Q & S_{R_2}^Q & 0 & S_{C_2}^Q \\ S_{R_1}^K & S_{R_2}^K & S_{C_1}^K & S_{C_2}^K \end{pmatrix} \begin{pmatrix} \frac{\Delta R_1}{R_1} \\ \frac{\Delta R_2}{R_2} \\ \frac{\Delta C_1}{C_1} \\ \frac{\Delta C_2}{C_2} \end{pmatrix}$$

$$= \begin{pmatrix} S_{R_1}^{\omega_0} & 0 & 0 \\ S_{R_1}^Q & S_{R_2}^Q & 0 \\ S_{R_1}^K & S_{R_2}^K & S_{C_1}^K \end{pmatrix} \begin{pmatrix} \frac{\Delta R_1}{R_1} \\ \frac{\Delta R_2}{R_2} \\ \frac{\Delta C_1}{C_1} \end{pmatrix} + \begin{pmatrix} S_{C_2}^{\omega_0} \\ S_{C_2}^Q \\ S_{C_2}^K \end{pmatrix} \frac{\Delta C_2}{C_2}$$

(17a)

Here the sensitivities to C_2 are irrelevant because C_2 is a free parameter and is assumed fixed so that the effects of C_2 tolerances can be corrected by varying the remaining elements. We see then that first ω_0 can be tuned by R_1 , next Q is tuned by R_2 without disturbing ω_0 because $S_{R_2}^{\omega_0}$ is zero, and finally K is tuned by C_1 without disturbing the previous two adjustments. Thus a sensitivity matrix of the structure indicated in Eq. (17a) with elements above the main diagonal equal to zero permits sequential “noninteractive” tuning if the tuning order is chosen correctly. Completely noninteractive tuning without regard to the tuning order requires all elements in the sensitivity matrix off the main diagonal to be zero as indicated for another circuit in Eq. (17b):

$$\begin{pmatrix} \frac{\Delta\omega_0}{\omega_0} \\ \frac{\Delta Q}{Q} \\ \frac{\Delta K}{K} \end{pmatrix} = \begin{pmatrix} S_{C_2}^{\omega_0} \\ S_{C_2}^Q \\ S_{C_2}^K \end{pmatrix} \frac{\Delta C_2}{C_2}$$

$$= \begin{pmatrix} S_{R_1}^{\omega_0} & 0 & 0 \\ 0 & S_{R_2}^Q & 0 \\ 0 & 0 & S_{C_1}^K \end{pmatrix} \begin{pmatrix} \frac{\Delta R_1}{R_1} \\ \frac{\Delta R_2}{R_2} \\ \frac{\Delta C_1}{C_1} \end{pmatrix}$$

(17b)

As can be verified readily, each component affects only one circuit parameter. Again, sensitivities to C_2 are irrelevant because C_2 is fixed, and the effects of its tolerances can be corrected by the remaining components.

An important observation on the effects of tolerances on circuit parameters and the resultant need for tuning can be made from Eq. (16). We see that the sensitivities of the dimensionless parameters (parameters with no physical unit) Q and K to the two resistors and similarly to the two capacitors are equal in magnitude but opposite in sign. Because dimensionless parameters are determined by ratios of like components [see Eq. (4)], we obtain from Eq. (4) with Eq. (10)

$$S_{R_1}^Q = -S_{R_2}^Q = S_R^Q = -0.5$$

$$S_{C_1}^Q = -S_{C_2}^Q = S_C^Q = -\frac{1}{2} \frac{C_1 - C_2}{C_1 + C_2}$$

(18)

Thus, the tolerances of Q are

$$\frac{\Delta Q}{Q} = S_R^Q \left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} \right) + S_C^Q \left(\frac{\Delta C_1}{C_1} - \frac{\Delta C_2}{C_2} \right)$$

(19)

with analogous expressions obtained for the gain K [see the last line of Eq. (16)]. Thus, if the technology chosen to implement the filter permits ratios of resistors and capacitors to be realized accurately (i.e., if all resistors have equal tolerances, as do all capacitors), tuning of dimensionless parameters will generally not be necessary. A prime example is integrated circuit technology, where absolute value tolerances of resistors and capacitors may reach 20–50%, but ratios, depending mainly on processing mask dimensions, are readily implemented with tolerances of a fraction of 1%. As an example, assume that the circuit in Fig. 2 was designed, as is often the case, with two identical capacitors $C_1 = C_2 = C$ with tolerances of 20% and that R_1 and R_2 have tolerances of 10% each

$$C_1 = C_2 = C_n + \Delta C = C_n(1 + 0.2)$$

$$R_1 = R_{1n} + \Delta R_1 = R_{1n}(1 + 0.1)$$

$$R_2 = R_{2n}(1 + 0.1)$$

(20)

where the subscript n stands for the nominal values. From Eq. (19), we find

$$\Delta Q = [S_R^Q(0.1 - 0.1) + S_C^Q(0.2 - 0.2)]Q = 0$$

Thus, the quality factor Q , depending only on ratios of like components, is basically unaffected because all like components have equal fabrication tolerances. This result can be confirmed directly from Eq. (4), where, for equal capacitors

$$Q = \frac{1}{2} \sqrt{\frac{R_2}{R_1}} = \frac{1}{2} \sqrt{\frac{R_{2n}(1 + 0.1)}{R_{1n}(1 + 0.1)}} \approx Q_n$$

(21)

Naturally, if R_1 and R_2 are selected from different manufacturing lots, or if R_1 and R_2 are from physically different fabrication processes (such as a carbon and a metal film resistor), tolerances cannot be assumed to be equal, Q errors are not zero, and tuning will be required.

The situation is quite different for any *dimensioned* circuit parameter, that is, a parameter with a physical unit (e.g., a frequency or time constant, or a voltage or a current). Such parameters are determined by *absolute* values of components, as seen for ω_0 in Eq. (4). Absolute values, depending on physical process parameters such as resistivity, permittivity, or diffusion depth, are very difficult to control and will usually suffer from large process variations. Thus, for the component tolerances in Eq. (20), sensitivity calculations predict from Eqs. (10) and (12) the realized center frequency error

$$\begin{aligned}\Delta\omega_0 &\approx -\frac{1}{2}\left(\frac{\Delta R_1}{R_1} + \frac{\Delta R_2}{R_2} + \frac{\Delta C_1}{C_1} + \frac{\Delta C_2}{C_2}\right)\omega_0 \\ &= -\frac{1}{2}(0.1 + 0.1 + 0.2 + 0.2) = -0.3\omega_0\end{aligned}\quad (22a)$$

that is, all individual component tolerances add to a -30% frequency error. Again, the validity of this sensitivity result can be confirmed directly from Eq. (4):

$$\begin{aligned}\omega_0 &= \frac{1}{\sqrt{R_1 R_2 C_1 C_2}} = \frac{1}{C\sqrt{R_1 R_2}} \\ &= \frac{1}{C_n(1+0.2)\sqrt{R_{1n}R_{2n}(1+0.1+0.1+0.01)}} \\ &\approx \frac{\omega_{0n}}{(1+.02)\sqrt{1+0.2}} \approx \frac{\omega_{0n}}{(1+0.2)(1+0.1)} \\ &= \frac{\omega_{0n}}{(1+0.32)} \approx \omega_{0n}(1-0.24)\end{aligned}\quad (22b)$$

The difference between the exact result in Eq. (22b) and the one obtained via the sensitivity approach in Eq. (22a) arises because the latter assumes *incremental* component changes whereas the former assumed the relatively large changes of 10 and 20%. The center frequency ω_0 is approximately 25–30% smaller than specified and must be corrected by tuning. This can be accomplished, for example, by trimming the two resistors to be 27% smaller than their *fabricated* values,

$$R_1 = R_{1n}(1+0.1)(1-0.27) \approx R_{1n}(1-0.2)$$

$$R_2 \approx R_{2n}(1-0.2)$$

so that sensitivity calculations yield

$$\Delta\omega_0 \approx -0.5(-0.2 - 0.2 + 0.2 + 0.2) = 0$$

More exact deterministic tuning requires the resistors to be trimmed to 24.2% smaller than the fabricated value as shown in Eq. (23):

$$\begin{aligned}\omega_0 &\approx \frac{1}{C_n(1+0.2)\sqrt{R_{1n}R_{2n}(1+0.1)(1-\delta)}} \\ &= \frac{\omega_{0n}}{1.32(1-\delta)} \Rightarrow \omega_{0n}\end{aligned}\quad (23)$$

where δ is the trimming change to be applied to the resistors as fabricated. Equation (23) results in $\delta = 0.242$. Of course, ω_0 tuning could have been accomplished by adjusting only one of the resistors by a larger amount; we trimmed both resistors by equal amounts to maintain *the value of their ratio* that determines Q according to Eq. (21), thereby avoiding the need to retune Q .

2. TUNING DISCRETE CIRCUITS

Whether implemented on a printed-circuit board, with chip and thin- or thick-film components in hybrid form, by use of wirewrapping, or in any other technology, an advantage of discrete circuits for the purpose of tuning is that circuit elements are accessible individually before or after assembly for deterministic or functional adjusting. Thus, after a circuit is assembled and found not to meet the design specifications, the circuit components (most commonly the resistors or inductors) can be varied until the performance is as required. All the previous general discussion applies to the rest of the article, so we shall present only those special techniques and considerations that have been found particularly useful or important for passive and active filters.

2.1. Passive Filters

Discrete passive filters are almost always implemented as lossless ladder circuits; that is, the components are inductors L and capacitors C as is illustrated in the typical circuit in Fig. 3. These LC filters are designed such that the maximum signal power is transmitted from a resistive source to a resistive load in the frequency range of interest; a brief treatment can be found in Schaumann et al. [3, Chapter 2, pp. 71–123]. As pointed out in our earlier discussion, accurate filter behavior depends on precise element values so that it is normally necessary to trim components. This tuning is almost always accomplished via variable inductors whose values are changed by screwing a ferrite slug (the “trimmer”) into or out of the magnetic core of the inductive windings. Variable discrete capacitors are hard to construct, expensive, and rarely used.

LC filters have the advantage of very low sensitivities to all their elements (see Schaumann et al. [3], Chapters 2 and 3, pp. 71–196), which makes it possible to assemble

Figure 3. Sixth-order LC lowpass filter. The filter is to realize a maximally flat passband with a 2dB bandwidth of $f_c = 6$ kHz, minimum stopband attenuation $\alpha_s = 67.5$ dB with transmission zeros at 12 and 24 kHz. The nominal components are listed in Table 1. Note that at DC the filter has $-20 \log[R_2/(R_1 + R_2)] = 6.02$ dB attenuation.

the filter using less expensive wide-tolerance components. This property is further enhanced by the fact that lossless ladders are very easy to tune so that large tolerances of one component can be compensated by accurately tuning another. For example, the resonant frequency $f_0 = 1/\sqrt{LC}$ of an LC resonance circuit has $\pm 15\%$ tolerances if both L and C have $\pm 15\%$ tolerances; if L is then trimmed to $\pm 0.5\%$ of its correct value for the existing capacitor (with $\pm 15\%$ tolerances), f_0 is accurate to within 0.25% without requiring any narrower manufacturing tolerances. Without tuning, a 0.25% f_0 error would require the same narrow 0.25% tolerance in both components, which is likely more expensive than a simple tuning step.

It is well known that lossless ladders can be tuned quite accurately simply by adjusting the components to realize the prescribed transmission zeros (see Heinlein and Holmes [4], Section 12.3, pp. 591–604, and Christian [5], Chapter 8, pp. 167–176). Transmission zeros, frequencies where the attenuation is infinite, usually depend on only two elements: a capacitor and an inductor in a parallel resonant circuit (see Fig. 3) with the parallel tank circuits L_1, C_1 and L_2, C_2 in the series branches of the filter, or alternatively with series LC resonance circuits in the shunt branches. The resonant frequencies $f_{zi} = 1/\sqrt{L_i C_i}$, $i = 1, 2$, of the LC tank circuits are not affected by other elements in the filter, so that tuning is largely noninteractive. As mentioned, the effect of the tolerances of one component, say, C , are corrected by tuning L . It is performed by adjusting the inductors for maximum attenuation at the readily identified frequencies of zero transmission while observing the response of the complete manufactured filter on a network analyzer. Tuning accuracies of the transmission zeros of 0.05% or less should be aimed at. Such tuning of the transmission zeros is almost always sufficient even if the circuit elements have fairly large tolerances (see Heinlein and Holmes [4], Section 12.3, pp. 594–604). If even better accuracy is needed, adjustments of those inductors that do not cause finite transmission zeros, such as L_3 in Fig. 3, may need to be performed (see Christian [5], Chapter 8, pp. 167–176). For instance, consider the filter in Fig. 3 realized with unreasonably large tolerances of $\pm 15\%$, using the components shown in Table 1. This places the two resonant frequencies at 10.3 and 20.7 kHz, with the minimum stopband attenuation equal to only 56.7 dB; the 2-dB passband corner is reduced to 5.36 kHz. If we next tune the transmission zero frequencies to 12 and 24 kHz by adjusting *only* the inductors L_1 and L_2 to 23.5 and 40 mH, respectively, the minimum stopband attenuation is increased to 57.8 dB, and the 2 dB band-

width of the passband is measured as $f_c = 6.07$ kHz (refer to Table 1).

We still note that when functional tuning is performed, the filter must be operated with the correct terminations for which it was designed (see Christian [5], Section 8.2, pp. 168–173). Large performance errors, not just at DC or low frequencies, will result if the nominal terminations are severely altered. For example, an LC filter designed for 600- Ω terminations cannot be correctly tuned by connecting it directly without terminations to a high-frequency network analyzer whose input and source impedances are 50 Ω . Also, if maintaining an accurate narrow passband ripple is important, the tolerances of the untuned capacitors must not be too large. Finally, we observe that the tuning properties of passive LC ladders translate directly to active simulations of these filters via transconductance- C and gyrator- C circuits, which are widely used in high-frequency integrated circuits for communications (see the following discussion).

2.2. Active Filters

Several differences must be kept in mind when tuning active filters as compared to passive lossless filters, particularly to ladders:

1. Active filters are almost always more sensitive to component tolerances than LC ladders. Consequently, tuning is always required in practice.
2. Tuning in active filters is almost always interactive; that is, a filter parameter depends on many or all circuit components as discussed in connection with the circuit in Fig. 2 and the sensitivity discussion related to Eqs. (15) and (16). Consequently, tuning active filters usually requires computer aids to solve the complicated nonlinear tuning equations [see, e.g., the relatively simple case in Eq. (4)].
3. The performance of the active devices, such as operational amplifiers (op amps), and their often large tolerances almost always strongly affects the filter performance and must be accounted for in design and in tuning. Because active-device behavior is often hard to model or account for, functional tuning of the fabricated circuit is normally the only method to ensure accurate circuit performance.

In discrete active filters constructed with resistors, capacitors, and operational amplifiers on a circuit board or in thin- or thick-film form, tuning is almost always performed by varying the resistors. Variable resistors,

Table 1. LC Lowpass Filter (Elements in mH, nF, and k Ω)

Components	L_1	C_1	L_2	C_2	L_3	C_3	C_4	C_5	R_1	R_2
Nominal values	27.00	6.490	46.65	0.943	12.67	6.977	45.55	33.90	1.00	1.00
Performance	$f_c = 6.0$ kHz at $\alpha_p = 8.03$ dB; $f_{z1} = 12.0$ kHz, $f_{z2} = 24.0$ kHz, $\alpha_s = 57.5$ dB									
15% tolerance values	31	7.5	52	1.1	14	8	51	38	1.05	1.05
Performance untuned	$f_c = 5.36$ kHz at $\alpha_p = 8.01$ dB; $f_{z1} = 10.3$ kHz, $f_{z2} = 20.7$ kHz, $\alpha_s = 56.7$ dB									
Tuned values	23.5	7.5	40	1.1	14	8	51	38	1.05	1.05
Performance tuned	$f_c = 6.07$ kHz at $\alpha_p = 8.03$ dB; $f_{z1} = 12.0$ kHz, $f_{z2} = 24.0$ kHz, $\alpha_s = 57.8$ dB									

potentiometers, are available in many forms, technologies, and sizes required to make the necessary adjustments.

2.2.1. Second-Order Filters. The main building blocks of active filters are second-order sections, such as the bandpass circuit in Fig. 2. Many of the tuning strategies and concepts were presented earlier in connection with that circuit and the discussion of sensitivity. An important consideration when tuning an active filter is its dependence on the active devices as mentioned previously in point 3 (above). To illustrate the problem, consider again the bandpass filter in Fig. 2. The transfer function $T(s)$ in Eq. (1) is independent of the frequency-dependent gain $A(s)$ of the op amp only because the analysis assumed that the amplifier is ideal, that is, it has constant and very large (ideally infinite) gain, $A = \infty$. In practice, $T(s)$ is also a function of $A(s)$ as a more careful analysis shows:

$$T(s) = \frac{V_2}{V_1} = -\frac{\frac{1}{R_1 C_1} s \frac{A(s)}{1+A(s)}}{s^2 + \frac{1}{R_2} \left\{ \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{R_1 C_1 [1+A(s)]} \right\} s + \frac{1}{R_1 R_2 C_1 C_2}} \quad (24)$$

Evidently, for $A = \infty$, Eq. (24) reduces to Eq. (1), but finite and frequency-dependent gain can cause severe changes in $T(s)$ in all but the lowest-frequency applications. Consider the often used integrator model for the operational amplifier, $A(s) \approx \omega_t/s$, where ω_t is the unity gain frequency (or the *gain-bandwidth product*) of the op amp with the typical value $\omega_t = 2\pi \times f_t = 2\pi \times 1.5$ MHz. Using this simple model, which is valid for frequencies up to about 10–20% of f_t , and assuming $\omega_t \gg \omega$, the transfer function becomes

$$T(s) = \frac{V_2}{V_1} \approx -\frac{\frac{1}{C_1 R_1} s}{s^2 \left(1 + \frac{1}{\omega_t C_1 R_1} \right) + \frac{1}{R_2} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) s + \frac{1}{R_1 R_2 C_1 C_2}} \quad (25)$$

To get an estimate of the resulting error, let the circuit be designed with $C_1 = C_2 = C = 10$ nF, $R_1 = 66.32 \Omega$ and $R_2 = 9.55$ k Ω to realize the nominal parameters $f_0 = 20$ kHz, $Q = 6$, and $K = 72$. Simulation (or measurement with a very fast op amp) shows that the resulting circuit performance is as desired. However, if the filter is implemented with a 741-type op amp with $f_t = 1.5$ MHz, the measured performance indicates $f_0 = 18.5$ kHz, $Q = 6.85$, and $K = 76.75$. Because of the complicated expressions involving a real op amp, it is appropriate to use functional tuning with the help of a network analyzer. Keeping C constant, the resulting resistor values, $R_1 = 68.5 \Omega$ and $R_2 = 8.00$ k Ω , lead to $f_0 = 20$ kHz and $Q = 6.06$. The midband gain for these element values equals $K = 62.4$ (remember from the

earlier discussion that K for the circuit in Fig. 2 cannot be separately adjusted if the capacitors are predetermined).

2.2.2. High-Order Filters. The two main methods for realizing active filters of order greater than two are active simulations of lossless ladders and cascading second-order sections. We mentioned in connection with the earlier discussion of LC ladders that tuning of active ladder simulations is completely analogous to that of the passive LC ladder: the electronic circuits that simulate the inductors are adjusted until the transmission zeros are implemented correctly. It remains to discuss tuning for the most frequently used method of realizing high-order filters, the cascading of first- and second-order sections. Apart from good sensitivity properties, relatively easy tuning is a main advantage of cascade implementations because each section performs in isolation from the others so that it can be tuned without interactions from the rest of the circuit. Remember, though, that each section by itself may require interactive tuning. Figure 4 shows the circuit structure where each of the blocks is a second-order section such as the ones in Figs. 2 and 5. If the total filter order is odd, one of the sections is, of course, of first order.

To illustrate this point, assume a fourth-order Chebyshev lowpass filter is to be realized with a 1-dB ripple passband in $0 \leq f \leq 28$ kHz with passband gain equal to $H = 20$ dB. The transfer function is found to be

$$T(s) = T_1(s) \times T_2(s) = \frac{1.66\omega_0^2}{s^2 + 0.279\omega_0 s + 0.987\omega_0^2} \frac{1.66\omega_0^2}{s^2 + 0.674\omega_0 s + 0.279\omega_0^2} \quad (26)$$

with $\omega_0 = 2\pi \times 28,000 \text{ s}^{-1} = 175.93 \times 10^3 \text{ s}^{-1}$ (see Schuermann et al. [3], Section 1.6, pp. 36–64). Let the function be realized by two sections of the form shown in Fig. 5. Assuming that the op amps are ideal, the transfer function of the lowpass section is readily derived as

$$\frac{V_2}{V_1} = \frac{K\omega_0^2}{s^2 + s \frac{\omega_0}{Q} + \omega_0^2} = \frac{\alpha_1 \alpha_2}{s^2 + s \left(\frac{1}{C_1 R_1} + \frac{1 - \alpha_1 \alpha_2}{C_2 R_2} \right) + \frac{1}{C_1 R_1 C_2 R_2}} \quad (27)$$

Figure 4. Cascade realization of $2n$ th-order filter. The n second-order sections do not interact with each other and can be tuned independently; that is, each section T_i can be tuned to its nominal values ω_i , Q_i , and H_i , $i = 1, 2, \dots, n$, without being affected by the other sections.

Figure 5. Two-amplifier active lowpass filter.

If the op amp gain is modeled as $A(s) = \omega_0/s$, α_i is to be replaced by

$$\alpha_i \Rightarrow \frac{\alpha_i}{1 + \alpha_i/A(s)} \approx \frac{\alpha_i}{1 + s\alpha_i/\omega_0} \quad (28)$$

We observe again that the circuit parameters ω_0 , Q , and gain K are functions of all the circuit elements so that design and tuning of each section will require iterative procedures, although Section 1 is independent of Section 2 as just discussed. Because there are six “components” (R_1 , R_2 , C_1 , C_2 , α_1 , and α_2) and only three parameters, some simplifying design choices can be made. Choosing $C_1 = C_2 = C$, $R_1 = R$, and $R_2 = k^2R$ (and assuming ideal op amps), Eq. (27) leads to in the expressions

$$\omega_0 = \frac{1}{kRC}, \quad Q = \frac{1}{k + \frac{1}{k}(1 - K)}, \quad K = \alpha_1\alpha_2 \quad (29)$$

The circuit is designed by first computing k from the given values Q and K ; next we choose a suitable capacitor value C and calculate $R = 1/(k\omega_0C)$. Finally, we determine the feedback resistors on the two op amps. Because only the product $\alpha_1\alpha_2$ is relevant, we choose $\alpha_1\alpha_2 = \alpha^2 = K$ (i.e., $\alpha = \sqrt{K} = \sqrt{1.66} = 1.288$). Working through the design equations and choosing all capacitors equal to $C = 150$ pF (standard 5% values) and $R_0 = 10$ k Ω results in $(\alpha - 1)R_0 = 2.87$ k Ω for both sections: $k = 0.965$, $R_1 = 40.2$ k Ω , $R_2 = 36.5$ k Ω for Section 1 and $k = 1.671$, $R_1 = 42.2$ k Ω , $R_2 = 120.1$ k Ω for Section 2. All resistors have standard 1% tolerance values. Building the circuit with 741-type op amps with $f_t = 1.5$ MHz results in a ripple width of almost 3 dB, the reduced cutoff frequency of 27.2 kHz, and noticeable peaking at the band edge. Thus, tuning is required. The errors can be attributed largely to the 5% capacitor errors and the transfer function changes as a result of the finite f_t in Eq. (28).

To accomplish tuning in this case, deterministic tuning may be employed if careful modeling of the op amp behavior, using Eq. (28), and of parasitic effects is used and if the untuned components (the capacitors) are measured carefully and accurately. Because of the many interacting effects in the second-order sections, using a computer program to solve the coupled nonlinear equations is unavoidable, and the resistors are trimmed to their computed values. Functional tuning in this case may

be more convenient, as well as more reliable in practice. For this purpose, the circuit is analyzed, and sensitivities are computed to help understand which components affect the circuit parameters most strongly. Because the sections do not interact, the high-order circuit is separated into its sections, and each section’s functional performance is measured and adjusted on a network analyzer. After the performance of all second-order blocks is found to lie within the specified tolerances, the sections are reconnected in cascade.

3. TUNING INTEGRATED CIRCUITS

With the increasing demand for fully integrated microelectronic systems, naturally, analog circuits will have to be placed on an integrated circuit (IC) along with digital ones. Of considerable interest are communication circuits where bandwidths may reach many megahertz. Numerous applications call for on-chip high-frequency analog filters. Their frequency parameters, which in discrete active filters are set by RC time constants, are in integrated filters most often designed with voltage-to-current converters (transconductors), $I_o = g_m V_i$, and capacitors (i.e., as $\omega = 1/\tau = g_m/C$). As discussed earlier, filter performance must be tuned regardless of the implementation method because fabrication tolerances and parasitic effects are generally too large for filters to work correctly without adjustment. Understandably, tuning in the traditional sense is impossible when the complete circuit is integrated on an IC because individual components are not accessible and cannot be varied. To handle this problem, several techniques have been developed. They permit tuning the circuits electronically by varying the bias voltages V_B or bias currents I_B of the active electronic components (transconductors or amplifiers). In the usual approach, the performance of the fabricated circuit is compared to a suitably chosen accurate reference, such as an external precision resistor R_e to set the value of an electronic on-chip transconductance to $g_m = 1/R_e$ or to a reference frequency ω_r to set the time constant to $C/g_m = 1/\omega_r$. This approach is indeed used in practice, where often the external parameters, R_e or ω_e , are adjusted manually to the required tolerances. Tuning can be handled by connecting the circuit to be tuned into an on-chip control loop, which automatically adjusts bias voltages or currents until the errors are reduced to zero or an acceptable level (see Schaumann et al. [3], Section 7.3, pp. 418–446, and Johns and Martin [6], Section 15.7, pp. 626–635). (A particularly useful reference is Tsvividis and Voorman [7]; it contains papers on all aspects of integrated filters, including tuning). Naturally, this process requires that the circuit be designed to be tunable, that is, that the components are variable over a range sufficiently wide to permit errors caused by fabrication tolerances or temperature drifts to be recovered. We also must try to keep the tuning circuitry relatively simple because chip area and power consumption are at a premium. Although digital tuning schemes are conceptually attractive, analog methods are often preferred. The reason is the need to minimize or eliminate generating digital (switching) noise, which

can enter the sensitive analog signal path through parasitic capacitive coupling or through the substrate, causing the dynamic range or the signal-to-noise ratio to deteriorate.

3.1. Automatic Tuning

Let us illustrate the concepts and techniques with a simple second-order example. Higher-order filters are treated in an entirely analogous fashion; the principles do not change. Consider the g_m - C filter in Fig. 6, which realizes the transfer function

$$T(s) = \frac{V_0}{V_1} = \frac{\alpha s^2 + s \left(\alpha \frac{g_{m1}}{C_1} - \beta \frac{g_{m2}}{C_2} \right) + \frac{g_{m0}g_{m2}}{C_1C_2}}{s^2 + s \frac{g_{m1}}{C_1} + \frac{g_{m1}g_{m2}}{C_1C_2}} \quad (30)$$

with pole frequency and pole Q equal to

$$\omega_0 = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}}, \quad Q = \frac{\omega_0 C_1}{g_{m1}} = \sqrt{\frac{C_1/C_2}{g_{m1}/g_{m2}}} \quad (31)$$

Comparing Eq. (31) to Eq. (2) indicates that the filter parameters for this technology are determined in fundamentally the same way as for discrete active circuits: the frequency is determined by time constants (C_i/g_{mi}) and the quality factor, by ratios of like components. Analogous statements are true for the numerator coefficients of $T(s)$. We can conclude then that, in principle, tuning can proceed in a manner quite similar to the one discussed in the beginning of this article if we can just develop a procedure for varying the on-chip components. To gain an understanding of what needs to be tuned in an integrated filter, let us introduce a more convenient notation that uses the ratios of the components to some suitably chosen unit values g_m and C

$$g_{mi} = g_i g_m, \quad C_i = c_i C, \quad i = 1, 2 \quad \text{and} \quad \omega_u = \frac{g_m}{C} \quad (32)$$

where ω_u is a unit frequency parameter and g_i and c_i are the dimensionless component ratios. With this notation,

Figure 6. A general second-order transconductance- C filter. The circuit realizes arbitrary zeros by feeding the input signal into portions βC_1 and αC_2 of the capacitors C_1 and C_2 .

Eq. (30) becomes

$$T(s) = \frac{V_0}{V_1} = \frac{\alpha s^2 + s \left(\alpha \frac{g_1}{c_1} - \beta \frac{g_2}{c_2} \right) \omega_u + \frac{g_0 g_2}{c_1 c_2} \omega_u^2}{s^2 + s \frac{g_1}{c_1} \omega_u + \frac{g_1 g_2}{c_1 c_2} \omega_u^2} \quad (33)$$

Casting the transfer function in the form shown in Eq. (33) makes clear that the coefficient of s^i is proportional to ω_u^{n-i} , where n is the order of the filter, $n=2$ in Eq. (33); the constants of proportionality are determined by ratios of like components, which are very accurately designable with IC technology. The same is true for filters of arbitrary order. For example, the pole frequency for the circuit in Fig. 6 is determined as ω_u times a designable quantity, $\omega_0 = \omega_u \sqrt{g_1 g_2 / (c_1 c_2)}$. We may conclude therefore that it is only necessary to tune $\omega_u = g_m / C$, which, as stated earlier, as a ratio of two electrically dissimilar components will have large fabrication tolerances. In addition, the electronic circuit that implements the transconductance g_m depends on temperature, bias, and other conditions, so that ω_u can be expected to drift during operation. It can be seen from Eq. (33) that ω_u simply scales the frequency, that is, the only effect of varying ω_u is a shift of the filter's transfer function along the frequency axis.

We stated earlier that tuning a time constant, or, in the present case, the frequency parameter ω_u , is accomplished by equating it via a control loop to an external reference, in this case a reference frequency ω_R such as a clock frequency. Conceptually, the block diagram in Fig. 7 shows the method [8]. The control loop equates the inaccurate unit frequency $\omega_u = g_m / C$ to the accurate reference frequency ω_R in the following way: ω_R is chosen in the vicinity of the most critical frequency parameters of the filter (the band edge for a lowpass, midband for a bandpass filter), where sensitivities are highest. The transconductance g_m to be tuned is assumed to be proportional to the bias voltage V_B , such that $g_m = k V_B$, where k is a constant of proportionality with units of A/V^2 . g_m generates an output current $I = g_m V_R$, which results in the capacitor voltage $V_C = g_m V_R / (j \omega_R C)$. The two matched peak detectors PD convert the two signals V_R and V_C to their DC

Figure 7. Automatic control loop to set $\omega_u = g_m / C$ via an applied reference signal V_R with frequency ω_R . The capacitor voltage equals $V_C = V_R (g_m / j \omega_R C)$, which makes the control current $I_c = g_{mc} V_R (1 - g_m / j \omega_R C)$. The operation is explained in the text.

peak values, so that any phase differences do not matter when comparing the signals at the input of g_{mc} . The DC output current $I_c = g_{mc}V_R\{1-[g_m/(j\omega_R C)]\}$ of the control-transconductance g_{mc} charges the storage capacitor C_c to the required bias voltage V_B for the transconductance g_m . The values g_{mc} and C_c determine the loop gain; they influence the speed of conversion but are otherwise not critical. If the value of g_m gets too large because of fabrication tolerances, temperature, or other effects, I_c becomes negative, C_c discharges, and V_B , that is $g_m = kV_B$, is reduced. Conversely, if g_m is too small, I_c becomes positive and charges C_c , and the feedback loop acts to increase V_B and g_m . The loop stabilizes when V_C and V_R are equal, that is, when $g_m(V_B)/C$ is equal to the accurate reference frequency ω_R . The g_{mc} - C_c combination is, of course, an integrator with ideally infinite DC gain to amplify the shrinking error signal at the input of g_{mc} . In practice, the open-loop DC gain of a transconductance of 35–50 dB is more than adequate. Note that the loop sets the value of ω_u to ω_R regardless of the causes of any errors: fabrication tolerances, parasitic effects, temperature drifts, aging, or changes in DC bias.

We point out that although the scheme just discussed only varies g_m , it actually controls the time constant C/g_m ; that is, errors in both g_m and C are accounted for. If one wishes to control only g_m , the capacitor C in Fig. 7 is replaced by an accurate resistor R_e , and the feedback loop will converge to $g_m = 1/R_e$.

Note that the feedback loop in Fig. 7 directly controls only the transconductance g_m (as does the frequency control circuit in Fig. 8) such that the unit frequency parameter ω_u within the control circuit is realized correctly. The actual filter is not tuned. However, good matching and tracking can be assumed across the IC because all g_m cells are on the same chip and subject to the same error-causing effects. This assumes that the ratios g , defined in Eq. (32) are not so large that matching problems will arise and that care is taken to account for

(model the effect of) filter parasitics in the control circuit. The same is true for the unit capacitor C in the control loop and the filter capacitors (again, if the ratios c_i are not too large). Consequently, the control bias current I_B can be sent to all the main filter's transconductance cells as indicated in Fig. 7 and thereby tune the filter. Clearly, this scheme depends on good matching properties across the IC chip. Accurate tuning cannot be performed if matching and tracking cannot be relied upon or, in other words, if the g_m - C circuit in the control loop is not a good representative model of the filter cells.

An alternative method for frequency tuning (see Schaumann et al. [3], Section 7.3, pp. 418–446, and Johns and Martin [6], Section 15.7, pp. 626–635) relies on phase-locked loops (see Johns and Martin [6], Chapter 16, pp. 648–695). The top half of Fig. 8 shows the principle. A sinusoidal reference signal V_R at $\omega = \omega_R$ and the output of a voltage-controlled oscillator (f -VCO) at ω_{vco} are converted to square waves by two matched limiters. Their outputs enter an XOR gate acting as a phase detector whose output contains a DC component proportional to the frequency difference $\Delta\omega = \omega_{vco} - \omega_R$ of the two input signals. The lowpass filter LPF 1 eliminates second- and higher-order harmonics of the XOR output and sends the DC component to the oscillator f -VCO, locking its frequency to ω_R . Just as the g_m - C circuit in Fig. 7, the oscillator is designed with transconductances and capacitors to represent (model) any frequency parameter errors of the filter to be tuned so that, relying on matching, the filter is tuned correctly by applying the tuning signal also to its g_m cells. The lowpass filter LPF 2 is used to clean the tuning signal V_f further before applying it to the filter.

We saw in Eq. (33) that all filter parameters depend, apart from ω_u , only on ratios of like components and are, therefore, accurately manufacturable and should require no tuning. This is indeed correct for moderate frequencies and filters with relatively low Q . However, Q is extremely sensitive (see Schaumann et al. [3], Chapter 7, pp. 410–486) to small parasitic phase errors in the feedback loops of active filters, so that Q errors may call for tuning as well, especially as operating frequencies increase. The problem is handled in much the same way as frequency tuning. One devises a model (the Q model in Fig. 8) that represents the Q errors to be expected in the filter and encloses this model circuit in a control loop where feedback acts to reduce the error to zero. Figure 8 illustrates the principle. In the Q control loop, a Q -VCO (tuned correctly by the applied frequency control signal V_f) sends a test signal to the Q model that is designed to represent correctly the Q errors to be expected in the filter to be tuned, and through a peak detector PD to an amplifier of gain K . K is the gain of an accurately designable DC amplifier. Note that the positions of PD and K could be interchanged in principle, but a switch would require that K is the less well-controlled gain of a high-frequency amplifier. The output of the Q model goes through a second (matched) peak detector. Rather than measuring Q directly, which is very difficult in practice, because it would require accurate measurements of two amplitudes and two frequencies, the operation relies on the fact that Q errors are usually proportional to magnitude errors. The

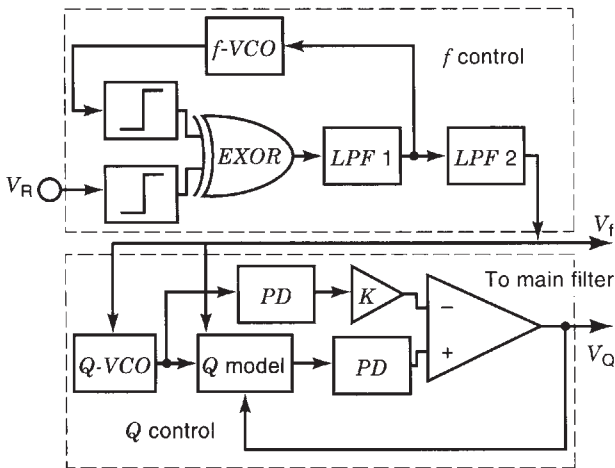

Figure 8. Dual-control loop-tuning system for tuning frequency parameters and quality factors of an integrated filter. Note that the frequency loop converges always, but for the Q loop to converge on the correct Q value, the frequency must be correct. Details of the operation are explained in the text.

diagram in Fig. 8 assumes that for correct Q the output of the Q model is K times as large as its input so that for correct Q the inputs of the comparator are equal. The DC error signal V_Q resulting from the comparison is fed back to the Q model circuit to adjust the bias voltages appropriately, as well as to the filter. In these two interacting control loops, the frequency loop will converge independently of the Q control loop, but to converge on the correct value of Q , the frequency must be accurate. Hence, the two loops must operate together. The correct operation and convergence of the frequency and Q control scheme in Fig. 8 has been verified by experiments (see Schaumann et al. [3], Chapter 7, pp. 410–486) but because of the increased noise, power consumption, and chip area needed for the control circuitry, the method has not found its way into commercial applications.

Systems, Baltimore, Maryland)

1. INTRODUCTION

The circular waveguide is occasionally used as an alternative to the rectangular waveguide. Like other wave-

guides constructed from a single, enclosed conductor, the circular waveguide supports transverse electric (TE) and transverse magnetic (TM) modes. These modes have a cutoff frequency, below which electromagnetic energy is severely attenuated. Circular waveguide's round cross section makes it easy to machine, and it is often used to feed conical horns. Further, the TE_{0n} modes of circular waveguide have very low attenuation. A disadvantage of circular waveguide is its limited dominant mode bandwidth, which, compared to rectangular waveguide's maximum bandwidth of 2–1, is only 1.3. In addition, the polarization of the dominant mode is arbitrary, so that discontinuities can easily excite unwanted cross-polarized components.

In this article, the electromagnetic features of the circular waveguide are summarized, including the transverse and longitudinal fields, the cutoff frequencies, the propagation and attenuation constants, and the wave impedances of all transverse electric and transverse magnetic modes.

2. TRANSVERSE ELECTRIC (TE^z) MODES

The transverse electric to z (TE^z) modes can be derived by letting the vector potential \mathbf{A} and \mathbf{F} be equal to

$$\mathbf{A} = 0 \quad (1a)$$

$$\mathbf{F} = \hat{a}_z F_z(\rho, \phi, z) \quad (1b)$$

The vector potential \mathbf{F} must satisfy the vector wave equation, which reduces the \mathbf{F} of (1b) to

$$\nabla^2 F_z(\rho, \phi, z) + \beta^2 F_z(\rho, \phi, z) = 0 \quad (2)$$

When expanded in cylindrical coordinates, (2) reduces to

$$\frac{\partial^2 F_z}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial F_z}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 F_z}{\partial \phi^2} + \frac{\partial^2 F_z}{\partial z^2} + \beta^2 F_z = 0 \quad (3)$$

whose solution for the geometry of Fig. 1 is of the form

$$F_z(\rho, \phi, z) = [A_1 J_m(\beta_\rho \rho) + B_1 Y_m(\beta_\rho \rho)] \\ \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] \\ \times [A_3 e^{-j\beta_z z} + B_3 e^{+j\beta_z z}] \quad (4a)$$

where

$$\beta_\rho^2 + \beta_z^2 = \beta^2 \quad (4b)$$

The constants $A_1, B_1, C_2, D_2, A_3, B_3, m, \beta_\rho$, and β_z can be found using the boundary conditions of

$$E_\phi(\rho = a, \phi, z) = 0 \quad (5a)$$

$$\text{The fields must be finite everywhere} \quad (5b)$$

$$\text{The fields must repeat every } 2\pi \text{ radians in } \phi \quad (5c)$$

CIRCULAR WAVEGUIDES¹

CONSTANTINE A. BALANIS
 Arizona State University
 Tempe, Arizona
 (edited by Eric Holzman
 Northrop Grumman Electronic
 Systems, Baltimore, Maryland)

1. INTRODUCTION

The circular waveguide is occasionally used as an alternative to the rectangular waveguide. Like other wave-

guides constructed from a single, enclosed conductor, the circular waveguide supports transverse electric (TE) and transverse magnetic (TM) modes. These modes have a cutoff frequency, below which electromagnetic energy is severely attenuated. Circular waveguide’s round cross section makes it easy to machine, and it is often used to feed conical horns. Further, the TE_{0n} modes of circular waveguide have very low attenuation. A disadvantage of circular waveguide is its limited dominant mode bandwidth, which, compared to rectangular waveguide’s maximum bandwidth of 2–1, is only 1.3. In addition, the polarization of the dominant mode is arbitrary, so that discontinuities can easily excite unwanted cross-polarized components.

In this article, the electromagnetic features of the circular waveguide are summarized, including the transverse and longitudinal fields, the cutoff frequencies, the propagation and attenuation constants, and the wave impedances of all transverse electric and transverse magnetic modes.

2. TRANSVERSE ELECTRIC (TE^z) MODES

The transverse electric to z (TE^z) modes can be derived by letting the vector potential \mathbf{A} and \mathbf{F} be equal to

$$\mathbf{A} = 0 \tag{1a}$$

$$\mathbf{F} = \hat{a}_z F_z(\rho, \phi, z) \tag{1b}$$

The vector potential \mathbf{F} must satisfy the vector wave equation, which reduces the \mathbf{F} of (1b) to

$$\nabla^2 F_z(\rho, \phi, z) + \beta^2 F_z(\rho, \phi, z) = 0 \tag{2}$$

When expanded in cylindrical coordinates, (2) reduces to

$$\frac{\partial^2 F_z}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial F_z}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 F_z}{\partial \phi^2} + \frac{\partial^2 F_z}{\partial z^2} + \beta^2 F_z = 0 \tag{3}$$

whose solution for the geometry of Fig. 1 is of the form

$$F_z(\rho, \phi, z) = [A_1 J_m(\beta_\rho \rho) + B_1 Y_m(\beta_\rho \rho)] \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] \times [A_3 e^{-j\beta_z z} + B_3 e^{+j\beta_z z}] \tag{4a}$$

where

$$\beta_\rho^2 + \beta_z^2 = \beta^2 \tag{4b}$$

The constants $A_1, B_1, C_2, D_2, A_3, B_3, m, \beta_\rho$, and β_z can be found using the boundary conditions of

$$E_\phi(\rho = a, \phi, z) = 0 \tag{5a}$$

$$\text{The fields must be finite everywhere} \tag{5b}$$

$$\text{The fields must repeat every } 2\pi \text{ radians in } \phi \tag{5c}$$

¹This article is derived from material in *Advanced Engineering Electromagnetics*, by Constantine Balanis, Wiley, New York, 1989, Sect. 9.2.

Figure 1. Cylindrical waveguide of circular cross section.

According to (5b), $B_1 = 0$ since $Y_m(\rho = 0) = \infty$. In addition, according to (5c)

$$m = 0, 1, 2, 3, \dots \tag{6}$$

Consider waves that propagate only in the +z direction. Then (4) reduces to

$$F_z^+(\rho, \phi, z) = A_{mn} J_m(\beta_\rho \rho) [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \tag{7}$$

From Eq. (7), the electric field component of E_ϕ^+ can be written as

$$E_\phi^+ = \frac{1}{\epsilon} \frac{\partial F_z^+}{\partial \rho} = \beta_\rho \frac{A_{mn}}{\epsilon} J'_m(\beta_\rho \rho) [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \tag{8a}$$

where

$$\beta_\rho = \frac{\partial}{\partial(\beta_\rho \rho)} \tag{8b}$$

Applying the boundary condition of (5a) in (8a), we then have that

$$E_\phi^+(\rho = a, \phi, z) = \beta_\rho \frac{A_{mn}}{\epsilon} J'_m(\beta_\rho a) [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} = 0 \tag{9}$$

which is satisfied only provided that

$$J'_m(\beta_\rho a) = 0 \Rightarrow \beta_\rho a = \chi'_{mn} \Rightarrow \beta_\rho = \frac{\chi'_{mn}}{a} \tag{10}$$

In (10) χ'_{mn} represents the n th zero ($n = 1, 2, 3, \dots$) of the derivative of the Bessel function J_m of the first kind of order m ($m = 0, 1, 2, 3, \dots$). An abbreviated list of the zeros χ'_{mn} of the derivative J'_m of the Bessel function J_m is found in Table 1. The smallest value of χ'_{mn} is 1.8412 ($m = 1, n = 1$).

Using (4b) and (10), β_z of the mn mode can be written as

$$(\beta_z)_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2} = \sqrt{\beta^2 - \left(\frac{\chi'_{mn}}{a}\right)^2} \\ \text{when } \beta > \beta_\rho = \frac{\chi'_{mn}}{a} \end{cases} \tag{11a}$$

$$(\beta_z)_{mn} = \begin{cases} 0 & \text{when } \beta = \beta_c = \beta_\rho = \frac{\chi'_{mn}}{a} \end{cases} \tag{11b}$$

$$(\beta_z)_{mn} = \begin{cases} -j\sqrt{\beta_\rho^2 - \beta^2} = -j\sqrt{\left(\frac{\chi'_{mn}}{a}\right)^2 - \beta^2} \\ \text{when } \beta < \beta_\rho = \frac{\chi'_{mn}}{a} \end{cases} \tag{11c}$$

Cutoff is defined when $(\beta_z)_{mn} = 0$. Thus, according to (11b)

$$\beta_c = \omega_c \sqrt{\mu\epsilon} = 2\pi f_c \sqrt{\mu\epsilon} = \beta_\rho = \frac{\chi'_{mn}}{a} \tag{12a}$$

$$(f_c)_{mn} = \frac{\chi'_{mn}}{2\pi a \sqrt{\mu\epsilon}} \tag{12b}$$

By using (12a) and (12b), we can write (11a)–(11c) as

$$(\beta_z)_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2} = \beta \sqrt{1 - \left(\frac{\beta_\rho}{\beta}\right)^2} = \beta \sqrt{1 - \left(\frac{\beta_c}{\beta}\right)^2} \\ = \beta \sqrt{1 - \left(\frac{\chi'_{mn}}{\beta a}\right)^2} = \beta \sqrt{1 - \left(\frac{f_c}{f}\right)^2} \\ \text{when } f > f_c = (f_c)_{mn} \end{cases} \tag{13a}$$

$$(\beta_z)_{mn} = \begin{cases} 0 & \text{when } f = f_c = (f_c)_{mn} \end{cases} \tag{13b}$$

Table 1. Zeros χ'_{mn} of Derivative $J'_m(\chi'_{mn}) = 0$ ($n = 1, 2, 3, \dots$) of Bessel Function $J_m(x)$

	$m = 0$	$m = 1$	$m = 2$	$m = 3$	$m = 4$	$m = 5$	$m = 6$	$m = 7$	$m = 8$	$m = 9$	$m = 10$	$m = 11$
$n = 1$	3.8318	1.8412	3.0542	4.2012	5.3175	6.4155	7.5013	8.5777	9.6474	10.7114	11.7708	12.8264

$n = 3$	10.1735	8.5363	9.9695	11.3459	12.6819	13.9872	15.2682	16.5294	17.7740	19.0046	20.2230	21.4309
$n = 4$	13.3237	11.7060	13.1704	14.5859	15.9641	17.3129	18.6375	19.9419	21.2291	22.5014	23.7607	25.0085
$n = 5$	16.4706	14.8636	16.3475	17.7888	19.1960	20.5755	21.9317	23.2681	24.5872	25.8913	27.1820	28.4609

$$(\beta_z)_{mn} = \begin{cases} -j\sqrt{\beta_\rho^2 - \beta^2} = -j\beta\sqrt{\left(\frac{\beta_\rho}{\beta}\right)^2 - 1} = -j\beta\sqrt{\left(\frac{\beta_c}{\beta}\right)^2 - 1} \\ = -j\beta\sqrt{\left(\frac{\lambda'_{mn}}{\beta a}\right)^2 - 1} = -j\beta\sqrt{\left(\frac{f_c}{f}\right)^2 - 1} \\ \text{when } f < f_c = (f_c)_{mn} \end{cases} \quad (13c)$$

The guide wavelength λ_g is defined as

$$(\lambda_g)_{mn} = \frac{2\pi}{(\beta_z)_{mn}} \quad (14a)$$

which, according to (13a) and (13b), can be written as

$$(\lambda_g)_{mn} = \begin{cases} \frac{2\pi}{\beta\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} = \frac{\lambda}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} & \text{when } f > f_c = (f_c)_{mn} \\ \infty & \text{when } f = (f_c)_{mn} \end{cases} \quad (14b)$$

$$(\lambda_g)_{mn} = \{\infty \text{ when } f = (f_c)_{mn}\} \quad (14c)$$

In (14b) λ is the wavelength of the wave in an infinite medium of the kind that exists inside the waveguide. There is no definition of the wavelength below cutoff since the wave is exponentially decaying and there is no repetition of its waveform.

According to (12b) and the values of λ'_{mn} in Table 1, the order (lower to higher cutoff frequencies) in which the TE_{mn}^z modes occur is TE_{11}^z , TE_{21}^z , TE_{01}^z , and so on. It should be noted that for a circular waveguide, the order in which the TE_{mn}^z modes occur does not change, and the bandwidth between modes is also fixed. For example, the bandwidth of the first single-mode TE_{11}^z operation is $3.042/1.8412 = 1.6588 : 1$, which is less than $2 : 1$. This bandwidth is fixed and cannot be varied. A change in the radius only varies, by the same amount, the absolute values of the cutoff frequencies of all the modes but does not alter their order or relative bandwidth.

The electric and magnetic field components can be written from Eq. (7) as

$$\begin{aligned} E_\rho^+ &= -\frac{1}{\varepsilon\rho} \frac{\partial F_z^+}{\partial\phi} \\ &= -A_{mn} \frac{m}{\varepsilon\rho} J_m(\beta_\rho\rho) [-C_2 \sin(m\phi) \\ &\quad + D_2 \cos(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (15a)$$

$$\begin{aligned} E_\phi^+ &= \frac{1}{\varepsilon} \frac{\partial F_z^+}{\partial\rho} \\ &= A_{mn} \frac{\beta_\rho}{\varepsilon} J'_m(\beta_\rho\rho) [C_2 \cos(m\phi) \\ &\quad + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (15b)$$

$$E_z^+ = 0 \quad (15c)$$

$$\begin{aligned} H_\rho^+ &= -j \frac{1}{\omega\mu\varepsilon} \frac{\partial^2 F_z^+}{\partial\rho\partial z} \\ &= -A_{mn} \frac{\beta_\rho\beta_z}{\omega\mu\varepsilon} J'_m(\beta_\rho\rho) [C_2 \cos(m\phi) \\ &\quad + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (15d)$$

$$\begin{aligned} H_\phi^+ &= -j \frac{1}{\omega\mu\varepsilon\rho} \frac{\partial^2 F_z^+}{\partial\phi\partial z} = -A_{mn} \frac{m\beta_z}{\omega\mu\varepsilon\rho} J_m(\beta_\rho\rho) \\ &\quad \times [-C_2 \sin(m\phi) + D_2 \cos(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (15e)$$

$$\begin{aligned} H_z^+ &= -j \frac{1}{\omega\mu\varepsilon} \left(\frac{\partial^2}{\partial z^2} + \beta^2 \right) F_z^+ = -jA_{mn} \frac{\beta_\rho^2}{\omega\mu\varepsilon} J_m(\beta_\rho\rho) \\ &\quad \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (15f)$$

where

$$\beta_\rho = \frac{\partial}{\partial(\beta_\rho\rho)} \quad (15g)$$

By using (15a)–(15f), the wave impedance (Z_w^{+z})^{TE} of the TE_{mn}^z (H_{mn}^z) modes in the $+z$ direction can be written as

$$Z_{mn}^h = (Z_w^{+z})_{mn}^{\text{TE}} = \frac{E_\rho^+}{H_\phi^+} = -\frac{E_\phi^+}{H_\rho^+} = \frac{\omega\mu}{(\beta_z)_{mn}} \quad (16a)$$

With the aid of (13a)–(13c) the wave impedance of (16a) reduces to

$$Z_{mn}^h = (Z_w^{+z})_{mn}^{\text{TE}} = \begin{cases} \frac{\omega\mu}{\beta\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} = \frac{\sqrt{\frac{\mu}{\varepsilon}}}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} = \frac{\eta}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \\ \text{when } f > f_c = (f_c)_{mn} \end{cases} \quad (16b)$$

$$Z_{mn}^h = (Z_w^{+z})_{mn}^{\text{TE}} = \begin{cases} \frac{\omega\mu}{0} = \infty & \text{when } f = f_c = (f_c)_{mn} \end{cases} \quad (16c)$$

$$Z_{mn}^h = (Z_w^{+z})_{mn}^{\text{TE}} = \begin{cases} \frac{\omega\mu}{-j\beta\sqrt{\left(\frac{f_c}{f}\right)^2 - 1}} = +j \frac{\sqrt{\frac{\mu}{\varepsilon}}}{\sqrt{\left(\frac{f_c}{f}\right)^2 - 1}} = +j \frac{\eta}{\sqrt{\left(\frac{f_c}{f}\right)^2 - 1}} \\ \text{when } f < f_c = (f_c)_{mn} \end{cases} \quad (16d)$$

By examining through (16b)–(16d), we can make the following statements about the impedance.

1. Above cutoff it is real and greater than the intrinsic impedance of the medium inside the waveguide.
2. At cutoff it is infinity.

3. Below cutoff it is imaginary and inductive. This indicates that the waveguide below cutoff behaves as an inductor that is an energy storage element.

3. TRANSVERSE MAGNETIC (TM^z) MODES

The transverse magnetic to z (TM ^{z}) modes can be derived in a similar manner as the TE ^{z} modes of Section 2 by letting

$$\mathbf{A} = \hat{a}_z A_z(\rho, \phi, z) \tag{17a}$$

$$\mathbf{F} = 0 \tag{17b}$$

The vector potential \mathbf{A} must satisfy the vector wave equation, which reduces for the \mathbf{A} of (17a) to

$$\nabla^2 A_z(\rho, \phi, z) + \beta^2 A_z(\rho, \phi, z) = 0 \tag{18}$$

The solution of (18) is obtained in a manner similar to that of (2), as given by (4), and it can be written as

$$\begin{aligned} A_z(\rho, \phi, z) = & [A_1 J_m(\beta_\rho \rho) + B_1 Y_m(\beta_\rho \rho)] \\ & \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] \\ & \times [A_3 e^{-j\beta_z z} + B_3 e^{+j\beta_z z}] \end{aligned} \tag{19a}$$

with

$$\beta_\rho^2 + \beta_z^2 = \beta^2 \tag{19b}$$

The constants $A_1, B_1, C_2, D_2, A_3, B_3, m, \beta_\rho$, and β_z can be found using the boundary conditions of

$$E_\phi(\rho = a, \phi, z) = 0 \tag{20a}$$

or

$$E_z(\rho = a, \phi, z) = 0 \tag{20b}$$

$$\text{The fields must be finite everywhere} \tag{20c}$$

$$\text{The fields must repeat every } 2\pi \text{ radians in } \phi \tag{20d}$$

According to (20c), $B_1 = 0$ since $Y_m(\rho = 0) = \infty$. In addition, according to (20d),

$$m = 0, 1, 2, 3, \dots \tag{21}$$

Considering waves that propagate only in the $+z$ direction, (19a) then reduces to

$$\begin{aligned} A_z^+(\rho, \phi, z) = & B_{mn} J_m(\beta_\rho \rho) [C_2 \cos(m\phi) \\ & + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \tag{22}$$

The eigenvalues of β_ρ can be obtained by applying either (20a) or (20b).

From Eq. (22), we can write the electric field component E_z^+ as

$$\begin{aligned} E_z^+ = & -j \frac{1}{\omega \mu \epsilon} \left(\frac{\partial^2}{\partial z^2} + \beta^2 \right) A_z^+ \\ = & -j B_{mn} \frac{\beta_\rho^2}{\omega \mu \epsilon} J_m(\beta_\rho \rho) [C_2 \cos(m\phi) \\ & + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \tag{23}$$

Application of the boundary condition of (20b) using (23) gives

$$\begin{aligned} E_z^+(\rho = a, \phi, z) = & -j B_{mn} \frac{\beta_\rho^2}{\omega \mu \epsilon} J_m(\beta_\rho a) \\ & \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} = 0 \end{aligned} \tag{24}$$

which is satisfied only provided that

$$J_m(\beta_\rho a) = 0 \Rightarrow \beta_\rho a = \chi_{mn} \Rightarrow \beta_\rho = \frac{\chi_{mn}}{a} \tag{25}$$

In (25) χ_{mn} represents the n th zero ($n = 1, 2, 3, \dots$) of the Bessel function J_m of the first kind of order m ($m = 0, 1, 2, 3, \dots$). An abbreviated list of the zeros χ_{mn} of the Bessel function J_m is found in Table 2. The smallest value of χ_{mn} is 2.4049 ($m = 0, n = 1$).

By using (19b) and (25), β_z can be written as

$$(\beta_z)_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2} = \sqrt{\beta^2 - \left(\frac{\chi_{mn}}{a}\right)^2} \\ \text{when } \beta > \beta_\rho = \frac{\chi_{mn}}{a} \end{cases} \tag{26a}$$

Table 2. Zeros χ_{mn} of $J_m(\chi_{mn}) = 0$ ($n = 1, 2, 3, \dots$) of Bessel function $J_m(x)$

	$m = 0$	$m = 1$	$m = 2$	$M = 3$	$m = 4$	$m = 5$	$m = 6$	$m = 7$	$m = 8$	$m = 9$	$m = 10$	$m = 11$
$n = 1$	2.4049	3.8318	5.1357	6.3802	7.5884	8.7715	9.9361	11.0864	12.2251	13.3543	14.4755	12.8264
$n = 2$	5.5201	7.1056	8.4173	9.7610	11.0647	12.3386	13.5893	14.8213	16.0378	17.2412	18.4335	19.6160
$n = 3$	8.6537	10.1735	11.6199	13.0152	14.3726	15.7002	17.0038	18.2876	19.5545	20.8071	22.0470	23.2759

$n = 5$	14.9309	16.4706	17.9598	19.4094	20.8269	22.2178	23.5861	24.9349	26.2668	27.5838	28.8874	30.1791

$$(\beta_z)_{mn} = \begin{cases} 0 & \text{when } \beta = \beta_c = \beta_\rho = \frac{\chi_{mn}}{a} \end{cases} \quad (26b)$$

$$(\beta_z)_{mn} = \begin{cases} -j\sqrt{\beta_\rho^2 - \beta^2} = -j\sqrt{\left(\frac{\chi_{mn}}{a}\right)^2 - \beta^2} \\ \text{when } \beta < \beta_\rho = \frac{\chi_{mn}}{a} \end{cases} \quad (26c)$$

By following the same procedure as for the TE^z modes, we can write the expressions for the cutoff frequencies $(f_c)_{mn}$, propagation constant $(\beta_z)_{mn}$, and guide wavelength $(\lambda_g)_{mn}$ as

$$(f_c)_{mn} = \frac{\chi_{mn}}{2\pi a \sqrt{\mu\epsilon}} \quad (27)$$

$$(\beta_z)_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2} = \beta\sqrt{1 - \left(\frac{\beta_\rho}{\beta}\right)^2} = \beta\sqrt{1 - \left(\frac{\beta_c}{\beta}\right)^2} \\ = \beta\sqrt{1 - \left(\frac{\chi_{mn}}{\beta a}\right)^2} = \beta\sqrt{1 - \left(\frac{f_c}{f}\right)^2} \\ \text{when } f > f_c = (f_c)_{mn} \end{cases} \quad (28a)$$

$$(\beta_z)_{mn} = \begin{cases} 0 & \text{when } f = f_c = (f_c)_{mn} \end{cases} \quad (28b)$$

$$(\beta_z)_{mn} = \begin{cases} -j\sqrt{\beta_\rho^2 - \beta^2} = -j\beta\sqrt{\left(\frac{\beta_\rho}{\beta}\right)^2 - 1} = -j\beta\sqrt{\left(\frac{\beta_c}{\beta}\right)^2 - 1} \\ = -j\beta\sqrt{\left(\frac{\chi_{mn}}{\beta a}\right)^2 - 1} = -j\beta\sqrt{\left(\frac{f_c}{f}\right)^2 - 1} \\ \text{when } f < f_c = (f_c)_{mn} \end{cases} \quad (28c)$$

$$(\lambda_g)_{mn} = \begin{cases} \frac{2\pi}{\beta\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} = \frac{\lambda}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} & \text{when } f > f_c = (f_c)_{mn} \end{cases} \quad (29a)$$

$$(\lambda_g)_{mn} = \begin{cases} \infty & \text{when } f = f_c = (f_c)_{mn} \end{cases} \quad (29b)$$

According to (27) and the values of χ_{mn} of Table 2, the order (lower to higher cutoff frequencies) in which the TM^z modes occur is TM_{01} , TM_{11} , TM_{21} , and so forth. The bandwidth of the first single-mode TM_{01}^z operation is $3.8318/2.4059 = 1.5927:1$. Comparing the cutoff frequencies of the TE^z and TM^z modes, as given by (12b) and (27) along with the data of Tables 1 and 2, the order of the TE_{mn}^z and TM_{mn}^z modes is that of TE_{11} ($\chi'_{11} = 1.8412$), TM_{01} , ($\chi_{01} = 2.4049$), TE_{21} ($\chi'_{21} = 3.0542$), TE_{01} ($\chi'_{01} = 3.8318$) = TM_{11} ($\chi'_{11} = 3.8318$), TE_{31} ($\chi'_{31} = 4.2012$), and so forth. The dominant mode is TE_{11} and its bandwidth of single-mode operation is $2.4049/1.8412 = 1.3062:1$. Plots of the field configurations over a cross section of the waveguide,

both E and H , for the first 30 TE_{mn}^z and/or TM_{mn}^z modes are shown in Fig. 2 [1].

It is apparent that the cutoff frequencies of the TE_{0n} and TM_{1n} modes are identical; therefore they are referred to here also as *degenerate modes*.

The electric and magnetic field components can be written using (22) as

$$\begin{aligned} E_\rho^+ &= -j \frac{1}{\omega\mu\epsilon} \frac{\partial^2 A_z^+}{\partial\rho\partial z} \\ &= -B_{mn} \frac{\beta_\rho\beta_z}{\omega\mu\epsilon} J'_m(\beta_\rho\rho) \\ &\quad \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (30a)$$

$$\begin{aligned} E_\phi^+ &= -j \frac{1}{\omega\mu\epsilon} \frac{1}{\rho} \frac{\partial^2 A_z^+}{\partial\phi\partial z} \\ &= -B_{mn} \frac{m\beta_z}{\omega\mu\epsilon\rho} J_m(\beta_\rho\rho) \\ &\quad \times [-C_2 \sin(m\phi) + D_2 \cos(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (30b)$$

$$\begin{aligned} E_z^+ &= -j \frac{1}{\omega\mu\epsilon} \left(\frac{\partial^2}{\partial z^2} + \beta^2 \right) A_z^+ \\ &= -j B_{mn} \frac{\beta_\rho^2}{\omega\mu\epsilon} J_m(\beta_\rho\rho) \\ &\quad \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (30c)$$

$$\begin{aligned} H_\rho^+ &= \frac{1}{\mu} \frac{1}{\rho} \frac{\partial A_z^+}{\partial\phi} = B_{mn} \frac{m}{\mu} \frac{1}{\rho} J_m(\beta_\rho\rho) \\ &\quad \times [-C_2 \sin(m\phi) + D_2 \cos(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (30d)$$

$$\begin{aligned} H_\phi^+ &= -\frac{1}{\mu} \frac{\partial A_z^+}{\partial\rho} = -B_{mn} \frac{\beta_\rho}{\mu} J'_m(\beta_\rho\rho) \\ &\quad \times [C_2 \cos(m\phi) + D_2 \sin(m\phi)] e^{-j\beta_z z} \end{aligned} \quad (30e)$$

$$H_z^+ = 0 \quad (30f)$$

where

$$' = \frac{\partial}{\partial(\beta_\rho\rho)} \quad (30g)$$

By using (30a)–(30f), the wave impedance in the $+z$ direction can be written as

$$(Z_w^{+z})_{mn}^{\text{TM}} = \frac{E_\rho^+}{H_\phi^+} = -\frac{E_\phi^+}{H_\rho^+} = \frac{(\beta_z)_{mn}}{\omega\epsilon} \quad (31)$$

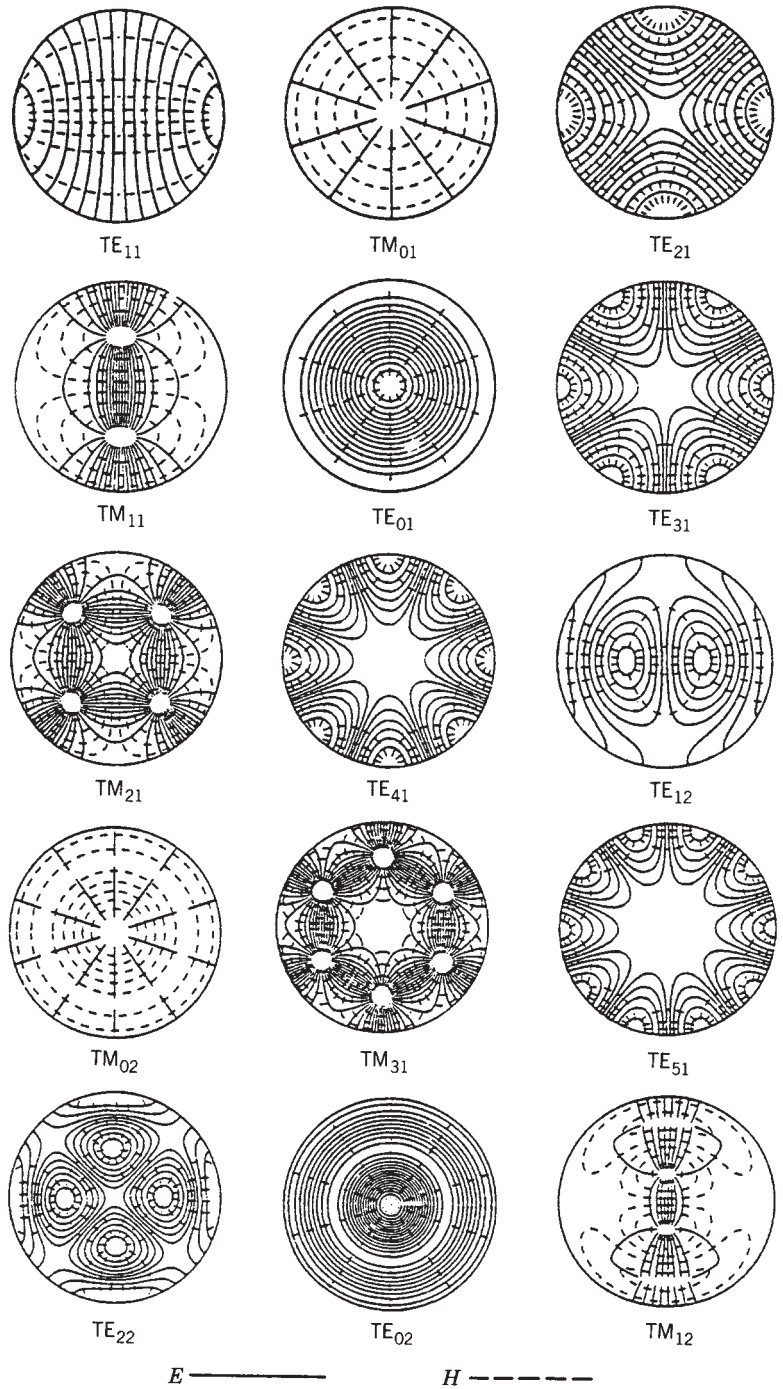

Figure 2. Field configurations of first 30 TE^z and/or TM^z modes in a circular waveguide. (Source: C. S. Lee, S. W. Lee, and S. L. Chuang, Plot of modal field distribution in rectangular and circular waveguides, *IEEE Trans. Microwave Theory Tech.*, © 1985, IEEE.)

With the aid of (28a)–(28c) the wave impedance of (31) reduces to

$$(Z_w^{+z})_{mn}^{TM} = \begin{cases} \frac{\beta \sqrt{1 - \left(\frac{f_c}{f}\right)^2}}{\omega \epsilon} = \sqrt{\frac{\mu}{\epsilon}} \sqrt{1 - \left(\frac{f_c}{f}\right)^2} = \eta \sqrt{1 - \left(\frac{f_c}{f}\right)^2} \\ \text{when } f > f_c = (f_c)_{mn} \end{cases} \quad (32a)$$

$$(Z_w^{+z})_{mn}^{TM} = \begin{cases} 0 \\ \frac{0}{\omega \epsilon} = 0 \end{cases} \text{ when } f = f_c = (f_c)_{mn} \quad (32b)$$

$$(Z_w^{+z})_{mn}^{TM} \left\{ \begin{aligned} \frac{-j\beta \sqrt{\left(\frac{f_c}{f}\right)^2 - 1}}{\omega \epsilon} &= -j\sqrt{\frac{\mu}{\epsilon}} \sqrt{\left(\frac{f_c}{f}\right)^2 - 1} \\ &= -j\eta \sqrt{\left(\frac{f_c}{f}\right)^2 - 1} \\ &\text{when } f < f_c = (f_c)_{mn} \end{aligned} \right. \quad (32c)$$

Examining (32a)–(32c) we can make the following statements about the wave impedance for the TM^z modes.

Figure 2. (Continued).

1. Above cutoff it is real and smaller than the intrinsic impedance of the medium inside the waveguide.
2. At cutoff it is zero.
3. Below cutoff it is imaginary and capacitive. This indicates that the waveguide below cutoff behaves as a capacitor that is an energy storage element.

Whenever a given mode is desired, it is necessary to design the proper feed to excite the fields within the waveguide and detect the energy associated with such modes. To maximize the energy exchange or transfer, this is accomplished by designing the feed, which is usually a probe

or antenna, so that its field pattern matches that of the field configuration of the desired mode. Usually the probe is placed near the maximum of the field pattern of the desired mode; however, that position may be varied somewhat in order to achieve some desired matching in the excitation and detection systems. Shown in Fig. 3 are suggested designs to excite and/or detect the TE_{11} and TM_{01} modes in a circular waveguide, to transition between the TE_{10} of a rectangular waveguide and the TE_{11} mode of a circular waveguide, and to couple between the TE_{10} of a rectangular waveguide and TM_{01} mode of a circular waveguide.

Figure 3. Excitation of TE_{mn} and TM_{mn} modes in a circular waveguide: (a) TE_{11} mode; (b) TM_{01} mode; (c) TE_{10} (rectangular)- TE_{11} (circular); (d) TE_{10} (rectangular)- TM_{01} (circular).

4. ATTENUATION FROM OHMIC LOSSES

It has been shown that the attenuation coefficients of the TE_{0n} ($n = 1, 2, \dots$) modes in a circular waveguide monotonically decrease as a function of frequency [2,3]. This is a very desirable characteristic, and because of this the excitation, propagation, and detection of TE_{0n} modes in a circular waveguide have received considerable attention. The attenuation coefficient for the TE_{mn}^z and TM_{mn}^z modes inside a circular waveguide are given, respectively, by

$$\begin{aligned}
 & TE_{mn}^z \\
 (\alpha_c)_{mn}^{TE^z} &= \frac{R_s}{a\eta \sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \\
 & \times \left[\left(\frac{f_c}{f}\right)^2 + \frac{m^2}{(\gamma'_{mn})^2 - m^2} \right] \text{Np/m}
 \end{aligned} \tag{33a}$$

$$\begin{aligned}
 & TM_{mn}^z \\
 (\alpha_c)_{mn}^{TM^z} &= \frac{R_s}{a\eta} \frac{1}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \text{Np/m}
 \end{aligned} \tag{33b}$$

where

$$R_s = \sqrt{\frac{\omega\mu}{2\sigma}} \tag{34}$$

Plots of the attenuation coefficient versus the normalized frequency f/f_c , where f_c is the cutoff frequency of the dom-

inant TE_{11} mode, are shown for six modes in Fig. 4a and b for waveguide radii of 1.5 and 3 cm, respectively. Within the waveguide is free space and its walls are made of copper ($\sigma = 5.7 \times 10^7 \text{ S/m}$).

It is evident from the results of the preceding example that as f_c/f becomes smaller the attenuation coefficient decreases monotonically (as shown in Fig. 4), which is a desirable characteristic. It should be noted that similar monotonically decreasing variations in the attenuation coefficient are evident in all TE_{0n} modes ($n = 1, 2, 3, \dots$). According to (15a)–(15f), the only tangential magnetic field component to the conducting surface of the waveguide for all these TE_{0n} ($m = 0$) modes is the H_z component, while the electric field lines are circular. Therefore these modes are usually referred to as circular electric modes. For a constant power in the wave, the H_z component decreases as the frequency increases and approaches zero at infinite frequency. Simultaneously the current density and conductor losses on the waveguide walls also decrease and approach zero. Because of this attractive feature, these modes have received considerable attention for long-distance propagation of energy, especially at millimeter-wave frequencies. Typically attenuations as low as 1.25 dB/km (2 dB/mi) have been attained [2]. This is to be compared with attenuations of 120 dB/km for WR-90 copper rectangular waveguides, and 3 dB/km at $0.85 \mu\text{m}$, and less than 0.5 dB/km at $1.3 \mu\text{m}$ for fiberoptic cables.

Although the TE_{0n} modes are very attractive from the attenuation point of view, there are a number of problems associated with their excitation and retention. One of the problems is that the TE_{01} mode, which is the first of the TE_{0n} modes, is not the dominant mode. Therefore in order for this mode to be above its cutoff frequency and propagate in the waveguide, a number of other modes (such as the TE_{11} , TM_{01} , TE_{21} , and TM_{11}) with lower cutoff frequencies can also exist. Additional modes can also be present if the operating frequency is chosen well above the cutoff frequency of the TE_{01} mode in order to provide a margin of safety from being too close to its cutoff frequency.

To support the TE_{01} mode, the waveguide must be oversized and it can support a number of other modes. One of the problems faced with such a guide is how to excite the desired TE_{01} mode with sufficient purity and suppress the others. Another problem is how to prevent coupling between the TE_{01} mode and undesired modes. The presence of the undesired modes causes not only higher losses but also dispersion and attenuation distortion to the signal since each exhibits different phase velocities and attenuation. Irregularities in the inner geometry, surface, and direction (bends, nonuniform cross sections, etc.) of the waveguide are the main contributors to the coupling to the undesired modes. However, for the guide to be of any practical use, it must be able to sustain and propagate the desired TE_{01} and other TE_{0n} modes efficiently over bends of reasonable curvature. One technique that has been implemented to achieve this is to use mode conversion before entering the corner and another conversion when exiting to convert back to the desired TE_{0n} mode(s).

Figure 4. Attenuation for TE_{mn}^z and TM_{mn}^z modes in a circular waveguide: (a) $a = 1.5$ cm; (b) $a = 3$ cm.

Another method that has been used to discriminate against undesired modes and avoid coupling to them is to introduce filters inside the guide that cause negligible attenuation to the desired TE_{0n} mode(s). These filters introduce cuts that are perpendicular to the current paths of the undesired modes and parallel to the current direction

of the desired mode(s). Since the current path of the undesired modes is along the axis (z direction) of the guide and the path of the desired TE_{0n} modes is along the circumference (ϕ direction), a helical wound wire placed on the inside surface of the guide can serve as a filter that discourages any mode that requires an axial

α_c	$\frac{R_s}{a \eta \sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \left[\left(\frac{f_c}{f}\right)^2 + \frac{m^2}{(\gamma'_{mn})^2 - m^2} \right]$	$\frac{R_s}{a \eta} \frac{1}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}}$

component of current flow but propagates the desired TE_{0n} modes [3,4].

Another means to suppress undesired modes is to introduce within the guide very thin baffles of lossy material that will act as attenuating sheets. The surfaces of the baffles are placed in the radial direction of the guide so that they are parallel to the E_ρ and E_z components of the undesired modes (which will be damped) and normal to the E_φ component of the TE_{0n} modes that will remain unaffected. Typically two baffles are placed in a crossed pattern over the cross section of the guide.

A summary of the pertinent characteristics of the TE_{mn}^z and TM_{mn}^z modes of a circular waveguide are found listed in Table 3.

open-ended configuration, impedance steps, capacitive windows, T junctions, small elliptical and circular apertures, aperture coupling between two coaxial lines, and bifurcation of a coaxial line. The configurations and the equivalent circuits for some of the discontinuities are shown in Fig. 1. The mode-matching technique with variational formulation is the commonly used approach to arrive at the equivalent-circuit parameters of discontinuities. The available results for some of these discontinuities are summarized in the following sections.

COAXIAL LINE DISCONTINUITIES

R. GARG
 Indian Institute of Technology
 Kharagpur
 Kharagpur, India

Various types of coaxial-line discontinuities have been discussed in the literature [1-4], including: capacitive gaps,

1. CAPACITIVE GAPS IN COAXIAL LINES

A gap in the center conductor of a coaxial line, as shown in Fig. 1a, introduces mainly a series capacitance in the line. This type of discontinuity finds common use in microwave filters, DC blocks, and coaxial-line reentrant cavity.

Figure 1. Discontinuities in coaxial lines and their equivalent circuits.

Figure 2. Equivalent circuit for the evaluation of capacitive gap discontinuities.

If the gap width is small compared to the wavelength, the problem can be treated electrostatically and the equivalent circuit of the gap discontinuity may be formulated as shown in Fig. 1a. For the purpose of analysis, the equivalent circuit may be written as shown in Fig. 2. The series and shunt capacitances are determined by computing three capacitances: total capacitances of a length of line (1) with a short circuit at plane AA, (2) with an open circuit at the plane AA, and (3) with no discontinuity. The section of line must be sufficiently long to ensure that an undisturbed field distribution is obtained at the end located away from the discontinuity. This condition is fulfilled if the linelength is equal to or greater than the diameter of the outer conductor. Numerical results for various gap widths and diameter ratios are given in Table 1 [3].

Gap capacitances for diameter ratios 5-1 and 7-1 are also given in Refs. 3 and 4. The values of capacitances C_1 and C_2 of Table 1 can also be utilized to determine capacitances for the open-end configuration and for the configuration shown in Fig. 3. The open-end capacitance is given by C_2 when $s \rightarrow \infty$. The capacitance with the short-circuiting plane at a distance s from the inner conductor is C , and is given by $(2C_1 + C_2)$. A closed-form expression for the capacitance C is written as follows [3,4]:

$$C = \frac{\pi a^2 \epsilon_0 \epsilon_r}{s} + 4a \epsilon_0 \epsilon_r \ln \left(\frac{b-a}{s} \right) \quad (1)$$

This equation is valid under the condition $\lambda_0 \gg (b-a) \gg s$. The first term in (1) is the parallel-plate capacitance between the face of the inner conductor and the short-circuiting plane. The second term is the fringing capacitance.

Figure 3. Coaxial line with short circuit (coaxial-line reentrant cavity) and its equivalent circuit.

It may be observed from Table 1 that C_2 approaches zero for vanishingly small gap width and therefore, the series capacitance C_1 is dominant in (1). As gap width increases, C_2 increases linearly but the decrease in C_1 is faster. Expression (1) is accurate to within 5% for small gaps ($s/a < 0.1$). For a 50-Ω line the error is less than 1.5%.

Variational analysis of the geometry of Fig. 2 shows that the capacitances C_1 and C_2 increase with frequency [5]. Variation of these capacitances with normalized frequency $k_0 b$ is shown in Fig. 4 for $s/a = 0.25$ and 0.025 in a 50-Ω line [5]. It is seen that while the shunt capacitance C_2 increases very slowly (almost negligibly) with frequency, the series capacitance C_1 increases much more rapidly and shows a sharp increase near the cutoff frequency of cylindrical waveguide TM_{01} mode. Variational analysis of a gap in the central conductor of a rectangular coaxial line has been reported [6]. The behavior of gap capacitances with gap width and frequency is similar to that in a cylindrical coaxial line. The gap capacitance in the coaxial line can also be described in terms of the associated reflection coefficient Γ . Eom et al. have used the mode-matching method to determine Γ for a coaxial line terminated in a gap [7]. A rapidly converging series for Γ has been obtained. The effect of dielectric inhomogeneity in the gap has been included.

2. OPEN-ENDED COAXIAL LINE

The schematic of an open-ended coaxial line with an infinite flange and its equivalent circuit are shown in Fig. 1b. The equivalent circuit consists of a parallel combination

of a capacitor C and a resistor R at the flange. The capacitance C arises from the fringing electric field between the center conductor and outer conductor of the coaxial line. The shunt resistance R represents the power loss due to radiation from the open end. Quasistatic analysis of the open-ended coaxial line has been described [8]. The aperture admittance at the flange may be written as [8]

$$Y_L = G_r + jB \quad (2)$$

where $G_r = 1/R$ and $B = \omega C$ and

$$B = \frac{2\omega\epsilon^*}{[\ln(b/a)]^2} \left[I_1 - \frac{k^2 I_2}{2} \right] \quad (3)$$

$$G_r = \frac{k^3 \pi \omega \epsilon^*}{12} \left[\frac{b^2 - a^2}{\ln(b/a)} \right]^2 \quad (4)$$

$$k^2 = \omega^2 \mu_0 \epsilon^*$$

where $\epsilon^* = \epsilon' - j\epsilon''$ represents the terminating medium at the flange. The coefficients I_1 and I_2 are defined as

follows:

$$I_1 = \int_a^b \int_a^b \int_0^\pi \frac{\cos \phi'}{(\rho^2 + \rho'^2 - 2\rho\rho' \cos \phi')^{1/2}} \times d\phi' d\rho' d\rho \quad (5a)$$

$$I_2 = \int_a^b \int_a^b \int_0^\pi \cos \phi' (\rho^2 + \rho'^2 - 2\rho\rho' \cos \phi')^{1/2} \times d\phi' d\rho' d\rho \quad (5b)$$

Computed values of integrals I_1 and I_2 for a few commercially available coaxial lines are given in Table 2 [8].

It may be pointed out that the first term in (3) describes the upper bound for the static capacitance of the opening, while the second term gives the frequency-dependent part of the capacitance. Comparison with the data based on finite-element method (FEM) or method-of-moment (MoM) analysis shows good agreement [8].

Using the values of I_1 and I_2 from Table 2, the following expressions for the capacitance C may be derived from (3):

For a 3.6-mm Teflon-filled coaxial line in free space (f in MHz):

$$C(\text{pF}) = 0.0221 + 0.3453 \times 10^{-11} f^2 \quad (6a)$$

For a 6.4-mm Teflon-filled coaxial line in free space (f in MHz):

$$C(\text{pF}) = 0.03999 + 1.9687 \times 10^{-11} f^2 \quad (6b)$$

An open-ended coaxial line exciting a monopole probe (Fig. 5) has been used for permittivity measurements of biological materials. The biological tissues consist essentially of water; free ions such as Na^+ , K^+ , Ca^{2+} , Cl^- ; and a number of proteins. This composition makes the dielectric properties of the tissues similar to those of saline solutions, which are characterized by a high loss factor at microwave frequencies. The probe is used as a sensor for permittivity measurements. The sensor is placed in

Figure 5. Coaxial-line-excited monopole probe for permittivity measurement.

contact with the material under test, and the reflection coefficient Γ is measured. Knowledge of the relationship between the measured Γ and the permittivity ϵ then allows one to determine the latter. A number of models have been developed to determine ϵ , including the capacitive model, the antenna model, the equivalent transmission-line model, and the rational function model. A comparative study of these models for a lossy material is available in Ref. 9, where it is concluded that the equivalent transmission-line model for biological tissue characterization is adequate.

3. REFLECTION STANDARD FOR COAXIAL LINES

A short-circuited coaxial line can be used as a reflection standard only at one frequency for which it is a quarter-wave long. However, an open-circuited coaxial line with extended outer conductor as shown in Fig. 1c, can be used as a broadband reflection standard with minimal losses. Also, this reflection standard can be fabricated easily using commercially available components. Variational analysis of this device has been reported elsewhere in the literature [2,10–12]. If the coaxial line/circular waveguide combination is operated below the cutoff frequency of the dominant mode in circular waveguide, the signal will get attenuated in the waveguide. In addition, if the waveguide is sufficiently long to attenuate the signal by ~ 50 dB, the radiation from the waveguide will be negligible. Therefore, the coaxial line/waveguide junction will be capacitive in nature. Bianco et al. [12] have computed the junction capacitance. The variation of junction capacitance with frequency for a 50- Ω 7-mm airline ($2b = 7$ mm, $\epsilon_r = 1.000640$) is given by the following expression [12]

$$C = \frac{C(0)}{(1 - (f_{\text{MHz}}/34450)^2)^{1/2}} \quad (7)$$

where $C(0)$ is the static capacitance and is 79.70 fF for the 7-mm line.

4. STEPS IN COAXIAL LINES

The step in a coaxial line can be due to (1) an abrupt change in the diameter of either the inner conductor (Fig. 1d) or the outer conductor (Fig. 1e) or (2) a simultaneous change in diameters of both the conductors. In other words, the step discontinuity may arise when two coaxial lines with different characteristic impedances are connected in cascade. Here, a_1 and b_1 are the radii of the inner and

outer conductors of one coaxial line and a_2 and b_2 represent the same for the other coaxial line. The step discontinuity may also result when a coaxial line is butt-terminated in a connector with the same impedance. The equivalent circuit of a step can be described by a shunt capacitance at the plane of the step as shown in Figs. 1d and 1e. The capacitance does not vary appreciably with frequency if the cross-sectional dimensions of the line at the plane of discontinuity are small fractions of the wavelength.

Discontinuity capacitance can be computed using the mode-matching technique for determining the difference in capacitances between that of the structure with the discontinuity, and that computed by adding the contributions of two single unperturbed lines with cross-sectional dimensions and lengths equal to the actual lines on each side of the step. The lines may be terminated by magnetic walls after a distance equal to one diameter on each side of the step. This technique has been used in Refs. 1 and 13. Gogioso et al. [14] have used the variational method to calculate the discontinuity capacitance. FEM has been used in Ref. 15 to analyze the double-step discontinuity; computed results for a butt transition between a coaxial line and a 7-mm precision connector are presented there.

Somlo [13] has obtained closed-form expressions for the discontinuity capacitance:

Step on the inner conductor (i.e., $b_1 = b_2 = b$; Fig. 1d):

$$\frac{C}{2\pi b} \text{ (F/m)} = \frac{\epsilon}{\pi} \left[\frac{\alpha^2 + 1}{\alpha} \ln \frac{1 + \alpha}{1 - \alpha} - 2 \ln \frac{4\alpha}{1 - \alpha^2} \right] + 1.11 \times 10^{-15} (1 - \alpha)(\tau - 1) \quad (8)$$

where $\alpha = (b - a_2)/(b - a_1)$ and $\tau = (b/a_1)$. The maximum error in (8) is ± 30 fF/m for $0.01 \leq \alpha \leq 1.0$ and $1.0 < \tau \leq 6.0$. In the limiting case when $a_1 \rightarrow 0$, $\tau \rightarrow \infty$, an expression for the step discontinuity obtained from Fig. 1 of Ref. 13 is given as follows:

$$\frac{C}{2\pi b} \text{ (F/m)} = \frac{2\epsilon}{\pi} (1.477 - \ln 4\alpha) \quad (9)$$

where $\alpha = (b - a)/b$. Equation (9) may be used to determine $C(0)$ for (7) [e.g., one obtains $C(0) = 80.7$ fF for 50- Ω 7-mm airline; this compares favorably with the computed value of 79.7 fF].

Step on the outer conductor (i.e., $a_1 = a_2 = a$; Fig. 1e):

$$\frac{C}{2\pi a} \text{ (F/m)} = \frac{\epsilon}{\pi} \left[\frac{\alpha^2 + 1}{\alpha} \ln \frac{1 + \alpha}{1 - \alpha} - 2 \ln \frac{4\alpha}{1 - \alpha^2} \right] + 4.12 \times 10^{-15} (0.8 - \alpha)(\tau - 1.4) \quad (10)$$

where $\alpha = (b_1 - a)/(b_2 - a)$ and $\tau = (b_2/a)$. The maximum error in (10) is ± 60 fF/m for $0.01 \leq \alpha \leq 0.7$ and $1.5 \leq \tau \leq 6.0$. The stepsize decreases as α increases from 0 to 1. For simultaneous steps in both the conductors, the discontinuity capacitance can be determined approximately from the discontinuity capacitances associated with step in either (inner or outer) conductor [3,4].

The frequency dependence of step capacitance has been included in Ref. 13 through a multiplier factor K that has been plotted for five different combinations of α and τ . This plot is included here as Fig. 6. The S matrix for a step discontinuity in the inner conductor of rectangular coaxial lines has been described by Xu et al. [16]. The mode-matching method in conjunction with FEM has been employed to improve accuracy and efficiency.

5. T JUNCTION OR STUB IN COAXIAL LINES

The configuration of a T junction and its equivalent circuit are shown in Fig. 7. The branchline can be viewed as a shunt circuit in parallel with the mainline. Experimental results for a specific set of parameters are available for $\lambda_0 = 10$ cm [17]. The T junction finds application in branchline couplers, filters, and other components and has been analyzed in a rectangular coaxial line [16] using mode matching, and FEM techniques. The analysis has been extended to a branchline directional coupler.

Other types of discontinuity in coaxial lines that occur less frequently, such as capacitive windows in a coaxial line, aperture coupling between two coaxial lines, bifurcation of a coaxial line, small elliptical and circular apertures in the outer conductor, and a coaxial line with infinite central conductor, are discussed in Ref. 1.

1. INTRODUCTION

Starting with Maxwell's theoretical concept of wave propagation in the 1870s, followed by Heinrich Hertz' experimental proof of the transmission of electromagnetic wave energy in the 1890s, RF-microwave technologies saw extraordinary advances during the nineteenth and twentieth centuries. Progress in this field, particularly its application in high-frequency wired and wireless communications technology, has hinged most critically on the efficient transmission and reception of electromagnetic energy through various media. Without carefully designed transmission lines, RF and microwave technologies could not have undergone further development and modern civilization could certainly not have reached the present "information age." In everything from a handheld GPS receiver to a jumbo jet, transmission-line design is of crucial importance to proper operation. The sheer diversity of RF-microwave devices available today means that RF-microwave designers must spend most of their time tuning transmission lines, matching various sections, and designing controlled attenuation to other parts of the system. For example, while a mobile phone consists of high-frequency microstrip transmission lines in planar multilayered circuits, a jumbo jet has 275 km of cables of various forms, including low-frequency lighting, high-frequency navigation tools, and wireless terrestrial and satellite navigation and communication equipment. Just as High-frequency devices and gadgets such as radios, television sets, satellite ground stations, and satellite payloads are useless without efficient transmission lines, adapters, and assemblies in the same way that the main engine block in an automobile is useless without conduits, nuts, and bolts. Transmission lines are guiding structures that convey high-frequency electromagnetic energy from one block to another. Their careful design for amplitude and phase matching is therefore extremely important.

The high-frequency transmission line industry is a huge enterprise. According to <http://www.global-spec.com>, 186 coaxial cable manufacturing companies and 60 waveguide manufacturing companies operate in the United States alone. Moreover, 585 companies

manufacture cable assemblies, including connectors, adapters, and attenuators. In the year 2000, the market volume increased by about 25%. This is due to rapid growth of wireless mobile communications and other sectors. With the emergence of new innovative technologies in the twenty-first century, such growth is expected to continue at a still higher rate.

High-frequency cables, waveguides, and accessories are usually very expensive items because they require manufacturing to high standards and tolerances. The most common forms of such transmission lines are coaxial cables and waveguides. For RF–microwave frequencies, which span anything from a few MHz to 30 GHz, the coaxial line is the oldest and most widely used devices for transferring RF energy from one point to another. Heinrich Hertz used coaxial cables in his experiments to prove Maxwell’s theory of electromagnetic wave propagation. Hertz used coaxial lines to generate the standing waves. In the 1930s when radios became very popular, coaxial transmission lines were used exclusively at low frequencies such as VHF and UHF applications. The shielding properties of coaxial lines minimize the static interference of charge leakage at low frequencies. For higher-frequency applications such as 1 GHz and above, waveguide structures are generally used. The waveguide is preferred because of its low transmission losses and high power-handling capabilities. In 1897, Lord Rayleigh mathematically proved the concept of wave propagation through single-conductor rectangular and circular waveguides. He also proved the existence of a cutoff frequency below which no wave can propagate through the waveguide. Following the example of Lord Rayleigh, Sir Jagadish Chandra Bose invented waveguides and used these waveguides in his wireless experiments in 1894. He also invented waveguide horn antennas for millimeter-wave transmission and reception. Sir Jagadish Bose extensively used scientific demonstrations of EM wave propagations and detections in his teaching classes in the Presidency College of Kolkata, India. Also in 1894, Sir Oliver Lodge observed directional radiation when he surrounded a spark oscillator with a metal tube. Because high-frequency sources were not widely available, not much work was conducted on waveguides until about 1930. After this time, scientists from AT&T and MIT radiation laboratory rediscovered the waveguide and developed a theoretical framework to explain the cutoff frequencies and propagation modes. During and after World War II, the design and use of various coaxial cables and waveguides advanced with new thrusts for emerging applications in radars and wireless communications.

In this article we first describe the classical theory in which transmission lines are assumed to be a distributed section of series resistance and inductance, as well as shunt capacitance and conductance. This model is then evolved into the “telegrapher equation,” which explains the wave nature of electromagnetic energy guided by a two-conductor transmission line. Basic characteristic parameters such as the propagation constant, phase velocity, and characteristic impedance are derived. This generalized transmission line theory can be applied to any transmission-line type. Finally, the field theory of transmission

lines is used to derive coaxial transmission-line theory. Practical examples of various coaxial cables and cable assemblies available on the market are also presented. Different waveguide configurations such as parallel-plate, rectangular, circular, and elliptical waveguides are discussed and propagation modes in the waveguide are defined. Planar waveguides such as microstrip lines, slotlines, and coplanar waveguides are also presented.

2. CLASSIFICATION OF TRANSMISSION LINES

Most practical waveguide structures rely on single-mode propagation in a particular direction. They can consequently be conveniently classified according to the polarization properties of the electromagnetic waves they carry: transverse electromagnetic (TEM), transverse electric (TE), or transverse magnetic (TM) modes. TEM modes have both electric and magnetic fields transverse to the direction of propagation. In TM mode, the magnetic field is transverse to the direction of propagation and in TE mode, the electric field is transverse to the direction of propagation. Mathematically, these modes for a wave propagating in the z direction can be represented as follows:

1. TEM waves: $E_z = 0, H_z = 0$
2. TM waves: $E_z \neq 0, H_z = 0$
3. TE waves: $E_z = 0, H_z \neq 0$
4. Hybrid waves: $E_z \neq 0, H_z \neq 0$

Transmission lines can be classified with respect to polarization, as shown in the tree diagram in Fig. 1. TEM is the dominant mode of propagation in coaxial lines and parallel-plate transmission lines where two conductors are involved. TE and TM propagation modes are typically found in single-conductor waveguides, which have rectangular, circular, elliptical or ridge-type cross sections. Other than TEM, TE, or TM modes, hybrid modes are also known that contain all six components ($E_x, E_y, E_z, H_x, H_y, H_z$) of electric and magnetic fields. Examples of transmission lines that support hybrid modes of propagation include microstrip (MS) transmission line, slotline (SL), and coplanar waveguide (CPW) structure.

The various forms of transmission lines are shown in Fig. 2. Figure 2a illustrates the most typical such lines: a parallel, two-conductor transmission line in which the conductors are uniformly separated by an air dielectric. The evolution of waveguides away from the two-conductor transmission line can perhaps be best understood in terms of the theory of quarter-wave transformers. A quarter-wave section of a short-circuited transmission line is transformed by an operating frequency into an open circuit at the input end of the line. The waveguide is then considered to be two short-circuited, quarter-wave sections along the two-wire transmission line. The cutoff in the waveguide’s frequency dependence can be understood in terms of the behavior of the quarter-wave section of the line.

Figure 2b depicts a coaxial cable where the center conductor is concentric with the outer cylindrical conductor,

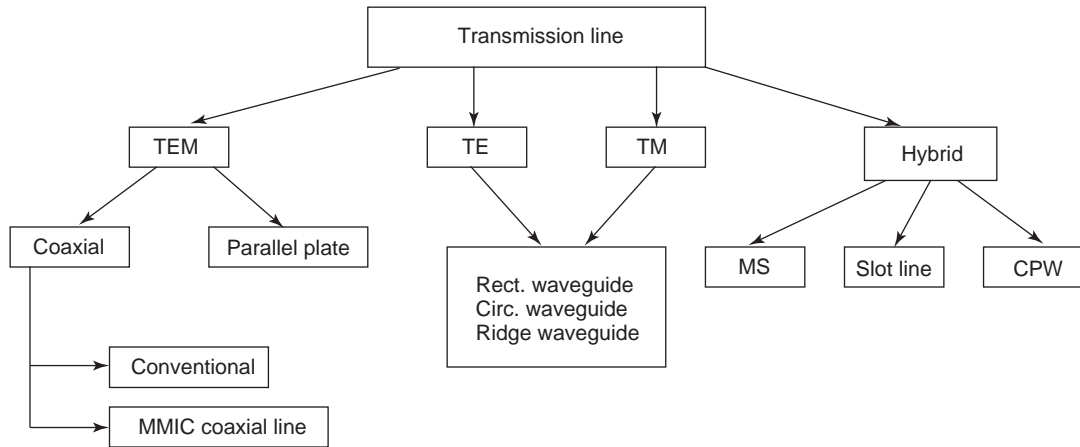

Figure 1. Classification of transmission lines based on a single mode of wave propagation.

which is usually the ground for the transmission line. As such, it acts as the shield for outside interference. The uniform gap between the two conductors is filled with a

dielectric material. The advantage of the coaxial cable is its high immunity to interfering signals due to the shielding provided by the outer conductor of the information-carrying signal.

Other forms of high-frequency transmission lines are dielectric waveguides (not shown here), parallel-plate waveguides (Fig. 2e), and planar transmission lines such as microstrip lines (Fig. 2f) and striplines (Fig. 2g).

Table 1 compares the three most popular transmission lines used in modern microwave circuits and systems: coaxial cables, waveguides, and microstrip lines. As can be seen, each line has its own advantages and disadvantages. While coaxial cables are popular in network-related, low- and medium-frequency operation, waveguides are preferred in high-frequency and high-power applications. At high frequencies, both coaxial cables and microstrip lines exhibit high power losses and signal distortions. Because of their better power-handling capability, waveguides are popular for radars and similar high-power, high-frequency applications in which their physical bulk is not a hindrance. For compact and portable, lightweight gadgets such as mobile phones, handheld GPS receivers, and some solid-state, high-power amplifier modules, microstrip lines are preferred. To compensate for the losses they suffer as a result of high attenuation, amplifiers are typically used. Transmission lines and circuit formats are therefore selected according to their specification requirements and applications.

Figure 2. Commonly used waveguide structures: (a) open two-wire line; (b) coaxial line; (c) rectangular waveguide; (d) circular waveguide; (e) parallel-plate waveguide; (f) microstrip line; (g) stripline.

3. TRANSMISSION LINE THEORY: LUMPED-ELEMENT CIRCUIT MODEL

A transmission line is often schematically represented by a two-wire line, because transmission lines for TEM wave propagation always have at least two conductors. Figure 3 illustrates a differential length (Δz) of a two-conductor transmission line represented by a distributed parameter network. The voltages and currents vary in magnitude and phase over its length. The distributive parameters are

$$R = \text{resistance per unit length}$$

$$L = \text{inductance per unit length}$$

Table 1. Comparison of Common Transmission Lines and Waveguides

Characteristic	Coaxial line	Rectangular Waveguide	Microstrip line
Preferred mode	TEM	TE ₁₀	Quasi-TEM
Dispersion	None	Medium	Low
Bandwidth	High	Low	High
Power-handling capacity	Medium	High	Low
Loss/attenuation	Medium	Low	High
Physical size	Large	Large	Small
Ease of fabrication	Medium	Medium	Easy
Integration with other components	Hard	Hard	Easy

G = conductance per unit length

C = capacitance per unit length

Δz = incremental length

One can determine the current and voltage relations for the short length of line Δz . Kirchhoff's voltage and current laws are applied along the transmission line shown in Fig. 3. In the derivation, the line length of $\Delta z \rightarrow 0$ is assumed. Equations for the instantaneous voltages and currents and for time-harmonic equivalents are as follows:

Instantaneous equations

$$-\frac{\partial v}{\partial z} = Ri + L \frac{\partial i}{\partial t} \quad (1)$$

$$-\frac{\partial i}{\partial z} = Gv + C \frac{\partial v}{\partial t} \quad (2)$$

Time-harmonic equations where $e^{j\omega t}$ is assumed

$$-\frac{dV}{dz} = RI + j\omega LI \quad (3)$$

$$-\frac{dI}{dz} = GV + j\omega CV \quad (4)$$

Figure 3. Lumped-element equivalent-circuit model of the differential length of a transmission line.

The solution for instantaneous voltages and currents is

$$v(z, t) = \text{Re}[V(z)e^{j\omega t}]; \quad i(z, t) = \text{Re}[I(z)e^{j\omega t}] \quad (5)$$

Wave equations for time-harmonic voltages and currents are rewritten as

$$\begin{aligned} -\frac{dV}{dz} &= (R + j\omega L)I \\ -\frac{dI}{dz} &= (G + j\omega C)V \\ \Rightarrow \begin{cases} -\frac{d}{dz} \left(\frac{dV}{dz} \right) = (R + j\omega L) \frac{dI}{dz} \\ \frac{d^2 V}{dz^2} = (R + j\omega L)(G + j\omega C)V \end{cases} \end{aligned} \quad (6)$$

The final expressions for time-harmonic voltage and current wave equations along the line are

$$\frac{d^2 V}{dz^2} = \gamma^2 V \quad (7)$$

$$\frac{d^2 I}{dz^2} = \gamma^2 I \quad (8)$$

The propagation constant γ for the line is defined as

$$\gamma = \sqrt{(R + j\omega L)(G + j\omega C)} = \alpha + j\beta \quad (9)$$

where α is the attenuation constant (Np/m) and β is the propagation constant (rad/m).

The traveling-wave solutions are

$$V(z) = V^+(z) + V^-(z) = V_0^+ e^{-\gamma z} + V_0^- e^{+\gamma z} \quad (10)$$

$$I(z) = I^+(z) + I^-(z) = I_0^+ e^{-\gamma z} + I_0^- e^{+\gamma z} \quad (11)$$

The plus sign indicates the forward-traveling wave, and the minus sign indicates the backward-traveling wave. Applying (11) to the voltage of (3) gives the current on the line:

$$I(z) = \frac{-1}{R + j\omega L} \frac{dV(z)}{dz} = \frac{\gamma}{R + j\omega L} [V_0^+ e^{-\gamma z} - V_0^- e^{+\gamma z}] \quad (12)$$

The characteristic impedance of the line is

$$Z_0 = \frac{V_0^+}{I_0^+} = \frac{R + j\omega L}{\gamma} = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \quad (13)$$

To relate the voltage and current on the line; $Z_0 = (V_0^+ / I_0^+) = -(V_0^- / I_0^-)$. The wavelength of the wave along the line is

$$\lambda_g = \frac{2\pi}{\beta} \quad (14)$$

and the phase velocity of the wave along the transmission line is

$$v_p = \frac{\omega}{\beta} = \lambda f \tag{15}$$

For lossless transmission lines, $R = G = 0$; the propagation constant is $\gamma = j\omega\sqrt{LC} = \alpha + j\beta$. Therefore, the attenuation constant $\alpha = 0$ and $\beta = \omega\sqrt{LC}$. The characteristic impedance is

$$Z_0 = \sqrt{\frac{L}{C}} \tag{16}$$

The general solution of a lossless transmission line is

$$V(z) = V^+(z) + V^-(z) = V_0^+ e^{-j\beta z} + V_0^- e^{j\beta z} \tag{17}$$

$$I(z) = I^+(z) + I^-(z) = (V_0^+ / Z_0) e^{-j\beta z} - (V_0^- / Z_0) e^{j\beta z} \tag{18}$$

The wavelength of the wave along the line $\lambda_g = (2\pi/\beta) = (2\pi/\omega\sqrt{LC})$ and the phase velocity of the wave along the transmission line is $v_p = (\omega/\beta) = \lambda f$.

3.1. Coaxial Lines

The key feature of coaxial lines is that their characteristic impedance is very broadband. The fundamental mode of operation is TEM, where the electric and magnetic fields are transverse in the direction of propagation. A typical coaxial cable, shown in Fig. 4, consists of two concentric conductors of inner and outer radii a and b , respectively, with the space between them filled with a dielectric (ϵ_r) such as Teflon or polyethylene. In this section we perform a field analysis on a coaxial cable to calculate the equivalent circuit parameters such as $R, G, L,$ and C as defined earlier in the telegrapher equation.

Let the voltage between the conductors be $V_0 e^{\pm j\beta z}$ and the current $I_0 e^{\pm j\beta z}$. The fields of a traveling TEM wave inside the coaxial line along the $+z$ direction are then given as follows:

$$\mathbf{E} = \frac{V_0 \hat{\rho}}{\rho \ln(b/a)} e^{-\gamma z} \quad (\text{V/m}) \tag{19}$$

$$\mathbf{H} = \frac{I_0 \hat{\phi}}{2\pi\rho} e^{-\gamma z} \quad (\text{A/m}) \tag{20}$$

Figure 4. Coaxial cable: (a) cross-sectional view; (b) isometric view.

The conductors are assumed to have a surface resistivity R_s . The material filling the space between the conductors is assumed to have a complex permittivity $\epsilon = \epsilon' - j\epsilon''$, and the permeability is $\mu = \mu_0\mu_r$. We now determine the transmission line parameters $R, G, L,$ and C .

The time-average magnetic energy store is defined as

$$W_m = \frac{\mu}{4} \int_S \mathbf{H}\mathbf{H}^* ds = L|I_0|^2/4 \tag{21}$$

The self-inductance per unit length is

$$L = \frac{\mu}{|I_0|^2} \int_S \mathbf{H}\mathbf{H}^* ds \quad (\text{H/m}) \tag{22}$$

$$= \frac{\mu}{2\pi} \ln(b/a) \quad (\text{H/m})$$

The time-average electric energy stores is defined as

$$W_e = \frac{\epsilon}{4} \int_S \mathbf{E}\mathbf{E}^* ds = C|V_0|^2/4 \tag{23}$$

The self-capacitance per unit length is

$$C = \frac{\epsilon}{|V_0|^2} \int_S \mathbf{E}\mathbf{E}^* ds \quad (\text{F/m}) = \frac{2\pi\epsilon'}{\ln(b/a)} \quad (\text{F/m}) \tag{24}$$

The power loss per unit length due to the finite conductivity σ of the metallic conductor is

$$P_c = \frac{R_S}{2} \int_{C_1+C_2} \mathbf{H}\mathbf{H}^* dl = R|I_0|^2/2$$

where the surface resistivity is defined as $R_S = 1/\sigma\delta_S$, where δ_S is the skin depth of the conductor. The series resistance R per unit length of the line is

$$R = \frac{R_S}{|I_0|^2} \int_{C_1+C_2} \mathbf{H}\mathbf{H}^* dl \quad (\Omega/m) \tag{25}$$

$$= \frac{R_S}{2\pi} \left(\frac{1}{a} + \frac{1}{b} \right) \quad (\Omega/m)$$

Due to the “lossy” dielectric, the time-average power dissipated per unit length is

$$P_d = \frac{\omega \epsilon''}{2} \int_S \mathbf{E} \mathbf{E}^* ds = G |V_0|^2 / 2 \quad (26)$$

The conductance per unit length is

$$G = \frac{\omega \epsilon''}{|V_0|^2} \int_S \mathbf{E} \mathbf{E}^* ds \quad (\text{S/m}) = \frac{2\pi \omega \epsilon''}{\ln(b/a)} \quad (\text{S/m}) \quad (27)$$

So far we have calculated the equivalent-circuit model parameters of a coaxial cable with the radii of the outer and inner conductors of b and a , respectively. Now we opt to calculate the characteristic impedance of the coaxial line Z_0 , which is frequency-independent and can be calculated as

$$Z_0 = \frac{V_0}{I_0} = \sqrt{\frac{\mu}{\epsilon}} \ln\left(\frac{b}{a}\right) = \frac{60}{\sqrt{\epsilon_r}} \ln\left(\frac{b}{a}\right) \quad (\Omega) \quad (28)$$

The approximate cutoff frequency of the cable can be calculated from (29), at which point the first non-TEM mode of propagation begins. At a frequency above f_{cutoff} [5], other propagation modes dominate and the characteristic impedance becomes frequency-dependent:

$$f_{\text{cutoff}}(\text{GHz}) = \frac{7.51}{\sqrt{\epsilon_r}} \left(\frac{1}{a+b} \right) \quad (29)$$

The line parameters L , R , C , and G of coaxial lines can be calculated from

$$C = \frac{55.63 \epsilon_r}{\ln(b/a)} \quad (\text{pF/m}) \quad (30)$$

$$L = 200 \ln\left(\frac{b}{a}\right) \quad (\text{nH/m}) \quad (31)$$

$$R = 10 \left[\frac{1}{a} + \frac{1}{b} \right] \sqrt{\frac{f_{\text{GHz}}}{\sigma}} \quad (\Omega/\text{m}) \quad (32)$$

$$G = \frac{0.3495 \epsilon_r f_{\text{GHz}} \tan(\delta)}{\ln\left(\frac{a}{b}\right)} \quad (\text{S/m}) \quad (33)$$

where $\tan \delta$ is the loss tangent of the dielectric material, σ is the conductivity of the conductor in S/m, and f_{GHz} is the signal frequency in GHz.

3.1.1. Cable Losses. The losses in a coaxial cable arise from two sources: resistance of the conductors and the dielectric losses between the two conductors. The conductor losses are ohmic and increase with the square root of the frequency due to the skin effect. The dielectric loss is due to the finite conductivity of the dielectric material and increases linearly with the frequency. Figure 5a shows the attenuation per foot and power-handling capability of a MegaPhase TM Series test cable. As can be seen in Fig. 5a, the per unit length attenuation increases with frequency. In Fig. 5b the power-handling capacity of the cable reduces with frequency. The frequency dependence of the attenuation and the power-handling capability is explained in the following section.

The transmitted power can be expressed in terms of the voltage or maximum value of the electric field inside the line:

$$P_T = \frac{1}{2Z_0} |V|^2 = \frac{1}{\eta} |E_a|^2 (\pi a^2) \ln\left(\frac{b}{a}\right) \quad (34)$$

The attenuation coefficients due to conductor and dielectric losses are

$$\begin{aligned} P'_{\text{loss}} &= \frac{1}{2} R_s [(2\pi a) |H_a|^2 + (2\pi a) |H_b|^2] \\ &= \frac{R_s |I|^2}{4\pi} \left(\frac{1}{a} + \frac{1}{b} \right) \end{aligned} \quad (35)$$

$$\alpha_c = \frac{P'_{\text{loss}}}{2P_T} = \frac{R_s}{2\eta} \left(\frac{1}{a} + \frac{1}{b} \right) \frac{1}{\ln\left(\frac{b}{a}\right)} \quad (36)$$

Figure 5. Attenuation per foot and power-handling capability of a coaxial cable as a function of frequency. (Source: <http://www.megaphase.com/html/test02.html>.)

$$\alpha_d = \frac{w}{2c} \tan(\delta) \quad (37)$$

Total losses will be

$$\alpha = \alpha_c + \alpha_d = \frac{R_s}{2\eta} \left(\frac{1}{a} + \frac{1}{b} \right) + \frac{\omega}{2c} \tan(\delta) \quad (38)$$

where the surface resistivity is

$$R_s = \sqrt{\frac{\omega\mu_0}{2\sigma}} \quad (39)$$

3.1.2. Types of Coaxial Cable. There are various types of coaxial cables available in the commercial market. They are broadly categorized as flexible cables and semirigid cables. Flexible cables are most widely used as measurement tools for test and characterization. There are two varieties of flexible cable available. The overall cable diameters vary from <0.25 in. to >1 in. depending on the power-handling capability of the wire. Some cables use a stranded inner conductor, while others employ solid wire with single braid or double-braided outer conductor. The outer jacket plays no part in the electrical performance of the cable—it simply holds everything together and supplies a waterproof covering. Selection of cable types depends primarily on the characteristic impedance of the cable, capacitance per unit length, power-handling capability, outer diameter, and attenuation per unit length at the specific frequency. Preference is also given to double-shielded/braided cable over the corresponding single-shielded cable due to the resilience against interference and physical ruggedness. Figure 6b shows an air-filled coaxial cable with spiral dielectric fin support. This cable displays low loss due to the air dielectric; the phase velocity is very close to that of the free space.

3.1.3. Semirigid Cables. Another popular transmission line is semirigid cable. Both inner and outer conductors are solid, and the two conductors are uniformly separated with dielectric material. Semirigid cables can be bent to moderate angles but, once bent, cannot be brought back to

their original shape. Cables of this type are neither rigid nor flexible; hence their name. Semirigid cables have better shielding capabilities and are more immune to outside interference than are flexible cables. Semirigid cables also have reduced attenuation and enhanced power-handling capabilities. Figure 7 shows various forms of semirigid cables soldered with SMA connectors at both ends. The inner conductors are made from various materials such as silver-coated copper, silver-plated copper-clad steel, and silver-plated aluminum. The dielectric filling is typically polyethylene, polytetrafluoroethylene (TFE Teflon), polytetrafluoroethylene-hexafluoropropylene (FEP Teflon), or kapton. The outer conductor is made of copper, aluminum, stainless steel, and special copper alloys. Selection of a particular type of semirigid cable involves consideration of factors such as power-handling capability, attenuation per unit length, size, higher-mode cutoff frequency, dielectric strength, and breakdown voltages (corona discharge voltage).

3.1.4. Coaxial Connectors. Coaxial cable is no use if interfacing with various components in a system is made. Various types of coaxial connectors and cable assemblies are used. Each type of connector can be attached to a cable in several ways: direct solder, crimp, and screw. Figure 7 shows various bent coaxial cable assemblies.

Interfacing cables with connectors and adapters need special care. Bending also requires special jigs to ensure minimum distortion of its regular shape. The cable must be cut to the exact length and then bent to the shape required. After shaping, the inner conductors are made in exact lengths such that they can be inserted into the inner conductor of a connector. Then solder is applied to the outer jacket to electrically connect the adapter and the cable. Adapter assemblies of this type are shown in Fig. 8.

3.1.5. More Recent Developments of Coaxial Line. Coaxial cables are nonplanar in nature, and compatibility with modern monolithic microwave integrated circuits (MMICs) and microelectromechanical structures (MEMS) is an issue. MMIC and MEMS support planar transmission lines such as microstrip lines, striplines, slotted lines, and coplanar waveguides (CPWs). More recently, with the advent of new processing techniques,

Figure 6. Flexible coaxial cable (coax) configurations: (a) double-braided solid-filled coax; (b) air-filled coax with spiral dielectric fin support.

Figure 7. Various semirigid cable bends. (Source: http://www.shibata.co.jp/extt/3_g_g6.htm.)

MMIC and MEMS coaxial lines have been developed. These lines are designed for use in extremely wide frequency ranges from DC to THz. Monolithic implementation of coaxial lines in silicon and gallium arsenide (GaAs) substrate up to 40 GHz (c.f. Fig. 9a) has been reported [12]. The MMIC line is composed of a center conductor surrounded by a homogeneous dielectric (Polymide) covered entirely with a gold-plated ground plane. The pure TEM mode propagation of the proper mode is verified from the measurement. The authors also theoretically verify the losses up to 1000 GHz frequency band, and the transmission loss is about 15 dB/mm. The line has a measured maximum attenuation of 1.6 dB/mm at 40 GHz.

Developments in MEMS technology have made many breakthroughs in RF and microwave technologies. This state-of-the-art manufacturing technology supports IC batch processing on silicon wafers. A MEMS microcoaxial transmission line with inclined shields has been developed by the Korea Advanced Institute of Science and Technology [13]. With the removal of dielectric between the conductors, a very low attenuation of 0.03 dB/mm at 10 GHz has been obtained from the fabricated microcoaxial transmission line. Investigation reveals that the microcoaxial line fabricated on a glass line is less lossy than that fabricated on a silicon device. The MEMS microcoaxial line is shown in Fig. 9b.

Thus far, we have discussed the two main types of microwave transmission lines, namely, coaxial cables and waveguides, including their historical perspectives and more recent market statistics. The basic transmission-line theory of the telegrapher equation is presented. The theories of coaxial lines based on lumped elements as well as

Figure 8. Various coaxial cable assemblies. (Source: <http://www.gordontech.com.au/>.)

field theory have been presented. Two types of coaxial lines—flexible and semirigid cables—are discussed. Different connectors and adaptors of coaxial cables and cable assemblies are presented. Finally, the most recent development in MMIC and MEMS microcoaxial lines at higher frequencies are presented. In the following section, we will discuss waveguides.

3.2. Waveguide

In the preceding section, we discussed various types of coaxial transmission lines. In this section we shall discuss various nonplanar and planar waveguide structures and their modes of operations. Waveguides are extensively used to transfer electromagnetic energy efficiently from one point to another in a wide spectrum of frequency. Nonplanar waveguides are hollow tubes in which waves can propagate only at certain frequencies and cannot propagate below the cutoff frequencies. The cross section of the enclosed boundaries of the waveguide is transverse to the direction of propagation. Waveguides are used at microwave frequencies for two reasons: (1) they are often easier to fabricate than are coaxial lines and (2) they can be made to have less attenuation. Coaxial lines require the center conductor to be supported by the solid dielectric in the center of the outer cylindrical jacket. In contrast, a waveguide does not need any center conductor and its dielectric is air. Because of the high losses in a coaxial line over any distance (> 2 ft), along with the cable leakage at

Figure 9. (a) MMIC rectangular coaxial line on GaAs [12]; (b) MEMS microcoaxial line [13].

Figure 10. Different forms of waveguides: (a) rectangular waveguide; (b) twist polarizer; (c) circular waveguide; (d) rectangular waveguide bend.

higher frequencies, the waveguide structure is preferred at higher frequencies. If the waveguide boundaries change direction within reasonable limits, the wave is bound to follow the changing direction without much distortion and discontinuity. In practice, such bends and junctions are very common in high-power radar systems where waveguides carry high-power high-frequency EM energy from the transmitter to the antenna. In waveguides, the waves are guided according to the distributions of the EM fields in the waveguide and their dependence on currents and charges on the conducting boundaries and the reflections of the fields in the conducting boundaries.

The most common hollow waveguides have rectangular or circular cross sections; however, the rectangular waveguides are preferred over circular ones for many applications. Figure 10 illustrates various forms of rectangular waveguides. Very often rectangular waveguides are designed such that one side of the rectangular wall is twice the length of the other side. This cross-sectional dimension has the advantage of enabling the operator to control the polarization of the wave to be transmitted. The electrical fields remain parallel to the smaller dimension of the waveguide cross section. If the dimension is made much larger, the electric field does not remain parallel to the side any more. On the other hand, if the dimension is made much smaller, then there will be considerable attenuation. The dimensions of the waveguide are generally designed such that only the fundamental or dominant mode can propagate. All other higher-order modes attenuate quite rapidly. Furthermore the dimensions are to be chosen such that there is a significant difference between the cutoff frequencies of the successive modes. This is necessary to ensure that only one designed mode may propagate.

Another popular type is the circular waveguide. In contrast to the rectangular waveguide, a circular waveguide lacks the sense of polarization of the wave that is being transmitted through. This is because there is no preferred direction across the circular cross-sectional plane. Furthermore, the cutoff frequencies of different modes are very close. As a consequence, it is very hard to determine an operating frequency that will yield a low attenuation for the dominant mode and high attenuation for the other higher-order modes. The advantage of the circular waveguide is exploited from its circular symmetry. Rotary joints use circular symmetry. For rotating antenna feeds used in radars, rotary joints are employed. The quality (Q) factor of the circular waveguide cavity is higher than that of the rectangular waveguide. This inherent characteristic is exploited in frequency meters.

Before proceeding further with the discussion of the hollow metallic waveguides, we shall first examine whether any wave can propagate within the waveguide (i.e., in a guide whose conducting boundaries form a simple connected region) and, if so, how the propagation takes place. As mentioned earlier with respect to coaxial cables, a TEM wave can propagate through the two-conductor transmission line. In contrast, in the single-conductor hollow waveguide such a TEM wave cannot propagate. This can be proved by field theory and solving the Helmholtz wave equation. Another very simple and interesting concept has been developed [14]. The waveguide can be perceived by a two-conductor transmission line supported by two quarter-wavelength short-circuited sections as shown in Fig. 11. Since the short-circuited quarter-wavelength section transforms into an open circuit (with infinity impedance, which is electrically invisible) at its input, there is no effect on power transmission. In many sections of this type, a rectangular waveguide such as that shown in Fig. 11 is used. To preserve the transmission-line property of the waveguide, the dimension d must not be less than one wavelength. Any frequency in the dimension a less than a half-wavelength (i.e., $< 0.5\lambda$) causes the circuit to become an inductive shunt ($j\omega L$), which prevents propagation. The frequency at which the a dimension is a half-wavelength is called the *cutoff frequency*.

Complete solutions to field equations are known for a limited number of structures with a well-defined geometry that is compatible with the coordinate system. Each mode

Figure 11. A rectangular waveguide derived from a two-wire transmission line supported by two quarter-wavelength short-circuited sections.

can be characterized by its electrical and magnetic components and can be visualized as field patterns by its electric and magnetic vectors.

In wave propagating structures, the transmission of microwave energy takes place in a region surrounded by boundaries, in most cases a metallic wall; and, for analytical purpose, these are assumed lossless. Other assumption is that, within the frequency of interest, a waveguide can support at least one propagating mode above its cutoff frequency, which is the function of waveguide geometry.

The time-harmonic electric and magnetic fields are assumed to have the following forms

$$E(x, y, z, t) = E(x, y)e^{j\omega t - j\beta z} \quad (40)$$

$$H(x, y, z, t) = H(x, y)e^{j\omega t - j\beta z} \quad (41)$$

where β is the propagation constant along the guide direction. The corresponding wavelength is the guide wavelength ($\lambda_g = 2\pi/\beta$):

$$\lambda_g = \frac{\lambda_0}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \quad (42)$$

where λ_0 is the wavelength of a plane wave propagating in an infinite medium. Two important features can be noted from this equation: (1) at higher operating frequency $\lambda = \lambda_0$ and (2) as f approaches f_c , λ_g becomes infinite and the corresponding mode does not propagate. Therefore, for a given mode of propagation, the operating frequency is always selected above the cutoff frequency.

3.2.1. Parallel-Plate Waveguide. The parallel-plate waveguide normally supports TM and TE modes. It can also support the TEM mode of propagation as it is formed with two flat plates or strips as shown in Fig. 2e. The stripwidth W is assumed to be much greater than the separation distance d so that the fringing field and any x components of the field can be ignored. A material with relative permittivity ϵ_r and permeability μ_0 is assumed to fill the region between the plates.

3.2.1.1. TEM Modes. The TEM mode solution can be obtained by solving Laplace's equation as in (43) for the electrostatic potential ϕ between the two plates:

$$\nabla_t^2 \phi(x, y) = 0 \text{ for } 0 \leq x \leq W \text{ and } 0 \leq y \leq d \quad (43)$$

The initial boundary conditions for potentials are

$$\begin{aligned} \phi(x, 0) &= 0 \\ \phi(x, d) &= V_0 \end{aligned} \quad (44)$$

Since there is no variation in the x plane, the equation can be solved with given boundary conditions and the transverse electric field and magnetic field components can be calculated. Once the electric field is derived, the voltage and the current on the top plate can be calculated from the

electric field component and the surface current density, respectively. The characteristic impedance of the parallel plate can be found as follows:

$$Z_0 = \frac{V}{I} = \frac{d\eta}{\omega} \quad (45)$$

The Z_0 depends only on geometry and the material parameter. The attenuation due to dielectric loss is given as follows:

$$\alpha_d = \frac{k \tan \delta}{2} \text{ (Np/m)} \quad (46)$$

The conductor attenuation for different mode of propagation can be calculated from the following equations:

$$\alpha_c = \frac{R_s}{\eta d} \text{ (Np/m) (for TEM mode)} \quad (47)$$

$$\alpha_c = \frac{2k_c^2 R_s}{k\beta\eta d} \text{ (Np/m) (for TE}_n \text{ mode)} \quad (48)$$

$$\alpha_c = \frac{2kR_s}{\beta\eta d} \text{ (Np/m) (for TM}_n \text{ modes)} \quad (49)$$

The cutoff frequency and propagation constant for TE_{*n*} and TM_{*n*} modes are

$$f_{c, \text{TM}} = \frac{\eta}{2d\sqrt{\mu\epsilon}} \quad (50)$$

and the propagation constant is

$$\beta_{\text{TE}} = \sqrt{k^2 - \left(\frac{n\pi}{d}\right)^2} \quad (51)$$

The wave impedance of TE_{*n*} and TM_{*n*} modes are frequency-dependent and are given as

$$Z_{\text{TM}} = \frac{-E_y}{H_x} = \frac{\beta\eta}{k} \quad (52)$$

$$Z_{\text{TE}} = \frac{E_x}{H_y} = \frac{k\eta}{\beta} \quad (53)$$

The attenuation due to conductor loss for TM₁, TE₁, and TEM modes in a parallel-plate waveguide is shown in Fig. 12. At the cutoff frequency the attenuation reaches infinity, prohibiting the propagation of modes.

3.2.2. Rectangular Waveguide. The rectangular waveguide can propagate TM or TE modes, but not TEM modes. The uniform rectangular waveguide structure is shown in Fig. 13. The propagation is in the z direction.

The cutoff frequency for TE_{*m*}_{*n*} modes can be calculated as follows:

$$f_{c, mn} = \frac{1}{2\pi\sqrt{\mu\epsilon}} \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2} \quad (54)$$

Figure 12. Attenuation due to conductor loss for TEM, TM_1 , and TE_1 modes of a parallel-plate waveguide.

The mode with the lowest cutoff frequency is called the *dominant mode*. As we have assumed previously that $a > b$, the lowest f_c occurs for the TE_{10} mode (for $m = 1$ and $n = 0$):

$$f_{c,10} = \frac{1}{2a\sqrt{\mu\epsilon}} \tag{55}$$

The propagation constant of TE mode is

$$\beta_{TE} = \sqrt{k^2 - k_c^2} = \sqrt{k^2 - \left(\frac{m\pi}{a}\right)^2 - \left(\frac{n\pi}{b}\right)^2} \tag{56}$$

Figure 13. Coordinate system and electric field distribution in a rectangular waveguide.

Figure 14. Attenuation of various modes of rectangular waveguide WR-90 with aluminum wall: (1) WR-90 waveguide; (2) WR-90 waveguide with $b = 2a$.

The wave impedance that relates the transverse electric and magnetic fields is

$$Z_{TE} = \frac{E_x}{H_y} = \frac{k\eta}{\beta} \tag{57}$$

where $\eta = \sqrt{\mu\epsilon}$, the intrinsic impedance of the material filling the waveguide.

The attenuation due to dielectric loss is shown in Fig. 14 for various TE and TM modes of rectangular waveguide WR-90 with an aluminum wall.

3.2.3. Circular Waveguide. The cross sectional view of a circular waveguide is shown in Fig. 15. Circular waveguides support TE and TM modes of propagation. Circular waveguides also used in many applications as guiding structures in the propagation of microwave energy.

The field equations are solved in cylindrical coordinates for both TE_{mn} and TM_{mn} modes as

$$\left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \phi^2} + k_c^2 \right) h_z(\rho, \phi) = 0 \tag{58}$$

where h_z and e_z respectively are electric and magnetic fields. The dominant mode in circular waveguide is TE_{11} mode. The propagation constant and cutoff frequency for TE_{mn} modes are expressed as follows:

$$\beta_{TE,nm} = \sqrt{k^2 - k_c^2} = \sqrt{k^2 - \left(\frac{\rho'_{nm}}{a}\right)^2} \tag{59}$$

$$f_{c,nm} = \frac{k_c}{2\pi\sqrt{\mu\epsilon}} = \frac{\rho'_{nm}}{2a\pi\sqrt{\mu\epsilon}} \tag{60}$$

Figure 15. Cross sectional view of a circular waveguide.

For TM_{nm} modes the propagation constant and cutoff frequency are expressed as

$$\beta_{TM,nm} = \sqrt{k^2 - k_c^2} = \sqrt{k^2 - \left(\frac{\rho_{nm}}{a}\right)^2} \quad (61)$$

$$f_{c,nm} = \frac{k_c}{2\pi\sqrt{\mu\epsilon}} = \frac{\rho_{nm}}{2a\pi\sqrt{\mu\epsilon}} \quad (62)$$

where ρ and ρ' are the m th roots of Bessel's functions $J_n(x)$ and its first derivatives $J_n'(x)$ with order n , respectively. The attenuation due to conductor loss in an aluminum circular guide with radius 2.45 cm for different modes is shown in Fig. 16. As can be seen, the attenuation decreases to a very small quantity at higher frequency of operation. The transverse field patterns and the cutoff frequencies of various modes are shown in Figs. 17a and 17b, respectively.

3.2.4. Elliptic Waveguide. The elliptic waveguide is a cylindrical waveguide where the transverse section is of elliptical form, as shown in Fig. 18.

The readers are referred to other sources [1–3] for quantitative information on elliptic waveguides. The

Figure 16. Attenuation due to metallic conductor of various modes of circular aluminum waveguide, with $a = 2.54$ cm.

dominant mode in elliptic waveguide is the eH_{11} mode. One major application of elliptical waveguide is impedance matching. The transverse electric and magnetic field patterns of several lower order modes in an elliptical waveguide with eccentricity $e = 0.75$ are shown in Fig. 19 [2].

3.2.5. Microstrip Line. The microstrip line is one of the most popular transmission lines [10] because it can be fabricated using the photolithography process and easily integrated with other active and passive microwave devices up to the millimeter-wave frequency band. The geometry of the microstrip transmission line is shown in Fig. 20.

The broad range of microwave components such as filters, resonators, diplexer, distribution networks, and matching circuits are made with microstrip lines. Although the microstrip structure is physically simple, the theoretical analysis is rather complex. A number of methods are employed to analyze the behavior of the microstrip line. However, there are closed-form analytical expressions for the characteristic impedance and propagation velocity [11]. The microstrip line supports quasi-TEM mode as the pure TEM mode is impossible because of the air-dielectric interface. Most of the power is confined to the region bounded by the width of the microstrip line, called the *fringing field*. Due to the presence of air in the fringing-field region, some of the power may radiate into free space. However, using a high-dielectric substrate and shielding the structure, the power loss due to radiation can be minimized. The microstrip medium is dispersive and supports higher-order modes. Nevertheless, its popularity is the result of the ease in integration with surface mountable chip components such as chip capacitors, chip resistors, and other lumped elements with good thermal dissipation properties of the medium without disturbing the RF propagation.

To design a basic microstrip line, it is important to know the characteristic impedance and effective permittivity, which is normally frequency-dependent. Many varieties of approximations have been reported in the literature [3]. However, the fairest and most accurate method in determining the characteristic impedance and effective permittivity [7] is outlined below:

$$Z_0 = \frac{\eta}{2\pi\sqrt{\epsilon_{re}}} \ln\left(\frac{8d}{W} + 0.25\frac{W}{d}\right) \quad \text{for } \left(\frac{W}{d} \leq 1\right)$$

$$Z_0 = \frac{\eta}{\sqrt{\epsilon_{re}}} \left(\frac{W}{d} + 1.393 + 0.667 \ln\left(1.444 + \frac{W}{d}\right)\right)^{-1} \quad (63)$$

$$\text{for } \left(\frac{W}{d} \geq 1\right)$$

where W is the width of the microstrip line, h is the height, and ϵ_{re} is the effective relative permittivity of the dielectric slab.

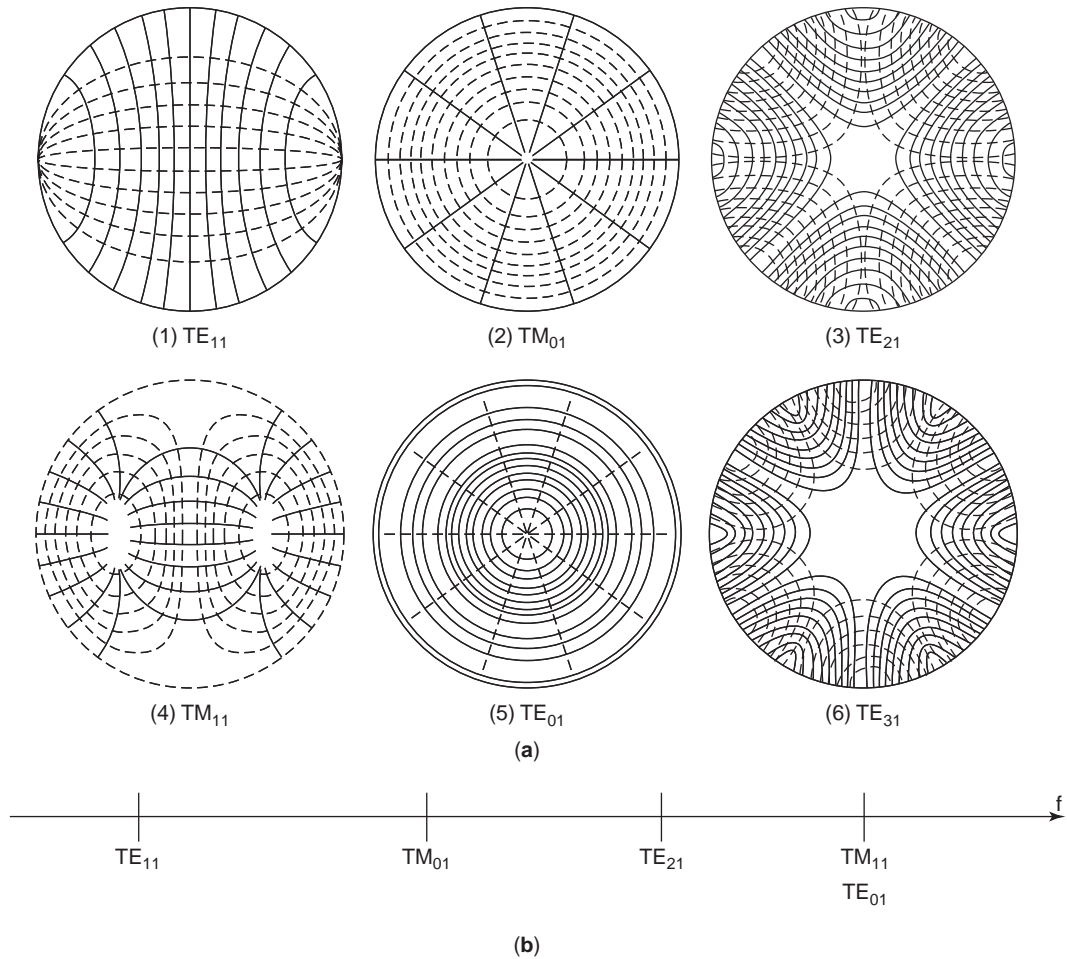

Figure 17. (a) Transverse field patterns of various modes in circular waveguide; (b) locations of cutoff frequencies of the first few TE and TM modes.

The effective permittivity can be expressed as

$$\epsilon_{re} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} F \frac{W}{d} \tag{64}$$

$$F \frac{W}{d} = \left(1 + 12 \frac{d}{W}\right)^{-0.5} + 0.04 \left(1 - \frac{W}{d}\right)^2 \text{ for } \left(\frac{W}{d} \geq 1\right)$$

$$F \frac{W}{d} = \left(1 + 12 \frac{d}{W}\right)^{-0.5} \text{ for } \left(\frac{W}{d} \leq 1\right) \tag{65}$$

Figure 18. Geometry of the elliptical waveguide.

With these equations, the characteristic impedance and effective dielectric constant of a microstrip line can be evaluated. All modern microwave computer-aided design tools are equipped with these calculations for the characteristic impedance, linewidth, and effective dielectric constant of microstrip lines. At higher-frequency operation other factors such as decreased *Q* factors, radiation loss, surface-wave loss, and higher-order mode propagation are very critical in the design of microstrip lines. Figure 21 illustrates variation in the characteristic impedance and effective dielectric constants with respect to width for a microstrip line designed for two different substrates of

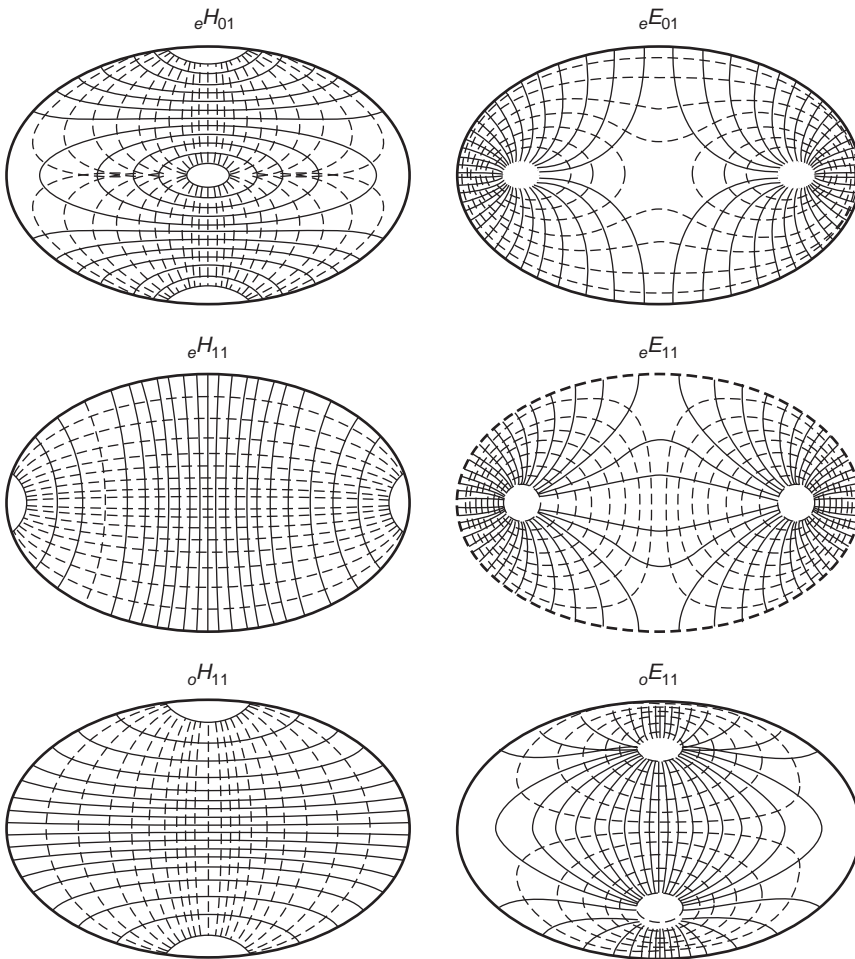

Figure 19. Field distribution of modes in elliptic waveguides [2].

dielectric constant of 2.0 and 10.5. As can be seen in Fig. 21a, the characteristic impedance decreases with the width–height ratio of the dielectric substrate. With higher dielectric constants the characteristic impedance is lower for the same dimension of line. As shown in Fig. 21b, the effective dielectric constant increases with the width–height ratio of microstrip lines. A microstrip realization of a quadrature direct conversion receiver [15] designed on RT Duroid substrate of dielectric constant of

10.5 and 0.635 mm thickness is presented in Fig. 22. As can be seen in the figure, all active and passive microwave devices such as quadrature hybrid coupler, asymmetric coupled-line bandpass filters, lowpass filters, Wilkinson power divider, and even harmonic mixer (EHMIX) are designed using photolithographic processes. The lumped components such as chip resistors, capacitors, and diode mixers are soldered on the microstrip lines. Thus microstrip lines have created a revolution in high-frequency and microwave circuits.

Figure 20. Structure of the microstrip line.

3.2.6. Slotline. Slotlines are planar transmission-line structures that are widely used in MMIC circuits. The basic slotline structure, shown in Fig. 23, consists of a dielectric slab with a narrow slot etched on the ground plane on only one side of the dielectric slab. This geometry is planar and well suited for MIC/MMIC designs. The wave propagates along the slot with the major electric field component oriented across the slot while the magnetic field is in the plane perpendicular to the slot. The mode of propagation in slotline is non-TEM in nature. Unlike the conventional waveguide, in the slotline there is no cutoff frequency and propagation occurs at all frequencies down to zero. Because of the slotline's non-TEM

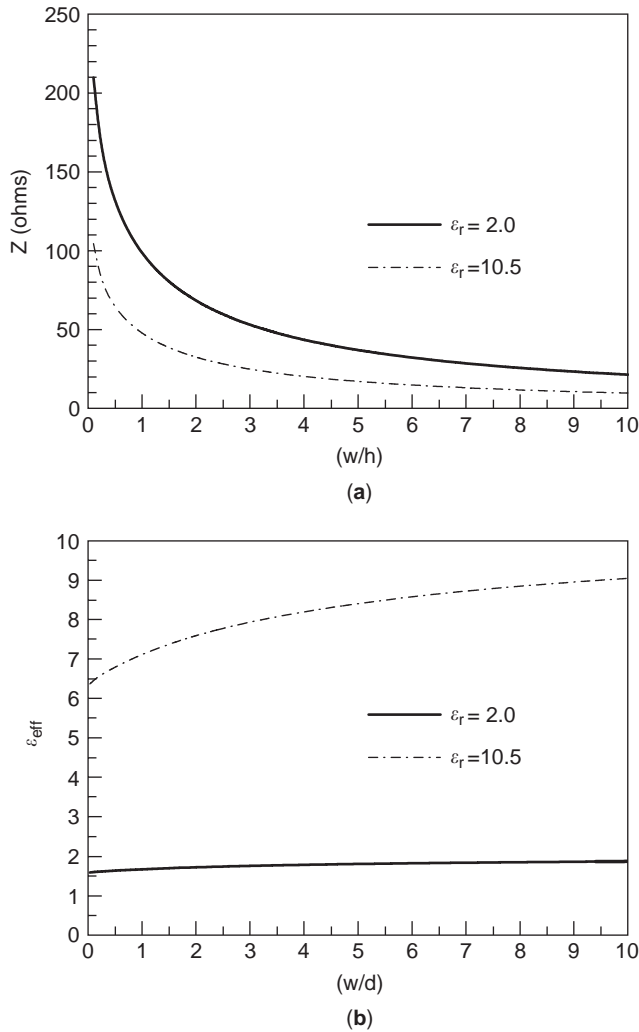

Figure 21. The characteristic of microstrip line. The variation of (a): characteristic impedance and (b): effective permittivity of the medium as a parameter of width.

nature, the characteristic impedance and phase velocity are not constant but vary with frequency at a slow rate. The characteristics of the slotline with regard to dielectric thickness are shown in Fig. 24 [6]. Readers are referred to

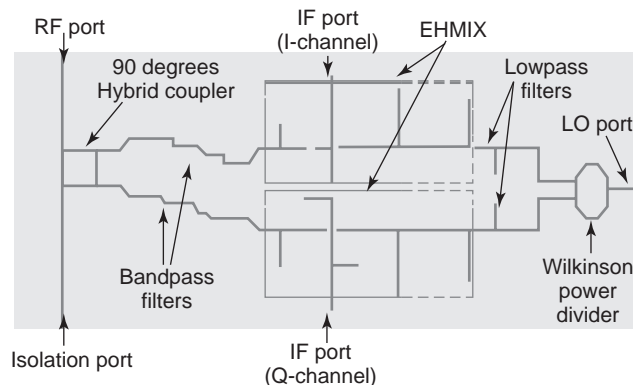

Figure 22. Microstrip realization of a mixer circuit.

Figure 23. Slotline geometry.

the literature [3] for a detailed theoretical analysis of slotline structures.

3.2.7. Coplanar Waveguide Transmission Line. The geometry of coplanar waveguide (CPW), shown in Fig. 25, consists of two slots of width w etched on the ground plane of a dielectric substrate and separated by a spacing s . This structure is also referred to as a *uniplanar structure* as the signal-carrying line lies along with the ground plane in the same plane. This structure often demonstrates better dispersion behavior than does the microstrip line [4,5]. As a result of low parasitic effects, this structure is a good choice for higher-frequency operation. The characteristic impedance of the line depends primarily on the width of slots and their spacing for a given substrate.

The characteristic of a CPW line are shown in Fig. 26. The variation of effective dielectric constant and charac-

Figure 24. The dispersion characteristics of slotline from Ref. 6.

teristic impedance as line parameters can be a useful tool for the design of the CPW line and its associated components. A detailed analysis and closed-form expressions of CPWs are reported in Ref. 8.

Figure 27 is a photograph of various MMIC slot antennas on coplanar waveguides designed on GaAs substrate near 24 GHz. The slot dipole is fed through a CPW line, and the calculated and measured performances of

the antenna is shown in Fig. 28. The details of antenna design are reported in Ref. 9.

4. CONCLUSION

This article has presented a historic perspective of coaxial cables and waveguides and has reviewed market potentials of coaxial cables, waveguides, and accessories. The classifications of various transmission lines according to the modes excited in the particular transmission lines have been shown. Two-wire transmission lines such as coaxial cables, parallel-plate waveguides, and microstrip lines support TEM mode fields. The single-conductor transmission lines support non-TEM mode fields such as TE and TM modes. Next, the classical transmission line theory has been derived in the “telegrapher” equation. Next, the coaxial cable has been discussed. The design parameters, higher-order mode cutoff frequency, and attenuation of coaxial cables were presented. The two main types of coaxial cable are flexible and semirigid coaxial cables. The most recent developments of extremely high-frequency coaxial cables exploiting MMIC and MEMS processing techniques were presented. It was shown that MEMS microcoaxial cable is low-loss even at very high frequencies such as in the millimeter-wave range.

Various waveguides in the form of parallel-plate waveguides and rectangular, circular, and elliptical waveguides were presented in terms of their cutoff frequencies and attenuation. Finally different planar waveguides such as microstrip lines, slotlines, and coplanar waveguides were presented. Their design formulas were also given for the benefit of designers.

COMBLINE FILTERS

CHI WANG
Orbital Sciences Corporation
Dulles, Virginia

1. INTRODUCTION

Comblines filters are one of the most widely used types of bandpass filters in many communication systems and other microwave applications because of many of their unique merits. The first comblines filter was introduced by Matthaei in 1963 [2]. The design equations and procedures of the rectangular bar comblines filter with narrow to moderate bandwidth, using the coupled rectangular bar design data from Getsinger [3], were also given by Matthaei [1,2]. Cristal [4,5] later presented the data for coupled circular cylindrical rods between parallel ground planes; thus, more manufacturing-advantageous and cost-effective cylindrical rod comblines filters can be designed with reasonable accuracy and excellent electrical performance. Although Matthaei's design equations were based on approximations, the results were shown to be reasonably good for narrow-to-octave bandwidth applications. Wenzel's exact analysis approach or full-wave electromagnetic simulations can be used for more accurate designs [9–11]. Comblines filters with elliptic function frequency responses, first presented by Rhodes and Levy, give great flexibility in their configuration and responses [6].

With the rapid development of satellite communications since the 1970s and mobile communications since the 1980s, generalized filters with elliptic function responses having cross-couplings between nonadjacent resonators are widely used [6–8,13,22–27]. Comblines filters are particularly suitable for achieving elliptic function response and for high-volume, low-cost production, because all the resonator rods can be mounted or built in on the common surface of the filter housing, while all the tuning

screws are mounted in a single cover. In addition, the resonator locations of the combline filter may be flexibly arranged according to the filter's coupling matrix and system mechanical requirement. The combination allows filters with large numbers of resonators and complicated cross-coupling configuration to be tuned nearly to theoretical performance without excessive cost.

In the physical realization of combline filters, the input and output couplings can be achieved by a short-circuited coupled line as part of an impedance transforming section, or an inductively coupled loop, a capacitive coupled probe, or by a direct, tapped-in line. The direct-tapped input/output configuration makes the combline filter more compact and easy to fabricate and therefore is more advantageous than other types of input/output structures [14–20]. This method was first described in the literature by Dishal [15] for small-percentage-bandwidth interdigital filters, and by Cohn [16] for combline filters. Cristal [17] gave exact general equivalent circuits for combline and interdigital arrays using graph transformations; thus the tapped line can be designed with high accuracy.

It is well known that the difference between the measured results and the design based on the conventional TEM combline theory can be as much as 30% depending on the filter's bandwidth [21]. Using full-wave electromagnetic computer-aided design (CAD) tools, combline filters can be designed in high accuracy with arbitrary resonator and coupling aperture dimensions [21,48]. The unloaded Q and the spurious responses of the resonators can be computed accurately from the electromagnetic simulators. Furthermore, the temperature characteristic and power handling capability of combline filters can be accurately determined [50–52].

Ceramic combline filters were introduced in the 1980s to satisfy the needs for miniature filters for mobile communications taking advantage of the development of high-dielectric-constant, low-loss dielectric materials. They have been widely used in many communication systems [40–47]. Ceramic combline filters can be manufactured using single or multiple solid ceramic blocks with a metallized exterior. The resonator rods are realized by a series of metallized holes that are grounded at one end of the block, where the opposite ends of the blocks are kept open. Therefore, the resonator lines are around a quarter-wavelength long at resonance. Couplings between adjacent resonators can be achieved by either series capacitors or apertures [42,48]. These ceramic combline filters can be designed and manufactured with high accuracy, and are very suitable for low-cost mass production.

Comblines are most suitable for applications requiring relatively low insertion loss in the frequency range between 500 MHz and 12 GHz, and they have following attractive features:

1. They are compact. The length of the resonator rods may be designed to be $\lambda_0/8$ or less at resonance. The unloaded Q of the resonator cavity is a function of its cross section. Therefore the size of the combline filter can be varied depending on the applications.
2. Combline filters possess the ability to be tuned over a wide range of frequencies without suffering significant degradation in performance [2,12]. The tuning range is a function of the amount of capacitance adjustment provided by the tuning screw.
3. The combline resonator has very high unloaded Q : volume ratio compared with other types of resonators, such as empty waveguide cavity and dielectric loaded resonators, although the combline resonator doesn't give the highest unloaded Q value.
4. They have strong stopbands, and the stopband above the primary passband can be made very broad. Combline filters may be designed to be spurious-free over 3–4 times the center frequency of the filter.
5. Adequate coupling can be maintained between resonator elements with sizable spacing between such resonator lines.
6. They are reliable, low in cost, and very suitable for manufacturing. All resonator rods can be mounted or built in to the filter housing, and all tuning screws can be directly attached to the housing or cover. In addition, all the materials are readily available and can be modified easily.

2. CONFIGURATIONS

A combline filter usually consists of a conductive enclosure and a number of parallel conductive rods serving as resonators, which are short-circuited at one end and open-circuited at the other end. The open ends of the resonator rods are usually close to one side of the enclosure in order to create sufficient capacitance between the rod and the ground. Coupling between resonators is achieved by way of the EM coupling between resonator lines. The input and output coupling may be achieved in several ways as stated in the introduction.

Figure 1 shows a combline bandpass filter in transmission-line form. The resonators of the filter consist of TEM-mode transmission-line elements that have a lumped capacitor C_b^s between the open end of each resonator line element and ground. Lines 1 through n and their associated capacitances C_1^s to C_n^s constitute resonators, while lines 0 and $n+1$ are not resonators but part of impedance transforming sections at both ends of the filter.

With the lumped capacitors present, the resonator lines will be less than a quarter-wavelength long at resonance, and the coupling between resonators will be predominantly magnetic in nature. It is usually desirable to make the capacitances of the combline filter sufficiently large so that the resonator lines will have a length of $\lambda_0/6$ or less at resonance.

The second passband of the combline filter occurs when the resonator line elements are somewhat over a half-wavelength long, so if the resonator lines are $\lambda_0/8$ long at the primary passband, the second passband will be centered at somewhat over 4 times the frequency of the first passband [2]. Therefore, the combline filters can have

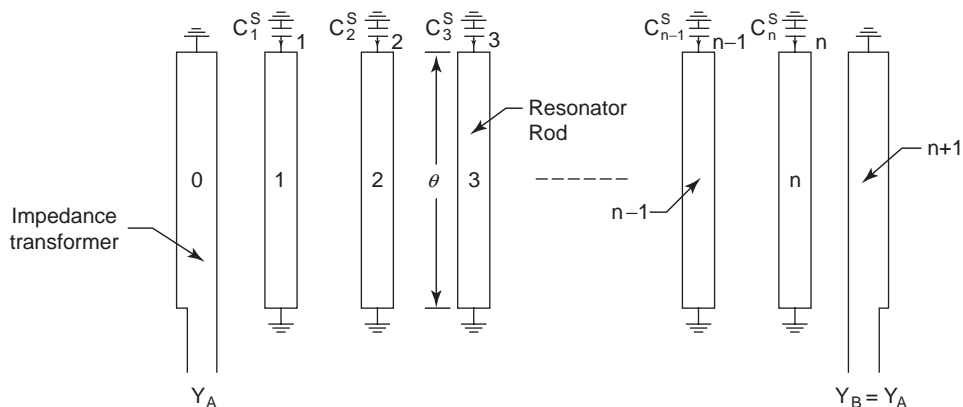

Figure 1. A combline filter with short-circuited input/output lines.

extremely broad spurious-free stopband compared with other types of filter.

Figure 2 shows the original four-pole combline filter having the configuration shown in Fig. 1 published by Matthaei in 1963 with its top cover removed. Figure 3 shows an alternate configuration of the combline filter that is currently widely used in the industry and is more favorable for manufacturing. The cross section of the resonator rods may be rectangular or circular; the circular configuration is more common because it is easier to manufacture. Each resonator rod has a counterbored hole at its open end. A tuning screw in the cover can be adjusted to penetrate in or out concentrically to the resonator rod to adjust the resonant frequency of the resonator to the desired value. The tuning screws between the resonator rods are used to adjust the coupling coefficient between the resonators.

Figure 2. The original combline filter [1].

The input/output coupling can be achieved by short (or open)-circuited impedance transformer bars as shown in Matthaei's original configuration [2], or by direct tap as shown in Fig. 3. The input/output coupling can also be achieved by a coupling loop or probe. As the later input/output coupling methods do not need an extended transmission rod at each end of the combline filter, the filter is more compact.

The resonator rods can be separate parts mounted into the filter housing, using screws to achieve good contact, or can be built into the filter housing so that resonators and enclosure constitute a single piece, with only a top cover, tuning screws, and connectors needed to complete the filter. The couplings between resonators can be controlled by the spacing between them or by varying the aperture dimension on a conductive wall between two resonators. The resonators can be arranged in a row or in any desired layout depending on the coupling structure of the filter.

Significant progress in microwave filter technology has taken place since the 1970s, particularly the use of elliptic function responses using nonadjacent couplings between resonators together with compact filter configurations [6–8,13,22,23]. Transmission zeros can be achieved on the lower, higher side or both sides of the filter's passband depending on the attenuation requirements. The resultant filter may have sharper attenuation response; thus fewer resonators are required, which results in a more compact filter with lower insertion loss. Figure 4 shows an example of an elliptic function combline filter with built-in resonators and a very compact configuration [39].

There are several ways to design a combline filter, but the most popular method is to use a lowpass prototype filter. This is transformed into the desired bandpass filter, and then the physical dimensions are determined by either approximation or full-wave 3D electromagnetic simulations. Figure 5 shows the typical design procedure of a combline filter based on this approach. First, the specifications are used to determine the desired filter parameters, such as number of resonators, bandwidth, passband ripple, and the desired ideal frequency responses from the lowpass prototype filter. Then the filter topology and equivalent-circuit parameters, such as filter element values g_k , the admittance inverters $J_{k,k+1}$, impedance inverters $K_{k,k+1}$, or coupling matrix $M_{k,k+1}$, are

Figure 3. A combline filter with tapped-in input/output couplings.

determined. The required unloaded Q of the resonators is determined, and the basic cavity and rod dimensions can then be decided. Finally the rod, spacing, or aperture dimensions can be obtained from Matthaei's approximate design equations using Getsinger's or Cristal's design charts. A prototype is made to verify the correctness of the design and to perform some minor adjustments. Other practical issues such as temperature compensation and power handling capability should also be considered.

3. LOWPASS PROTOTYPE

Figure 6 shows a typical Chebyshev response of a lowpass prototype filter and that of the corresponding bandpass filter. The lowpass prototype filter is usually chosen to have unit bandwidth ω_1' for convenience, while the

bandwidth of the bandpass filter can be arbitrarily specified.

The relationship between the lowpass prototype response and the corresponding bandpass filter is given as [1,2]

$$L_A(\omega) = L'_A(\omega') \quad (1)$$

where

$$\omega' = \frac{\omega'_1}{\bar{\omega}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (2)$$

$$\bar{\omega} = \frac{\omega_2 - \omega_1}{\omega_0}, \quad \omega_0 = \sqrt{\omega_2 \omega_1} \quad (3)$$

The mapped lowpass prototype filter response has the same characteristics as that of the bandpass filter, or vice versa. Therefore, if the desired bandpass filter has n return loss poles in passband and m finite transmission zeros in stopband, the corresponding lowpass prototype filter will also have n poles in passband from $-\omega_1'$ to ω_1' at location a_i ($i = 1, 2, \dots, n$) and m zeros in stopband at location b_i ($i = 1, 2, \dots, m$). The insertion loss and return loss of the lowpass prototype filter versus frequency can be expressed in terms of the poles and zeros as

$$L_A = 10 \log \left(\frac{1}{1 + \varepsilon |\phi|^2} \right) \quad (4)$$

$$L_R = 10 \log \left(\frac{\varepsilon |\phi|^2}{1 + \varepsilon |\phi|^2} \right) \quad (5)$$

Figure 4. A 12-pole elliptic function combline filter [39].

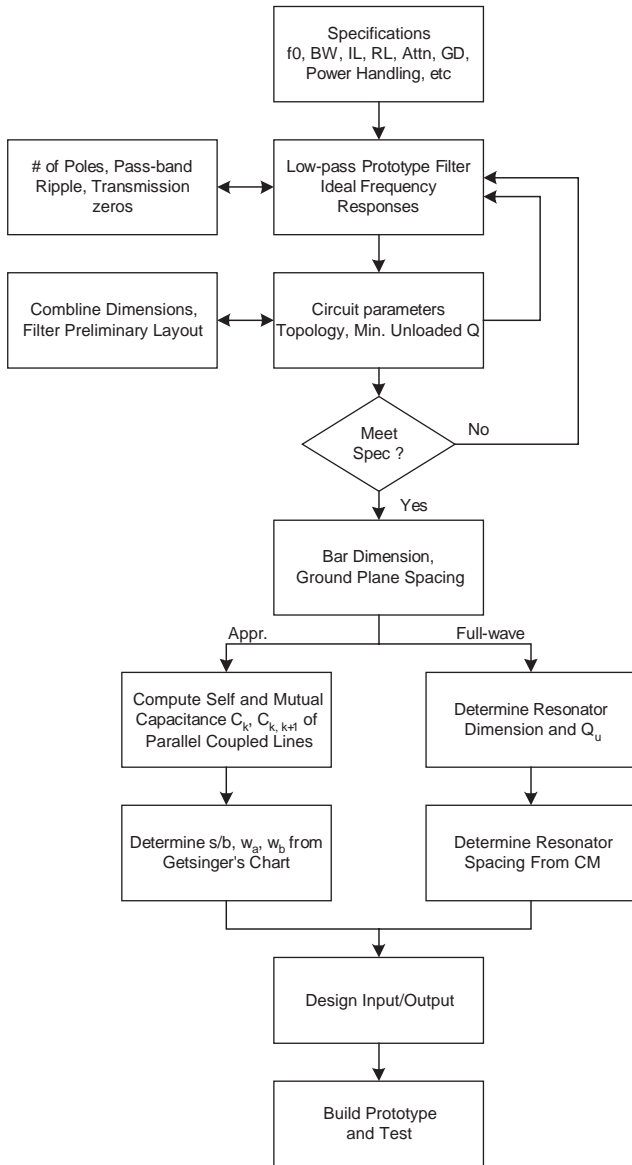

Figure 5. Typical combline filter design procedure.

where

$$\phi = \frac{P(\omega')}{Q(\omega')} = \frac{\prod_{i=1}^n (\omega' - a_i)}{\prod_{i=1}^m (\omega' - b_i)} \quad (6)$$

$$\varepsilon = 10^{L_{Ar}/10} - 1 \quad (7)$$

The approximation problem is to find the locations of the poles with locations of the given zeros to determine the equal-ripple passband response. The pole and zero locations of the transfer function can be determined by optimizing the polynomial function $P(\omega')$ through iterations [7] or by the recursive technique shown by Cameron [26]. For a Chebyshev response, all the transmission zeros are at infinity, and a closed-form expression for the pole loca-

Figure 6. Lowpass prototype and corresponding bandpass filter responses.

tions exists, as follows:

$$a_i = \cos \left[\frac{(2i - 1)\pi}{2n} \right], \quad i = 1, 2, \dots, n \quad (8)$$

Figure 7 shows the attenuation characteristics for a 0.01-dB-ripple Chebyshev filter versus number of poles. The 0.01-dB passband ripple gives better than 25 dB return loss for the ideal case; therefore it is often used as the starting point for a practical filter design.

Given the transfer function and pole-zero locations of the lowpass prototype filter, the circuit element values of the lowpass and bandpass filters can be obtained by network synthesis. The commonly used forms for the prototype filter circuits are shown in Fig. 8 using g_k ($k = 0, 1, \dots, n, n + 1$) as the element values. The prototype filters in Fig. 8a using the shunt capacitor as the first element and in Fig. 8b using the series inductor as the first element have identical responses and g_k values; therefore, either form may be used depending on the applications. When converting a prototype filter to a bandpass filter, a lowpass prototype with n reactive elements leads to a bandpass filter with n resonators.

For Chebyshev filters having passband ripple L_{Ar} dB, $g_0 = 1$, and $\omega'_1 = 1$, the remaining g values can be obtained analytically as follows:

$$g_1 = \frac{2a_1}{\sinh \left(\frac{\beta}{2n} \right)} \quad (9)$$

$$g_k = \frac{4a_{k-1}a_k}{b_{k-1}g_{k-1}} \quad (10)$$

$$g_{n+1} = \begin{cases} 1 & \text{for } n \text{ odd} \\ \coth^2 \left(\frac{\beta}{4} \right) & \text{for } n \text{ even} \end{cases} \quad (11)$$

Figure 7. Attenuations of the 0.01-dB-ripple Chebyshev filters.

Here

$$\beta = \ln \left(\coth \frac{L_{Ar}}{17.37} \right) \tag{12}$$

$$a_k = \sin \left[\frac{(2k - 1)\pi}{2n} \right] \tag{13}$$

$$b_k = \sinh^2 \left(\frac{\beta}{2n} \right) + \sin^2 \left(\frac{k\pi}{n} \right) \tag{14}$$

Table 1 presents the computed g element values for Chebyshev filters for $n=1$ through 10 with 0.01- and 0.1-dB passband ripple levels.

The g values of the lowpass prototype filter given in Eqs. (9)–(11) are normalized to unit input impedance $g_0 = 1$ and unit bandwidth $\omega'_1 = 1$. For filters having different input port impedance and bandwidth, the desired inductance or capacitance values can be easily scaled from the normalized g values by the following equations

$$L = \frac{R_0}{\omega'} L' \tag{15}$$

$$C = \frac{C'}{R_0 \omega'} \tag{16}$$

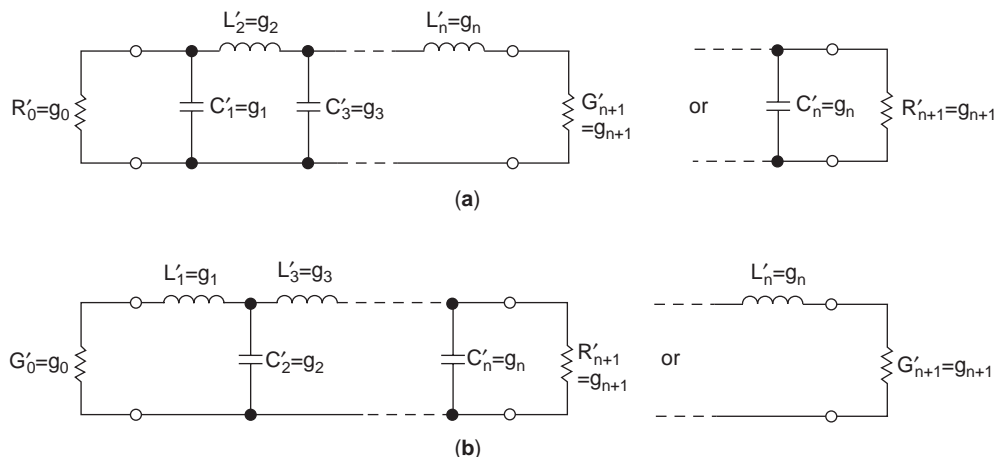

Figure 8. Lowpass filter circuit and parameters (a) a shunt capacitor as first element; (b) a series inductor as first element.

where the values of the normalized inductor L' and capacitor C' are equal to the particular g value of the prototype filter.

The lowpass prototype filter circuits in Fig. 8 consist of both inductors and capacitors. However, in bandpass and bandstop filter designs, it is desirable to use the same type of resonator having all inductors or all capacitors in the prototype filters.

This can be achieved by using the impedance inverter (K inverter) or admittance inverter (J inverter) as shown in Fig. 9. The inverters act like frequency-independent quarter-wavelength lines, so that only inductors exist in the K -inverter prototype, and only

capacitors in the J -inverter prototype networks. Figure 9 also gives the equations for converting the g value of the lowpass filter prototype to these forms. The components value such as $R, L, C,$ or G in the prototype circuit using J or K inverters can be chosen arbitrarily. The frequency responses of the inverter circuits in Fig. 9 are identical to those of the original prototype filters.

Another commonly used analysis method in the cavity-type bandpass filter design is to use the coupling matrix. Figure 10 presents the equivalent circuit of a generalized coupled bandpass prototype filter using the coupling matrix [7,26].

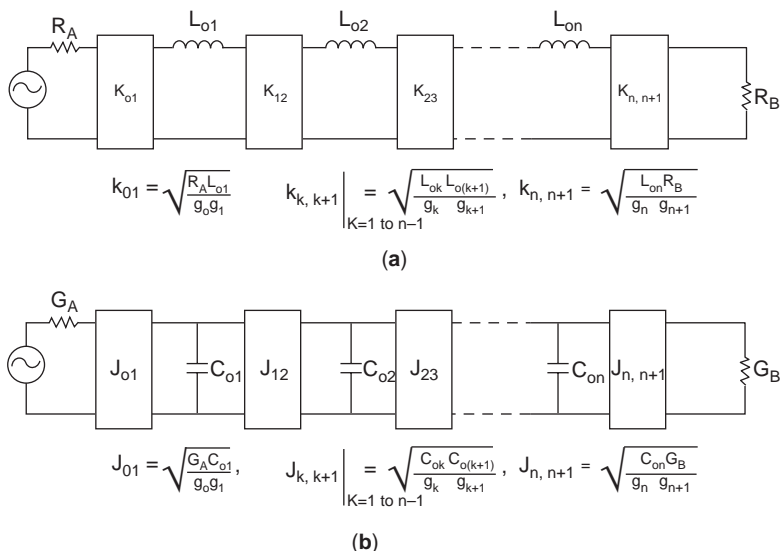

Figure 9. Modified prototype using impedance and admittance inverters.

Figure 10. A bandpass filter equivalent circuit.

A general solution of the narrowband coupled cavity filter described above has been presented in a paper by Atia and Williams in the form of the loop equations as [7]

$$[Z] \cdot [I] = [V] \quad (17)$$

$$([R] + s[I] + j[M]) \begin{bmatrix} i_1 \\ i_2 \\ \vdots \\ i_{n-1} \\ i_n \end{bmatrix} = \begin{bmatrix} e_1 \\ 0 \\ \vdots \\ 0 \\ 0 \end{bmatrix} \quad (18)$$

where

$$s = j\omega' \quad (19)$$

$$[M] = \begin{bmatrix} \lambda_{11} & M_{12} & M_{13} & \cdots & M_{1,n-1} & M_{1n} \\ M_{12} & \lambda_{22} & M_{23} & \cdots & M_{2,n-1} & M_{2n} \\ M_{13} & M_{23} & \lambda_{33} & \cdots & M_{3,n-1} & M_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ M_{1,n-1} & M_{2,n-1} & M_{3,n-1} & \cdots & \lambda_{n-1,n-1} & M_{n-1,n} \\ M_{1n} & M_{2n} & M_{3n} & \cdots & M_{n-1,n} & \lambda_{nn} \end{bmatrix} \quad (20)$$

The matrix R has all-zero entries except for the (1, 1) and (n, n) elements, which are R_1 and R_n , respectively. M is the so-called coupling matrix and has general entries of M_{ij} for $i \neq j$, and λ_{ii} for $i = j$. λ_{ii} gives the resonant frequency of each resonator mapped to the lowpass prototype domain according to Eqs. (2) and (3).

The coupling matrix of the bandpass filter can be determined by the network synthesis method as described in Refs. 7 and 26 or by optimization from the pole and zero locations of the filter's transfer function [24]. For the case of direct network optimization, the coupling matrix elements are the optimization variables and the objective error function can be established by determining the

difference between the transfer function frequency response of the prototype filter and the frequency response of the optimized filter. The Chebyshev coupling matrix of the same order can be used as the starting guess of the coupling matrix.

For filters with Chebyshev frequency responses, the coupling matrix of the filter can be obtained analytically from the g values of the prototype filter as

$$R_1 = \frac{1}{g_0 g_1} \quad (21)$$

$$M_{i,i+1} = \frac{1}{\sqrt{g_i g_{i+1}}} \quad (22)$$

$$R_n = \frac{1}{g_{n-1} g_n} \quad (23)$$

where the remaining elements in the coupling matrix are zero.

As in the case of the lowpass prototype filter, the coupling matrix shown in Eq. (20) is normalized to the passband from -1 to $+1$ and zero center frequency. For a bandpass filter with center frequency f_0 , and bandwidth BW, the required couplings of the filter are the normalized filter's coupling elements multiplied by the bandwidth with the unit same as that of the bandwidth.

4. DIRECT-COUPLED COMBLINE FILTER DESIGN

Matthaei gave the approximate design equations for the direct-coupled comblines filter shown in Fig. 1 in terms of the resonator rod's self-capacitance to ground C_j per unit length, and the mutual capacitance $C_{j,j+1}$ per unit length between neighboring resonator bars j and $j+1$ [1,2]. The design equations use the lowpass prototype filter parameters g_j ($i = 0, 1, \dots, n, n+1$) to achieve the desired frequency responses. The equations are sufficiently accurate for the applications of narrow bandpass filters with bandwidths up to octave.

By specifying the width of the filter enclosure and the resonator rod dimension, the admittance Y_{aj} of the resonator lines can be computed. It is usually desirable

to choose the ratio of enclosure width to resonator line-width in the range between 3 and 4 so that optimum unloaded Q can be achieved. In addition, the electrical length θ_0 of the resonator lines ranges between $\pi/4$ and $\pi/3$ at center frequency so that the filter will have both wide spurious-free stopband and less unloaded Q degradation due to excessive end loading in case shunt resonators are used.

4.1. Design Equations

The normalized J -inverter parameters of the combline filter can then be computed as

$$G_{T1} = \frac{(\omega_2 - \omega_1)b_1}{g_0g_1\omega_0\omega'_1} \tag{24}$$

$$J_{j,j+1} = \frac{(\omega_2 - \omega_1)}{\omega_0\omega'_1} \sqrt{\frac{b_j b_{j+1}}{g_j g_{j+1}}} \tag{25}$$

$$G_{Tn} = \frac{(\omega_2 - \omega_1)b_n}{g_n g_{n+1}\omega_0\omega'_1} \tag{26}$$

where

$$b_j = Y_{aj} \left(\frac{\cot \theta_0 + \theta_0 \csc^2 \theta_0}{2} \right) \tag{27}$$

The normalized self-capacitances per unit length between each resonator rod and ground are

$$\frac{C_0}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(1 - \frac{G_{T1}}{Y_A} \right) \tag{28}$$

$$\frac{C_1}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(\frac{Y_{a1}}{Y_A} - 1 + \frac{G_{T1}}{Y_A} - \frac{J_{12}}{Y_A} \tan \theta_0 \right) + \frac{C_0}{\epsilon} \tag{29}$$

$$\frac{C_j}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(\frac{Y_{aj}}{Y_A} - \frac{J_{j-1,j}}{Y_A} \tan \theta_0 + \frac{G_{Tn}}{Y_A} - \frac{J_{j,j+1}}{Y_A} \tan \theta_0 \right), \tag{30}$$

$j = 2 \text{ to } n - 1$

$$\frac{C_n}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(\frac{Y_{an}}{Y_A} - 1 + \frac{G_{Tn}}{Y_A} - \frac{J_{n-1,n}}{Y_A} \tan \theta_0 \right) + \frac{C_{n+1}}{\epsilon} \tag{31}$$

$$\frac{C_{n+1}}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(1 - \frac{G_{Tn}}{Y_A} \right) \tag{32}$$

The normalized mutual capacitances per unit length between two adjacent resonator rods are

$$\frac{C_{01}}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} - \frac{C_0}{\epsilon} \tag{33}$$

$$\frac{C_{j,j+1}}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} \left(\frac{J_{j,j+1}}{Y_A} \tan \theta_0 \right), \quad j = 1 \text{ to } n - 1 \tag{34}$$

$$\frac{C_{n,n+1}}{\epsilon} = \frac{Z_0 Y_A}{\sqrt{\epsilon_r}} - \frac{C_{n+1}}{\epsilon} \tag{35}$$

The required lumped capacitances C_j^s between the open end of the resonator rod and ground are

$$C_j^s = Y_{aj} \frac{\cot \theta_0}{\omega_0}, \quad j = 1 \text{ to } n \tag{36}$$

Knowing the desired self- and mutual capacitances of the combline filter resonator rods, we can determine the spacing between the adjacent resonators from the Getsinger or Cristal's design curves for the parallel-coupled rectangular or circular bars as described in the following section.

4.2. Parallel-Coupled Bars

The resonator bars of a combline filter can be considered as an array of the parallel lines. The cross section of the bar is usually rectangular or circular. The dimensions of the lines can be related to the various line capacitances per unit length. The self- and mutual capacitances obtained from Eqs. (28)–(36) can be used to determine the bar dimensions from Getsinger's parallel-coupled rectangular line curves for the rectangular cross section resonator rod combline filters, or from Cristal's parallel-coupled cylindrical rod design data for the circular cross section resonator rod combline filters.

4.2.1. Coupled Rectangular Bars between Parallel Plates. The cross section of a parallel-coupled rectangular bars under consideration and various line capacitances are shown in Fig. 11. There are two parallel ground planes spaced a distance b apart, and a pair of rectangular bars located parallel to and midway between the ground planes. Assuming that C_a is the self-capacitance per unit length between line a and ground, C_{ab} is the mutual capacitance per unit length between lines a and b , and C_b is the capacitance per unit length between line b and ground, then, in terms of odd- and even-mode capacitances for lines a and b , respectively, we have

$$C_{oo}^a = C_a + 2C_{ab}, \quad C_{oe}^a = C_a \tag{37}$$

$$C_{oo}^b = C_b + 2C_{ab}, \quad C_{oe}^b = C_b \tag{38}$$

In Fig. 11, the capacitance per unit length of each line has been separated into component parts by their contributions. C_p is the parallel-plate capacitance per unit length from the top or bottom side of one bar to the adjacent ground plane, C'_{fe} is the fringing capacitance per unit length to ground from the inner corner when the bars

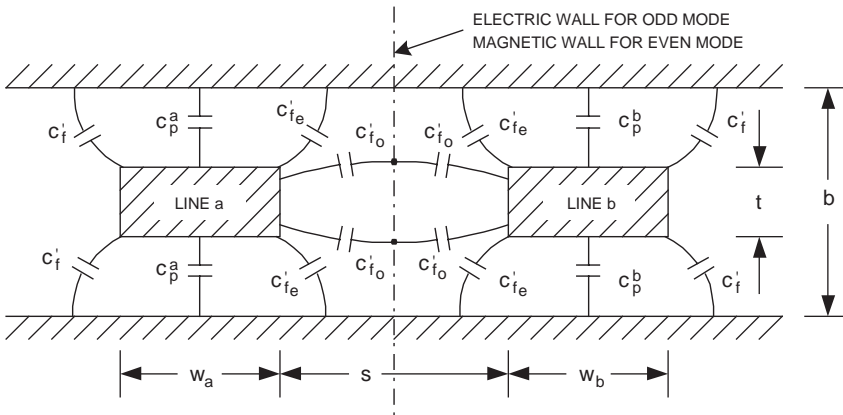

Figure 11. Cross section of parallel-coupled rectangular lines.

are excited in the even mode, and C'_{fo} is the fringing capacitance per unit length to ground from the inner corner when the bars are excited in the odd mode. The capacitance C'_f is the fringing capacitance per unit length for any of the outer corners of the rods. Assuming that all the coupled bars have the same height and thickness, so that the fringing capacitances are the same for both bars, the total self- and mutual capacitances of the coupled bars are

$$C_a = 2(C_p^a + C'_f + C'_{fe}) \tag{39}$$

$$C_{ab} = (C'_{fo} - C'_{fe}) \tag{40}$$

$$C_b = 2(C_p^b + C'_f + C'_{fe}) \tag{41}$$

Figures 12–14 give the normalized design charts by Getzinger [3], which relate $\Delta C/\epsilon$, C'_{fe}/ϵ , C'_{fo}/ϵ , and C'_f/ϵ to the rectangular bar dimensions, where

$$\Delta C = C_{ab} \tag{42}$$

To design a combline filter with rectangular cross section resonator bars, first compute the C_j and $C_{j,j+1}$ values of the filter using Eqs. (28)–(36), and then select a convenient value for t/b , and use Fig. 12 of $\Delta C/\epsilon$ and C'_{fe}/ϵ versus s/b to determine $s_{j,j+1}/b$ and also C'_{fe}/ϵ . Using t/b and Fig. 14 of C'_f/ϵ versus t/b , C'_f/ϵ can be determined. As the parallel-plate capacitance C_p/ϵ is given by

$$\frac{C_p}{\epsilon} = 2 \frac{w/b}{1 - t/b} \tag{43}$$

Figure 12. Fringing capacitances for coupled rectangular bars.

Figure 13. Odd-mode fringing capacitances for coupled rectangular bars.

when the ground-plane spacing b is specified, the desired bar width w_j can be determined as follows:

$$\frac{w_j}{b} = \frac{1}{2} \left(1 - \frac{t}{b} \right) \left[\frac{1}{2} \left(\frac{C_j}{\epsilon} \right) - \frac{(C'_{fe})_{j-1,j}}{\epsilon} - \frac{(C'_{fe})_{j,j+1}}{\epsilon} \right] \quad (44)$$

$$\frac{w_j}{b} = \frac{1}{2} \left(1 - \frac{t}{b} \right) \left[\frac{1}{2} \left(\frac{C_j}{\epsilon} \right) - \frac{C'_{fe}}{\epsilon} - \frac{C'_f}{\epsilon} \right] \quad (45)$$

4.2.2. Coupled Circular Rods between Parallel Plates. Comblines filters made from circular cylindrical

resonator rods can achieve the same excellent electrical performance and at the same time may offer manufacturing advantages. Cristal has given design data for coupled circular cylindrical rods between parallel ground planes [4] that can be used to accurately design a comblines filter with circular resonator rods. Figure 15 shows the geometry of the periodic, circular cylindrical rods between parallel ground planes under consideration. The circular rods have diameter d and are spaced periodically at a distance c . The ground planes are separated at distance b .

The spacing between adjacent rod surfaces is denoted by s and is given by

$$s = c - d \quad (46)$$

The total static capacitances of the rods are related to the mutual capacitance between two adjacent rods C_m and the self-capacitance C_g of each rod. The total capacitance measured between one rod and ground when the rods are driven in the odd mode is

$$C_o = C_g + 4C_m \quad (47)$$

Figure 14. Fringing capacitance for an isolated rectangular bar.

Figure 15. Cross section of parallel-coupled circular rods.

Figure 16. Graph of normalized mutual capacitance C_m/ϵ versus $\frac{1}{2}(s/b)$.

assuming that both sides of the rod are having the same potential conditions. The total capacitance measured between one rod and ground when the rods are driven in the even mode is

$$C_e = C_g \quad (48)$$

From Eqs. (47) and (48) we can obtain

$$C_m = \frac{1}{4}(C_o - 4C_e) \quad (49)$$

Cristal's design graphs of the normalized capacitance C/ϵ versus normalized spacing s/b are given in Fig. 16 for C_m/ϵ and in Fig. 17 for $\frac{1}{2}C_g/\epsilon$.

As in the rectangular cross section resonator bar case, to design a combline filter with circular cylindrical resonator rod, one first needs to compute the C_j and $C_{j,j+1}$ values of the filter using Eqs. (28)–(36), where

$$C_o = C_j \quad (50)$$

$$C_m = C_{j,j+1} \quad (51)$$

and then use Fig. 17 of C_m/ϵ to determine the rod spacing $s_{j,j+1}/b$ and use Fig. 16 of C_g/ϵ to determine the normalized rod diameter d/b .

4.3. Tapped-Line Input and Output

For a tap point located around the bottom 20% of a $\lambda/4$ -long resonator rod, the relationship between the tap point and the resulting loaded Q_e is given approximately by [15]

$$Q_e = \frac{\pi}{4} \left(\frac{R}{Z_o} \right) \left[\frac{1}{\sin^2[(\pi/2)(l/L)]} \right] \quad (52)$$

$$Q_e = \frac{f_o}{R_1 BW} \quad (53)$$

where l is the height of the tap point to the bottom of the resonator rod; L is the equivalent height of the resonator rod, which is equal to $\lambda/4$; R is the impedance of the input or output port; R_1 is the element of the filter's coupling matrix; and Z_o is the impedance of the resonator rod. Figure 18 shows the graph of the equation for the loaded Q .

Figure 17. Graph of normalized half self-capacitance $\frac{1}{2} C_g/\epsilon$ versus $\frac{1}{2} (s/b)$.

Cristal [17] later presented a general open-wire equivalent circuit considering the effects of the coupled resonators using a graph transformation process for combline and interdigital filter designs. In previous papers he assumed that the input or output port will be directly connected to the tapped-in point. However, for practical applications, the tapped line will have an impedance different from that of the input/output port and resonator rod with a given electrical length. The tapped-line length and impedance can have significant effect and therefore should be included in the analysis of the combline filter input/output couplings. Figure 19 shows an equivalent circuit of the tapped-line input/output coupling neglecting the effect of the rest of the resonators. In Cristal’s approach, the graph transformation process or a circuit simulator can be used to solve the tapped-line coupling circuit.

5. FILTER TOPOLOGIES

The combline filter design equations presented in the previous sections are approximate and based on the direct-coupled filter type, typically exhibiting Chebyshev frequency responses. The stopband attenuation level is determined mainly by the number of stages of the filter. The use of nonadjacent or cross-couplings in the narrow-bandwidth bandpass filter with elliptic function response permits great flexibility in the choice of the frequency response. As a result, a smaller number of resonators are required to meet the attenuation specification.

Theoretically, cross-coupling can be applied between any two nonadjacent resonators of the filter, and also including the input and output ports. However, in practical applications the cross-couplings that can be applied are usually limited by the physical layout and complexity of

Figure 18. Loaded combline resonator Q versus tapped-line position.

the filters. The advantage of the filter with an extra number of cross-couplings may be offset by the layout limitation, with much more development effort and the sensitivity of the filter network, leading to longer tuning time and poorer temperature stability.

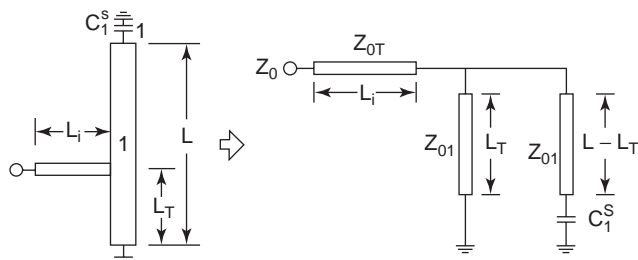

Figure 19. An equivalent circuit for the tapped-line input/output coupling geometry.

Comblines filters with either asymmetric or symmetric frequency response may be realized to meet the desired attenuation characteristics by applying the proper cross-coupling topology and values. For each desired filter transfer function, the configuration or topology that can achieve the targeted frequency response is not unique. However, it is usually preferable to achieve the desired frequency response by using known simple topologies. Figure 20 shows typical canonical-form coupled resonator filters with cross-couplings that can achieve the asymmetric frequency response in part (a), and symmetric frequency response in part (b) [13]. Topologies for so-called CQ and CT filters are shown in Fig. 21.

Filters having complicated cross-coupling structures as shown in Fig. 20 can achieve more transmission zeros using a minimum number of cross-couplings. However, each cross-coupling may affect more than one transmission zero location, which usually makes them more difficult to tune. For commercial applications when cost is a main concern,

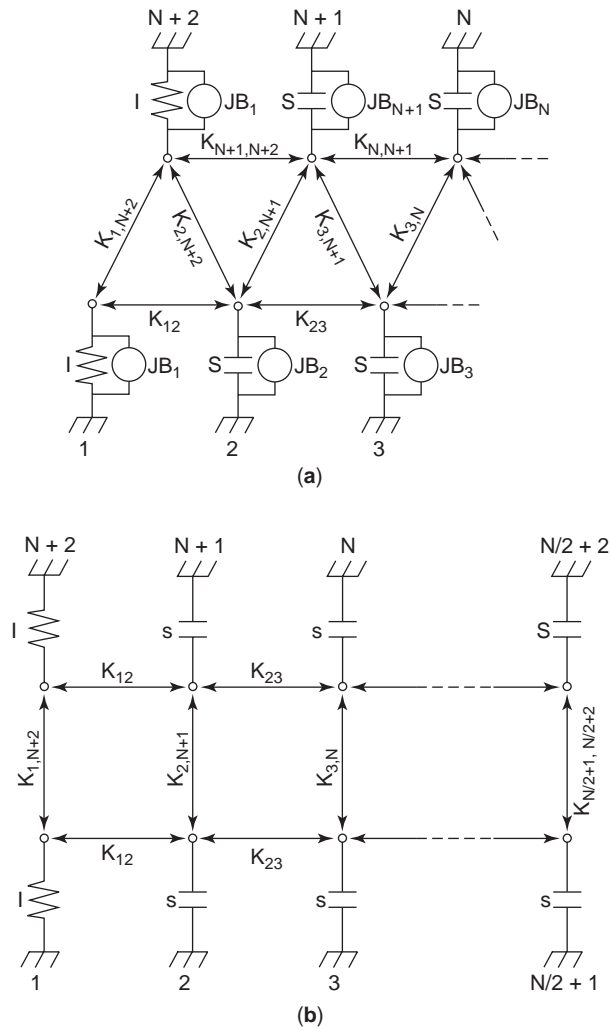

Figure 20. Canonical prototype networks having (a) asymmetric and (b) symmetric frequency responses.

the filter topology that makes the filter easy to design and to tune will be very attractive to filter designers.

The cascaded triplet (CT) or cascaded quadruplet (CQ) sections are relatively simple to tune. Each section is typically responsible only for the transmission zeros that it generates and therefore can be used as a basic building block to create more complicated filter structures. Figure 22 presents the examples using two CT or CQ sections in the cascaded filters.

A CT filter consists of cascaded groups of three cavities or nodes, each with one cross-coupling between first and third resonators in the CT section. The cross section will introduce one transmission zero at either the lower or the higher side of the passband depending on the sign of the cross-coupling. A cross-coupling with negative sign or capacitive-type coupling will generate the transmission zero at the lower side, while the positive or inductive cross-coupling will generate the transmission zero at the higher side. An aperture between two combline resonators usually achieves positive coupling unless the aperture is at the top of the cavity and the electrical length of the comb-

Figure 21. Typical filter building blocks: (a) cascaded triplet (CT) section; (b) cascaded quadruplet (CQ) section.

line rod is over 75° [48]. A coupling bar or probe between the top of the resonators can usually achieve the required capacitive coupling.

Similarly, a CQ filter consists of cascaded groups of four cavities or nodes, each with one cross-coupling between the first and fourth resonators in the CQ section. When the cross-coupling is capacitive, one symmetric pair of transmission zeros one at each side can be achieved. For inductive cross-coupling, a pair of zeros will be on the real axes, and as a result the group delay frequency response of the filter may be equalized.

Figure 22. Cascaded coupling diagram: (a) a six-pole CT filter; (b) an eight-pole CQ filter.

Figure 23. Generalized quadruplet section for two-transmission-zero implementation.

If the quadruplet section has two cross-couplings as shown in Fig. 23, two asymmetric transmission zeros may then be achieved. The locations of the zeros depend on the relative sign of the couplings. Assuming that all the adjacent couplings are inductive, Table 2 summarizes the locations of the zeros corresponding to the sign of the cross-couplings. Similarly, a general five-resonator section with three transmission zeros can be analyzed [25]. Figure 24 gives an example of an eight-pole combline filter having five transmission zeros using multiple cross-coupling four- and five-resonator sections. The three high-side zeros are realized by the 1–5 cross-coupled five-resonator section, while the two low-side zeros are realized by the 5–8 cross-coupled four-resonator section.

As a general rule, a simple Chebyshev response filter that meets the passband, but not the stopband, requirements would be used as the starting point of the design. By bringing transmission zeros from DC or infinity to finite frequencies, the desired stopband characteristics can be achieved. In most cases, the overall degree of the filter can be reduced compared with a Chebyshev design that meets the same requirements.

6. EM SIMULATIONS

To realize narrowband combline filters with relatively complex resonator topologies, all physical parameters such as cavity and aperture dimensions need to be determined from the given coupling matrix. Such filter designs are now increasingly dependent on accurate electromagnetic (EM) computer simulations, due to complexity of the filter structures. As a result, strong interaction

Table 2. Locations of Transmission Zeros for Generalized Quadruplet Section

Case	M_{14}	M_{24}	Number of Zeros ($<f_0, >f_0$)
1	= 0	< 0	1 (1, 0)
2	= 0	> 0	1 (0, 1)
3	< 0	= 0	2 (1, 1)
4	> 0	= 0	2 (j, j)
5	> 0	> 0	2 (0, 2)
6	> 0	< 0	2 (2, 0)
7	< 0	< 0	2 (1, 1)
8	< 0	> 0	2 (1, 1)

between resonators cannot be neglected and should be considered in the design. These requirements usually can be satisfied only by EM simulation. As shown in Fig. 5, the approximate design equations from Eqs. (24)–(53) for space-coupled combline cases can be replaced completely by EM simulations.

6.1. EM Simulators and Methods

Three-dimensional (3D) EM simulation software is usually preferred for use in cavity-type combline filter design. The most commonly used numerical techniques for arbitrary structures are the finite-element method (FEM) and the finite-difference time-domain method (FDTD). These methods can analyze complex structures but usually require large amounts of memory and long computation time. Other computer software can solve some common structures very efficiently (using much less memory) by utilizing the properties of the structure, such as the mode-matching (MM) and transmission-line matrix (TLM) methods. For planar structure problems, the method of moment method (MoM) is usually used.

The commonly used commercial EM simulators are Ansoft or Agilent's HFSS using FEM, CST's Microwave Studio using the FDTD method for 3D arbitrary structures, Agilent's Momentum using FEM, Sonnet's Em, and Zeland's IE3D using MoM for 3D planar structures.

For narrow-bandwidth-coupled resonator filter design, it is usually convenient to divide the filter into individual pieces to determine the cavity and aperture dimension separately when using the EM simulation software to perform the design from the efficiency and memory usage point of view; otherwise too much simulation time will be

Figure 25. Typical electric field distributions of a combline cavity.

needed. Most of the parameters will be fine-tuned by tuning screws at the prototype stage and during production.

6.2. Resonant Frequency

An EM simulator can model the resonator and determine the resonant frequencies of both the fundamental and higher-order modes. In addition, the field distributions of the resonant cavity can be obtained, including the tuning screw as shown in Fig. 25. Figure 26 presents the typical higher-order mode chart of the combline resonators with the airgap between the rod and enclosure as a variable. It is shown that TM_{02} and HE_{11} are the first two higher-order modes of the typical combline resonator. For the small-gap case, a resonator with a shorter length has a larger mode separation. The resonant frequency of the first higher-order mode can be 3–5 times the dominant

Figure 26. Typical mode chart of a combline resonator relative to dominant mode as a function of gap.

mode resonant frequency when the height of the cavity is 0.5–1.0 times the diameter of the cavity. The typical small-gap reentrant cavity bandpass filter can achieve a spurious-free range of more than twice the center frequency. This mode separation ratio decreases as the gap increases.

6.3. Unloaded Q

Accurate determination of the unloaded Q factor of the resonator is very important for combline filter design, since it directly relates to loss, size, and cost of the filter. Empirically, the unloaded Q of a combline resonator can be estimated from the measurements of many practical filters using the equation [21]

$$Q = Kb\sqrt{f_0} \tag{54}$$

where b is the width of the cavity in inches, f_0 is the resonant frequency in gigahertz, and K is a constant approximately equal to 1600 with b less than 0.08λ for a practical silver-plated combline resonator. However, when b is above 0.08λ , K increases, and can be as much as 2800 for $b = 0.18\lambda$. Figure 27 shows the measured unloaded Q of the combline resonator expressed in K values with b/λ in terms of K as a function of b/λ in the range between 0.12 and 0.20. The practical Q is dependent on factors such as surface roughness, plating quality, tuning screw penetration, and possible surface contact problems, which partially explains the spread in the K values of various designs having the same b/λ .

EM simulation software can compute the unloaded Q of a cavity accurately. Since a combline resonator has small

Figure 27. Measured normalized unloaded Q as a function of b/λ .

Figure 28. Computed unloaded Q of a combline resonator versus D_2/D_1 Ratio.

loss, a perturbation method is usually incorporated for this kind of computation. Figure 28 shows the computed unloaded Q of the combline resonators versus the ratio of the outer/inner diameter ratio D_2/D_1 with different rod lengths. It is shown that maximum unloaded Q of the resonators occurs when D_2/D_1 is approximately 3.6. Longer rod length yields higher unloaded Q for the same D_1 and D_2 .

Both the resonant frequency and unloaded Q decrease when the tuning screw penetrates into the cavity. The tuning screw may have a strong effect on unloaded Q of the combline resonator, which should be considered in the filter design. Figure 29 shows the computed unloaded Q of a combline resonator versus resonant frequency change by the tuning screw.

Figure 29. Unloaded Q of a combline resonator versus resonant frequency as an effect of the tuning screw.

7. TYPICAL APPLICATIONS

Comblines filters have been widely used in many communication systems and microwave applications. They have become more and more important for low-loss microwave filters in the 0.5–12 GHz frequency band for both narrow- and wideband applications. Applications of combline filters also include diplexers (duplexers), multiplexers, and delay-line filters. When a combline cavity is filled with a high dielectric constant material, it results in a dielectric resonator having significantly reduced dimensions.

Another application for combline filters is to replace the lowpass filter to achieve a very wideband spurious-free response in the system [49]. For this type of application, the bandwidth of the filter is usually relatively large and

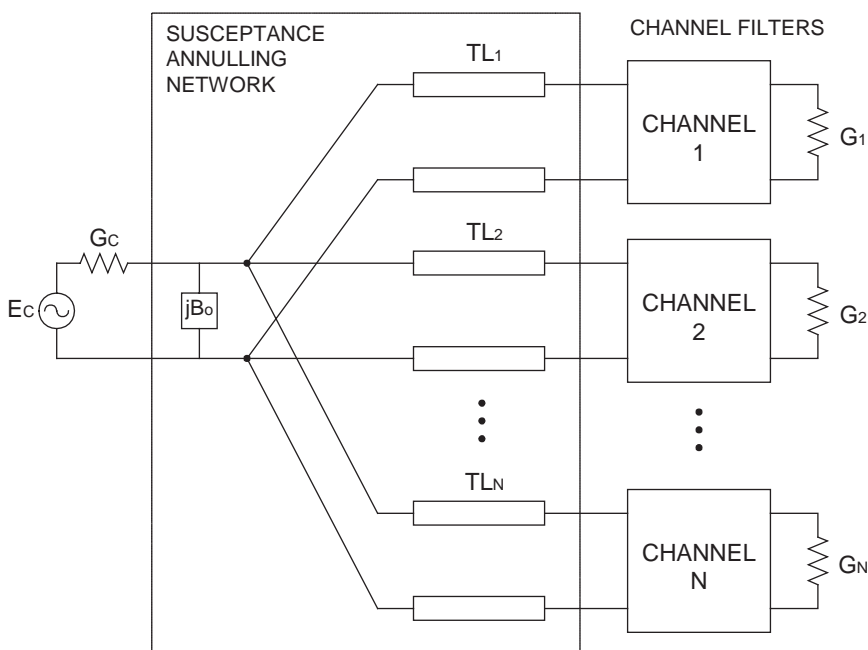

Figure 30. Schematic of a parallel-connected multiplexer.

Figure 31. A 1.8-GHz DCS duplexer.

therefore does not require very high unloaded Q ; thus the filter can be very small in size. As the combline resonator can have superior stopband performance, wideband spurious-free performance with a sharp rolloff skirt can be achieved easily with combline resonator filters.

Multiplexers, particularly duplexers, are frequently required by communication systems for RF front ends to separate or combine both transmit and receive signals [28–37]. A schematic drawing of a commonly used parallel-connected multiplexer with N channels is shown in Fig. 30. The multiplexer consists of channel filters and a susceptance annulling network, which in turn consists of transmission lines series-connected to each channel filter

and a shunt susceptance element at a common input port to help provide a nearly constant total input admittance [33–38]. The susceptance annulling network is achieved by optimizing the length and characteristic impedance of the transmission lines and the shunt susceptance element value to minimize the interaction among the channels. For narrowband applications, the susceptance jB_0 of the annulling network can be maintained by offsetting the resonant frequency of the first cavities of the channel filters to cancel the susceptance of the channel filters. Figure 31 is a photograph of a DCS (digital communication system) duplexer consisting of two 6-pole combline filters. Each channel filter has two CT sections having two transmission zeros at one side. Figure 32 presents the measured frequency response of the duplexer.

Singapore
Kent Ridge, Singapore

1. CONSTITUTIVE RELATIONS

For most media, the general form of constitutive relations that account for multiple effects resulting from interaction between electromagnetic waves and media can be expressed by [1]

$$D_i = \varepsilon_{ij} E_j + \gamma_{ij}^E \partial_t E_j + \zeta_{ij}^E \Delta_j E_k + \beta_{ij}^E B_j + \alpha_{ij}^E \partial_t B_j + \eta_{ijk}^E \Delta_j B_k + \dots \quad (1a)$$

$$H_i = \mu_{ij}^{-1} B_j + \gamma_{ij}^B \partial_t B_j + \eta_{ijk}^B \Delta_j B_k + \beta_{ij}^B E_j + \alpha_{ij}^B \partial_t E_j + \eta_{ijk}^B \Delta_j E_k + \dots \quad (1b)$$

where E_k and H_i are the electric and magnetic field components; D_i and B_k are electric and magnetic induction components; and ε_{ij} , γ_{ij}^B , η_{ijk}^E , and so on are constitutive tensors of different ranks. The space Δ_j and time ∂_t derivatives take into account spatial and temporal variations of the field.

For linear, stationary, and dispersive bianisotropic media in the frequency domain, their constitutive relations can be described by a set of equations as follows [2–25] ($e^{j\omega t}$):

$$\vec{D} = \varepsilon_0[\varepsilon(\omega)]\vec{E} + \sqrt{\mu_0\varepsilon_0}[\zeta(\omega)]\vec{H} \quad (2a)$$

$$\vec{B} = \mu_0[\mu(\omega)]\vec{H} + \sqrt{\mu_0\varepsilon_0}[\eta(\omega)]\vec{E} \quad (2b)$$

where ω is the operating angular frequency; the tensors $[\varepsilon(\omega)]$, $[\mu(\omega)]$, $[\zeta(\omega)]$ and $[\eta(\omega)]$ are the relative permittivity, permeability and magnetoelectric tensors, respectively. Apparently, Eqs. (2a) and (2b) are applicable for the constitutive description of electromagnetically anisotropic, biisotropic chiral, uniaxially, or biaxially bianisotropic media [26–45]. Therefore, Eqs. (2a), and (2b) can incorporate most practical applications of complex linear media used in RF engineering.

2. CLASSIFICATION OF BIANISOTROPIC¹ MEDIA

2.1. Continuous Groups of Symmetry (CGS)

In Eqs. (2a) and (2b), four constitutive tensors are usually described by a 3×3 matrix, respectively. However, according to the theory of continuous groups of symmetry (CGS) developed by Dmitriev [1,46–49], the number of independent elements in $[\varepsilon(\omega)]$, $[\mu(\omega)]$, $[\zeta(\omega)]$ and $[\eta(\omega)]$ for a given bianisotropic medium is completely governed by a certain magnetic group of symmetry. From CGS theory, we can understand the four constitutive tensors if the CGS of medium is known. Typically, these tensors correspond to the following CGSs:

$$D_{4h}(D_{2d}), D_{4h}(D_{2h}), C_{4h}(S_4), C_{4h}(C_{2h}),$$

$$D_4(D_2), D_{2d}(S_4), D_{2d}(D_2), D_{2d}(C_{2v}),$$

$$C_{4v}(C_{2v}), D_{2h}(D_2), D_{2h}(C_{2h}),$$

$$D_{2h}(C_{2v}), S_4(C_2), C_4(C_2), D_2(C_2), C_{2h}(C_i),$$

$$C_{2h}(C_2), C_{2h}(C_s), C_{2v}(C_2),$$

$$C_{2v}(C_s), C_i(C_1), C_2(C_1), C_s(C_1) \quad (3)$$

¹The term *bianisotropic* denotes the property of being biisotropic and/or anisotropic.

The constitutive tensors for these 23 linear complex media are given as follows [1]:

$$\begin{aligned}
 1^\circ(D_{4h}(D_{2d}); N_f = 5): [\varepsilon] &= \begin{bmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{xx} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{bmatrix}, \\
 [\mu] &= \begin{bmatrix} \mu_{xx} & 0 & 0 \\ 0 & \mu_{xx} & 0 \\ 0 & 0 & \mu_{zz} \end{bmatrix} \quad (4a) \\
 [\xi] &= \begin{bmatrix} 0 & \xi_{xy} & 0 \\ \xi_{xy} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad [\eta] = [\xi]
 \end{aligned}$$

$$\begin{aligned}
 2^\circ(D_{4h}(D_{2h}); N_f = 4): [\varepsilon] &= \begin{bmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{xx} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{bmatrix}, \\
 [\mu] &= \begin{bmatrix} \mu_{xx} & 0 & 0 \\ 0 & \mu_{xx} & 0 \\ 0 & 0 & \mu_{zz} \end{bmatrix}, \quad (4b) \\
 [\xi] &= [\eta] = [0]
 \end{aligned}$$

$$\begin{aligned}
 3^\circ(C_{4h}(S_4); N_f = 6): [\varepsilon] &= \begin{bmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{xx} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{bmatrix}, \\
 [\mu] &= \begin{bmatrix} \mu_{xx} & 0 & 0 \\ 0 & \mu_{xx} & 0 \\ 0 & 0 & \mu_{zz} \end{bmatrix} \quad (4c) \\

 \end{aligned} \tag{4w}$$

It is obvious that the constitutive features of normal uniaxially anisotropic media such as microwave laminates can be represented by the CGSs of $C_{4h}(C_{2h})$ or $D_{4h}(D_{2h})$. Uniaxially bianisotropic media, such as chiroomega media, can be described by $D_{2d}(C_{2v})$ or $C_{4v}(C_{2v})$. For gyroelectric and gyromagnetic anisotropic media, their constitutive features can be represented by $D_{2h}(C_{2h})$. On the other hand, it should be pointed out that in these constitutive tensors, each element could be the function of operating frequency, or even a complex quantity. The interaction

features of electromagnetic waves with various composite bianisotropic structures can be found in the literature [50–54]. The constitutive tensors of some CGSs of bianisotropic media are described in detail below.

2.2. Ferroelectric Materials [55–57]

Ferroelectric thin films can be used as the substrate or superstrate of various microstrip- or coplanar-waveguide-based microwave devices (Fig. 1) that possess certain tunabilities in their electromagnetic features. When the crystalline principal axes of the ferroelectric film are oriented in the coordinate directions, the film is reduced to the simplified case of the CGS described above, namely, $D_{2h}(C_{2v})$ and $[\mu] = \mu_0 \bar{I}$, $\zeta_{xy} = \zeta_{yx} = 0$. The film's permittivity tensor $[\varepsilon_f]$ in the unbiased condition, the biasing electric field $\vec{E}_{\text{bias}} = 0$, can be expressed by

$$[\varepsilon_f(0)] = \begin{bmatrix} \varepsilon_{xx}(0) & 0 & 0 \\ 0 & \varepsilon_{yy}(0) & 0 \\ 0 & 0 & \varepsilon_{zz}(0) \end{bmatrix} \tag{5}$$

When the biasing DC electric field is applied, $[\varepsilon_f]$ becomes

$$[\varepsilon_f(\vec{E}_{\text{bias}})] = \begin{bmatrix} \varepsilon_{xx}(\vec{E}_{\text{bias}}) & 0 & 0 \\ 0 & \varepsilon_{yy}(\vec{E}_{\text{bias}}) & 0 \\ 0 & 0 & \varepsilon_{zz}(\vec{E}_{\text{bias}}) \end{bmatrix} \tag{6}$$

Here, each element $[\varepsilon_f(\vec{E}_{\text{bias}})]$ can be a function of each of the three bias field components $E_{x,y,z,\text{bias}}$. If we assume, for simplicity, diagonal functional projection of the bias field components onto the permittivity tensor $[\varepsilon_f]$ elements, then we have

$$[\varepsilon_f(\vec{E}_{\text{bias}})] = \begin{bmatrix} \varepsilon_{xx}(E_{x,\text{bias}}) & 0 & 0 \\ 0 & \varepsilon_{yy}(E_{y,\text{bias}}) & 0 \\ 0 & 0 & \varepsilon_{zz}(E_{z,\text{bias}}) \end{bmatrix} \tag{7}$$

Using the hexagonal perovskite crystalline form for $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ (BSTO) thin film, with the c axis parallel to the y axis and having properties different from those in the a - and b -axis directions parallel to the xz plane and having the same effects, $[\varepsilon_f]$ takes an uniaxial form as

$$[\varepsilon_f(0)] = \begin{bmatrix} \varepsilon_{xx}(0) & 0 & 0 \\ 0 & \varepsilon_{yy}(0) & 0 \\ 0 & 0 & \varepsilon_{xx}(0) \end{bmatrix} \tag{8}$$

Figure 1. Cross-sectional views of two composite ferroelectric coplanar waveguides: (a) BSTO substrate; (b) BSTO superstrate-substrate.

In the case of $E_{\text{bias}} = E_x$, the ferroelectric effect renders $[\epsilon_f]$ as

$$[\epsilon_f(E_{\text{bias}})] = \begin{bmatrix} \epsilon_{xx}(E_{x,\text{bias}}) & 0 & 0 \\ 0 & \epsilon_{yy}(0) & 0 \\ 0 & 0 & \epsilon_{zz}(0) \end{bmatrix} \quad (9)$$

and $[\epsilon_f(E_{\text{bias}})]$ is biaxial.

It is understood that, as a rule, the losses in ferroelectrics decreases with decreasing temperature. So, after the discovery of high-temperature superconductivity (HTS), much effort has been devoted to combining HTS with ferroelectrics to realize the tunability of microwave devices in a low-loss situations. The modified microstrip structure in Fig. 1 consists of a dielectric substrate (LAO

or MgO, typically 254 μm thick), a ferroelectric thin-film layer with thickness ranging from 300 to 2000 nm for various applications, and a gold or YBCO thin film of 0.35 or 2 μm thick for the top strip, respectively.

On the other hand, in order to achieve the desired propagation characteristics of a ferroelectric microstrip line or coplanar waveguide, an additional ferrite layer can also be introduced in the substrate or superstrate-substrate structures presented above.

2.3. Sapphire

A nonmagnetic sapphire is also very important for high-frequency applications, and its relative permittivity tensor can be expressed by

$$[\epsilon] = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} & 0 \\ \epsilon_{yx} & \epsilon_{yy} & 0 \\ 0 & 0 & \epsilon_{zz} \end{bmatrix} \quad (10a)$$

$$\epsilon_{xx} = \epsilon_x(T) \cos^2 \theta_e + \epsilon_y(T) \sin^2 \theta_e$$

$$\epsilon_{xy} = \epsilon_{yx}(T) = [\epsilon_y(T) - \epsilon_x(T)] \sin \theta_e \cos \theta_e$$

$$\epsilon_{yy} = \epsilon_x(T) \sin^2 \theta_e + \epsilon_y(T) \cos^2 \theta_e, \epsilon_{zz} = \epsilon_z(T) \quad (10b)$$

where θ_e ($0^\circ \leq \theta_e \leq 360^\circ$) is the misalignment angle between the coordinates of the line and principal axes of $[\epsilon]$ with respect to the x direction in x - y plane, $\epsilon_{x,y,z}(T)$ are the three principal-axis permittivities, and T is the operating temperature of sapphire.

2.4. Gyroelectric Media [58–61]

A great deal of attention has been paid to the microwave propagation in gyroelectric or solid-state magnetoplasmas in the past a few decades, since this type of medium ($[\zeta] = [\eta] = 0$) can be used to make various nonreciprocal devices for microwave and millimeter-wave applications, such as gyroelectric waveguides and planar microstrip transmission lines, as shown in Figs. 2a–2d. These models provide a basis for further developing planar integrated nonreciprocal devices, where the bulk gyroelectric media present the advantage of a very good coupling between the wave and the media. So, owing to the good mobility of the media, the losses are reduced.

In Fig. 2a, the longitudinal DC magnetic field is along the z -axis direction. On the other hand, if the DC magnetic field is wrapped around the z axis into a cylindrical shape, it forms an azimuthally magnetized solid-state plasma-filled coaxial waveguide that can support the cylindrically symmetric TM_{01} mode, and the corresponding permittivity tensor can be written as [61]

$$[\epsilon] = \begin{bmatrix} \epsilon_{xx} & 0 & \epsilon_{xz} \\ 0 & \epsilon_{yy} & 0 \\ -\epsilon_{xz} & 0 & \epsilon_{xx} \end{bmatrix} \quad (11)$$

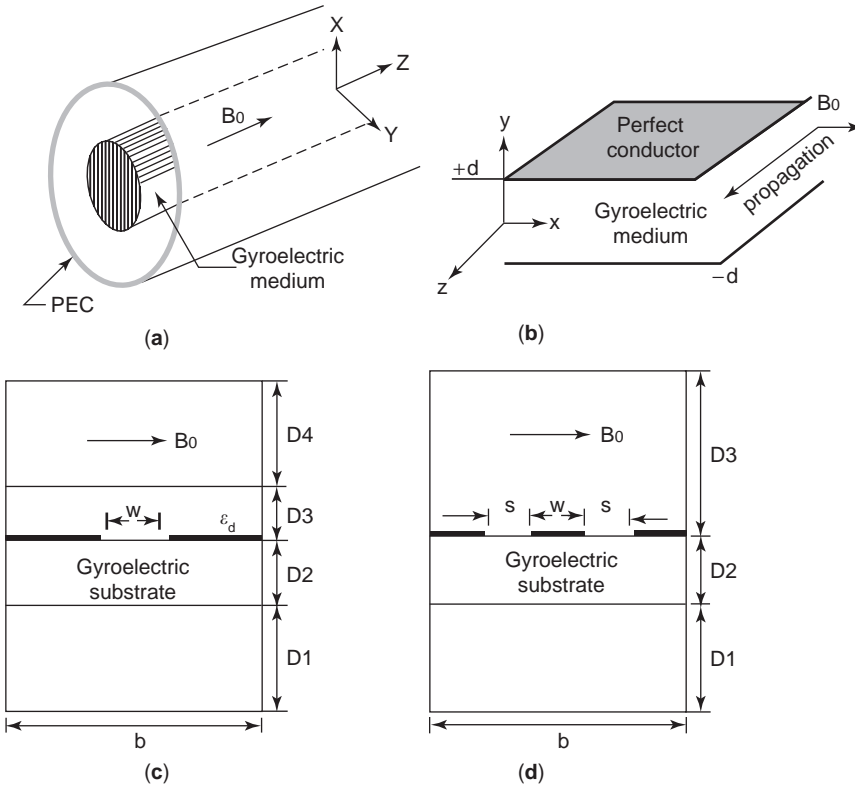

Figure 2. Schematic diagrams of gyroelectric waveguides and planar transmission lines: (a) circular; (b) planar; (c) slotline; (d) coplanar waveguide.

In Fig. 2b, there is a transversely magnetized plasma between two perfectly conducting parallel plates separated by a distance $2d$, where the static magnetic field is applied in the x direction and wave propagation is in the z direction. If the plasma is magnetized in the y direction, normal to the conducting plates, the modes are not, in general, separable into TE and TM modes. Here the relative permittivity tensor can be written in the form

$$[\varepsilon] = \begin{bmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{yy} & \varepsilon_{yz} \\ 0 & -\varepsilon_{yz} & \varepsilon_{zz} \end{bmatrix} \quad (12)$$

where each element in (12) is given in Ref. 61. Figure 2c shows a suspended single-slotline structure and Fig. 2d, a suspended coplanar waveguide.

When the biasing DC magnetic field \vec{B}_0 of the solid-state plasma in Fig. 2 is in an arbitrary direction (φ_0, θ_0) , its permittivity tensor can be described by $(e^{j\omega t})$

$$[\varepsilon(\omega)] = \begin{bmatrix} \varepsilon_{xx}(\omega) & \varepsilon_{xy}(\omega) & \varepsilon_{xz}(\omega) \\ \varepsilon_{yx}(\omega) & \varepsilon_{yy}(\omega) & \varepsilon_{yz}(\omega) \\ \varepsilon_{zx}(\omega) & \varepsilon_{zy}(\omega) & \varepsilon_{zz}(\omega) \end{bmatrix} \quad (13a)$$

$$\begin{aligned} \varepsilon_{xx}(\omega) &= \varepsilon_1(\omega) + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin^2 \nu \cos^2 \psi \\ \varepsilon_{xy}(\omega) &= -jg(\omega) \cos \nu + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin \psi \cos \psi \sin^2 \nu \\ \varepsilon_{xx}(\omega) &= \{jg(\omega) \sin \psi + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \cos \psi \cos \nu\} \sin \nu \\ \varepsilon_{yx}(\omega) &= jg(\omega) \cos \nu + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin \psi \cos \psi \sin^2 \nu \\ \varepsilon_{yy}(\omega) &= \varepsilon_1(\omega) + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin^2 \nu \sin^2 \psi \\ \varepsilon_{yz}(\omega) &= \{-jg(\omega) \cos \psi + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin \psi \cos \nu\} \sin \nu \\ \varepsilon_{zx}(\omega) &= \{-jg(\omega) \sin \psi + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \cos \psi \cos \nu\} \sin \nu \\ \varepsilon_{zy}(\omega) &= \{jg \cos \psi + [\varepsilon_2(\omega) - \varepsilon_1(\omega)] \sin \psi \cos \nu\} \sin \nu \\ \varepsilon_{zz}(\omega) &= \varepsilon_1(\omega) \sin^2 \nu + \varepsilon_2(\omega) \cos^2 \nu \end{aligned} \quad (13b)$$

In (13b), two consecutive rotations of angles ψ and ν are determined by the spherical angles φ_0 and θ_0 by

$$\cos \psi = \frac{\sin \theta_0 \cos \varphi_0}{\sqrt{(\sin^2 \theta_0 \cos^2 \varphi_0 + \cos^2 \theta_0)}} \quad (13c)$$

$$\cos \nu = \sin \theta_0 \sin \varphi_0 \quad (13d)$$

$$\varepsilon_1(\omega) = \varepsilon_s - \frac{\omega_p^2(\omega - j\tau^{-1})}{\omega \varepsilon_0 [(\omega - j\tau^{-1})^2 - \omega_c^2]} \quad (13e)$$

$$\varepsilon_2(\omega) = \varepsilon_s - \frac{\omega_p^2}{\omega \varepsilon_0 (\omega - j\tau^{-1})} \quad (13f)$$

$$g(\omega) = - \frac{\omega_p^2 \omega_c}{\omega \varepsilon_0 [(\omega - j\tau^{-1})^2 - \omega_c^2]} \quad (13g)$$

where $\omega_p = \sqrt{ne^2/\varepsilon_0 m^*}$ represents the plasma frequency; $\omega_c = eB_0/m^*$, the cyclotron frequency; n , the carrier concentration; e , the electron charge; m^* , the electron effective mass (kg) (i.e., $0.067 m_e$ for GaAs); m_e , the electron rest mass; B_0 , the DC magnetizing field; φ , the orientation angle of B_0 in the x - y plane; τ , the momentum relaxation time of the semiconductor material; and ε_s , the relative dielectric permittivity of the semiconductor.

2.5. Ferrites

Ferrites have been widely used as important elements in microwave and millimeter-wave devices, such as phase shifters, resonance isolators, circulators, and superstrates or substrates of microwave integrated circuits (MICs). One of the main advantages of using magnetized ferrites is that their characteristic parameters, as in Fig. 2, can be controlled by adjusting an applied DC magnetic bias field. Hence, various tunable microwave devices can also be designed when we combine ferrites with other materials, as shown in Fig. 3.

In Fig. 3b [62], a high-temperature superconductor (HTS) strip (2) of a width W is located on top of the dielectric substrate (1) and separated by a dielectric layer (3) from an epitaxial ferrite film (4) deposited on a dielectric substrate (5). The structure may contain either an HTS or metal bottom electrode (0), the microstrip resonator, or two HTS electrodes (Fig. 2a), placed at a distance W_1 from each other, the CPW resonator. The thickness of the HTS electrodes (2), ferrite layer (4), bottom electrode (0), and dielectric layers (1), (3), and (5) are t , t_f , t_0 and t_1 , t_3 , t_5 , respectively. An external DC biasing magnetic field H_e is applied parallel to the plane of the structure and makes an angle ϕ with the central stripline direction.

When the biasing DC magnetic field \vec{B}_0 takes an arbitrary orientation (φ_0, θ_0) , the permeability tensor $[\mu(\omega)]$ of ferrites can be written as [34]

$$[\mu(\omega)] = \begin{bmatrix} \mu_{xx}(\omega) & \mu_{xy}(\omega) & \mu_{xz}(\omega) \\ \mu_{yx}(\omega) & \mu_{yy}(\omega) & \mu_{yz}(\omega) \\ \mu_{zx}(\omega) & \mu_{zy}(\omega) & \mu_{zz}(\omega) \end{bmatrix} \quad (14a)$$

$$\mu_{xx}(\omega) = \mu(\omega) + [1 - \mu(\omega)] \sin^2 \theta_0 \cos^2 \varphi_0$$

$$\begin{aligned} \mu_{xy}(\omega) &= [1 - \mu(\omega)] \sin \varphi_0 \cos \varphi_0 \sin^2 \theta_0 \\ &\quad - j\kappa \cos \theta_0 \end{aligned}$$

$$\begin{aligned} \mu_{xz}(\omega) &= j\kappa \sin \varphi_0 \sin \theta_0 \\ &\quad + [1 - \mu(\omega)] \sin \theta_0 \cos \theta_0 \cos \varphi_0 \end{aligned}$$

$$\begin{aligned} \mu_{yx}(\omega) &= [1 - \mu(\omega)] \sin \varphi_0 \cos \varphi_0 \\ &\quad \times \sin^2 \theta_0 + j\kappa \cos \theta_0 \end{aligned}$$

$$\mu_{yy}(\omega) = \mu(\omega) + [1 - \mu(\omega)] \sin^2 \theta_0 \sin^2 \varphi_0$$

$$\begin{aligned} \mu_{yz}(\omega) &= -j\kappa \cos \varphi_0 \sin \theta_0 \\ &\quad + [1 - \mu(\omega)] \sin \theta_0 \cos \theta_0 \sin \varphi_0 \end{aligned}$$

$$\begin{aligned} \mu_{zx}(\omega) &= -j\kappa \sin \varphi_0 \sin \theta_0 + [1 \\ &\quad - \mu(\omega)] \sin \theta_0 \cos \theta_0 \cos \varphi_0 \end{aligned}$$

$$\begin{aligned} \mu_{zy}(\omega) &= j\kappa \cos \varphi_0 \sin \theta_0 + [1 \\ &\quad - \mu(\omega)] \sin \theta_0 \cos \theta_0 \sin \varphi_0 \end{aligned}$$

$$\mu_{zz}(\omega) = 1 - [1 - \mu(\omega)] \sin^2 \theta_0$$

$$\mu(\omega) = \mu_1(\omega) - j\mu_2(\omega) \quad (14b)$$

$$\mu_1(\omega) = 1 + \frac{\omega_0 \omega_m [\omega_0^2 - \omega^2 (1 - \alpha_m^2)]}{F_m}$$

$$\mu_2(\omega) = \frac{\omega \omega_m \alpha_m [\omega_0^2 + \omega^2 (1 + \alpha_m^2)]}{F_m}$$

$$\kappa(\omega) = \kappa_1(\omega) - j\kappa_2(\omega)$$

$$\kappa_1(\omega) = - \frac{\omega \omega_m [\omega_0^2 - \omega^2 (1 + \alpha_m^2)]}{F_m}$$

$$\kappa_2 = - \frac{2\omega_m \omega_0 \alpha_m \omega^2}{F_m}$$

$$F_m = [\omega_0^2 - \omega^2 (1 + \alpha_m^2)]^2 + 4(\omega \omega_0 \alpha_m)^2$$

where $\omega = |\gamma|H_0$, $\omega_m = |\gamma|M_s$, M_s is the saturation magnetization of the ferrite, γ denotes to the gyromagnetic ratio ($= -2.21 \times 10^5$ rad·m/C), α_m identifies the Landau damping coefficient, and the loss is taken into account.

2.6. Biisotropic Chiral Medium

Since the early 1990s many researchers have explored the diverse chirality effects in biisotropic chiral media on electromagnetic wave propagation, radiation, and scattering. Electromagnetic waves in chiral media show some very interesting features, such as optical rotatory dispersion (ORD), which causes the rotation of polarization; and circular dichroism, due to the different absorption coefficients of right- and left-handed circularly polarized waves. Some component models using chiral media have been proposed, such as chirowaveguides, chiro-lens, chiro-domes, chiro-strip antennas, chiral resonators, and chiral-mode transformers [63–83].

The constitutive equation for biisotropic chiral media can be easily obtained from Eqs. (2a) and (2b), as follows

$$\vec{D} = \varepsilon_0 \varepsilon_r \vec{E} + \sqrt{\mu_0 \varepsilon_0} \vec{\zeta} \vec{H} \quad (15a)$$

$$\vec{B} = \mu_0 \mu_r \vec{H} + \sqrt{\mu_0 \varepsilon_0} \vec{\eta} \vec{E} \quad (15b)$$

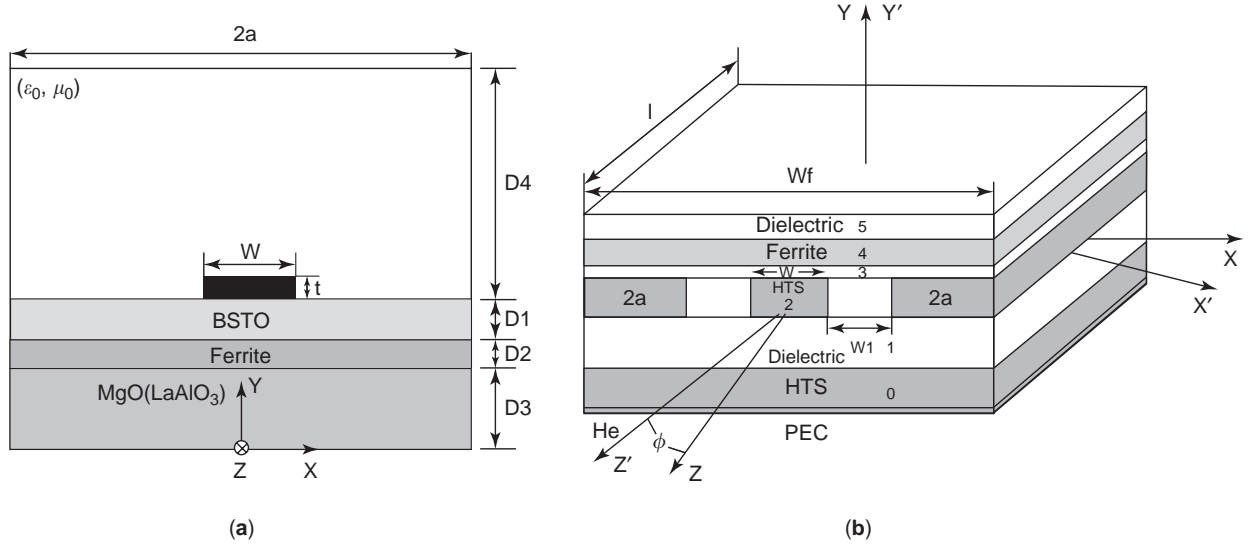

Figure 3. Geometries of ferrite-based tunable microstrip line and coplanar resonator: (a) BSTO-ferrite microstrip line; (b) multilayer composite HTS-ferrite coplanar resonator.

where we let $[\underline{\epsilon}] = \epsilon_r \bar{I}$, $[\underline{\mu}] = \mu_r \bar{I}$, $[\underline{\xi}] = \xi \bar{I} = j\kappa \bar{I}$, and $[\underline{\eta}] = \xi^* \bar{I} = -j\kappa \bar{I}$, where \bar{I} is the unit dyad, κ is the chirality parameter, and the frequency-dependent property of constitutive quantities should be understood but here ω is suppressed. In a chiral medium, the eigenmodes are the left- and right-handed circular polarized waves, as observed in ferrites. However, there is no biasing DC magnetic field needed. Some models of chiral devices are outlined as follows.

2.6.1. Chirowaveguides. Figure 4 shows the geometries of circular (a) and a rectangular (b) chirowaveguides, which have been extensively studied by some researchers.

The guided-mode characteristics in chirowaveguides in Fig. 4 are completely controlled by chirality parameter. It can be predicated that the ordinary modes of transverse electric TE_{nm} , transverse magnetic TM_{nm} , or transverse electromagnetic (TEM) modes cannot be supported in circular bianisotropic waveguides. The propagating modes along z axis are always hybrid, but they can be classified into hybrid modes HE_{nm} and EH_{nm} . The descriptor EH_{nm} is used here for hybrid modes originating in ordinary TM_{nm} modes, and HE_{nm} is used for hybrid modes stemming from ordinary TE_{nm} modes. Here $n(= -\infty, \dots, 0, \dots, \infty)$ and $m(= 1, \dots, \infty)$ respectively denote the azimuthal and radial quantum numbers, of which n implies an azimuthal variation $e^{-jn\phi}$ and m implies that the mode is number m when ordered after increasing cutoff frequency for given n .

The longitudinal components E_z and H_z are coupled with each other; however, E_z and H_z can be decoupled as follows

$$E_z = S_+ U_+ + S_- U_- \quad (16a)$$

$$H_z = q_+ U_+ + q_- U_- \quad (16b)$$

where U_{\pm} are determined by

$$\nabla_t^2 U_{\pm} + S_{\pm} U_{\pm} = 0 \quad (16c)$$

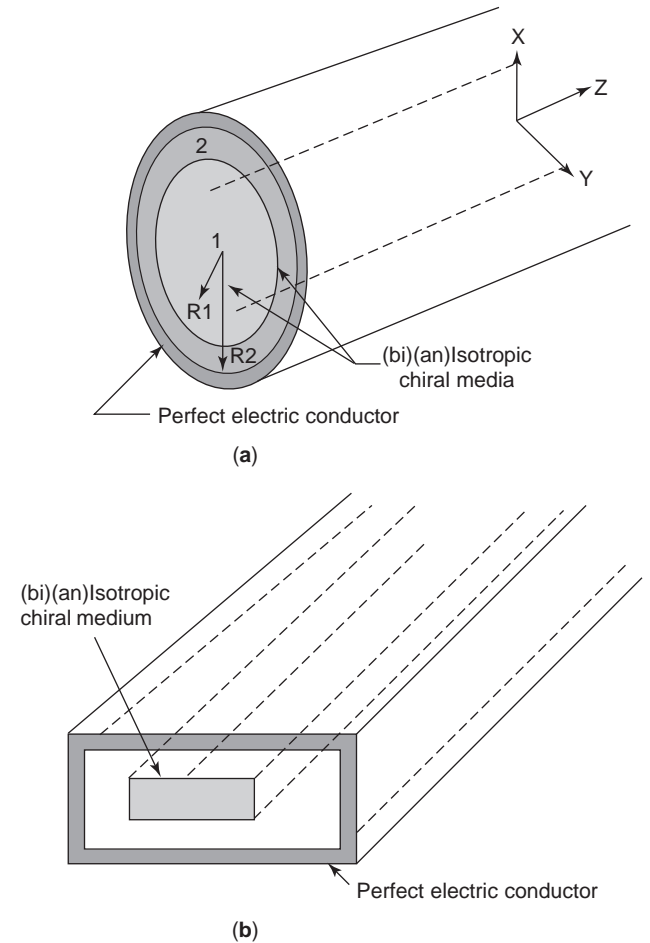

Figure 4. Geometries of chirowaveguides: (a) circular; (b) rectangular.

and more generally, by

$$S_{\pm} = \frac{-(C_1 + C_4) \pm \sqrt{(C_1 - C_4)^2 + 4C_2C_3}}{2} \quad (16d)$$

$$q_{\pm} = \frac{-S_{\pm}(S_{\pm} + C_1)}{C_2} \quad (16e)$$

$$C_1 = \frac{j\omega(A_{43}\eta_{zz} + A_{41}\varepsilon_{zz})}{\Delta_0}, \quad C_2 = \frac{j\omega(A_{43}\mu_{zz} + A_{41}\xi_{zz})}{\Delta_0}$$

$$C_3 = -\frac{j\omega(A_{21}\varepsilon_{zz} + A_{23}\eta_{zz})}{\Delta_0}, \quad C_4 = -\frac{j\omega(A_{21}\xi_{zz} + A_{23}\mu_{zz})}{\Delta_0}$$

$$\Delta_0 = A_{21}A_{43} - A_{23}A_{41} \quad (16f)$$

Further, the transverse components electric and magnetic fields inside the chiro-waveguide can be expressed in terms of E_z and H_z as follows [31,32,35,69–71]

$$\begin{bmatrix} E_x \\ E_y \\ H_x \\ H_y \end{bmatrix} = \begin{bmatrix} A_{22} & A_{21} & A_{42} & A_{41} \\ -A_{21} & A_{22} & -A_{41} & A_{42} \\ A_{24} & A_{23} & A_{44} & A_{43} \\ -A_{23} & A_{24} & -A_{43} & A_{44} \end{bmatrix} \begin{bmatrix} \frac{\partial E_z}{\partial x} \\ \frac{\partial E_z}{\partial y} \\ \frac{\partial H_z}{\partial x} \\ \frac{\partial H_z}{\partial y} \end{bmatrix} \quad (17a)$$

where

$$A_{21} = \frac{a_3b_2 + a_4b_3 - a_2b_1}{\Delta}, \quad A_{22} = \frac{a_1b_1 + a_4b_2 - a_3b_3}{\Delta}$$

$$A_{23} = \frac{a_1b_2 + a_2b_3 - a_4b_4}{\Delta}, \quad A_{24} = \frac{a_3b_4 - a_1b_3 - a_2b_2}{\Delta}$$

$$A_{41} = \frac{a_1b_5 + a_2b_8 - a_6b_9}{\Delta}, \quad A_{42} = \frac{a_2b_5 - a_3b_6 + a_4b_7}{\Delta}$$

$$A_{43} = \frac{a_1b_7 + a_3b_9 + a_2b_{10}}{\Delta}, \quad A_{44} = \frac{a_1b_6 + a_2b_8 + a_4b_9}{\Delta}$$

$$b_1 = a_7^2 + a_8^2, \quad b_2 = a_6a_7 - a_5a_8, \quad b_3 = a_6a_8 + a_5a_7,$$

$$b_4 = a_5^2 + a_6^2, \quad b_5 = a_3a_8 - a_4a_7$$

$$b_6 = a_1a_7 - a_3a_5, \quad b_7 = a_4a_5 - a_1a_8,$$

$$b_8 = a_2a_7 - a_3a_6, \quad b_9 = a_1a_6 - a_2a_5$$

$$a_1 = -(\gamma + \omega\eta_{xy}), \quad a_2 = j\omega\eta_{xx}, \quad a_3 = -\omega\mu_{xy},$$

$$a_4 = j\omega\mu_{xx}, \quad a_5 = \omega\varepsilon_{xy}, \quad a_6 = -j\omega\varepsilon_{xx}$$

$$a_7 = -(\gamma - \omega\xi_{xy}), \quad a_8 = -j\omega\xi_{xx}$$

$$\Delta = a_1(a_1b_1 + a_2b_4 - a_3b_3) + a_2(a_2b_1 - a_4b_3 - a_3b_2)$$

$$+ a_3(a_3b_4 - a_2b_2 - a_1b_3)$$

$$+ a_4(a_1b_2 - a_2b_3 + a_4b_4) \quad (17b)$$

where γ is the mode propagation constant. In Fig. 4a, six field components of the guided hybrid modes $HE(EH)_{nm}$ can be expressed in a set of closed-form equations. For example, in the inner chiral region ($\rho \leq R_1$) in Fig. 4a, the tangential field components are given by [69]

$$E_z^{(1)} = [D_1^{(1)}S_+^{(1)}J_n(\sqrt{S_+^{(1)}}\rho) + D_2^{(1)}S_-^{(1)}J_n(\sqrt{S_-^{(1)}}\rho)]e^{-jn\phi} \quad (18a)$$

$$E_{\phi}^{(1)} = \{D_1^{(1)}[-M_+^{(1)}J_n'(\sqrt{S_+^{(1)}}\rho) - \frac{jnN_+^{(1)}}{\rho}J_n(\sqrt{S_+^{(1)}}\rho)]$$

$$+ D_2^{(1)}[-M_-^{(1)}J_n'(\sqrt{S_-^{(1)}}\rho) - \frac{jnN_-^{(1)}}{\rho}J_n(\sqrt{S_-^{(1)}}\rho)]\}e^{-jn\phi} \quad (18b)$$

$$H_z^{(1)} = [D_1^{(1)}q_+^{(1)}J_n(\sqrt{S_+^{(1)}}\rho) + D_2^{(1)}q_-^{(1)}J_n(\sqrt{S_-^{(1)}}\rho)]e^{-jn\phi} \quad (18c)$$

$$H_{\phi}^{(1)} = \{D_1^{(1)}[-X_+^{(1)}J_n'(\sqrt{S_+^{(1)}}\rho) - \frac{jnY_+^{(1)}}{\rho}J_n(\sqrt{S_+^{(1)}}\rho)]$$

$$+ D_2^{(1)}[-X_-^{(1)}J_n'(\sqrt{S_-^{(1)}}\rho) - \frac{jnY_-^{(1)}}{\rho}J_n(\sqrt{S_-^{(1)}}\rho)]\}e^{-jn\phi} \quad (18d)$$

where $D_1^{(1)}$ and $D_2^{(1)}$ are unknown mode-expanding constants to be determined. Here, J_n and J_n' are the Bessel function of the first kind and its derivative, respectively. After some mathematical treatments, the mode dispersion and attenuation characteristics in chiro-waveguides can be understood.

As in normal waveguides, various discontinuities may also exist in chiro-waveguides, as shown in Fig. 5. This structure is symmetric in the z -axis direction, and the scattering of the guided mode may be analyzed in terms of the symmetric and asymmetric excitations as indicated in Ref. 79.

Figure 6 shows two cases of a normal waveguide partially filled with bianisotropic chiral media, and these may be easily met in the measurement of chiral parameter using some standard waveguide methods.

In the case of coaxial line filled with a biisotropic chiral medium, the influence of permittivity and length of chiral sample W on the amplitude of scattering parameters is depicted in Fig. 7, where $a = 3.04$ mm, $b = 7.0$ mm, $c = 6.0$ mm, $\zeta_c = 10^{-4}$ mho, and $\mu = \mu_0$.

2.6.2. Chiral Resonators. Chiral media can be used to produce circular cylindrical and spherical dielectric resonators that are further used in filters and antennas. Figure 8 shows the configurations of two chiral spherical resonators [81].

Figure 5. Cross-sectional view of a chirowaveguide grating [79].

The inner and outer electromagnetic fields of the chiral sphere shown in Fig. 8a can be expressed by

$$\begin{aligned} \vec{E}_{\text{chiral}}^{(1)} = & - \sum_{m,n} \{ ja_{mn} [\vec{N}_{e,mn}^{(1)}(k_+r) + \vec{M}_{e,mn}^{(1)}(k_+r)] \\ & + jb_{mn} [\vec{N}_{o,mn}^{(1)}(k_+r) + \vec{M}_{o,mn}^{(1)}(k_+r)] \\ & + c_{mn} [\vec{N}_{e,mn}^{(1)}(k_-r) - \vec{M}_{e,mn}^{(1)}(k_-r)] \\ & + d_{mn} [\vec{N}_{o,mn}^{(1)}(k_-r) - \vec{M}_{o,mn}^{(1)}(k_-r)] \} \end{aligned} \quad (19a)$$

$$\begin{aligned} \vec{H}_{\text{chiral}}^{(1)} = & \frac{1}{\eta_c} \sum_{m,n} \{ a_{mn} [\vec{N}_{e,mn}^{(1)}(k_+r) + \vec{M}_{e,mn}^{(1)}(k_+r)] \\ & + b_{mn} [\vec{N}_{o,mn}^{(1)}(k_+r) + \vec{M}_{o,mn}^{(1)}(k_+r)] \\ & + jc_{mn} [\vec{N}_{e,mn}^{(1)}(k_-r) - \vec{M}_{e,mn}^{(1)}(k_-r)] \\ & + jd_{mn} [\vec{N}_{o,mn}^{(1)}(k_-r) - \vec{M}_{o,mn}^{(1)}(k_-r)] \} \end{aligned} \quad (19b)$$

and

$$\begin{aligned} \vec{E}_{\text{free}} = & - \sum_{m,n} \{ je_{mn} \vec{N}_{e,mn}^{(4)}(k_0r) + jf_{mn} \vec{N}_{o,mn}^{(4)}(k_0r) \\ & + g_{mn} \vec{M}_{e,mn}^{(4)}(k_0r) + h_{mn} \vec{M}_{o,mn}^{(4)}(k_0r) \} \\ \vec{H}_{\text{free}} = & \frac{1}{\eta_0} \sum_{m,n} \{ -jg_{mn} \vec{N}_{e,mn}^{(4)}(k_0r) - jh_{mn} \vec{N}_{o,mn}^{(4)}(k_0r) \\ & + e_{mn} \vec{M}_{e,mn}^{(4)}(k_0r) + f_{mn} \vec{M}_{o,mn}^{(4)}(k_0r) \} \end{aligned} \quad (19c)$$

Figure 7. Influence of dielectric constant and length of chiral sample on the amplitude of scattering parameters for a coaxial line partially filled with case [80].

where a_{mn} , b_{mn} , c_{mn} , d_{mn} , e_{mn} , f_{mn} , g_{mn} , h_{mn} , are unknown coefficients that can be determined by boundary conditions at $r=R_1$; $\vec{M}_{e(o)mn}^{(1,4)}(k_{+(0)}r)$ and $\vec{N}_{e(o)mn}^{(1,4)}(k_{+(0)}r)$ are spherical vector wavefunctions. In the case of a multilayer chiral spherical resonator, as shown in Fig. 8b, the electromagnetic fields in each layer can be easily obtained as given in Refs. 72 and 73. Straightforwardly, a set of characteristic equations can be derived after some mathematical treatments, and the Q factor as a function of chirality parameter is shown in Fig. 9 for hybrid modes of different orders [81]. As an example, the Q factor of hybrid mode HE_{m22} varies from 30 to 500 as ξ_r increases from zero to one.

2.6.3. Chiral Striplines and Chiral Slotlines. A chiral medium can also be combined with other materials, such as ferrites, to form some novel nonreciprocal chirostrip transmission lines. Figure 10 shows the shielded chiralstripline and two chiral slotlines with chiral and ferrite substrates [42].

Figure 6. A waveguide partially filled with chiral media: (a) coaxial line; (b) rectangular waveguide.

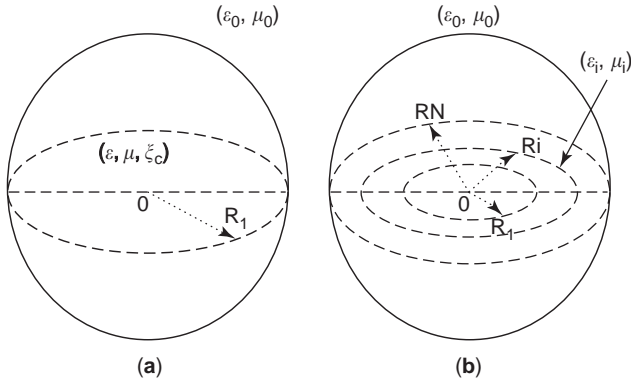

Figure 8. A single- (a) and a multilayer (b) chiral resonators.

Using the technique of exponential matrix in the spectral domain, together with the Galerkin MoM (method of moments) procedure, the mode dispersion characteristics in these structures can be understood. As an example, Fig. 11 shows the frequency dependence of effective permittivity $\epsilon_{\text{eff}+}$ in the structure shown in Fig. 10b, and both chirality and gyrotropy are considered here. The parameters chosen for calculation are assumed to be $f = 40$ GHz, $a = 3.556$ mm, $D_1 = D_4 = 3.3935$ mm, $D_2 = D_3 = 0.1625$ mm, $[\epsilon^{(2)}(\omega)] = 12.6 I$, $M_s^{(2)} \mu_0 = 0.275$, $\omega_0^{(2)}/\omega_m^{(2)} = 0.30$, $\alpha_m^{(2)} = 0.0$, $\theta_0^{(2)} = 90^\circ$, $\phi_0^{(2)} = 0^\circ$, $[\xi^{(2)}(\omega)] = [\eta^{(2)}(\omega)]^* = 10^{-6} I$, $[\epsilon^{(3)}(\omega)] = 2.2 I$, $[\mu^{(3)}(\omega)] = I$, $[\xi^{(3)}(\omega)] = [\eta^{(3)}(\omega)]^* = j0.5 I(a)$, and $j0.8 I(b)$.

In Fig. 11, the ferrite substrate is magnetically biased by a magnetic field fixed to the x -axis direction with saturation magnetization $M_s^{(2)} \mu_0 = 0.275$, $\omega_0^{(2)}/\omega_m^{(2)} = 0.3$. Physically, such a unilateral chiral ferrite slotline is a nonreciprocal structure, but only the effective dielectric constant of forward wave is demonstrated here. It is obvious that, at high frequency $f = 40$ GHz and for strong chirality, ϵ_{eff} decreases rapidly with increasing the slot width.

2.6.4. Faraday Chiral Media. Faraday chiral media are classified as chiropasmas or chiroferrites in which the effects of both gyrotropy and chirality are combined [49,84]. Corresponding to the CGS of C_∞ , their four constitutive tensors can be described by

$$[C] = \begin{bmatrix} C_{xx} & -jC_{xy} & 0 \\ jC_{xy} & C_{xx} & 0 \\ 0 & 0 & C_{zz} \end{bmatrix}, \quad C = \epsilon, \mu, \zeta, \eta \quad (20)$$

where these tensors contain a total of 12 scalar quantities. When a circular waveguide is filled with Faraday chiral media, as shown in Fig. 4a, the longitudinal components E_z and H_z can be decoupled and expressed by Eqs. (16a) and (16b). Following a procedure similar to that described in Refs. 32 and 35, the field distribution in each layer can be derived, and also the mode dispersion characteristics can be understood. Some hybrid analytical and numerical techniques, as proposed in Refs. 85–89, can be employed to

Figure 9. Q factor versus chirality parameter for hybrid modes of different orders: (a) $\epsilon_r = 10$, $\mu_r = 1$, $n = 1$; (b) $\epsilon_r = 10$, $\mu_r = 1$, $n = 2$.

study the combined effects of gyrotropy and chirality on the guided hybrid mode characteristics. On the other hand, it should be mentioned that to design and fabricate Faraday chiral media, and further to extract their constitutive parameters at microwave frequencies, is very challenging work. Although some methods have been proposed [90], many difficult problems need to be explored by the researchers in both material and microwave fields.

3. TYPICAL METHODOLOGIES

3.1. Exponential Matrix Technique in the Spectral Domain

Among the techniques used to deal with the interaction of an electromagnetic wave with multilayer bianisotropic media, we should mention the exponential matrix technique proposed by Tsalamengas [4], which has been successfully used to study source radiation and wave

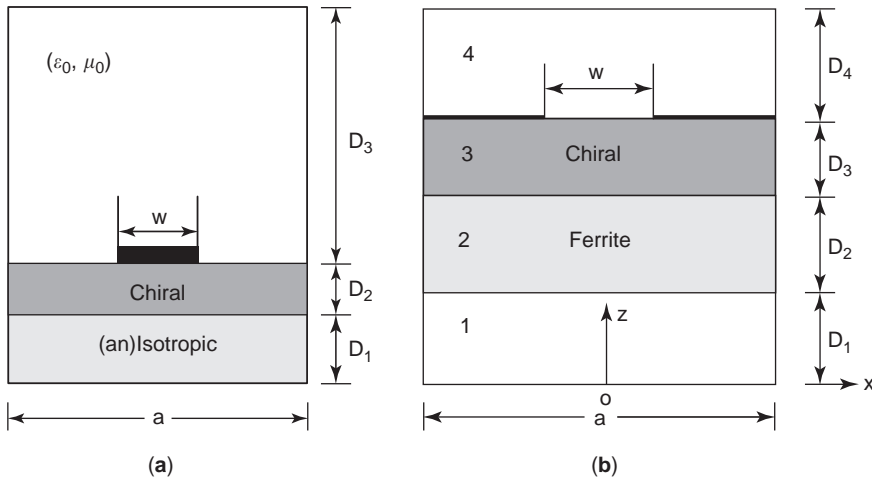

Figure 10. Cross-sectional views of three microstrip transmission lines with chiral and ferrite substrate: (a) chiral stripline; (b) unilateral chiral slotline; (c) bilateral chiral slotline.

Figure 11. Slot width dependence of $\epsilon_{\text{eff}+}(\beta_+/k_0)^2$ in a unilateral slotline on a double-layer chiral-ferrite substrate.

propagation problems related to single-, double-, and multilayer bianisotropic structures [34,38–40,42,50–54] as shown in Fig. 12. Here, we let the z axis of a rectangular coordinate system be normal to all boundaries and the x and y axes lie in the plane of the top interface. In the z -axis direction, the geometry has discrete variation in material characteristics, and this structure may be with or without a backed plane at $z = -d^{(N)}$ ($d^{(N)} = \sum_{i=1}^N D^{(i)}$). For the nonbacked case the regions $z > 0$ and $z < -d^{(N)}$ are usually assumed to be free space (ϵ_0, μ_0) . The thickness of each layer is denoted by $D^{(1)}, \dots, D^{(i)} (|d^{(i)} - d^{(i-1)}|), \dots,$ and $D^{(N)}$. Mathematically, the four constitutive tensors $[\epsilon^{(i)}(\omega)], [\mu^{(i)}(\omega)], [\zeta^{(i)}(\omega)],$ and $[\eta^{(i)}(\omega)]$ ($i = 1, \dots, N$) of each layer may take any type of the above mentioned 23 CGSs or even another form [1].

Assuming that a linearly polarized electromagnetic wave is obliquely incident on a multilayer bianisotropic medium, as shown in Fig. 12, four propagating modes with different phase velocities can be generated in each layer. After propagation through the medium, the polarization of the transmitted field is rotated with respect to the polarization of the incident wave. Now we introduce the

Figure 12. Cross section of multilayer bianisotropic medium with(out) backed plane.

one-dimensional Fourier transform domain defined by

$$\tilde{\psi}(k_x, z) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \psi(x; z) e^{jk_x x} dx \quad (21a)$$

$$\psi(x, z) = \int_{-\infty}^{+\infty} \tilde{\psi}(k_x; z) e^{-jk_x x} dk_x \quad (21b)$$

into the following Maxwell equations ($e^{j\omega t}$):

$$\begin{aligned} \nabla \times \tilde{\mathbf{H}}^{(i)} &= j\omega \{ \epsilon_0 [\epsilon^{(i)}(\omega)] \tilde{\mathbf{E}}^{(i)} \\ &+ \sqrt{\mu_0 \epsilon_0} [\zeta^{(i)}(\omega)] \tilde{\mathbf{H}}^{(i)} \}, \end{aligned} \quad (22a)$$

$$\begin{aligned} \nabla \times \tilde{\mathbf{E}}^{(i)} &= -j\omega \{ \mu_0 [\mu^{(i)}(\omega)] \tilde{\mathbf{H}}^{(i)} \\ &+ \sqrt{\mu_0 \epsilon_0} [\eta^{(i)}(\omega)] \tilde{\mathbf{E}}^{(i)} \} \end{aligned} \quad (22b)$$

Following a procedure similar to that proposed in Ref. 4, the transverse field components in each layer of multilayered bianisotropic slabs can be expressed as

$$\begin{aligned} \frac{d}{dz} \begin{bmatrix} \tilde{\mathbf{E}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{E}}_y^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_y^{(i)}(k_x; z) \end{bmatrix} &= \begin{bmatrix} q_{11}^{(i)} & q_{12}^{(i)} & q_{13}^{(i)} & q_{14}^{(i)} \\ q_{21}^{(i)} & q_{22}^{(i)} & q_{23}^{(i)} & q_{24}^{(i)} \\ q_{31}^{(i)} & q_{32}^{(i)} & q_{33}^{(i)} & q_{34}^{(i)} \\ q_{41}^{(i)} & q_{42}^{(i)} & q_{43}^{(i)} & q_{44}^{(i)} \end{bmatrix} \\ &\times \begin{bmatrix} \tilde{\mathbf{E}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{E}}_y^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_y^{(i)}(k_x; z) \end{bmatrix} \end{aligned} \quad (23)$$

where the matrix elements $q_{11}^{(i)} - q_{44}^{(i)}$ are functions of spectral variable k_x and material parameters (all the elements of $[\epsilon^{(i)}(\omega)]$, $[\mu^{(i)}(\omega)]$, $[\zeta^{(i)}(\omega)]$ and $[\eta^{(i)}(\omega)]$). After some mathematical manipulations, their exact expressions can be derived and presented [38]. Furthermore, the general solution to the vector differential Eq. (23) can be written as follows:

$$\begin{bmatrix} \tilde{\mathbf{E}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{E}}_y^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_x^{(i)}(k_x; z) \\ \tilde{\mathbf{H}}_y^{(i)}(k_x; z) \end{bmatrix} = \begin{bmatrix} T_{11}^{(i)}(\tilde{z}) & T_{12}^{(i)}(\tilde{z}) & T_{13}^{(i)}(\tilde{z}) & T_{14}^{(i)}(\tilde{z}) \\ T_{21}^{(i)}(\tilde{z}) & T_{22}^{(i)}(\tilde{z}) & T_{23}^{(i)}(\tilde{z}) & T_{24}^{(i)}(\tilde{z}) \\ T_{31}^{(i)}(\tilde{z}) & T_{32}^{(i)}(\tilde{z}) & T_{33}^{(i)}(\tilde{z}) & T_{34}^{(i)}(\tilde{z}) \\ T_{41}^{(i)}(\tilde{z}) & T_{42}^{(i)}(\tilde{z}) & T_{43}^{(i)}(\tilde{z}) & T_{44}^{(i)}(\tilde{z}) \end{bmatrix}_{\tilde{z} = -(z+d^{(i)})} \times \begin{bmatrix} \tilde{\mathbf{E}}_x^{(i)}(k_x; -d^{(i)}) \\ \tilde{\mathbf{E}}_y^{(i)}(k_x; -d^{(i)}) \\ \tilde{\mathbf{H}}_x^{(i)}(k_x; -d^{(i)}) \\ \tilde{\mathbf{H}}_y^{(i)}(k_x; -d^{(i)}) \end{bmatrix} \quad (24)$$

The matrix $[T^{(i)}(\tilde{z})]_{4 \times 4}$ in (24) is a transmission matrix, which physically relates to the tangential electromagnetic fields on one surface $z = -d^{(i)}$ to the tangential fields on another surface in the i th layer. Further, $[T^{(i)}(\tilde{z})]_{4 \times 4}$ can be expressed in the form of exponential matrix as follows:

$$[T^{(i)}(\tilde{z})]_{4 \times 4} = e^{z[q^{(i)}]_{4 \times 4}} \quad (25)$$

The procedure for calculating the exponential matrix in (25) can be followed as described in Ref. 4, and is omitted here.

The incident plane wave in the spectral domain can be expressed as a superposition of TM and TE (with respect to the y axis) as follows:

$$\begin{bmatrix} \tilde{\mathbf{E}}^{\text{inc}}(k_x; z) \\ \tilde{\mathbf{H}}^{\text{inc}}(k_x; z) \end{bmatrix} = \begin{bmatrix} -E_{\text{inc}}^{\text{TM}} \tilde{\mathbf{e}}_y - E_{\text{inc}}^{\text{TE}} \tilde{\mathbf{e}}_+ \\ [-E_{\text{inc}}^{\text{TM}} \tilde{\mathbf{e}}_+ + E_{\text{inc}}^{\text{TE}} \tilde{\mathbf{e}}_y] / \eta_0 \end{bmatrix} \times e^{-jk_0(x \sin \theta_0 - z \cos \theta_0)} \quad (26)$$

where θ_0 is the incident angle, $k_0 = \omega \sqrt{\mu_0 \epsilon_0}$, $k_x = k_0 \sin \theta_0$, $\eta_0 = \sqrt{\mu_0 / \epsilon_0}$, $\tilde{\mathbf{e}}_{\pm} = \pm \tilde{\mathbf{e}}_x \cos \theta_0 + \tilde{\mathbf{e}}_z \sin \theta_0$, and $\tilde{\mathbf{e}}_x$, $\tilde{\mathbf{e}}_y$, and $\tilde{\mathbf{e}}_z$ are the three unit vectors, respectively. The reflected wave fields in the spectral domain can be written as a superposition of TM and TE (to y)

$$\begin{bmatrix} \tilde{\mathbf{E}}^{(r)}(k_x; z) \\ \tilde{\mathbf{H}}^{(r)}(k_x; z) \end{bmatrix} = \begin{bmatrix} -E_0^{\text{TM}} \tilde{\mathbf{e}}_y - E_0^{\text{TE}} \tilde{\mathbf{e}}_- \\ [-E_0^{\text{TM}} \tilde{\mathbf{e}}_- + E_0^{\text{TE}} \tilde{\mathbf{e}}_y] / \eta_0 \end{bmatrix} \times e^{-jk_0 z \cos \theta_0} \quad (27)$$

where E_0^{TM} and E_0^{TE} refer to the TM and TE components in the reflected waves, respectively. In Fig. 12, if there is no backed plane at $z = -d^{(N)}$, the transmitted waves into region $z < -d^{(N)}$ are denoted by

$$\begin{bmatrix} \tilde{E}^{(t)}(k_x; z) \\ \tilde{H}^{(t)}(k_x; z) \end{bmatrix} = \begin{bmatrix} -E_2^{\text{TM}} \vec{e}_y - E_2^{\text{TE}} \vec{e}_+ \\ [-E_2^{\text{TM}} \vec{e}_+ + E_2^{\text{TE}} \vec{e}_y] / \eta_0 \end{bmatrix} \quad (28)$$

$$\times e^{jk_0(z+d^{(N)}) \cos \theta_0}$$

where E_2^{TM} and E_2^{TE} refer to the TM and TE components in transmitted waves, respectively. Furthermore, $E_{0,2}^{\text{TM}}$ and $E_{0,2}^{\text{TE}}$ above can be determined by enforcing the boundary conditions at each interface in Fig. 12. When the structure shown above is backed by a perfectly conducting backed plane, we have

$$\begin{bmatrix} E_0^{\text{TE}} \\ E_0^{\text{TM}} \end{bmatrix} = \begin{bmatrix} R_{11} & R_{21} \\ R_{12} & R_{22} \end{bmatrix} \begin{bmatrix} E_{\text{inc}}^{\text{TE}} \\ E_{\text{inc}}^{\text{TM}} \end{bmatrix} \quad (29)$$

where $R_{11,22}$ denotes for the copolarized reflection coefficients and $R_{12,21}$ represents the cross-polarized reflection coefficients [4]. In the no-backing case, the transmitted matrix is determined by

$$\begin{bmatrix} E_2^{\text{TE}} \\ E_2^{\text{TM}} \end{bmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} E_{\text{inc}}^{\text{TE}} \\ E_{\text{inc}}^{\text{TM}} \end{bmatrix} \quad (30)$$

where $T_{11,12}$ and $T_{12,21}$ are the co- and cross-polarized transmission coefficients, respectively. A more detailed study on the co- and cross-polarized reflection and transmission characteristics of different layered omega(chiro)-ferrite geometries can be seen in Ref. 53. As an example, Fig. 13 shows the variations of the co(cross)-polarized reflection and transmission coefficients as a function of the incident angle for a chiroferrite slab in free space, and we let

$$\varepsilon_{xx}^{(1)} = \varepsilon_{yy}^{(1)} = 5.0, \quad \varepsilon_{zz}^{(1)} = 6.0, \quad \varepsilon_{xy}^{(1)} = -\varepsilon_{yx}^{(1)} = j0.3$$

$$\mu_{xx}^{(1)} = \mu_{yy}^{(1)} = 0.9, \quad \mu_{zz}^{(1)} = 1.5, \quad \mu_{xy}^{(1)} = -\mu_{yx}^{(1)} = j0.4$$

$$\zeta_{xx}^{(1)} = \eta_{xx}^{(1)} = \zeta_{yy}^{(1)} = \eta_{yy}^{(1)} = j0.5, \quad \zeta_{zz}^{(1)} = \eta_{zz}^{(1)} = j0.9$$

$$\zeta_{xy}^{(1)} = \eta_{xy}^{(1)} = j0.1, \quad \zeta_{yx}^{(1)} = \eta_{yx}^{(1)} = -j0.1$$

The biasing DC magnetic fields \vec{H}_0 of all chiroparticles are all along the z axis.

On the other hand, the technique described above, combined with the Galerkin MoM procedure, can also be extended to treat bianisotropic microstrip structures, as shown in the literature [39,40,42,54]. However, it should be mentioned that to deal with the mode dispersion characteristics in a microstrip transmission line with bianisotropic material, a general multilayer model is shown in Fig. 14. It is evident that this model can incorporate various applications [55–57]. However, we

Figure 13. $R(T)_{pq}$ ($pq = 11, 22, 12, 21$) as a function of the incident angle θ_0 for a single-layer chiroferrite slab in free space (solid dotted lines— $T_{11;12;21;22}$; empty dotted lines— $R_{11;12;21;22}$), $D^{(1)}/\lambda = 0.5$ (where λ is the incident wavelength).

need to be careful about the destroy in image symmetry of the constitutive tensors [54,91].

3.2. Extended Finite-Element Method (FEM)

The extended FEM as well as the FEM–boundary-element method (FEM-BEM) is able to treat wave propagation and

Figure 14. Cross-sectional view of a multiple microstrip transmission lines embedded in a multilayer bianisotropic superstrate–substrate.

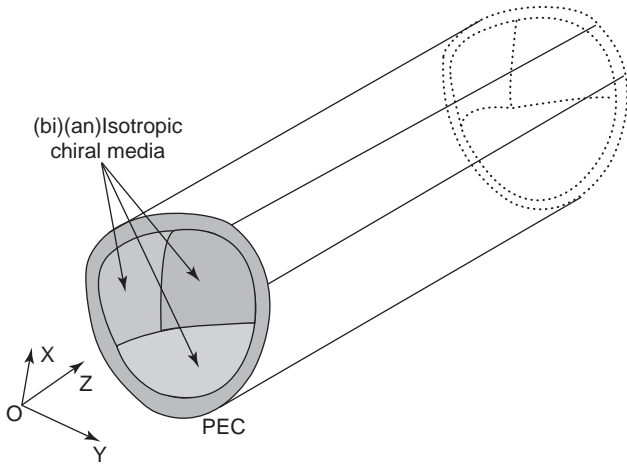

Figure 15. The bianisotropic waveguide with an arbitrary cross section.

radiation problems related to complex bianisotropic media [26,92,93]. Figure 15 shows the geometry of a bianisotropic waveguide with an arbitrary cross section, where the filled bianisotropic medium can be lossless or lossy. More generally, the bianisotropic region may consist of several types of bianisotropic media, but the structure must be homogeneous in the z -axis direction.

Following a procedure similar to that used in Refs. 92–94, for admissible test functions \vec{E}_{test} and \vec{H}_{test} , we must have

$$\sum_e \int \int_e \{ \vec{E}_{\text{test}}^* \cdot [j\nabla \times \vec{H} + \omega([\epsilon]\vec{E} + [\xi]\vec{H})] + \vec{H}_{\text{test}}^* \cdot [-j\nabla \times \vec{E} + \omega([\mu]\vec{H} + [\eta]\vec{E})] \} dx dy = 0 \quad (31)$$

where the appropriate interelement and boundary conditions are handled during the assembly \sum_e over all elements. Here, both the necessary continuity requirements on $\vec{n} \times \vec{E}$ and $\vec{n} \times \vec{H}$ and the additional requirements on $\vec{n} \cdot \vec{B}$ and $\vec{n} \cdot \vec{D}$ are, as described below, explicitly enforced on the test and expansion functions. The six components of the electric and magnetic test and expansion fields are approximated on each element in terms of the values at each nodal point according to

$$\begin{Bmatrix} \vec{E} \\ \vec{H} \end{Bmatrix} = [N]^T \begin{Bmatrix} \{E_x\} \\ \{E_y\} \\ \{E_z\} \\ \{H_x\} \\ \{H_y\} \\ \{H_z\} \end{Bmatrix} e^{-j\beta z} \quad (32a)$$

where

$$[N] = \begin{bmatrix} Z_0\{N\} & \{0\} & \{0\} & \{0\} & \{0\} & \{0\} \\ \{0\} & Z_0\{N\} & \{0\} & \{0\} & \{0\} & \{0\} \\ \{0\} & \{0\} & -jZ_0\{N\} & \{0\} & \{0\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{N\} & \{0\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{0\} & \{N\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{0\} & 0 & -j\{N\} \end{bmatrix} \quad (32b)$$

and $Z_0 = \sqrt{\mu_0/\epsilon_0}$. The real $m \times 1$ column vector $\{N\}$ is the element shape function vector, m is the number of nodal points on each element, $\{0\}$ is a $m \times 1$ null vector, and the superscript “T” denotes a matrix transposition. The column vectors $\{E_x\}$, $\{E_y\}$, $\{E_z\}$, $\{H_x\}$, $\{H_y\}$, and $\{H_z\}$ are $m \times 1$ complex field vectors representing the nodal point values of, respectively, E_x/Z_0 , E_y/Z_0 , jE_z/Z_0 , H_x , H_y , and jH_z on each element.

By employing the standard Galerkin procedure with the expansion in (32a) and (32b), we can obtain the following generalized eigenvalue equation

$$\{ \omega[P] + \beta[Q] + [R] \} \begin{Bmatrix} \{E_x\} \\ \{E_y\} \\ \{E_z\} \\ \{H_x\} \\ \{H_y\} \\ \{H_z\} \end{Bmatrix} = \{0\} \quad (33)$$

where the column vector is composed of all the nodal point variables used to represent \vec{E} and \vec{H} throughout the waveguide cross section. Note that both the complex propagation constant β and the real angular frequency ω may be treated as the eigenvalue, depending on which is numerically most advantageous or of primary interest.

By expanding (31) in component form, the quadratic sparse matrices $[P]$, $[Q]$, and $[R]$ take forms similar to those in Ref. 94, and

$$[Q] = -Z_0 \sum_e \iint_e \begin{bmatrix} \{0\} & \{0\} & \{0\} & \{0\} & -\{A\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{A\} & \{0\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{0\} & \{0\} & \{0\} \\ \{0\} & \{A\} & \{0\} & \{0\} & \{0\} & \{0\} \\ -\{A\} & \{0\} & \{0\} & \{0\} & \{0\} & \{0\} \\ \{0\} & \{0\} & \{0\} & \{0\} & \{0\} & \{0\} \end{bmatrix} dx dy \quad (34)$$

$$[R] = Z_0 \sum_e \iint_e \begin{bmatrix} \{0\} & \{0\} & \{0\} & \{0\} & \{0\} & -\{C\} \\ \{0\} & \{0\} & \{0\} & \{0\} & \{0\} & \{B\} \\ \{0\} & \{0\} & \{0\} & -\{C\} & \{B\} & \{0\} \\ \{0\} & \{0\} & \{C\} & \{0\} & \{0\} & \{0\} \\ \{0\} & \{0\} & -\{B\} & \{0\} & \{0\} & \{0\} \\ \{C\} & -\{B\} & \{0\} & \{0\} & \{0\} & \{0\} \end{bmatrix} dx dy \quad (35)$$

and

$$[A] = \{N\}\{N\}^T \quad (36a)$$

$$[B] = \{N\} \frac{\partial \{N\}^T}{\partial x} \quad (36b)$$

$$[C] = \{N\} \frac{\partial \{N\}^T}{\partial y} \quad (36c)$$

The continuity of $\vec{n} \times \vec{E}$, $\vec{n} \times \vec{H}$, $\vec{n} \cdot \vec{D}$, and $\vec{n} \cdot \vec{B}$, where \vec{n} is the unit normal vector perpendicular to an element side in the transversal x - y plane, is enforced. Also, the sample third-order triangular mesh is shown in Fig. 16, and in order to satisfy the interelement conditions, it is sufficient to apply the following at each nodal point along each internal side

$$\vec{n} \times (\vec{E}_p - \vec{E}_q) = 0 \quad (37)$$

$$\vec{n} \times (\vec{H}_p - \vec{H}_q) = 0 \quad (38)$$

$$\vec{n} \cdot ([\varepsilon_p] \vec{E}_p + [\xi_p] \vec{H}_p - [\varepsilon_q] \vec{E}_q - [\xi_q] \vec{H}_q) = 0 \quad (39)$$

$$\vec{n} \cdot ([\mu_p] \vec{H}_p + [\eta_p] \vec{E}_p - [\mu_q] \vec{H}_q - [\eta_q] \vec{E}_q) = 0 \quad (40)$$

where $\{\vec{E}_p, \vec{H}_p\}$ and $\{\vec{E}_q, \vec{H}_q\}$ represent unconnected field components in adjacent elements, p and q . To satisfy the external boundary conditions at each nodal point along each external side it is sufficient to enforce

$$\vec{n} \times \vec{E}_p = 0 \quad (41a)$$

$$\vec{n} \cdot ([\mu_p] \vec{H}_p + [\eta_p] \vec{E}_p) = 0 \quad (41b)$$

on electric walls and

$$\vec{n} \times \vec{H}_p = 0 \quad (42a)$$

$$\vec{n} \cdot ([\varepsilon_p] \vec{E}_p + [\xi_p] \vec{H}_p) = 0 \quad (42b)$$

on magnetic walls. From these equations, it can be found that the total number of unknown is $\leq 6N_p$, where N_p is the number of nodal points.

As indicated in Ref. 94, the most important property of the eigenvalue problem (30) now is the $O(1/N)$ density of the matrices $[P]$, $[Q]$, and $[R]$. This property ensures that

Figure 16. A portion of a sample of third-order mesh in the bianisotropic region.

the maximum number of nontrivial matrix elements on each row is independent of the dimension of the matrices. Thus an upper bound of the densities becomes $\rho = NN_z/N^2 \sim O(1/N)$, where N_z is the maximum number of nonzero elements on each row and N is the matrix dimension. Therefore, for large problems, sparse eigenvalue codes can be used to save significant amounts of computer time and memory.

3.3. Extended Method of Line (MoL)

The normal method of line (MoL) [28] is very useful in the analysis of planar radiative and transmissive microwave components. This method was developed by mathematicians and physicists in order to solve partial-differential equations in the electromagnetic analysis of optical and microwave devices, for the numerical solution of the partial-differential Helmholtz equation. Originally developed to study planar waveguides, MoL was also extended to study stratified microwave components with arbitrarily shaped cross sections and microstrip discontinuities, including one-dimensional and bidimensional resonators and antennas. The latest extensions of this method have been achieved to study gyrotropic media and microwave components mounted on cylindrical or spherical structures.

The standard version of MoL, does not allow for the study of elements with bianisotropic superstrate-substrates. More recently, an extended MoL numerical procedure, which allows for the analysis of components in the presence of any linear, inhomogeneous, or lossy bianisotropic medium, has been developed [28]. Such an extension is based on the generalization of the transmission-line equations for a general linear medium.

Applying the curl Maxwell equations in a sourceless bianisotropic region, and after some mathematical manipulations, a set of transmission-line equations for a bianisotropic medium in Cartesian coordinates can be derived as follows ($e^{j\omega t}$)

$$\frac{\partial[\mathbf{E}_t]}{\partial z} = \begin{bmatrix} A_{xx} & A_{xy} \\ A_{yx} & A_{yy} \end{bmatrix} [\mathbf{E}_t] + \begin{bmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{bmatrix} [\tilde{\mathbf{H}}_t] \quad (43a)$$

$$\frac{\partial[\mathbf{H}_t]}{\partial z} = \begin{bmatrix} Y_{xx} & Y_{xy} \\ Y_{yx} & Y_{yy} \end{bmatrix} [\mathbf{E}_t] + \begin{bmatrix} B_{xx} & B_{xy} \\ B_{yx} & B_{yy} \end{bmatrix} [\tilde{\mathbf{H}}_t] \quad (43b)$$

where $[\mathbf{E}_t] = \begin{bmatrix} E_x \\ E_y \end{bmatrix}$, $[\mathbf{H}_t] = \begin{bmatrix} H_x \\ H_y \end{bmatrix}$, $[\tilde{\mathbf{H}}_t] = \eta_0[\mathbf{H}_t]$, and $\eta_0 = \sqrt{\mu_0/\epsilon_0}$. The 16 operatorial tensor elements A_{ij} , B_{ij} , Y_{ij} , Z_{ij} , where $i, j = x, y, z$, involve both the constitutive tensor entries and the transverse derivatives and are given in Ref. 28 and omitted here, and are very similar to the expressions shown in Ref. 34.

It should be noted that Eqs. (43a) and (43b) can be decoupled only for particular bianisotropic media whose constitutive parameters allow the coupling matrices $[A]$ and $[B]$ to vanish. The necessary and sufficient condition on the medium constitutive tensors to obtain decoupled equations, independently from the excitation, can be written in the following form [28]

$$[\epsilon] = \begin{pmatrix} \epsilon_{xx} & \epsilon_{xy} & 0 \\ \epsilon_{yx} & \epsilon_{yy} & 0 \\ 0 & 0 & \epsilon_{zz} \end{pmatrix}, [\mu] = \begin{pmatrix} \mu_{xx} & \mu_{xy} & 0 \\ \mu_{yx} & \mu_{yy} & 0 \\ 0 & 0 & \mu_{zz} \end{pmatrix},$$

$$[\zeta] = \begin{pmatrix} 0 & 0 & \zeta_{xz} \\ 0 & 0 & \zeta_{yz} \\ \zeta_{zx} & \zeta_{zy} & 0 \end{pmatrix}, [\eta] = \begin{pmatrix} 0 & 0 & \eta_{xz} \\ 0 & 0 & \eta_{yz} \\ \eta_{zx} & \eta_{zy} & 0 \end{pmatrix} \quad (44)$$

which represents the CGS of $C_{2h}(C_s)$ above. Under such circumstances, a standard MoL procedure similar to that expressed in (43) can be used, and we have

$$\frac{\partial^2[\mathbf{E}_t]}{\partial z^2} = -[P_E][\mathbf{E}_t], \quad \frac{\partial^2[H_t]}{\partial z^2} = -[Q_E][H_t]. \quad (45a,b)$$

This set of equations can be easily discretized in two dimensions and then diagonalized, and the electromagnetic characteristics of the structure, as shown in Figs. 17a and 17b, can be further understood.

In the general case, an extended version of MoL needs to be developed, as discussed in Ref. 28. Starting from (43a) and (43b) and discretizing in the transverse plane as in the standard MoL, a set of equations involving trans-

Figure 17. Microstrip transmission lines and antenna on bianisotropic substrates.

verse field components can be derived as follows

$$\frac{d[\hat{\mathbf{E}}_t]}{dz} = [\hat{\mathbf{A}}][\hat{\mathbf{E}}_t] + [\hat{\mathbf{Z}}][\hat{\mathbf{H}}_t] \quad (46a)$$

$$\frac{d[\hat{\mathbf{H}}_t]}{dz} = [\hat{\mathbf{Y}}][\hat{\mathbf{E}}_t] + [\hat{\mathbf{B}}][\hat{\mathbf{H}}_t] \quad (46b)$$

where the symbol $\hat{}$ stands for bidimensional discretization. Here $[\hat{\mathbf{E}}_t]$ and $[\hat{\mathbf{H}}_t]$ depend only on z , respectively, as shown in Fig. 18, where $\hat{\mathbf{E}}_x$ and $\hat{\mathbf{H}}_y$ are calculated on lines denoted by “o”, while $\hat{\mathbf{E}}_y$ and $\hat{\mathbf{H}}_x$ are sampled on lines denoted by \bullet . The other two sets, denoted by empty and solid square dots, respectively, contain the lines in which the central-difference derivatives are computed.

In Fig. 18, d_x and d_y are the discretization steps for the central-difference operators along x and y , respectively. The matrices $[\hat{\mathbf{A}}]$, $[\hat{\mathbf{Z}}]$, $[\hat{\mathbf{Y}}]$, and $[\hat{\mathbf{B}}]$ are obtained from Eqs. (4), given in Ref. 28, substituting their elements with discretized quantities. First of all, partial derivatives are substituted with central-difference matrices $[\hat{\mathbf{D}}]$, also including the boundary conditions.

Figure 18. Rectangular patch with discretization lines.

Figure 19. A patch cavity resonator loaded with a bianisotropic substrate.

Equations (46a) and (46b) are the algebraic discretized versions of the generalized transmission line equations, and they can be changed into

$$\frac{d[\hat{\psi}]}{dz} = \begin{bmatrix} \hat{\mathbf{A}} & \hat{\mathbf{Z}} \\ \hat{\mathbf{Y}} & \hat{\mathbf{B}} \end{bmatrix} [\hat{\psi}] \quad (47)$$

where $[\hat{\psi}] = [\hat{\mathbf{E}}_t \quad \hat{\mathbf{H}}_t]^T$ and the superscript “T” represents the transpose of matrix. It is evident that the solution to (47) is in the form of an exponential matrix, which is well documented in Ref. 4 and used elsewhere in the literature [34,38–40,50–54] by enforcing certain boundary conditions.

As a numerical example, Fig. 19 shows the geometry of a patch cavity resonator loaded with a bianisotropic substrate, and the resonant frequency versus patch side length is depicted in Fig. 20 for $\epsilon_r = 2.0$, $D = 0.8$ mm, and $a = b = 10$ cm.

In Fig. 18, the bianisotropic substrate is characterized by the CGS of $D_{2d}(C_{2v})$, and

$$[\epsilon] = \epsilon_0 \epsilon_r \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad [\mu] = \mu_0 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (48)$$

$$[\xi] = c_0^{-1} \begin{bmatrix} 0 & j\xi & 0 \\ j\xi & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad [\eta] = -[\xi]$$

where $c_0 = 3 \times 10^8$ m/s. It is seen that, compared to the isotropic case, the resonant frequency changes very little for a given patch width, and this is because the bianisotropic substrate is supposed to be very thin and the magnetoelectric coupling effect is very weak [28].

3.4. Finite-Difference Time-Domain Method (FDTD)

The finite-difference time-domain (FDTD) method [95] is the most popular three-dimensional full-wave numerical algorithm that has been used to model electromagnetic

phenomena and interactions in various fields. The simplicity and effectiveness of FDTD method stem from the utilization of a Cartesian grid from the discretization of the structure, with appropriate staggering of the unknown discrete values of the components of the electric and magnetic field vectors in such a manner that the curl operations in Maxwell’s equations can be approximated in terms of second-order accurate finite differences. The staggering of the fields is known as the *Yee lattice*. This discretization results in a state space representation of the discrete values of all six components of the electric and magnetic fields on the grid. The simplicity and versatility of the FDTD algorithm, combined with its suitability for parallel implementation, has prompted aggressive research and development toward its further enhancement.

In the time domain, the constitutive equations of biisotropic chiral media can be expressed by

$$\vec{D}(t) = \epsilon \vec{E}(t) + \frac{\chi}{c_0} \vec{H}(t) - \frac{1}{c_0} \int_0^t \kappa'(\tau) \vec{H}(t - \tau) d\tau \quad (49a)$$

$$\vec{B}(t) = \mu \vec{H}(t) + \frac{\chi}{c_0} \vec{E}(t) - \frac{1}{c_0} \int_0^t \kappa'(\tau) \vec{E}(t - \tau) d\tau \quad (49b)$$

Figure 20. Resonant frequency versus patch side length [28].

and (49a) and (49b) respectively can be further discretized as

$$\begin{aligned} \vec{D}(n) = \varepsilon \vec{E}(n) + \frac{\chi}{c_0} \vec{H}(n) \\ - \frac{1}{c_0} \sum_{m=0}^{n-1} \vec{H}(n-m) \int_{m\Delta t}^{(m+1)\Delta t} \kappa'(\tau) d\tau \end{aligned} \quad (50a)$$

$$\begin{aligned} \vec{B}(n) = \mu \vec{H}(n) + \frac{\chi}{c_0} \vec{E}(n) \\ - \frac{1}{c_0} \sum_{m=0}^{n-1} \vec{E}(n-m) \int_{m\Delta t}^{(m+1)\Delta t} \kappa'(\tau) d\tau \end{aligned} \quad (50b)$$

The complex time-domain chirality parameter $\hat{\kappa}'(t)$ is defined as [95]

$$\hat{\kappa}'(t) = -j \frac{\tau \omega_0^2}{\sqrt{1-\xi^2}} e^{[-\xi \omega_0 t + j(\phi - \omega_0 \sqrt{1-\xi^2} t)]} \quad (51)$$

while the time-domain chirality parameter should be the real part of $\hat{\kappa}'(t)$, and

$$\kappa'(m\Delta t) = \int_{m\Delta t}^{(m+1)\Delta t} \kappa'(\tau) d\tau \quad (52a)$$

$$\hat{\kappa}'(m\Delta t) = \int_{m\Delta t}^{(m+1)\Delta t} \hat{\kappa}'(\tau) d\tau \quad (52b)$$

In the time domain, the time dependences of both permittivity and permeability are described by the following equations:

$$\varepsilon(t) = \varepsilon_0 \left[\varepsilon_\infty \delta(t) + \frac{(\varepsilon_s - \varepsilon_\infty) \omega_0 e^{-\omega_0 \xi_e t}}{\sqrt{1-\xi_e^2}} \sin(\omega_0 e \sqrt{1-\xi_e^2} t) \right] \quad (53a)$$

$$\mu(t) = \mu_0 \left[\mu_\infty \delta(t) + \frac{(\mu_s - \mu_\infty) \omega_0 m e^{-\omega_0 m \xi_m t}}{\sqrt{1-\xi_m^2}} \sin(\omega_0 m \sqrt{1-\xi_m^2} t) \right] \quad (53b)$$

Further, (50a) and (50b) respectively become [95]

$$\begin{aligned} \vec{D}(n) = \varepsilon_0 \varepsilon_\infty \vec{E}(n) + \frac{\chi}{c_0} \vec{H}(n) + \varepsilon_0 \text{Re}[\hat{\chi}_e(0)] \vec{E}(n) \\ + \varepsilon_0 \text{Re} \left[\hat{\psi}_{\chi_e}^E(n-1) e^{(-\xi_e + j\sqrt{1-\xi_e^2}) \omega_0 \Delta t} \right. \\ \left. - \frac{\text{Re}[\hat{\kappa}'(0)]}{c_0} \vec{H}(n) - \frac{1}{c_0} \text{Re}[\hat{\psi}_\kappa^H(n-1)] \right. \\ \left. \times e^{(-\xi - j\sqrt{1-\xi^2}) \omega_0 \Delta t} \right] \end{aligned} \quad (54a)$$

$$\begin{aligned} \vec{B}(n) = \mu_0 \mu_\infty \vec{H}(n) + \frac{\chi}{c_0} \vec{E}(n) + \mu_0 \text{Re}[\hat{\chi}_m(0)] \vec{H}(n) \\ + \mu_0 \text{Re} \left[\hat{\psi}_{\chi_m}^H(n-1) e^{(-\xi_m + j\sqrt{1-\xi_m^2}) \omega_0 \Delta t} \right. \\ \left. + \frac{\text{Re}[\hat{\kappa}'(0)]}{c_0} \vec{E}(n) + \frac{1}{c_0} \text{Re}[\hat{\psi}_\kappa^E(n-1)] \right. \\ \left. \times e^{(-\xi - j\sqrt{1-\xi^2}) \omega_0 \Delta t} \right] \end{aligned} \quad (54b)$$

where

$$\hat{\psi}_\phi^F(n) = \sum_{m=0}^{n-1} \vec{F}(n-m) \hat{\phi}(m) \quad (54c)$$

Finally, the general algorithm for dispersive biisotropic chiral media can be found, and in this algorithm [95], we must

1. Update the y component of the electric displacement $D_{i+(1/2)}^y(n+\frac{1}{2})$ and the magnetic flux density $B_{i+(1/2)}^y(n+\frac{1}{2})$ by

$$\begin{aligned} D_{i+1/2}^y \left(n + \frac{1}{2} \right) = \varepsilon_0 \varepsilon_\infty E_{i+1/2}^y \left(n + \frac{1}{2} \right) \\ + \varepsilon_0 \text{Re}[\hat{\chi}_e(0)] E_{i+1/2}^y \left(n + \frac{1}{2} \right) \\ + \varepsilon_0 \text{Re}[\hat{\psi}_{\chi_{e+(1/2)}}^E \left(n - \frac{1}{2} \right)] e^{(-\xi_e + j\sqrt{1-\xi_e^2}) \omega_0 \Delta t} \\ + \frac{\chi}{c_0} H_{i+(1/2)}^y \left(n + \frac{1}{2} \right) \\ - \frac{\text{Re}[\hat{\kappa}'(0)]}{c_0} H_{i+(1/2)}^y \left(n + \frac{1}{2} \right) \\ - \frac{1}{c_0} \text{Re}[\hat{\psi}_{\kappa_{i+(1/2)}}^H \left(n - \frac{1}{2} \right)] e^{(-\xi - j\sqrt{1-\xi^2}) \omega_0 \Delta t} \end{aligned} \quad (55a)$$

$$\begin{aligned} B_{i+1/2}^y \left(n + \frac{1}{2} \right) = \mu_0 \mu_\infty H_{i+1/2}^y \left(n + \frac{1}{2} \right) \\ + \mu_0 \text{Re}[\hat{\chi}_m(0)] H_{i+1/2}^y \left(n + \frac{1}{2} \right) \\ + \mu_0 \text{Re}[\hat{\psi}_{\chi_{m+(1/2)}}^H \left(n - \frac{1}{2} \right)] e^{(-\xi_m + j\sqrt{1-\xi_m^2}) \omega_0 \Delta t} \\ + \frac{\chi}{c_0} E_{i+1/2}^y \left(n + \frac{1}{2} \right) \\ + \frac{\text{Re}[\hat{\kappa}'(0)]}{c_0} E_{i+(1/2)}^y \left(n + \frac{1}{2} \right) \\ + \frac{1}{c_0} \text{Re}[\hat{\psi}_{\kappa_{i+(1/2)}}^E \left(n - \frac{1}{2} \right)] e^{(-\xi - j\sqrt{1-\xi^2}) \omega_0 \Delta t} \end{aligned} \quad (55b)$$

2. Update the x component of the electric displacement $D_i^x(n+1)$ and the magnetic flux density $B_{i+1}^x(n+1)$ by

$$\begin{aligned}
 D_i^x(n+1) = & \varepsilon_0 \varepsilon_\infty E_{i+1}^x(n+1) + \varepsilon_0 \operatorname{Re}[\hat{\gamma}_e(0)] E_{i+1}^x(n+1) \\
 & + \varepsilon_0 \operatorname{Re}[\hat{\psi}_{\lambda_{ei+1}}^{E^x}(n) e^{(-\xi_e + j\sqrt{1-\xi_e^2})\omega_0 \Delta t} + \frac{\chi}{c_0} H_i^x(n+1) \\
 & - \frac{\operatorname{Re}[\hat{\kappa}(0)]}{c_0} H_i^x(n+1) \\
 & - \frac{1}{c_0} \operatorname{Re}[\hat{\psi}_{\kappa_i}^{H^x}(n) e^{(-\xi - j\sqrt{1-\xi^2})\omega_0 \Delta t}]]
 \end{aligned} \tag{56a}$$

$$\begin{aligned}
 B_i^x(n+1) = & \mu_0 \mu_\infty H_i^x(n+1) \\
 & + \mu_0 \operatorname{Re}[\hat{\gamma}_m(0)] H_i^x(n+1) \\
 & + \mu_0 \operatorname{Re}[\hat{\psi}_{\lambda_{mi}}^{E^x}(n) e^{(-\xi_m + j\sqrt{1-\xi_m^2})\omega_0 \Delta t} \\
 & + \frac{\chi}{c_0} E_i^x(n+1) + \frac{\operatorname{Re}[\hat{\kappa}'(0)]}{c_0} E_i^x(n+1) \\
 & + \frac{1}{c_0} \operatorname{Re}[\hat{\psi}_{\kappa_i'}^{E^x}(n) e^{(-\xi - j\sqrt{1-\xi^2})\omega_0 \Delta t}]]
 \end{aligned} \tag{56b}$$

On the basis of (56a) and (56b), the interaction of a transient microwave signal with biisotropic media can be fully understood, in particular the material dispersion and loss effects.

To use biisotropic and bianisotropic chiral media to fabricate certain microwave devices, there are still many challenging problems that need to be explored further, such as the control or optimization of material parameters and their measurements.

lower-frequency regions, without affecting the radiation pattern.

3. TRIANGULAR (BOWTIE) ANTENNAS

A triangular plate antenna above a conducting ground plane and a bowtie antenna are shown in Figs. 10a and 10b. These antennas also possess broadband characteristics, though not as broad as a solid conical antenna. The theoretical characteristics of the bowtie antenna have been obtained numerically [20] by using the method of finite-difference time domain (FDTD). Figures 11a and 11b show the calculated input impedance. The input impedance of the triangular plate antenna above the ground plane is half of that of the bowtie antenna.

The far-zone electric field patterns in the x - y plane and in the x - z plane are shown in Figs. 12a and 12b, respectively. Note that the radiation is enhanced in the direction perpendicular to the antenna plate for the antenna length $2h \lesssim \lambda$, because the radiation from the antenna surface current is added in phase in that direction. The theoretical directivity gain of the bowtie antenna in the direction of the x axis is shown in dBi in Fig. 13 versus the antenna length $2h/\lambda$ for various cone angles [20]. It is noted here that the bowtie antenna can also be simulated by several radial wire rods as the solid biconical antenna.

COPLANAR STRIPLINE (CPS) COMPONENTS

YOUNG-HO SUH
Mimix Broadband Inc.
Houston, Texas

1. INTRODUCTION

Coplanar stripline (CPS) is an attractive uniplanar transmission line offering flexibility in the design of planar microwave and millimeter-wave circuits, especially in mounting the solid-state device in series or shunt with no via holes. Its balanced structure is useful in applications such as printed dipole antenna feeding, rectennas, uniplanar mixers [1], integrated optic traveling-wave

modulators [2], optical control microwave attenuators and modulators [3], and other optoelectric devices [4,5]. CPS characteristics include low loss, small dispersion, small discontinuity parasitics, comparable insensitivity to substrate thickness, and simple implementation of open-ended or short-ended strips.

A few studies regarding CPS components modeling and filter applications have been performed. In 1996, CPS discontinuities such as open and short circuits, series gap, spur slot, and spur strip were investigated [6]. In Ref. 6, each discontinuity was represented as an equivalent lumped element. The CPS open circuit was represented as a shunt capacitor, CPS short circuit was represented as a shunt inductor, and the CPS series gap was represented as a series capacitor. A quarter-wavelength spur slot and spur strip were represented as a series short circuit and a shunt open circuit, respectively. Simons et al. [6] also proposed CPS component measurement method using thru-reflect-line (TRL) calibration with CPS on-water standards for the first time. In 1997, CPS discontinuities and their applications to bandstop [7] and bandpass [8] filters were studied by using the spur-strip and the spur-slot resonators. Goverdhanam et al. [7] introduced various CPS components such as a narrow transverse slit, a symmetric step, a right-angle bend, and a tee junction. Fan et al. [9] proposed uniplanar hybrid ring couplers and a branchline hybrid coupler using an asymmetric CPS with 25% and 10% bandwidths, respectively, at a center frequency of 3 GHz in 1997. A lumped-element CPS lowpass filter was designed in 1998 [10] using spiral inductors and interdigital capacitors, and a CPS lowpass filter using a transverse slit and a parallel-coupled gap of CPS discontinuities was presented in 1999 [11]. Kim et al. introduced a CPS MEMS phase shifter that could be easily packaged or integrated into the waveguide in 2003 [12]. Lumped-element models of CPS circuits and discontinuities were extracted using a full-wave method of moments [13]. A new deembedding technique called a “short (circuit)/open(circuit) calibration scheme” is applied to calibrate these calculated models for accurate circuit model extraction.

Comparably extensive work has been reported in coplanar waveguide (CPW) components such as resonators and filters. Dib et al. investigated CPW discontinuities based on the solution of an appropriate surface integral equation in the space domain in 1991 [14]. In 1998, [15], Hettak et al. reported various types of CPW series resonators and their applications to filters and in 1999 they described CPW shunt stubs printed within the center conductor and implemented miniature filters were with these shunt stubs [16]. However, CPW shunt stub resonator requires additional airbridges or bonding wires, which might increase the fabrication cost and complexity. CPW series resonators require a large conductor area and, the structure of the CPW bandpass filter using CPW series resonators is comparably complex.

This article is organized into three major parts: (1) review and investigation of CPS characteristics; (2) introduction of CPS circuit components such as resonators, filters, and tee junction; and (3) CPS applications to antennas and wireless power transmission.

First, a CPS characteristics analysis using a quasi-TEM analytical equation derived by the conformal mapping method is described. The relationship between the characteristic impedance and CPS strip width and gap is analyzed. Transmission-line loss is analyzed as a function of characteristic impedance of CPS. Parameter variations due to change in substrate height are discussed. From the analysis, the design considerations for practical CPS component implementations are discussed. Following a brief analysis of CPS, new types of CPS components and their performances are presented. Six types of CPS resonator are first introduced and their performances are analyzed in terms of Q factor or bandwidth. CPS resonators are realized with open-ended and short-ended strips in various configurations, and lumped-element equivalent circuits for the resonators are presented. The appropriate circuit configuration for high Q factor is analyzed. The relationship between CPS characteristic impedance and CPS attenuation is briefly discussed for high Q factor. Two new classes of CPS bandpass filter are presented using the resonators discussed here for narrow- and wideband applications, and their lumped-element equivalent circuits are presented. A novel, simple CPS lowpass filter is presented using a CPS line loaded with interdigital capacitors. The lowpass filter is easily reproducible using a prototype of the desired filter type with the selected cut-off frequency.

A new method of microstrip-fed CPS tee junction is introduced without using bonding wires or via holes. For the tee junction, novel coupled CPS (CCPS) is presented and its performance is discussed. Tee-junction applications are demonstrated in a twin-dipole antenna and a dipole phased array with detailed illustrations and photographs.

Microstrip-to-CPS transition for CPS component measurements is briefly discussed. The transition presented in this article enables convenient CPS components measurement with a conventional network analyzer using the common short (circuit)/open (circuit) load-thru (SOLT) calibration method.

All the CPS components presented in this article is fabricated on the RT/Duroid 5870 substrate with 1 oz copper cladding, 20 mil substrate height, and the dielectric constant of 2.33.

2. CPS CHARACTERISTICS ANALYSIS FOR THE DESIGN CONSIDERATION

The structure of CPS on a finite substrate is illustrated in Fig. 1. Analytical techniques for calculating the characteristic impedance, the effective dielectric constant, and dielectric and conductor losses of the CPS are described in Refs. 12–14. Closed-form quasi-TEM parameters for the symmetric coplanar stripline on finite substrate thickness are necessary for practical purposes, which is extensively discussed in Ref. 20a. Loss mechanisms considered in this article are conductor (α_c) and dielectric (α_d) losses.

Figure 1. Coplanar stripline (CPS) structure (from Ref. 20b with permission from IEEE).

Dielectric loss (α_d) is independent of the geometry of the line and can be expressed as follows:

$$\alpha_d = 27.3 \frac{\epsilon_r}{\sqrt{\epsilon_{re}}} \frac{\epsilon_{re} - 1}{\epsilon_r - 1} \frac{\tan \delta}{\lambda_0} \quad (\text{dB/unit length}) \quad (1)$$

Effective dielectric constant (ϵ_{re}) is represented as

$$\epsilon_{re} = 1 + \frac{\epsilon_r - 1}{2} \frac{K'(k_1)}{K(k_1)} \frac{K(k_2)}{K'(k_2)} \quad (\text{F/unit length}) \quad (2)$$

where ϵ_r is the dielectric constant and $K(\bullet)$, $K'(\bullet)$ are the complete elliptic integrals of the first kind and its complement, respectively. k_1 and k_2 are expressed as

$$k_1 = \frac{s}{s + 2W} = \frac{a}{b} \quad (3)$$

$$k_2 = \frac{\sinh(\pi a/2h)}{\sinh(\pi b/2h)} \quad (4)$$

where h represents substrate thickness, s is the gap between the CPS strips, and W is the width of the CPS strip. $K(k)$ can be found with series expansion approximation as for $0 \leq k \leq 0.707$

$$K(k) = \frac{\pi}{2} \left\{ 1 + 2 \frac{k^2}{8} + 9 \left(\frac{k^2}{8} \right)^2 + 50 \left(\frac{k^2}{8} \right)^3 + 306.25 \left(\frac{k^2}{8} \right)^4 + \dots \right\} \quad (5)$$

and for $0.707 \leq k \leq 1$

$$K(k) = p + (p - 1) \left(\frac{k^2}{4} \right) + 9 \left(p - \frac{7}{6} \right) \left(\frac{k^4}{64} \right) + 25 \left(p - \frac{37}{30} \right) \left(\frac{k^6}{256} \right) + \dots \quad (6)$$

where

$$p = \ln \frac{4}{k'} \quad (7)$$

$$k' = \sqrt{1 - k^2} \quad (8)$$

$K'(k)$ can be obtained from $K'(k) = K(k')$ and applied to series expansions.

The conductor loss (α_c) of a CPS expression is given as

$$\alpha_c = \frac{8.68 R_s \sqrt{\epsilon_{re}}}{480 \pi K(k_1) K'(k_1) (1 - k_1^2)} \times \left\{ \frac{1}{a} \left[\pi + \ln \left(\frac{8 \pi a (1 - k_1)}{t (1 + k_1)} \right) \right] + \frac{1}{b} \left[\pi + \ln \left(\frac{8 \pi b (1 - k_1)}{t (1 + k_1)} \right) \right] \right\} \quad (\text{dB/unit length}) \quad (9)$$

a , b , and k_1 are as defined in (3). $K(\bullet)$ and $K'(\bullet)$ can be obtained from (5)–(8) with the property of $K'(\bullet) = K(\bullet')$. t is the strip thickness and R_s is the surface resistance, defined as

$$R_s = \sqrt{\frac{\omega \mu_0}{2 \sigma}} \quad (\Omega) \quad (10)$$

where σ is the metallic strip conductivity. These equations assume strip thickness $t > 3\delta$, $t \ll a$, and $t \ll (b - a)$, where δ is skin depth, expressed as

$$\delta = \sqrt{\frac{2}{\omega \mu \sigma}} \quad (\text{unit length}) \quad (11)$$

Total attenuation, including dielectric and conductor losses at 10 GHz, is plotted in Fig. 2 with a fixed strip width ($W = 1.5$ mm) and separation between the strips (s) increased from 0.1 to 20 mm. It is observed that the wider is the separation (s), the lower the total attenuation ($\alpha_c + \alpha_d$) and the higher the characteristic impedance (Z_0) are achieved. In other words, the higher the characteristic impedance of CPS, the lower the transmission-line

Figure 2. Total attenuation ($\alpha_c + \alpha_d$) of a CPS as a function of gap separation (s) at 10 GHz. The strip width (W) is fixed at 1.5 mm. A 20-mil-height, 2.33 dielectric constant, and 1-oz copper cladding substrate was used (from Ref. 20b with permission from IEEE).

attenuation that can be achieved. In the relationship between the dielectric constant of the substrate and the total attenuation, the higher is the dielectric constant, the higher is the total attenuation. For a practical design, moderate characteristic impedance with a proper dielectric constant substrate is used for low attenuation. Hence, Fig. 2 is useful for selecting CPS component design parameters.

3. CPS RESONATORS

3.1. Open-Ended T-Strip Resonators

Two types (A and B) of open-ended T-strip resonator are presented in this section. The structure of resonator type A and its lumped-element equivalent circuit are illustrated in Fig. 3. Resonator type A consists of open-ended T strips with 0.5 mm width and around $\lambda_g/2$ ($0.42 \lambda_g$) or 25.4 mm length, placed outside the strips designed to operate at a center frequency of ~ 4.28 GHz. As shown in

Figure 3. CPS resonator using open-ended T strips and its lumped-element equivalent circuit (type A) (from Ref. 20b with permission from IEEE).

Table 1. Simulated Loaded Q (Q_L) and Unloaded Q (Q_U) of Resonator Type A (from Ref. 20b with permission from IEEE)

Gap ₁ (mm)	s (mm)	Q_L	Q_U
0.25	0.6	113.6	114.7
	1.2	114.1	115.6
0.5	0.6	101.9	102.05
	1.2	104.7	105.2
1	0.6	62.6	72.8
	1.2	76.3	79.1

Fig. 3, the CPS transmission line is represented as lumped-element LC circuits. The T strips become inductor, and gap₁ induces coupling capacitance due to the coupling with CPS strips. Hence, T strips can be represented as a shunt series resonator ($L'C$ circuit), which exhibits bandstop behavior. The narrower is the gap₁, the higher is the loaded Q (Q_L) value, due to the strong coupling and the low loss at gap₁.

As discussed in Section 2, CPS transmission-line attenuation is reduced when the CPS strip separation (s) widens, as shown in Fig. 2. Accordingly, the narrower the gap₁, and greater the s will increase the loaded Q (Q_L). Computed loaded (Q_L) and unloaded Q (Q_U) values are displayed in Table 1 with various gap₁ and s values. The computation was performed using a commercial full-wave electromagnetic simulator, which uses the method of moments. Table 1 shows that the narrow gap₁ and the wide s configuration provide a high Q_L value, and Q_U values are similar in every configuration. Q_U calculation of the bandstop resonator [21] is expressed as

$$Q_U = \frac{Q_L}{\sqrt{(1 - 2 \times 10^{-L/20})}} \quad (12)$$

Where Q_L is the loaded Q , expressed as

$$Q_L = \frac{f_0}{\Delta f_{3 \text{ dB}}} \quad (13)$$

f_0 , $\Delta f_{3 \text{ dB}}$, and L represent the center frequency, the 3 dB insertion loss bandwidth, and the insertion loss at the center frequency, respectively.

Measured and simulated frequency responses of this type of resonator with 0.6 mm of s and 0.5 mm of gap₁ are shown in Fig. 4. A measured Q_L of 97.27 is achieved with a resonance frequency of 4.28 GHz with a 3 dB insertion loss bandwidth of 44 MHz. Q_U of 97.44 is obtained from (12) with the insertion loss (L) of -27.53 dB at the center frequency. Measured Q values agree with simulated result ($Q_L = 101.9$ and $Q_U = 102.05$) displayed in Table 1.

Resonator type B consists of open-ended T strips placed inside the CPS transmission line. The structure of resonator type B and lumped-element equivalent circuit are shown in Fig. 5.

Gap₂, gap₃, and the open-ended T-strip width are all 0.5 mm. To place the open-ended T strips between the narrowly spaced CPS strips, the transmission-line gap s is widened from 0.6 to 2.5 mm, which corresponds to the

Figure 4. Simulated and measured frequency responses for open-ended T-strip resonator (type A) with gap_1 0.5 mm and s 0.6 mm (from Ref. 20b with permission from IEEE).

impedance value increase from 184 to 250 Ω . Despite this increase in impedance, little insertion loss deterioration occurs and the return loss response is better than 10 dB. The open-ended T-strip length is around $\lambda_g/2$ ($0.39\lambda_g$) or 25.4 mm at the center frequency of near 4.02 GHz. This type of resonator, similar to type A, has also coupling capacitance at gap_2 , and additional capacitance takes place at gap_3 .

Table 2 describes the simulated Q values of resonator type B with various gap_2 and gap_3 values. The gap_3 value corresponds to s value, which is the CPS separation between two strips. The narrower the gap_2 and the wider the s , the higher the Q_L values, due to the stronger coupling capacitance and, accordingly, the lower transmission-line attenuation, as shown in Fig. 2 from CPS analysis in Section 2. It can be concluded that the higher characteristic impedance corresponds to the higher Q_L values for CPS resonators as shown in Tables 1 and 2 and Fig. 2.

Simulated and measured frequency responses of the type B resonator are shown in Fig. 6. Measured Q_L and Q_U values of resonator type B, with 0.5 mm of gap_2 and gap_3 ,

Figure 5. CPS resonator using open-ended T strips and lumped-element equivalent circuit (type B) (from Ref. 20b with permission from IEEE).

Table 2. Simulated Loaded Q (Q_L) and Unloaded Q (Q_U) of Resonator Type B (from Ref. 20b with permission from IEEE)

Gap ₂ (mm)	Gap ₃ (mm)	Q_L	Q_U
0.25	0.5	127.2	129.1
	1.0	129.7	130.6
	2.0	136.1	137.4
0.5	0.5	121.25	121.27
	1.0	124.3	125.2
	2.0	134.3	134.9

are 98.04 and 98.09, respectively. The 3 dB insertion loss bandwidth is 41 MHz, and the insertion loss (L) is -32.22 dB at the center frequency. The simulated Q_L and Q_U values are 121.25 and 121.27, respectively, as given in Table 2.

3.2. T-Slot Resonator

A T-slot resonator (type C) can be considered as a complementary structure of the type A resonator. Its structure is illustrated in Fig. 7. Similar to the spur-slot resonator in Ref. 7, a T slot can be considered as series short-ended stubs or shunt open-ended stubs where each arm measures a quarter-wavelength.

The frequency response of this resonator exhibits band-stop behavior and the lumped-element equivalent circuit is represented as a shunt-series resonator ($L'C'$ circuit). The length of the T slot is about $\lambda_g/2$ ($0.47\lambda_g$) or 25.4 mm at a center frequency of ~ 4.78 GHz. The width of the T slot (gap_4) is 0.5 mm, and s and W are 0.6 and 1.5 mm, respectively.

It is found that the T-slot resonator has a Q_L value much higher than that of open-ended T-strip resonators, mainly because the T-slot resonator's metallic area is much smaller than that of the T-strip resonator due to and thus the radiation loss of the former is much less. Simulated Q_L and its corresponding Q_U are described in Table 3.

Loaded Q (Q_L) of the T-slot resonator is ~ 262.93 with gap_4 0.5 mm and s 0.6 mm, while open-ended T-strip resonators such as types A and B have $Q_L < 150$. The T-slot resonator is also found to be less sensitive to gap_4 and s than is the open-ended T-strip resonator.

Similar to the case of two T-strip resonators, the value of Q_L increases when gap_4 is reduced and s is increased. This is due to the higher coupling at gap_4 and lower attenuation when s is increased. Wider s corresponds to higher characteristic impedance with fixed W for CPS as discussed in Section 2. While the relationship between the characteristic impedance and the value of Q_L follows the results of T-strip resonators, values of Q_L are not very sensitive to gap_4 and s or the characteristic impedances. This implies that the resonance energy is stored more effectively with the slot configuration than with the strip one.

It can be concluded that the higher characteristic impedance corresponds to the higher Q_L values for CPS resonators from the results of T-strip and T-slot resonators, and that the T-slot resonator has better performance in

Figure 6. Simulated and measured frequency responses for open-ended T-strip resonator (type B) with gap_2 and gap_3 0.5 mm and s 0.6 mm (from Ref. 20b with permission from IEEE).

terms of the Q factors but insensitive to the characteristic impedance (see Tables 1–3 and Fig. 2).

Type C resonator simulated and measured frequency responses are shown in Fig. 8. Measured Q_L and its corresponding Q_U values of resonator type C, with 0.6 mm of s and 0.5 mm of gap_4 are 244.2 and 245.7, respectively. The 3 dB insertion loss bandwidth is 41 MHz, and the insertion loss (L) is -43.7 dB at the center frequency. These Q values are also close to simulated results ($Q_L=262.93$ and $Q_U=263.37$) given in Table 3.

3.3. Square-Ring-Shape Open-Ended Strip Resonator

The square-ring-shape open-ended strip resonator (type D) has two open-ended strips located outside the strips, similar to type A. These open-ended strips are bent to have square forms. The structure of square-ring-shape open-ended strip resonator is shown in Fig. 9.

The length of the open-ended strip is about $0.32\lambda_g$ (15.52 mm) at a center frequency of ~ 5.08 GHz. This resonator has a shorter coupling arm (4.625 mm) than do types A and B. Therefore, open-ended strips have loose coupling and induce high losses. Two open-ended strips are purposely located asymmetrically to prevent any pos-

sible radiation as does the dipole antenna. The asymmetric structure induces a spurious response around 6.1 GHz.

Measured and simulated return and insertion losses of this resonator are illustrated in Fig. 10. Measured Q_L and Q_U of this resonator are 23.51 and 23.87, respectively. The 3 dB insertion loss bandwidth is 216 MHz and the insertion loss (L) is -18.3 dB at the center frequency. Simulated Q_L and Q_U are 38.1 and 38.51, respectively.

Compared to resonators A and B, which consist of open-ended T strips, the type D resonator is compact but its Q_L is low. Hence, this resonator would be useful for applications requiring spatial efficiency with moderate bandstop purpose.

3.4. Short-Ended Strip Resonators

One merit of the uniplanar transmission line is the convenient implementation of the short-ended strips with no via holes. Two types of short-ended strip resonator (types E and F) are introduced and investigated. Resonator type E utilizes a short-ended strip, in contrast to resonator types A, B, and D as illustrated in Fig. 11.

The total length of the short-ended strip is about $0.44\lambda_g$ (13.7 mm), which is around $\lambda_g/2$, with 0.5 mm width at a center frequency of ~ 8 GHz. The transmission line is widened, similar to that of resonator type B, when the short-ended strip is placed between the CPS strips but little insertion loss deterioration occurs and return loss is >10 dB. The short-ended strip becomes an inductor and gap_4 induces coupling capacitance due to coupling with CPS strips. This short-ended strip and gap_4 consist of a

Figure 7. CPS resonator using T slots and its lumped-element equivalent circuit (type C).

Table 3. Simulated Loaded Q (Q_L) and Unloaded Q (Q_U) of Resonator Type C

Gap ₄ (mm)	s (mm)	Q_L	Q_U
0.25	0.6	265.00	265.52
	1.2	266.20	267.26
	1.8	267.24	267.97
0.5	0.6	262.93	263.37
	1.2	263.97	264.90

Figure 8. Simulated and measured frequency responses for a T-slot resonator (type C).

shunt-parallel resonator ($L''C''$ circuit), which acts as bandpass behavior.

Measured and simulated frequency responses of this resonator are illustrated in detail in Fig. 12. A measured insertion loss of 0.12 dB is achieved at a center frequency of 8.12 GHz. This type of resonator can be utilized for bandpass filter applications. The measured bandwidth of <3 dB insertion loss and >10 dB return loss is around 3 GHz (36.94%) with resonator type E.

For resonator type F, two short-ended strips are attached together in a closed polygon configuration as shown in Fig. 13. Similar to the type E resonator, coupling capacitance at gap₅ and the short-ended strip inductance consist in a shunt parallel resonator ($L''C''$ circuit), which exhibits bandstop behavior. The total length of the short-ended strip is about $1.1\lambda_g$ (48.1 mm) at a center frequency of ~5.4 GHz. The transmission-line gap s is widened similar to that of resonator types B and E.

Frequency responses of this resonator are illustrated in Fig. 14. The measured bandwidth of <3 dB insertion loss and >10 dB return loss is ~0.84 GHz (15.67%). A measured insertion loss of 0.5 dB was achieved at a center fre-

Figure 9. Square-ring-shape open-ended strip CPS resonator and its lumped-element equivalent circuit (type D) (from Ref. 20b with permission from IEEE).

quency of 5.36 GHz. The bandwidth of resonator type F is almost half that of resonator type E, which is due to the cascading of two identical resonators.

Six different types of resonator are presented, and their performances are analyzed. As discussed, the T-slot resonator (type C) has the highest Q_L among four different bandstop resonators and resonator type E has the widest passband bandwidth between the two different short-ended strip resonators. As shown in Tables 1-3 and Fig. 2, CPS resonators can have high Q_L when high characteristic impedance and strong coupling capacitance are employed. Many variations and combinations of these six resonators are possible. Therefore, these resonators would be very useful for designing CPS filters.

Figure 10. Simulated and measured frequency responses for square-ring-shape resonator (type D) (from Ref. 20b with permission from IEEE).

Figure 11. Short-ended strip CPS resonator and its lumped-element equivalent circuit (type E) (from Ref. 20b with permission from IEEE).

4. CPS FILTERS

This section describes two new classes of CPS bandpass filter that utilize combinations of the resonators presented in Section 3. Design methods for CPS bandpass filters are presented and discussed. These bandpass filters have good passband insertion loss and wide stopband suppressions. The simple CPS lowpass filter design method is also discussed with practical circuit implementation.

4.1. Bandpass Filter Realization Using Multiple Short-Ended Strips

This type of bandpass filter uses type E resonators presented in Section 3. The structure and the lumped-element equivalent circuit of this filter are shown in Fig. 15.

A transmission line with periodically loaded reactive cells has the characteristic of filters. One reactive cell can be formed with resonator type E, which exhibits bandstop behavior. The total length of the unit cell is around $\lambda_g/2$ ($0.41\lambda_g$) or 12.5 mm at a center frequency of 8 GHz. The spacing between neighboring cells is one of the most important factors for bandpass filter design in periodic structures.

Figure 12. Simulated and measured frequency responses for short-ended strip resonator (type E) (from Ref. 20b with permission from IEEE).

Figure 13. Closed polygon short-ended strip CPS resonator and its lumped-element equivalent circuit (type F) (from Ref. 20b with permission from IEEE).

Because of the structural dimension of the unit cell, uniform spacing between unit cells is impossible. Hence, two neighboring cells are grouped as a subcell. This bandpass filter, correspondingly, has two subcells. The inter-unit-cell spacing within the subcell is optimal at 2 mm; spacing under 2 mm manifests loose band rejection at stopbands, while spacing exceeding 2 mm exhibits sharper out-of-band rejection but shows unsatisfactory return loss at passband. A distance between subcells is about $\lambda_g/2$ ($0.46\lambda_g$) or 14 mm to ensure a good rejection at stopbands similar to conventional periodic structure. As shown in Fig. 15, CPS transmission-line sections are represented as the lumped-element LC circuits.

The short-ended strip consists a shunt parallel resonator ($L''C''$ circuits), discussed in Section 3 for resonator type E. The transmission-line gaps s is widened in the same way as in resonator types B, E, and F. For designing CPS components, transmission-line inductance and capacitance values play important roles and should be considered for CPS components modeling. Values of the capacitance and the inductance of CPS strips can be accurately extracted by the method of moments using commercial full-wave electromagnetic software.

Simulated and measured frequency responses of this filter are illustrated in Fig. 16. Measured insertion loss of 0.48 dB is achieved at a center frequency of 8.24 GHz. A

Figure 14. Simulated and measured frequency responses for closed polygon short-ended strip (type F) (from Ref. 20b with permission from IEEE).

wide bandwidth of 4.16 GHz (52%) is achieved with less than 3 dB insertion loss and better than 10 dB return loss, and the 1 dB insertion loss bandwidth ranges from 6.9 to 9.8 GHz. Stopbands range from 2 to 5.38 GHz in a lower stopband area and from 11.1 to 13.31 GHz in a higher stopband area.

4.2. Bandpass Filter Using Short-Ended Strips with T Strips

Figure 17 illustrates the bandpass filter structure using short-ended strips with T strips and shows its lumped-element equivalent circuit.

This type of filter consists of types A and F resonators and interdigital capacitors. Closed polygon short-ended strips (type F resonators) are represented as shunt-parallel resonators ($L''C''$ circuits) and T-strips (type A resonators) are represented as a shunt series resonator ($L'C'$ circuit). An interdigital capacitor (C) is placed inside each

type E resonator to provide higher capacitance. The interdigital capacitor is widely used as the microwave circuit's lumped-element component possessing tight coupling.

The capacitance of the interdigital capacitor is expressed as

$$C = \epsilon_0 \left(\frac{\epsilon_r + 1}{2} \right) \frac{K(k)}{K'(k)} Nl(F) \tag{14}$$

where $K(\bullet)$ is the complete elliptic integral of the first kind, which is expressed in (5)–(8). k is defined as

$$k = \sin \left(\frac{\pi W}{2d} \right) \tag{15}$$

where W is the width of the interdigital capacitor's finger and d is the distance between fingers; k' is as defined in (8).

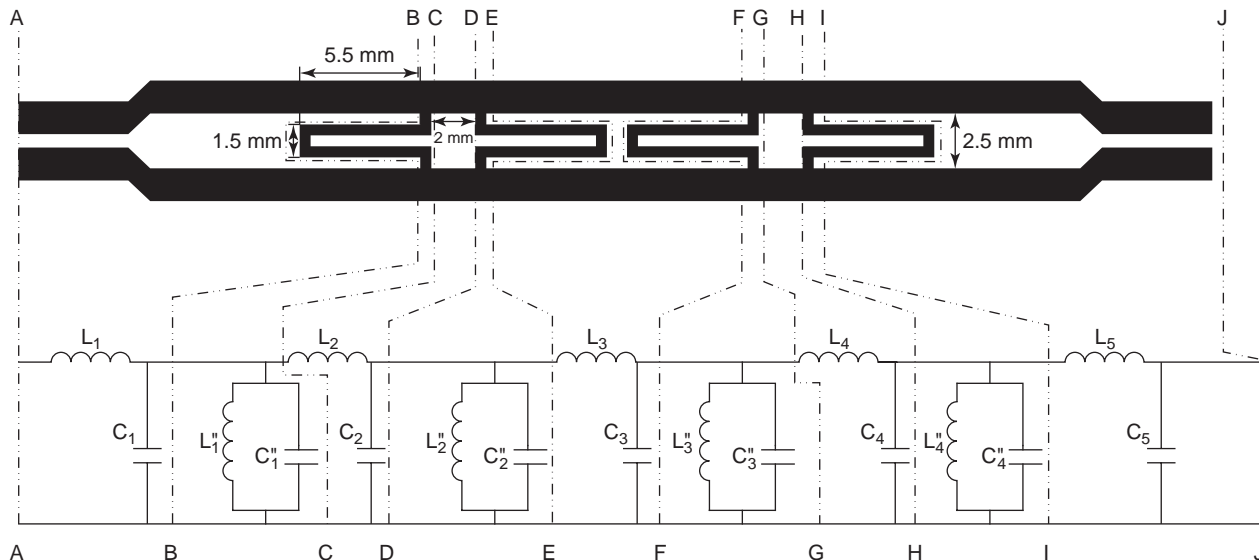

Figure 15. Bandpass filter structure using multiple short-ended strips and its lumped-element equivalent circuit (from Ref. 20b with permission from IEEE).

Figure 16. Simulated and measured frequency responses of a bandpass filter using multiple short-ended strips: (a) return loss; (b) insertion loss (from Ref. 20b with permission from IEEE).

The number and length of the interdigital capacitor fingers are $N = 3$ and $l = 2$ mm, respectively. All the interdigital capacitor gap distances are uniformly 0.5 mm, with a capacitance C of ~ 0.31 pF from full-wave electromagnetic simulation using the method of moments. Most of the capacitance takes place at the edges of the fingers. Hence, the gap distance between the fingers together with the number of fingers is important factor in determining the capacitance value.

The width of the short-ended strip is 0.5 mm and the length is $0.79 \lambda_g$ or 41.5 mm. The capacitance (C'') and inductance (L'') values of the short-ended strip are about 0.00563 pF/mm and 0.0763 nH/mm at 5 GHz, which can be found by simulation. The inductance (L'') and total capacitance, including interdigital capacitance ($C_T = C + C''$), can be found by the following equations

$$L'' = 0.0463 \times l(\text{nH}) \quad (16)$$

$$C_T = 0.31 + 0.00563 \times l(\text{pF}) \quad (17)$$

where l is the total length of the short-ended strip in millimeters. With (16) and (17), the approximate dimensions

of the short-ended strip can be found at the desired frequency.

Two unit cells are cascaded with a distance of $\sim \lambda_g/4$ ($0.28 \lambda_g$) or 13.6 mm. A type A resonator ($L'C'$ circuit) is combined with this filter to enhance the suppression at the lower stopband with a length of 29.1 mm ($0.48 \lambda_g$) at a center frequency of ~ 4 GHz. This is a good example an advantage of the uniplanar transmission line, namely, open-ended and short-ended strips together without any via holes.

Measured and simulated frequency responses are given in Fig. 18, showing good agreement between measured and simulated data. The measured bandwidth of < 1 dB insertion loss and > 10 dB return loss ranges from 4.82 to 5 GHz (3.64%). Stopbands with the suppression of less than -20 dB range from 3.56 to 3.98 GHz (0.42 GHz) at the lower band and from 5.48 to 6.08 GHz (0.6 GHz) at higher band. The low insertion loss of 0.61 dB was measured at a center frequency of 4.94 GHz.

Two types of bandpass filters are designed for wideband and narrowband applications using proposed resonators. Bandpass filters show low passband insertion loss and

Figure 17. Structure of a bandpass filter using short-ended strips with T strips and its lumped-element equivalent circuit (from Ref. 20b with permission from IEEE).

good stopband suppression. These filters would be useful for uniplanar circuit implementations.

4.3. CPS Lowpass Filter

Few CPS lowpass filters have been reported. CPS lowpass filters are very useful in rectenna circuits [15–20a]. CPS lowpass filter design examples have been reported [5,6] with complex structures, the design methods are not clear. In this section, a novel lowpass filter with the lumped-element equivalent circuit is presented. The design method for the desired filter type is described. A simple 0.2 dB equal-ripple Chebyshev CPS lowpass filter is designed with a cutoff frequency of 7.4 GHz. The structure of the lowpass filter is illustrated in Fig. 19.

For designing the lowpass filter with the chosen specification, a ladder circuit and its element definitions should be first performed. Tabulated element values of the ladder circuit can be easily found in Ref. 28. With those element values, a prototype of the lowpass filter can be designed. After proper scaling in terms of impedance and frequency, lumped-element values of the lowpass filter can be found.

As shown in Fig. 19, capacitance is realized with the interdigital capacitor, and inductance is realized

with the CPS transmission line itself. Capacitance of the interdigital capacitors can be found by simulation or in (14).

As mentioned earlier, the CPS transmission line has its own inductance and capacitance, and those values should be considered for designing CPS components. This design demonstrates how the CPS line inherent inductance can be utilized in the design of the CPS components. At the design frequency, the capacitance and inductance of CPS per unit length can be found using a commercial simulator.

For inserting interdigital capacitors inside the narrowly spaced CPS strips, the CPS strip gap s is widened in the same way as in CPS resonator types B, E, and F, but little insertion loss deterioration occurs and return loss is better than 10 dB.

Simulated and measured frequency responses of the CPS lowpass filter are shown in Fig. 20. Measured data show sharp suppression after the cutoff frequency of 7.4 GHz and suppression better than 20 dB up to 13.8 GHz. A low passband insertion loss of 0.7 dB is achieved at passband. Measured and simulated data show good agreement. With this configuration, any kinds of CPS filters can be easily synthesized with desired specifications.

Figure 18. Simulated and measured frequency responses of a bandpass filter using short-ended strips with T strips: (a) return loss; (b) insertion loss.

5. MICROSTRIP-FED CPS TEE JUNCTION

Little work has been reported for CPS tee junctions. A CPS tee junction was introduced in 1997 [7], and a coplanar waveguide (CPW)-fed CPS tee junction was developed for the twin-dipole antenna feeding [29a]. Both methods require bonding wires.

In this section, a new microstrip fed CPS tee junction using a coupled CPS (CCPS) is introduced. Because of the inherent CPS structure as shown in Fig. 21a, it is almost impossible to build a CPS tee junction without having a discontinuity in the CPS structure. With the aid of the CCPS structure, which uses the coupling method, a physical discontinuity is introduced to the CPS structure while fields are continuous over the entire transmission line. Bonding wire is not required for constructing the CPS tee junction.

The structure of the coupled CPS is illustrated in Fig. 21b. One of the CPS strips is discontinued and is terminated with radial stubs with a rotation angle of 30° and a radius of 1.5 mm for coupling to the bottom-layer metallization. The bottom-layer metallization, which is coupled from the top layer's radial stubs, functions as a CPS strip as shown in Fig. 22. The radial stub is used to accomplish

a smooth field transition. Figure 22 compares metallization at different layers of the CPS with those of the conventional CPS shown in Fig. 1. A little insertion and return loss deterioration takes place because electric fields of the CCPS are not exactly normal to the strips.

Measured CCPS frequency responses are shown in Fig. 23, and its performance is compared with that of conventional CPS. Figure 23 also shows that the insertion loss of CCPS is around 0.5 dB deterioration compared with that of conventional CPS at 1.7–7.58 GHz and that the return loss is >10 dB. Insertion loss deterioration of <1 dB covers a wider frequency range, from 1.7 to 13.3 GHz.

The tee-junction configuration is illustrated in Fig. 24. Characteristic impedance of the CCPS is 184Ω , and the microstrip feedline has an input impedance of 50Ω . A quarter-wavelength transformer was used to transform the microstrip's impedance from 50Ω to 92Ω . Part of the microstrip feedline's ground plane forms the coupled CPS (CCPS).

The measured and simulated frequency responses of the tee junction are shown in Fig. 25. An ideal lossless tee junction equally splits the power between each output port with $S_{21} = S_{31} = -3$ dB. The measurements in Fig. 25 show an insertion loss of 0.7 dB and a return loss of

Figure 19. CPS lowpass filter and its lumped-element equivalent circuit.

> 10 dB at 2–4.15 GHz. It is expected that wider bandwidth can be achieved if a binomial or Chebyshev transformer is used instead of a quarter-wavelength transformer at the microstrip feeding.

Measured phases are almost identical at each output port as shown in Fig. 26.

6. CPS TRANSITION

For CPS component measurements, transition to other transmission lines, which enables convenient measurement with the conventional network analyzer, is required.

CPS-to-CPW, CPS-to-slotline, and CPS to-microstrip transitions have been reported.

In 1993 Ho et al. [30] developed a CPS-to-CPW transition. This transition included CPW-to-slotline transition as an intermediate transition. The measured frequency responses of the CPW-to-CPS-to-CPW back-to-back transition showed less than 1 dB insertion loss from 1.6 to 7 GHz (1–4.3), and the return loss was better than 13 dB.

Simons [31] developed a CPS-to-slotline transition with a bandwidth of 30% at 9.5 GHz in 1994. The measured insertion loss was 1.5 dB for the frequency range from 8 to 11.2 GHz (1–1.4) and a return loss of > 10 dB.

Figure 20. Simulated and measured frequency responses of CPS lowpass filter.

Figure 21. Coupled CPS (CCPS) structure: (a) conventional CPS; (b) CCPS (from Ref. 29b with permission from IEEE).

In 1994, Tilley et al. [32] presented a wideband CPW-to-CPS-to-CPW transition with 1 dB back-to-back insertion loss from 0.45 to 5 GHz (1–11). In 1995, Li et al. [33] proposed a CPW-to-CPS-to-CPW back-to-back transition with the bandwidth ranging from 0.4 to 3.6 GHz (1–9) using Chebyshev multisection impedance transformers in the CPW transmission line. In 2000, Mao et al. [34] demonstrated a CPS-to-CPW transition operating up to 20 GHz with an insertion loss of <0.5 dB and a return loss of >10 dB.

Various methods of designing CPS-to-microstrip transitions have been reported. In 1995, Dib et al. [35] reported a type of uniplanar transitions based on the concept of mode conversion with a 3 dB back-to-back insertion loss bandwidth from 7 to 11.5 GHz (1–1.6) for the CPS-to-microstrip transition. In 1997, Qian and Itoh [36] improved the performance with a 3 dB back-to-back insertion loss bandwidth from 6 to 13 GHz (1–2.1) by employing symmetric tee junction for the structure reported by Dib et al. [35]. Simons et al. [37] also proposed a CPS-to-microstrip transition using a coupling method with a 2.4 dB back-to-back insertion loss bandwidth from 5.1 to 6.1 GHz (1–1.2). However, this design used a CPS-to-microstrip-to-CPS back-to-back structure and required special CPS TRL (thru-reflect-line) on-wafer calibration standards with a National Institute of Standards and Technology (NIST) deembedding software program for a network analyzer calibration [37–39a]. Most of these CPS-to-microstrip

Figure 22. Cross-sectional view at A–A' with field distributions of CCPS for different layers of metallization (from Ref. 29b with permission from IEEE).

transitions used high-dielectric-constant substrate ($\epsilon_r > 10$) to reduce the CPS characteristic impedance [28–30].

This section introduces two types of broadband CPS-to-microstrip transitions. One operates from 1.3 to 13.3 GHz (1–10.2) with an insertion loss of <3 dB and a return loss of >10 dB for a back-to-back transition, and the other operates from 2 to 20 GHz (1–10) with an insertion loss of <3.5 dB and a return loss of >10 dB. Both have simple structures and can be easily fabricated using a low-dielectric-constant substrate ($\epsilon_r = 2.33$). Microstrip-to-CPS-to-microstrip back-to-back structures have been fabricated, which is convenient for CPS component measurement with a conventional network analyzer.

6.1. Transition with a Radial Stub Radius of 5.5 mm and its Performance

The structure of a back-to-back microstrip-to-CPS-to-microstrip transition is illustrated in Fig. 27. RT/Duroid 5870 is used as the substrate with a dielectric constant of 2.33 and a thickness of 20 mil.

The gap s and strip width W of the CPS are 0.6 and 1.5 mm, respectively. The CPS characteristic impedance is 184Ω , as was simulated with a commercial full-wave electromagnetic simulator, which uses the method of moments.

As shown in Fig. 1, electric field lines of CPS are directed from one strip conductor to the other on a layer. Electric field lines for microstrip are directed from top layer conductor to bottom layer ground-plane metallization. The radial stub is used to accomplish the rotation of the electric field lines and is rotated with an angle of ϕ to change electric field orientation from parallel to vertical

Figure 23. Frequency responses comparison between CPS and CCPS (from Ref. 29b with permission from IEEE).

Figure 24. Structure of microstrip-fed CPS tee junction (from Ref. 29b with permission from IEEE).

against the substrate. The rotation angle ϕ is optimized at 30° for good coupling.

A broadband coupling can be accomplished by terminating one of the CPS strips with the radial stub as shown in Fig. 27.

The radius and the rotation angle (ϕ) were optimized at 5.5 mm and 30° , respectively. The width of microstrip line was optimized at 1.3 mm for $50\ \Omega$ matching. Length of the microstrip line is chosen as 40 mm. For the impedance transformation from the high characteristic impedance of CPS ($184\ \Omega$) to the microstrip line's impedance ($50\ \Omega$),

smooth insertion of the ground plane toward the microstrip line is important with the proper microstrip line width. Since this method does not employ any quarter-wavelength transformer, which would limit the bandwidth as seen in other methods [28,29a], broadband performance is achieved.

The radial stub length determines the highest operating frequency of the transition. This is because the radial stub creates a virtual short circuit to the bottom metallization with a quarter-wavelength, which is a ground plane of the transition. The shorter is the radial stub, the higher is the operating frequency. Therefore, factors such as radial stub length, rotation angle (ϕ), and length of microstrip determine performance of the transition.

The measured return and insertion loss of back-to-back transition, excluding the SMA (end launch assembly) connector loss, are illustrated in Fig. 28.

The measured $<3\ \text{dB}$ insertion loss bandwidth of back-to-back transition is from 1.3 to 13.3 GHz (1–10.2) with a return loss of better than 10 dB. The $<1\ \text{dB}$ insertion loss bandwidth for the back-to-back transition is from 1.4 to 7.3 GHz (1–5.2). For an insertion loss of less than 0.5 dB for the back-to-back transition, the bandwidth ranges from 1.5 to 6 GHz (1–4) with a return loss of $>10\ \text{dB}$.

The transition can be modified to operate at higher frequencies with shorter-radius radial stubs. Shorter-radius radial stubs enable higher frequency coupling between top

Figure 25. Frequency responses of tee junction: (a) simulated; (b) measured (from Ref. 29b with permission from IEEE).

(a)

(b)

Figure 26. Phase responses of tee junction: (a) simulated; (b) measured (from Ref. 29b with permission from IEEE).

and bottom metallization, but because of the smaller coupling area of the stub, insertion loss is increased. The transition with the radial stub radius of 2.5 mm has been designed and tested. The geometry of transition with a radial stub radius of 2.5 mm is illustrated Fig. 29.

Frequency responses of the transition are shown in Fig. 30. Measured back-to-back return loss is better than 10 dB from 2 to 20 GHz (1–10) with an insertion loss of

< 3.5 dB. Although the insertion loss is higher in the smaller radial stub structure than in the larger radial stub transition, the transition would be useful in feeding high-frequency dipole type antennas.

These transitions are convenient in measuring CPS components with the conventional network analyzer without any special on-wafer calibration standards for CPS TRL calibrations and should find many useful

Figure 27. Microstrip-to-CPS-to-microstrip back-to-back transition structure with a radial stub radius of 5.5 mm (from Ref. 39b with permission from IEEE).

Figure 28. Measured return and insertion losses of the microstrip-to-CPS-to-microstrip back-to-back transition with a radial stub radius of 5.5 mm (from Ref. 39b with permission from IEEE).

applications for CPS components and circuits measurement as well as dipole type antenna feeding.

7. ANTENNA APPLICATION—A MILLIMETER-WAVE PRINTED DIPOLE PHASED-ARRAY ANTENNA FED BY A MICROSTRIP-TO-CPS TEE JUNCTION

A printed dipole antenna has the benefits of low profile, light weight, low cost, and compact size. To construct a printed dipole array, several configurations have been proposed. Nesic et al. [40] reported a one-dimensional printed dipole antenna array fed by microstrip at 5.2 GHz. Scott [41] introduced a microstrip-fed printed dipole array using a microstrip-to-CPS balun. In Refs. 40 and 41, the balun designs did not permit easy impedance matching, and the structures were too big and complicated. In 1998, a wide-band microstrip-fed twin-dipole antenna was introduced with a double-sided structure operating at the frequency range from 0.61 to 0.96 GHz [42]. Zhu and Wu [29a] developed a 3.5-GHz twin-dipole antenna fed by a hybrid finite ground coplanar waveguide (FGCPW)/CPS tee junction. An X-band monolithic integrated twin-dipole antenna

mixer was reported [43] with devices directly integrated into the antenna, so no feeding network was necessary.

In this section, a new planar printed dipole phased-array antenna using a multi-transmission-line tunable phase shifter controlled by a piezoelectric transducer (PET) [44,45a] is presented at 30 GHz. The phased array antenna uses a new twin-dipole antenna excited by a microstrip-fed CPS tee junction introduced in Section 5. The PET-controlled phase shifter does not require any solid-state devices or their driving circuits. The 1×8 twin-dipole phased-array antenna has compact size, low loss, low cost, light weight, and reduced complexity as well as good beam scanning with low sidelobe levels.

7.1. Microstrip-Fed CPS Tee Junction at Ka Band

The twin-dipole antenna is fed by a CPS. Since the conventional planar transmission line is a microstrip line, a microstrip-to-CPS transition is needed to feed the dipole. A microstrip-fed CPS tee junction without using bonding wires or airbridges was introduced in Section 5, where an operating frequency centered near 3.5 GHz with 0.7 dB insertion loss ranging from 2 to 4.15 GHz was described.

Figure 29. Microstrip-to-CPS-to-microstrip back-to-back transition with a radial stub radius of 2.5 mm.

Figure 30. Measured return and insertion losses of the microstrip-to-CPS-to-microstrip back-to-back transition with a radial stub radius of 2.5 mm.

The tee junction utilized novel coupled CPS (CCPS). Using the CCPS, the transmission line can exhibit physical discontinuity while the fields are continuous over entire transmission line.

The structures of a conventional CPS and a CCPS at 30 GHz are identical to those in Fig. 21, but with different strip width W and gap s between strips. A 31-mil RT/Duroid 5870 substrate with a dielectric constant of 2.33 is used for the antenna and feeding network simulation and fabrication.

The width W of a CPS strip is 0.65 mm and the gap s between the strips is 0.5 mm, with a characteristic impedance of $202\ \Omega$. The wideband coupling performance of radial stubs is described in detail in the microstrip-to-CPS-to-microstrip back-to-back transition in Section 6, where the smaller radius of the radial stub is described as providing higher operating frequency with minimal insertion loss and return loss deterioration compared to the conventional CPS configuration.

Performances of CCPS are simulated and compared with those of conventional CPS as shown in Fig. 31. This figure shows that the insertion loss of CCPS deteriorates by ~ 1 dB compared with that of conventional CPS for the frequency range from 29.2 to 35 GHz and that the return loss is better than 10 dB. Insertion loss deterioration of less than 2 dB covers a wider frequency range, from 26.4 to

35 GHz. From the above mentioned results, CCPS shows that fields are continuous all over the transmission line with the aid of radial stub; however, a physical discontinuity is introduced at one of the CPS strips.

The structure of a microstrip-fed CPS tee junction at 30 GHz is shown in Fig. 32. The tee junction has the characteristic impedance of $202\ \Omega$ at each output port (ports 1 and 2). The input impedance to the microstrip feed at port 3 is about $101\ \Omega$, which is half of $202\ \Omega$. Radial stubs effectively rotate the electric fields from parallel to the normal to the substrate to ensure effective coupling to the bottom metallization, which provides the microstrip-line ground.

The tee junction is simulated to verify the performance at 30 GHz. Simulated performance of the tee junction, shown in Fig. 33, reveals that the tee junction splits the power equally to each CPS port with 1.2 dB insertion loss at 30 GHz. Simulated 2 dB insertion loss bandwidth of the tee junction is 27.2–34.8 GHz, and the return loss is > 20 dB.

7.2. Phased-Array Antenna with Multi-Transmission-Line PET-Controlled Phase Shifter

The structure of the twin-dipole antenna is illustrated in Fig. 34. The antenna array is placed in front of a reflector

Figure 31. Simulated performance comparison at Ka band between conventional and coupled CPS (from Ref. 45b with permission from IEEE)

Figure 32. Structure of Ka-band microstrip-fed CPS tee junction for twin-dipole antenna feeding (from Ref. 45b with permission from IEEE).

for unidirectional radiation. The reflector is spaced from the antenna at the distance of 1.5 mm (60 mil), which is $\sim 0.15\lambda_0$.

The length of the dipole is 5.3 mm or $0.53\lambda_0$ and the distance between dipoles is optimized to 3.6 mm or $0.36\lambda_0$, which is less than a half-wavelength in order to provide low sidelobe and grating lobe levels as well as low insertion loss incurred from the CPS tee junction.

The input impedance of a single-dipole antenna is around 202Ω . The strip width W and gap s between strips of CCPS at the CPS tee junction are determined to have a CCPS characteristic impedance identical to the dipole antenna input impedance for good impedance matching.

The structure of the 1×8 printed twin-dipole phased array is shown in Fig. 35. The spacing d between the twin-dipole antennas is about 7.4 mm or $0.82\lambda_0$. A conventional microstrip power divider with binominal impedance transformers is used to cover the wide bandwidth. The bottom metallization provides good ground plane for the microstrip.

To obtain the required phase shift, the 101- Ω microstrip feeding lines to the antenna, which have the same input impedance as the twin dipole antenna, are perturbed with

Figure 34. Structure of printed twin-dipole antenna fed by a microstrip-to-CPS tee junction (from Ref. 45b with permission from IEEE).

a dielectric perturber actuated by a piezoelectric transducer (PET). The length of dielectric perturber varies linearly from 5 to 35 mm on top of line 2 and on line 8. The first line is not perturbed. The PET is configured to have no deflection (no perturbation) when a DC voltage of 0 V is applied, and full deflection (full perturbation) when a DC voltage of 50 V is applied. A 50-mil RT/Duroid 6010 with a dielectric constant of 10.2 is used as the dielectric perturber.

The amount of differential phase shift ($\Delta\Phi_n$) is linearly proportional to the length of perturber [45a], which is expressed as

$$\Delta\Phi_n = L_{\text{perturber},n} \cdot \Delta\beta_n \tag{18}$$

where $L_{\text{perturber},n}$ is the perturber length along the n th transmission line. $\Delta\beta_n$ represents the differential

Figure 33. Simulated performance of tee junction near 30 GHz (from Ref. 45b with permission from IEEE).

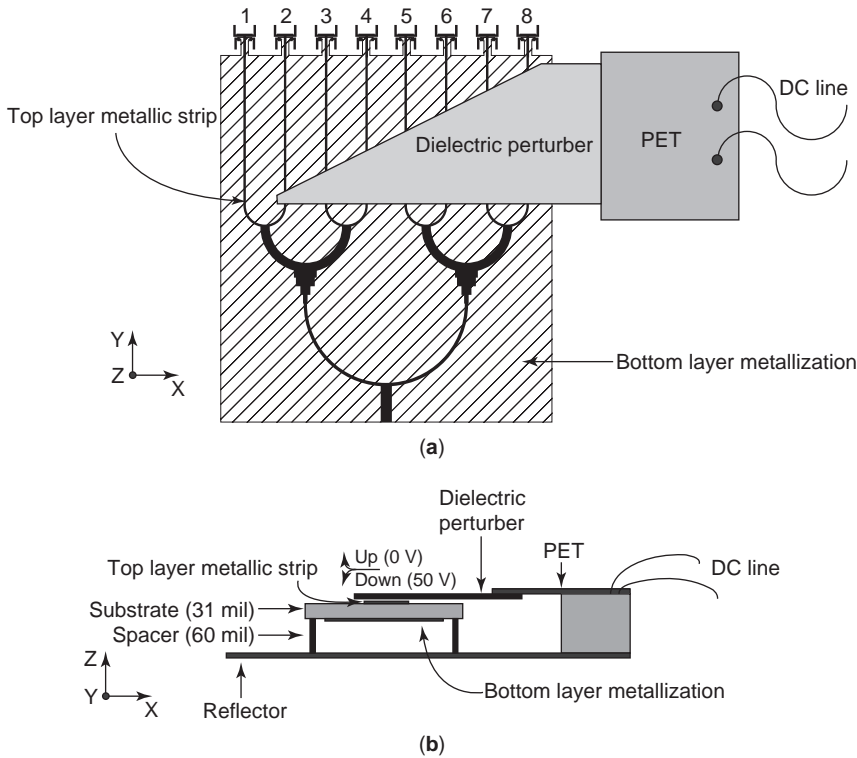

Figure 35. Structure of printed dipole phased-array antenna controlled by PET: (a) top view; (b) side view (from Ref. 45b with permission from IEEE).

propagation constant, expressed as

$$\Delta\beta_n = \beta_{\text{unperturbed}} - \beta_{\text{perturbed},n} \quad (19)$$

where $\beta_{\text{perturbed},n}$ represents the propagation constant of the n th perturbed transmission line, which is microstrip in this case. Since the first perturbed microstrip line (i.e., the second line) has the minimum perturbed length, the following relationship is obtained:

$$\Delta\Phi_2 = \Phi \quad (20)$$

With a dielectric perturber of 5 mm, the differential phase shift ($\Delta\Phi_n$) of 88.8° takes place with a 2 dB inser-

tion loss as shown in Fig. 36. The narrower microstrip line generates larger phase shift, but the insertion loss is increased. Hence, a proper microstrip line width should be chosen for having a good phase shift as well as low insertion loss.

Table 4 summarizes the design and measured parameters for the twin-dipole phased array. The parameters in Table 4 are useful in analytical calculations of the scan angle (θ_0), maximally achievable gain, and optimum element spacing d of the phased array.

According to (18) and (19), the perturber's length can be determined for a desired phase shift. A length of 5 mm dielectric perturber produces about 88.8° differential phase shift. Accordingly, the length of each neighboring

Figure 36. Measured differential phase shift for 5-mm dielectric perturber controlled by PET (from Ref. 45b with permission from IEEE).

Table 4. Parameter Values of Twin Dipole Phased Array (from Ref. 45b with permission from IEEE)

Frequency (GHz)	Single-Element Gain (dBi)	Progressive Phase Shift (Φ)	Element Spacing (d)	Number of Elements (N)
30	7.7	88.8°	7.4 mm	8

perturbed line is increased by 5 mm. The length of perturber for the final microstrip ($L_{\text{perturber,8th}}$) is ~ 35 mm, which gives a differential phase shift of 621.6° .

Measured return loss of the 1×8 twin dipole array is plotted in Fig. 37. The measured return loss is ~ 41.9 dB at 30.3 GHz for the unperturbed twin-dipole phased-array antenna. With perturbation by the dielectric perturber, the return loss is ~ 31.8 dB at 30.7 GHz, which shows a 0.4 GHz frequency shift compared with the unperturbed result. For a bandwidth from 30 to 31.5 GHz, a measured return loss is better than 15 dB.

7.3. Phased-Array Measurements

The phased array is measured in an anechoic chamber. As shown in Fig. 35, the antenna is arrayed for H -plane beam scanning. To accomplish bidirectional scanning, two triangular perturbers are used side by side [45a]. PET actuation for the dielectric perturber is configured as 0 V for no perturbation (no PET deflection) and 50 V for full perturbation (full PET deflection).

The measured twin-dipole phase-array antenna gain without perturbation (0 V for PET) is about 14.4 dB, with a 3 dB beamwidth of 6° as shown in Fig. 38. The fully perturbed antenna with a dielectric perturber controlled by PET shows about 42° ($-20^\circ \sim +22^\circ$) beam scanning with a gain of 12.2 dBi. Sidelobe levels of the steered beam are > 11 dB less than those of the mainbeam. The beam can be dynamically steered depending on the voltages applied to PET because the amount of phase shift changes according to the applied voltages on PET as shown in Fig. 36.

The comparison among analytical, simulation, and measured results of the phased array are exhibited in Table 5. The beam scanning angle follows closely among analytical, full-wave simulation, and measured results.

Measured unperturbed gain is about 2.3 dB lower than that found in analytical or simulated data. This is due to the insertion loss of the power divider and the mutual coupling effects among elements, which normally degrade antenna gain. The measured gains of steered beams are about 2.2 dB less than those of the unperturbed beam, due to the insertion loss incurred by dielectric perturbation.

8. CIRCUIT APPLICATION—A HIGH-EFFICIENCY DUAL-FREQUENCY RECTENNA FOR 2.45 AND 5.8 GHz WIRELESS POWER TRANSMISSION USING CPS TRANSMISSION LINE

As a circuit application of CPS, the dual-frequency rectenna is presented operating at both 2.45 and 5.8 GHz (ISM bands) simultaneously. The rectenna is an important element for wireless power transmission. Applications of the rectenna are mainly for receiving power where the physical connections are not possible. Various kinds of rectennas have been developed since Brown demonstrated the dipole rectenna using aluminum bars to construct the dipole and the transmission line [22]. He also presented a thin-film printed-circuit dipole rectenna [23] with an 85% conversion efficiency at 2.45 GHz. Linearly polarized printed dipole rectennas were developed at 35 GHz [25,46] with conversion efficiencies of 60% and 70%, respectively. A 5.8-GHz printed dipole rectenna was developed in 1998 [26] with a high conversion efficiency of 82%. Microstrip patch dual polarized rectennas were also developed at 2.45 GHz [27] and 8.51 GHz [47]. More recently, a circularly polarized rectenna, which does not require strict alignment between transmitting and receiving antennas, was developed at 5.8 GHz [48a] with a conversion efficiency of 60%. Strassner and Chang also developed a circularly polarized rectenna using dual-rhombic-loop antennas at 5.8 GHz in 2003 [49]. The 4×1 rectenna array showed a conversion efficiency of 82% operating at low power density.

Several rectenna operating frequencies have been considered and investigated. Components of microwave power transmission have traditionally focused at 2.45 GHz and have more recently moved up to 5.8 GHz, where the antenna aperture area is smaller than at 2.45 GHz. Both

Figure 37. Measured return loss of printed twin-dipole phased-array antenna (from Ref. 45b with permission from IEEE).

Figure 38. Measured H -plane radiation pattern for twin-dipole phased-array antenna at 30 GHz. Measured beam scanning is from -20° to $+22^\circ$ with full perturbation (from Ref. 45b with permission from IEEE). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

frequencies have comparably low atmospheric loss, cheap components availability, and reported high conversion efficiency.

If the rectenna operates at dual band, it can be used for wireless power transmission at either frequency depending on power availability. A rectifying diode is analyzed to obtain design parameters for high efficiencies at both frequencies. A diode parameter, that provides high conversion efficiency and insensitivity to operating frequency is discussed. To prevent the higher-order harmonics reradiation generated by the diode, a CPS lowpass filter integrated with two additional open-ended T-strip CPS bandstop filters is presented in this section.

8.1. Dual-Frequency Antenna Design

The structure of a rectenna is illustrated in Fig. 39. A schematic of the circuit is shown in Fig. 40. The rectenna consists of a receiving dual-frequency dipole antenna, a CPS input lowpass filter, two CPS bandstop filters, a rectifying diode, and a microwave block capacitor. The antenna receives the transmitted microwave power, and the input lowpass and the bandstop filters pass 2.45 and 5.8 GHz but block the higher-order harmonics from reradiation.

All microwave signals produced by the nonlinear rectifying diode, including fundamental and harmonics, are confined between the input filters and microwave block capacitor. Consequently, the conversion efficiency is improved.

As discussed in Section 2, a low-dielectric-constant substrate produces a low dielectric and conductor losses. Hence, a 20 mil RT/Duroid 5870 substrate with a low

Table 5. Comparison among Analytical, Simulation, and Measured Results of 1×8 Phased Array (from Ref. 45b with permission from IEEE)

Method	Beam Scanning θ_0 (deg)	Unperturbed Gain (dBi)	Element Spacing d (mm)

Full-wave simulation	± 20	16.48	7.4
Measured	$-20 \sim +22$	14.4	7.4

dielectric constant of 2.33 is used for the dual-frequency rectenna design to maximize conversion efficiency.

The CPS dipole dual-frequency antenna with a reflector plate is designed for 2.45 and 5.8 GHz (ISM bands). This type of dual-frequency antenna, introduced in 2000 [50], radiates bidirectionally and has a double-sided structure with a microstrip feed operating at 2.4 and 5.2 GHz. Double-sided dual-frequency printed dipole antennas were also reported [51,52] operating at 0.9 and 1.5 GHz.

The dual-frequency antenna presented in this section has a uniplanar structure, which has the advantage of convenient device mounting. A reflector plate is required for the unidirectional radiation/reception, and it also increases antenna gain.

As shown in Fig. 40, a long dipole is designed for operation at 2.45 GHz and a short dipole, at 5.8 GHz. The long dipole has a length of 126.7 mm or $1.072\lambda_0$ at 2.45 GHz, and the short dipole has a length of 45.04 mm or $0.812\lambda_0$ at 5.8 GHz. The feeding point has been moved about 0.8 mm from the edge of the short dipole for impedance matching. The coupling length and gap between the long and short dipole are around 6.32 and 4.2 mm, respectively.

The reflector plate is normally placed at a distance about a quarter-wavelength apart from the circuit at the design frequency for low sidelobes created from image sources. However, for dual-band operation, the reflector plate distance must be optimized in order to produce good radiation patterns and similar gains for both frequencies. The reflector plate distance is optimized at 17 mm, which is about $0.14\lambda_0$ of 2.45 GHz and $0.32\lambda_0$ of 5.8 GHz.

Measured frequency response of the antenna is shown in Fig. 41. This measurement was performed using the wideband CPS-to-microstrip transition presented in Section 6. Measured return losses for the antenna only are better than -30 and -25 dB at 2.45 and 5.8 GHz, respectively. Return losses at second-order harmonics of the antenna-only case are found to be around -8.6 and -3 dB at 4.9 and 11.6 GHz, respectively.

8.2. CPS Lowpass Filter Integrated with T-Strip Bandstop Filters

Filters are required for a rectenna to prevent all the harmonics from reradiating through the antenna. New simple

Figure 39. Circuit picture of dual-frequency rectenna. The circuit is separated from a reflector plate at a distance of 17 mm.

CPS lowpass filter integrated with bandstop filters are designed and shown in Fig. 42. As shown earlier at Fig. 19, the lowpass filter has a 0.2 dB ripple Chebyshev response with a cutoff frequency of 7 GHz to pass 2.45 and 5.8 GHz and to reject 11.6 GHz, which is the second-order harmonic of 5.8 GHz. However, the lowpass filter will pass the second-order harmonic of 2.45 GHz at 4.9 GHz, and the third-order harmonic level at 7.35 GHz will not be deeply suppressed.

Open-ended T-strip CPS bandstop filters, presented at Fig. 3, are placed outside the CPS strips for rejecting second- and third-order harmonics of 2.45 GHz at 4.9 and 7.35 GHz, respectively. The lengths of bandstop filters are 20.1 ($0.45\lambda_g$) and 10.5 ($0.35\lambda_g$) mm at 4.9 and 7.35 GHz, respectively.

The lowpass filter integrated with two additional open-ended T-strip bandstop filters needs to transform the antenna's input impedance of $95\ \Omega$ to the CPS characteristic

Figure 40. Dual-frequency rectenna circuit schematic (from Ref. 48b with permission from IEEE).

Figure 41. Measured frequency responses of the antenna and the antenna with filters. Good return loss is achieved at both 2.45 and 5.8 GHz (from Ref. 48b with permission from IEEE).

impedance of $250\ \Omega$ as well as blocking higher-order harmonics.

An impedance transformation section consisting of two CPS step discontinuities as shown in Fig. 42 is designed and optimized by a full-wave electromagnetic simulator.

The strip width W and the separation gap s of CPS, where the rectifying diode is placed, are designed as 1.5 and 0.6 mm, respectively, which corresponds to the $184\ \Omega$ of CPS characteristic impedance, (Z_0). The CPS characteristic impedance of $184\ \Omega$ is selective to ensure a high

Figure 42. Structure of CPS lowpass filter with bandstop filters (from Ref. 48b with permission from IEEE).

Figure 43. Measured frequency responses of CPS lowpass filter with bandstop filters. Low insertion losses of 0.15 and 0.75 dB are achieved at 2.45 and 5.8 GHz, respectively. Good band rejection performances are achieved at the second harmonics (4.9 and 11.6 GHz) of 2.45 and 5.8 GHz, and at the third harmonic (7.35 GHz) of 2.45 GHz (from Ref. 48b with permission from IEEE).

conversion efficiency according to the diode analysis, which will be discussed later.

Measured frequency responses of the lowpass filter integrated with bandstop filters are shown in Fig. 43. Low insertion losses of 0.15 and 0.75 dB are achieved at 2.45 and 5.8 GHz, respectively. Band rejections at the second (4.9 GHz) and the third (7.35 GHz) harmonics of 2.45 GHz are around 15 and 10 dB, respectively, and the band rejection at the second harmonic of 5.8 or 11.6 GHz is about 30 dB, which shows good bandstop performance for these harmonics.

8.3. Dual-Frequency Antenna Integrated with Filters

For comparison, the frequency response of the antenna integrated with filters is also shown in Fig. 41. Measured return losses of 15.1 and 18.2 dB are achieved at 2.45 and 5.8 GHz, respectively.

Measured return losses at the second-harmonic levels of 2.45 and 5.8 GHz are found to be 1.58 and 0.2 dB at 4.9

and 11.6 GHz, respectively. This shows that the lowpass filter integrated with two additional bandstop filters effectively block the second-order harmonics at both frequencies. The third-order harmonic level for 2.45 GHz is about 1.62 dB at 7.35 GHz. Higher-order harmonic levels are expected to be lower than second-order harmonics at both frequencies.

Radiation patterns of the antenna with filters are measured in the anechoic chamber. Measured radiation patterns at 2.45 and 5.8 GHz are shown in Figs. 44 and 45. Measured *E*-plane gains are 5 and 5.4 dBi with a 3 dB beamwidth of 31.5° and 36° at 2.45 and 5.8 GHz, respectively. Because the reflector's height has a longer wavelength at 5.8 GHz compared to that at 2.45 GHz, the radiation pattern for 5.8 GHz has a wider 3 dB beamwidth. It is possible to have an identical 3 dB beamwidth with similar radiation patterns for both frequencies by adjusting the reflector height, but the input impedances of the antenna for each frequency would be different. Hence, a tradeoff was made between the input impedance and the radiation pattern.

Figure 44. Radiation patterns of dual-frequency antenna at 2.45 GHz (from Ref. 48b with permission from IEEE). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 45. Radiation patterns of dual-frequency antenna at 5.8GHz (from Ref. 48b with permission from IEEE). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

At broadside, the cross polarization at 2.45 GHz is about 19.4 and 18.2 dB below the copolarizations in E and H planes, respectively. At 5.8 GHz, the cross-polarization is about 30.1 and 25 dB below the copolarizations in E and H planes, respectively. These low cross-polarization levels show good alignment between transmitting and receiving antennas. Relatively similar E -plane gains are achieved at both 2.45 and 5.8 GHz.

Second-order harmonic radiation patterns are measured and shown in Fig. 46. At broadside, the second-order harmonic radiation gains at 4.9 and 11.6 GHz are -10 and -15 dBi, respectively. Since the gains for the fundamental frequencies at 2.45 and 5.8 GHz are 5 and 5.4 dBi, the corresponding suppressions are about 15 and 20.4 dB, respectively.

8.4. Diode Analysis

A diode analysis is used to achieve high RF-to-DC conversion efficiencies at both frequencies. RF-to-DC conversion efficiency η_d and input impedance Z_d of the diode can be calculated from the closed-form equations in Ref. 26, which are expressed as

$$\eta_d = \frac{1}{1 + A + B + C} \quad (21)$$

where

$$A = \frac{R_L}{\pi R_s} \left(1 + \frac{V_{bi}}{V_0}\right)^2 \left[\theta_{on} \left(1 + \frac{1}{2 \cos^2 \theta_{on}}\right) - \frac{3}{2} \tan \theta_{on} \right] \quad (22)$$

$$B = \frac{R_s R_L (\omega C_j)^2}{2\pi} \left(1 + \frac{V_{bi}}{V_0}\right) \left(\frac{\pi - \theta_{on}}{\cos^2 \theta_{on}} + \tan \theta_{on} \right) \quad (23)$$

$$C = \frac{R_L}{\pi R_s} \left(1 + \frac{V_{bi}}{V_0}\right) \frac{V_{bi}}{V_0} (\tan \theta_{on} - \theta_{on}) \quad (24)$$

Diode input resistance is expressed as

$$R_d = \frac{\pi R_s}{\cos \theta_{on} \left(\frac{\theta_{on}}{\cos \theta_{on}} - \sin \theta_{on} \right)} \quad (25)$$

where R_L and R_s represent the load resistance and the series resistance of the diode, respectively. V_0 is an output

Figure 46. Second-harmonic radiation patterns. These patterns prove that the lowpass filter integrated with two open-ended T-strip bandstop filters effectively blocks higher-order harmonics. The second harmonics of 2.45 and 5.8 GHz are 4.9 and 11.6 GHz, respectively. (From Ref. 48b with permission from IEEE).

voltage produced at the load resistance, and V_{bi} is a diode's built-in voltage. θ_{on} is the diode conduction time in radians and C_j is the junction capacitance. The closed-form expression for θ_{on} and C_j is

$$\tan \theta_{on} - \theta_{on} = \frac{\pi R_s}{R_L \left(1 + \frac{V_{bi}}{V_0} \right)} \quad (26)$$

The junction capacitance C_j is defined as

$$C_j = C_{j0} \sqrt{\frac{V_{bi}}{V_{bi} + |V_0|}} \quad (27)$$

RF-to-DC conversion efficiency is frequency-dependent, as shown in parameter B in (23). To minimize the conversion efficiency dependence on the frequency, it is necessary to minimize the effect of parameter B . Since parameter B is proportional to the square of ωC_j , a small value of C_j will reduce the effect of parameter B on the conversion efficiency. For a small value of C_j , packaged diode is not suitable.

From the preceding analysis, a flip-chip-type GaAs Schottky barrier diode (MA4E1317) is selected as the rectifying device. The diode has a built-in voltage (V_{bi}) and a measured breakdown voltage (V_{br}) of 0.7 and 12 V, respectively. The maximum DC output voltage (V_0) is about 6 V. The zero-bias-junction capacitance (C_{j0}) is 0.02 pF with a series resistance (R_s) of a 4 Ω .

Using (21)–(27), RF-to-DC conversion efficiency η_d and input resistance of the diode R_d can be calculated in terms of load resistance R_L at 2.45 and 5.8 GHz, as shown in Fig. 47, where very little difference in conversion efficiency is observed between 2.45 and 5.8 GHz. This is due to the low zero-bias-junction capacitance (C_{j0}) of the diode. Since C_{j0} is low, the corresponding C_j is also low [26], and the value of parameter B is very small compared to those of parameters A and C . Consequently, parameter B , which is frequency-dependent, does not contribute much effect to the diode's conversion efficiency. From Fig. 47, the diode input resistance R_d and the load resistance R_L can be determined as design parameters for a desired target RF-to-DC conversion efficiency η_d .

Because of the diode dimension, the CPS strip width (s) is fixed at 0.6 mm and the corresponding characteristic impedance is 184 Ω . The diode input impedance is matched to this impedance of 184 Ω , which corresponds to a load resistance of 310 Ω as determined in Fig. 47. This gives $\sim 82\%$ target efficiency. To prevent the diode breakdown due to overload, determining the limit of output DC power is necessary.

Typically, the DC power level limit is determined by $P_{DC} < (V_{br}^2/4R_L)$ [26], where V_{br} is the breakdown voltage of the diode and R_L is the load resistance. Therefore, adequate load resistance R_L is required as well as adequate input resistance of the diode (R_d) to ensure a high efficiency and a high output DC power.

8.5. Rectenna Measurements

The rectenna is measured in free space. The measurement set up is shown in Fig. 48. Transmitting power is generated by a frequency synthesizer (HP 8341B) and amplified by power amplifiers. Two types of power amplifiers, L0203-42 and L0505-38 (Microwave Power Inc.), are used, which can produce up to +42 and +38 dBm at 2.45 and 5.8 GHz, respectively. For the transmitting power monitoring purpose, a directional coupler is used with 20 dB coupling along with a 20-dB attenuator for power meter (HP 437B) protection. Standard-gain horn antennas are used for transmitting power at 2.45 and 5.8 GHz, respectively. From the diode analysis described in Section 8.4, the load resistance R_L is taken as 310 Ω , for 82% target efficiency.

The microwave block capacitor not only bypasses the microwave signal to the diode but also cancels the capacitive reactance of the diode by selecting an appropriate distance from the diode at a specific frequency, which maximizes the RF-to-DC conversion efficiency [26]. For dual-band operation of the rectenna, the diode location is optimized at 7.5 mm to have high efficiencies at both frequencies.

Conversion efficiency of the rectenna is represented as

$$\eta = \frac{P_{DC}}{P_{received}} \times 100(\%) \quad (28)$$

Figure 47. Diode (MA4E1317) RF-to-DC conversion efficiency analyses in terms of the load resistance (R_L) and the diode input resistance (R_d) at 2.45 and 5.8 GHz. Diode parameter values of V_{bi} , V_0 , V_{br} are 0.7, 6, and 12 V, respectively. The zero bias junction capacitance (C_{j0}) of 0.02 pF, and a series resistance (R_s) of 4 Ω are used for the analyses (from Ref. 48b with permission from IEEE).

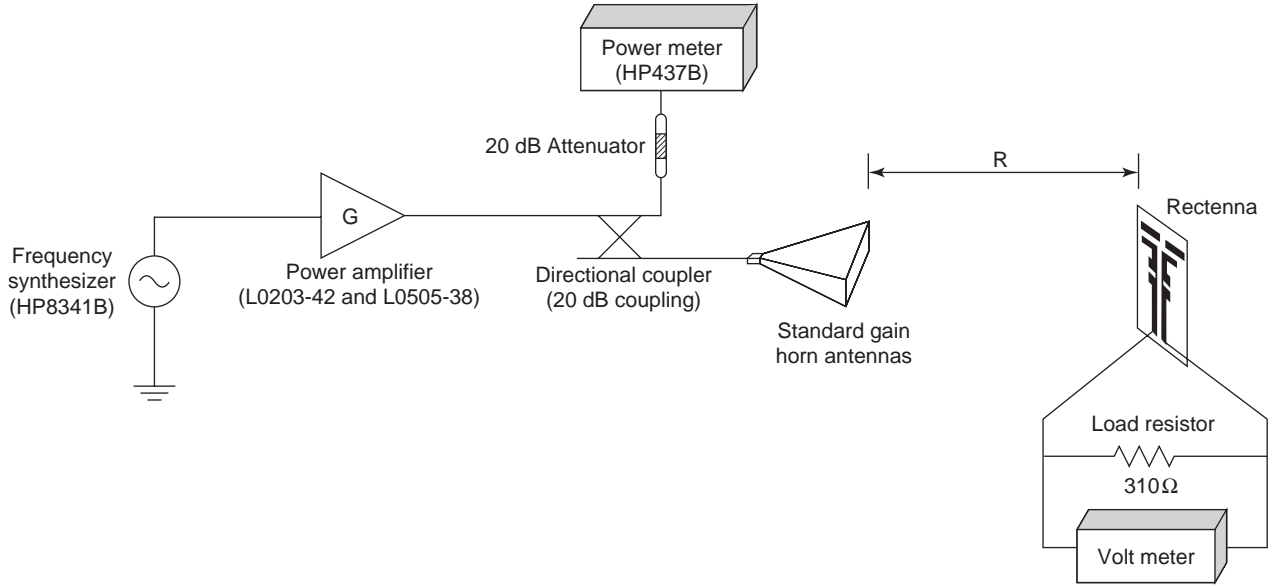

Figure 48. Rectenna measurement setup. Two different types of power amplifiers (L0203-42 and L0505-38) and transmitting standard-gain horn antennas are used for dual-frequency power transmissions (from Ref. 48b with permission from IEEE).

where P_{DC} is DC power produced at the load resistance (R_L) of the rectenna and $P_{received}$ is power received at antenna of the rectenna. $P_{received}$ is calculated from the Friis transmission equation expressed as

$$P_{received} = P_t \left(\frac{\lambda_0}{4\pi R} \right)^2 G_r G_t = P_t A_e \frac{G_t}{4\pi R^2} \quad (29)$$

where the effective area A_e is represented as

$$A_e = \frac{\lambda_0^2 G_r}{4\pi} \quad (30)$$

and where P_t represents transmitted power, G_t and G_r represent gains of transmitter and receiver antenna, respectively, and R is the distance between the transmitter and the receiver antennas.

For the rectenna measurements, R is taken to the edge of the far field. Parameters for calculating $P_{received}$ of the dual-frequency rectenna are displayed in Table 6. The efficiency is normally expressed as a function of power density. The power density is calculated by

$$P_D = \frac{P_r}{A_e} = \frac{P_t G_t}{4\pi R^2} \quad (31)$$

Table 6. Received Power Calculation parameters for Dual Frequency Rectenna (from Ref. 48b with permission from IEEE)

Frequency (GHz)	λ_0 (cm)	Far Field (cm)	G_r (dBi)	G_t (dBi)	A_e (cm ²)
2.45	12.2	87.1	5	14.5	37.7
5.8	5.1	48.5	5.4	17.6	7.4

Measured rectenna efficiencies are shown in Fig. 49. High efficiencies of 84.4% and 82.7% are measured at 2.45 and 5.8 GHz, respectively. Experimental efficiencies follow closely with the theoretical efficiency calculations. Received power at each highest efficiency points are 89.84 and 49.09 mW corresponding to power densities of 2.38 and 8.77 mW/cm² at 2.45 and 5.8 GHz, respectively, as shown in Fig. 49b.

At 80% efficiency points for both 2.45 and 5.8 GHz, the ideal received power levels at both frequencies are almost identical. Measurements show that received power levels at 80% efficiency points are 35.6 and 39.26 mW at 2.45 and 5.8 GHz, respectively. Considering the antenna's effective areas (A_e) listed in Table 6, the required power density of 5.8 GHz is around 5.1 times larger than that of 2.45 GHz to achieve 80% efficiency.

As shown in Fig. 46, the second-order harmonic radiations at 4.9 and 11.6 GHz are around 15 and 20 dB less than the fundamental frequency radiations at broadside. Therefore, second-order harmonic reradiations are quite small. Observing the return loss plot of the antenna integrated with filters in Fig. 41, higher-order harmonic reradiations are expected to be small.

9. CONCLUSION

In this article, the CPS transmission line was analyzed for practical components development. With this analysis, practical CPS components were developed, investigated, and their applications were implemented. It was found that a lower-dielectric-constant (ϵ_r) substrate and a higher CPS characteristic impedance (Z_0) are desired for lower CPS attenuation. Different CPS configurations such as varying s and W , can exhibit identical characteristic

Figure 49. RF-to-DC conversion efficiency for dual-frequency rectenna: (a) efficiency and DC output voltage versus received power; (b) efficiency versus power density (from Ref. 48b with permission from IEEE).

impedance (Z_0). Although characteristic impedance values (Z_0) are identical with different CPS configurations, their attenuation values might be different. Therefore, attenuation should be verified by plotting in terms of s and W .

As for CPS components, six new types of CPS resonators were presented with open-ended T strip, short-ended strip, and T slots, and their performances were analyzed in terms of quality factor (Q factor) or bandwidth. We found that, while T-strip (types A, B, and D) and T-slot (type C) resonators exhibit bandstop behavior, short-ended strip resonators (types E and F) have bandpass frequency responses. The T-slot resonator (type C) has the highest Q factor among the resonators, which means that resonance energy is stored better in the slots than in the strips. As discussed earlier, CPS attenuation is reduced when the characteristic impedance (Z_0) is high, meaning that the higher is Z_0 , the higher is the Q factor. Lumped-element equivalent circuits of each resonator were presented. Two types of CPS bandpass filters were designed using the proposed resonators. Multiple short-ended strip bandpass filter exhibited a wide passband bandwidth, but the bandpass filter using short-ended strips with T strips showed narrow passband bandwidth. A simple CPS lowpass filter

was developed with a cutoff frequency of 7 GHz using interdigital capacitors and a CPS transmission line. The measured performance showed low insertion loss at passband and deep suppression at stopband.

A new CPS tee junction was introduced using a coupled CPS (CCPS). The CCPS developed does not require any bond wires or via holes to connect physically disconnected CPS lines. The performance of CCPS was compared with conventional CPS configuration, and its usefulness was discussed. Using the CCPS, a novel microstrip-fed CPS tee junction has been invented.

As an antenna application of CPS, a novel printed twin-dipole phase-array antenna was developed at 30 GHz using a multi-transmission-line tunable phase shifter controlled by a piezoelectric transducer (PET). The new twin-dipole antenna was designed using a microstrip-fed CPS tee junction. To construct the tee junction, CCPS was used for a physical discontinuity at CPS while fields were continuous over the entire transmission line. The tee junction effectively split power to each CPS output port with low insertion loss. The PET-actuated phase shifter required only one (unidirectional beam scanning) or two (bidirectional beam scanning) applied voltage sources to produce

the progressive phase shift (Φ). The twin dipole phased-array antenna demonstrated a 42° ($-20^\circ \sim +22^\circ$) beam scanning with more than 11 dB sidelobe suppression across the scan.

As a circuit application of CPS, a dual-frequency rectenna was presented operating at both 2.45 and 5.8 GHz (ISM bands) simultaneously. The rectenna has a dual-frequency dipole antenna integrated with CPS lowpass and bandpass filter. For high conversion efficiency, a diode analysis and transmission-line analysis were performed for low attenuation. Second-order harmonic reradiations were well suppressed with CPS filters without losing conversion efficiency.

Since little research has been done on CPS and its components, this article should provide some useful guidelines for designing and implementing CPS circuits and the practical aspects of printed dipole antennas.

COPLANAR STRIPLINE TRANSITIONS

RAINEE N. SIMONS
NASA Glenn Research Center
Cleveland, Ohio

1. INTRODUCTION

A *balun* is a circuit that is used to transform an unbalanced line to a balanced transmission line. In this article, the design of baluns, which transform an unbalanced line, such as a coplanar waveguide (CPW) and a microstrip line, to a balanced line, such as a coplanar stripline (CPS), is presented. The applications of these baluns include double-balanced mixers, balanced amplifiers, and feed network for dipole antennas. These baluns are also commonly referred to as “transitions between transmission lines.” The baluns are divided into two categories for the purpose of analysis: the Marchand baluns and the double-Y baluns. Almost all the baluns discussed in this article fall into the category of Marchand baluns.

2. COPLANAR STRIPLINE-TO-COPPLANAR WAVEGUIDE TRANSITION

2.1. Coplanar Stripline-to-Coplanar Waveguide Balun

Figure 1 shows a CPS to a CPW balun [1]. In this balun at the balanced end currents of equal magnitude but opposite

Figure 1. Coplanar stripline-to-coplanar waveguide transition with three strip transmission lines.

in direction flow along the two strip conductors. At the unbalanced end currents of equal magnitude but opposite in direction flow along the center strip conductor and the ground planes on either side. A short circuit placed between conductors 1 and 2 at the balanced end results in an open-circuit quarter-wavelength away at the unbalanced end, forcing all the currents to flow between conductors 2 and 3. Further, conductors 1 and 3 are short-circuited at the unbalanced end by a bond wire. This short circuit appears as an open-circuit quarter-wavelength at the balanced end, and therefore conductor 1 is isolated from the balanced end.

This transition, in addition to serving as a balun, also provides impedance transformation. Since RF energy propagates between conductors 2 and 3, the characteristic impedance between these conductors determines the impedance transformation over the quarter-wavelength section. In Ref. 2 the application of this transition to a CPW feed network for a dipole antenna array is demonstrated. A reduced-size lumped-element version of this transition is demonstrated in Ref. 3.

2.2. Coplanar Stripline-To-Coplanar Waveguide Balun With Slotline Radial Stub

Figure 2 shows a coplanar stripline (CPS)-to-coplanar waveguide (CPW) balun. In this balun one of the slots of the CPW is terminated in a broadband slotline radial open stub, while the other slot extends further to meet the CPS. In Ref. 4 the characteristics of an experimental balun are reported. The measured insertion loss and return loss of the balun are typically 1.0 dB and less than -13.0 dB, respectively, over the frequency range of 1.6–7.0 GHz. The balun has a bandwidth greater than 2 octaves. In Refs. 5 and 6 a variant of this balun is used for exciting a strip dipole and a spiral antenna, respectively.

2.3. Coplanar Stripline-to-Coplanar Waveguide Double-Y Balun

The double-Y junction in this balun [7] is formed by placing alternatively three coplanar striplines (CPSs) and three coplanar waveguides with finite-width ground planes (FW-CPWs) as shown in Fig. 3. The advantage

Figure 2. Coplanar stripline-to-coplanar waveguide transition with radial slotline stub.

Figure 3. Coplanar stripline-to-coplanar waveguide double-Y balun or transition.

of FW-CPW over CPW in this design is the greatly reduced parasitics. Because of small parasitics the FW-CPW terminations behave almost like ideal open and short circuits, resulting in wider bandwidth. This balun is modeled as a six-port network as explained in Ref. 8. In Ref. 9 the characteristics of an experimental balun are reported. The geometry as well as typical measured characteristics are summarized in Table 1. These characteristics show that the balun has a bandwidth of several decades.

3. COPLANAR STRIPLINE-TO-MICROSTRIP TRANSITION

3.1. Coplanar Stripline-to-Microstrip Transition with an Electromagnetically Coupled Radial Stub

Coplanar stripline (CPS)-to-microstrip transitions [10] in a back-to-back arrangement are shown in Fig. 4. In each transition one of the CPS strip conductors is terminated in a microstrip radial stub of radius R and angle ϕ while the other strip conductor is extended forward to form the microstrip line. The CPS strip conductor width and separation are W and S , respectively. The width of the microstrip line is W_m . The resonance frequency of the radial stub depends on the radius R and angle ϕ . At resonance, the microstrip radial stub provides a virtual RF short circuit between the CPS strip conductor and the microstrip ground plane on the opposite side of the substrate. In the CPS, the electric field lines are across the strip conductors and parallel to the substrate. In the microstrip line, the electric field lines are normal to the substrate. Hence, to gradually rotate the electric field lines by 90° , the microstrip ground-plane edge is tapered at an angle θ . The electric field lines at various cross sections along the transition are illustrated in Fig. 5.

In Ref. 10, the characteristics of an experimental transition fabricated on a RT/Duroid 6010 substrate are reported. The measured insertion loss and return loss for

two back-to-back transitions over the frequency range of 5.1–6.1 GHz is 2.4 dB (max) and less than -10.0 dB, respectively. The -10.0 dB return loss bandwidth of both transitions is about 18% centered at 5.55 GHz. The numerical simulation of the transition carried out using the FDTD technique shows good agreement between measured and modeled results [10]. An optimized version of

Figure 4. Two back-to-back coplanar stripline-to-microstrip transition: topside circuit pattern— $W = 0.69$ mm, $S = 0.19$ mm, $R = 5.08$ mm, $\phi = 60^\circ$, $W_m = 0.19$ mm, $L_{\text{CPS}} = 6.9$ mm; bottomside circuit pattern— $L = 7.1$ mm, $L_m = 12.7$ mm, $\theta \approx 7^\circ$. Substrate parameters: $h = 0.254$ mm, $\epsilon_r = 10.5$. Segments A-A, B-B, C-C, and D-D refer to the various cross sections along the transition.

Figure 5. Electric field lines at various cross sections along the transition: (a) electric field between coplanar striplines at cross section A-A; (b) electric field between coplanar stripline and microstrip ground at cross section B-B; (c) electric field in cross section of asymmetric microstrip at C-C; (d) electric field in the cross section of the symmetric microstrip at D-D.

this transition has been demonstrated to have a decade bandwidth [11]. In addition, the radial stubs can be replaced by overlapping conductors as demonstrated in Ref. 12 to provide a virtual short circuit. In [13] and in [14] a transition from an asymmetric CPS (ACPS)-to-microstrip with radial stubs and with metal vias respectively, are demonstrated.

3.2. Uniplanar Coplanar Stripline-to-Microstrip Transition

A uniplanar coplanar stripline (CPS)-to-microstrip back-to-back transition [15] in a balanced arrangement is shown in Fig. 6. In this transition, a microstrip line of characteristic impedance $50\ \Omega$ is coupled to two orthogonal microstrip lines of characteristic impedance $70\ \Omega$ through a quarter-wave stepped impedance-matching transformer. The characteristic impedance of $70\ \Omega$ is chosen for ease of fabrication. In an ideal transition, the mean pathlength of the folded loop “a through b” is equal to $0.5\ \lambda_{g(\text{microstrip})}$, where $\lambda_{g(\text{microstrip})}$ is the guide wavelength in the microstrip of characteristic impedance $70\ \Omega$ at the center frequency f_0 . In a practical transition for wideband operation, the right-angle bend parasitic elements have to be compensated. A simple solution to this problem is to increase the mean pathlength of the microstrip. Hence, the mean pathlength is chosen as $0.638\ \lambda_{g(\text{microstrip})}$. This design ensures that the phase of the signals at the input locations a and b to the coupled microstrip line are 180° out of phase. The coupled microstrip lines are excited in the odd mode with the electric field lines predominantly across the gap S_2 . The dimensions of the gap S_2 is chosen such that the odd-mode characteristic impedance is $50\ \Omega$. The horizontal orientation of the electric field lines in the coupled microstrip makes the transition to a CPS simple. The width W and separation S of the CPS in the experimental transition is the same as the coupled microstrip width and separation.

In Ref. 15 the measured characteristics of the transition shown in Fig. 6 is reported. The transition is designed

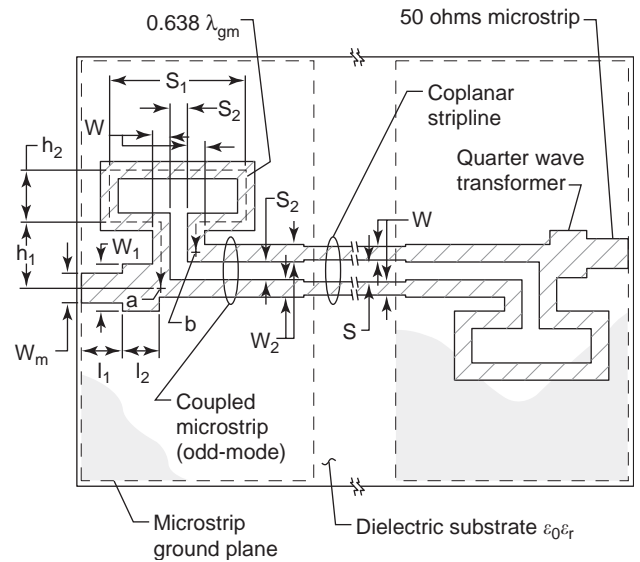

Figure 6. Two back-to-back balanced uniplanar coplanar stripline-to-microstrip transition. $W_m = 0.23\ \text{mm}$, $W_1 = 0.33\ \text{mm}$, $W_2 = W = S_2 = S = 0.1\ \text{mm}$, $l_1 = 4.9\ \text{mm}$, $l_2 = 2.8\ \text{mm}$, $S_1 = 2.1\ \text{mm}$, $h_1 = 0.54\ \text{mm}$, $h_2 = 1.34\ \text{mm}$. Substrate thickness $h = 0.254\ \text{mm}$, $\epsilon_r = 10.5$.

for operation at a center frequency $f_0 = 10.0\ \text{GHz}$; however, the measurements show that f_0 has shifted to $9.6\ \text{GHz}$. The measured insertion loss and return loss are about $2.0\ \text{dB}$ and less than $-10.0\ \text{dB}$, respectively, over 42% bandwidth centered at $9.6\ \text{GHz}$. The numerical simulation of the transition carried out using the FDTD technique shows that the measured and modeled results are in good agreement [15].

3.3. Stacked Coplanar Stripline-to-Microstrip Transition

Figure 7 shows a coplanar stripline (CPS)-to-microstrip transition [16] in a stacked configuration. In this transition the microstrip ground plane is attached using

Figure 7. Coplanar stripline-to-microstrip transition using ribbon bond.

electrically conducting epoxy to one of the strip conductors of the CPS. The connection between the remaining strip conductors is by a gold ribbon. Lee and Itoh [16] describe the characteristics of an experimental transition. The geometry as well as the measured characteristics of the transition are summarized in Table 2. The transition has a wide bandwidth.

3.4. Microcoplanar Stripline-to-Microstrip Transition

Figure 8 shows a microcoplanar stripline (MCPS)-to-microstrip transition [17] in a back-to-back arrangement. In this transition, the width of the microstrip ground plane is abruptly reduced to form a symmetric parallel-plate line. The parallel-plate conductors are next flared out to form the MCPS. The cross section at three locations along the transition are shown in the inset in Fig. 8. Sections A-A, B-B, and C-C show the microstrip, the parallel plate, and the MCPS regions, respectively. The relevant parameters of the transition are as follows: $h_1 = 254 \mu\text{m}$, $\epsilon_{r1} = 10.5$, $\epsilon_{r2} \approx 1.0$, $W = 889 \mu\text{m}$, $W_m = 254 \mu\text{m}$, and the characteristic impedance $Z_{0(\text{microstrip})} = 50 \Omega$. In Ref. 17 the characteristics of an experimental transition are reported. The measured insertion loss and return loss are 1.0 dB and less than -16.0 dB , respectively, for two back-to-back transitions over the frequency range of 0.045–14.0 GHz. These losses also include the loss of the test fixture. The measurements show that the transition has a broad bandwidth.

4. COPLANAR STRIPLINE-TO-SLOTLINE TRANSITION

An electromagnetically coupled coplanar stripline (CPS)-to-slotline transition [18] in a back-to-back arrangement is shown in Fig. 9. The CPS and the slotline are on opposite sides of a dielectric substrate. To demonstrate the design

Figure 8. Two back-to-back micro-coplanar stripline-to-microstrip transition.

Figure 9. Two back-to-back electromagnetically coupled coplanar stripline-to-slotline transition. A-A, B-B, C-C, and D-D refer to the various cross-sections along the transition.

of the transition, the cross sections at four locations along the length are shown in Fig. 10. The input port at section A-A is a CPS with strip conductor width W_1 and separation S_1 . At section B-B the CPS overlaps the ground plane and transforms to coupled microstrip lines of width W_2 with odd-mode excitation. The separation S_2 between the coupled microstrip lines gradually diverges beyond B-B to C-C, but the strip width remains fixed at W_2 . At section C-C, the coupled microstrip lines are totally decoupled and behave as two independent lines. Beyond this plane, the CPS is terminated in a short circuit arc of radius R . Coupling between the CPS and the slotline takes place at the location where the short circuit arc crosses

the slotline at right angles. The slotline has a slot of width W_s .

Further, the slotline is terminated in a short circuit at a distance L_3 , which is approximately $\lambda_{g(\text{slotline})}/4$, where $\lambda_{g(\text{slotline})}$ is the guide wavelength in the slotline at the design frequency f_0 . The measured return loss and insertion loss characteristics of the transition are presented in Figs. 11a and 11b, respectively. Table 3 summarizes the transition performance.

 Cleveland, Ohio

1. INTRODUCTION

Coplanar waveguide (CPW) is a type of planar transmission line suited for microwave integrated circuits (MICs) as well as for monolithic microwave integrated circuits (MMICs). The unique feature of this transmission line is that it is uniplanar in construction, which implies that all the conductors are on the same side of the substrate. This attribute simplifies realization of short- or open-circuited terminations and mounting of series and shunt lumped or active elements. In addition, it also circumvents the need for via holes. Furthermore, simplifies manufacturing and allows fast and inexpensive characterization using on-wafer techniques.

In this article, the design considerations for a CPW 3-dB hybrid coupler, 180° hybrid coupler, 3-dB magic-T, and aperture coupled patch antenna are presented. The hybrid couplers and the magic Ts are widely used in MICs as 90° and 180° power dividers and combiners that form the basic building blocks for subsystems such as balanced mixers, balanced upconverters, balanced modulators, balanced amplifiers, and balanced frequency multipliers. In addition, they are also used in the construction of image rejection mixers and upconverters. Furthermore, when hybrid couplers are integrated into the feed system of printed patch antennas and arrays, they can excite the radiator in the desired amplitude and phase to generate a linear or circular polarization. When magic Ts are integrated with antennas, they can form a comparator to produce the monopulse sum and difference signals needed in tracking radars.

In contrast with a Lange coupler, the above mentioned couplers do not require narrow strip conductors and slots, which impact tolerance and yield. To keep the chip size small and thus lower the cost, the designs presented here are for reduced-size hybrid couplers and magic Ts.

2. REDUCED-SIZE 3-dB BRANCHLINE HYBRID

Equivalent circuits of standard and reduced-size branchline hybrid are shown in Figs. 1a and 1b, respectively. In a standard hybrid the characteristic impedance of the branchline and the throughline are Z_0 and $Z_0/\sqrt{2}$, respectively. If in the reduced-size hybrid the characteristic impedance of the both the branchline and the throughline are Z , where Z is greater than Z_0 , then the electrical length of the branchline θ_1 , the electrical length of the throughline θ_2 , and the lumped capacitance C are given

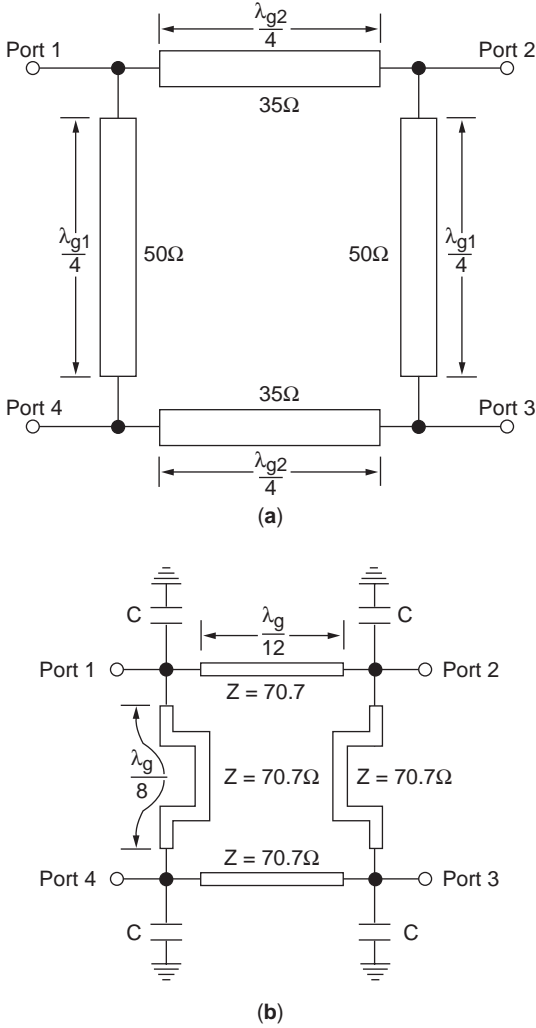

Figure 1. (a) Standard branchline hybrid; (b) reduced-size branchline hybrid. The guide wavelength on the line is denoted as λ_g .

by Ref. 1:

$$\theta_1 = \arcsin\left(\frac{Z_0}{Z}\right) \quad (1)$$

$$\theta_2 = \arcsin\left(\frac{Z_0}{\sqrt{2}Z}\right) \quad (2)$$

$$\omega CZ_0 = \sqrt{1 - \left(\frac{Z_0}{Z}\right)^2} + \sqrt{2 - \left(\frac{Z_0}{Z}\right)^2}. \quad (3)$$

As an example, when $Z_0 = 50\ \Omega$ and $Z = 70.7\ \Omega$, these three equations give $\theta_1 = 45^\circ$, $\theta_2 = 30^\circ$. This implies that the branchline and the throughline lengths θ_1 and θ_2 are $\lambda_g/8$ and $\lambda_g/12$, respectively, where λ_g is the guide wavelength.

The phase difference between the power to the direct port and the power to the coupled port, that is, the phase of (S_{21}/S_{31}) , is computed in Ref. 1 for the reduced-size hy-

brid and the standard quarter-wavelength hybrid. The results show that the bandwidth over which the phase difference is 90° is narrower in the case of the reduced-size hybrid.

In a coplanar waveguide (CPW) if the center strip conductor width is held fixed and the slot width increased, the characteristic impedance increases and the conductor loss reduces. Hence, the insertion loss of the reduced-size hybrid that has an impedance higher than that of the standard hybrid is not degraded by size reduction.

An experimental reduced-size hybrid fabricated on a semiinsulating GaAs is reported in Ref. 1. The constant-impedance transmission line is a CPW with a center strip width of $10\ \mu\text{m}$ and characteristic impedance of $70.0\ \Omega$. The lengths of the branchline and the throughline are $\lambda_{g(\text{CPW})}/8$ and $\lambda_{g(\text{CPW})}/12$, respectively, at 25 GHz. Air bridges are used at the CPW junctions to tie the ground planes at equal potential and suppress the coupled slotline even mode. Metal-insulator-metal (MIM) shunt capacitors are located at the corners of the inner ground metal. The insulator film is Si_3N_4 . The size of the fabricated hybrid is $500 \times 500\ \mu\text{m}$. This is more than 80% smaller than a standard branchline hybrid.

The measured performance of the hybrid in Ref. 1 over the frequency band of 24.0–26.0 GHz shows that the power coupled from port 1 to ports 2 and 3 is within $5.0 \pm 0.5\ \text{dB}$, return loss at port 1 is better than $-10.0\ \text{dB}$, and the isolation between ports 1 and 4 is better than $-12.0\ \text{dB}$. As a concluding remark, it may be mentioned that in Ref. 2 a small 90° hybrid coupler based on the Wheatstone bridge principle is demonstrated at a center frequency of 4.0 GHz.

3. REDUCED-SIZE 180° RING HYBRID

The equivalent-circuit representation of a standard 180° ring hybrid is shown in Fig. 2a. To reduce the size of the hybrid, first the quarter-wavelength lines of $70\ \Omega$ characteristic impedance are replaced by one-eighth wavelength lines of $100\ \Omega$ characteristic impedance with lumped capacitances at the ends. Then, the three-quarter wavelength line of $70\ \Omega$ characteristic impedance is replaced by a π -network consisting of lumped series capacitance and shunt inductances. The lumped shunt inductances and capacitances almost cancel each other, resulting in the equivalent circuit [1] shown in Fig. 2b.

Besides size reduction, the reduced-size ring hybrid has the advantage of being able to interchange ports at the location of the series metal-insulator-metal (MIM) capacitor [1] as illustrated in Fig. 3. In Fig. 3a, the output ports 2 and 3 are located on opposite sides of port 4. By interchanging the location of ports 2 and 4, the output ports 2 and 3 are located side by side as shown in Fig. 3b. Further, if port 4 is used as the input port, then the outputs at ports 2 and 3 are 180° out of phase as discussed in Ref. 3. This feature greatly simplifies balanced mixer construction using a ring hybrid [4].

An experimental reduced-size ring hybrid fabricated on a semiinsulating GaAs substrate with elevated CPW as the transmission line has been reported in Ref. 5. The

Figure 2. Representation of (a) standard 180° ring hybrid or rat race with transmission lines; (b) equivalent reduced-size 180° ring hybrid or ratrace with transmission lines and lumped elements. The wavelength on the line is denoted as λ_g .

elevated CPW has the advantage of reducing both the insertion loss as well as the chip area as discussed in Ref. 3. The hybrid consists of three $\frac{1}{8}$ th-wavelength 100- Ω elevated CPWs, a series capacitor and two shunt capacitors in place of the three $\lambda_g/4$, and a $3\lambda_g/4$ 70- Ω transmission line as in a standard ring hybrid. In the experimental hybrid, the elevated CPW is meandered to further reduce the overall size. The ring hybrid is schematically shown in Fig. 4.

The measurements show that the coupling loss ($|S_{12}|$, $|S_{42}|$) of the hybrid is on the order of 4.2 ± 0.8 dB, return loss ($|S_{22}|$) better than 17.0 dB, and isolation ($|S_{32}|$) better

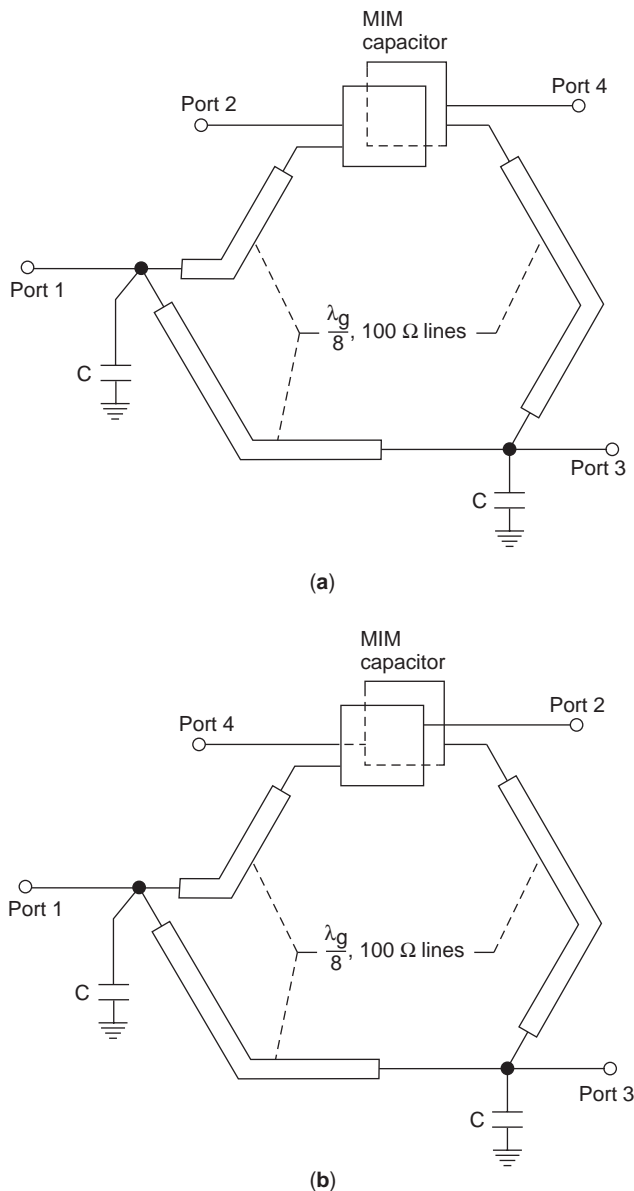

Figure 3. (a) Normal port layout; (b) port layout convenient for balanced mixer applications.

than 18.0 dB over the frequency range 15.0 ± 2.0 GHz. The chip size is on the order of 0.50×0.55 mm.

4. REDUCED-SIZE 3-dB MAGIC T

The circumference of a magic-T circuit is typically about one guide wavelength. To reduce the circumference and thereby the overall size, consider the hybrid ring topology [6] shown in Fig. 5. In this circuit it is assumed that the transmission lines in opposite ring arms are identical and that the hybrid ring is matched at all ports. The phase shifter may be located anywhere in any of the four arms. In this hybrid a signal fed to port 1 (*H* arm) will be split equally and be in phase between the two output ports 2

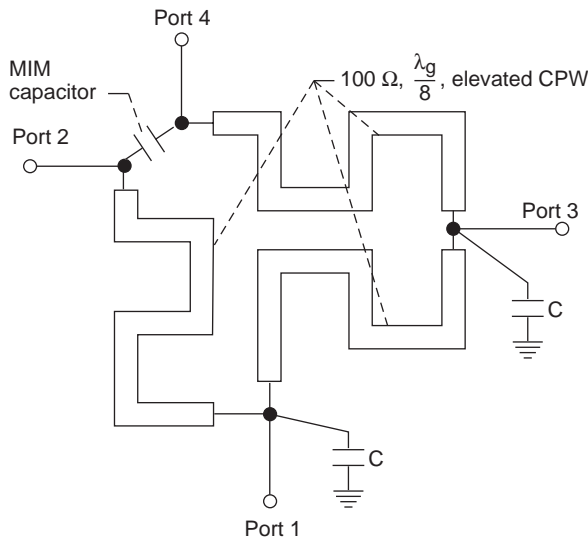

Figure 4. Reduced-size 180° ring hybrid with meandered elevated CPW.

and 3 (balanced arms). Similarly, a signal feed to port 4 (*E* arm) will be split equally and be out of phase between the two output ports 2 and 3. The following design equations hold good [6]:

$$Z_{c1}^2 = Z_0^2 \frac{\sin^2 \theta_1 + \sin^2 \theta_2 - 2 \cos \theta_1 \cos \theta_2}{\sin^2 \theta_1} \quad (4)$$

$$Z_{c2}^2 = Z_0^2 \frac{\sin^2 \theta_1 + \sin^2 \theta_2 - 2 \cos \theta_1 \cos \theta_2}{\sin^2 \theta_2} \quad (5)$$

where θ_i ($i = 1, 2$) is the electrical length of arm i at the center frequency f_0 . The impedances Z_{c1} and Z_{c2} are the

Figure 5. Generalized ring magic T.

characteristic impedances of the lines in the ring arms. The impedance Z_0 is the terminating impedance. To obtain real values for characteristic impedances, the following condition must be satisfied [6]:

$$\cos \theta_1 + \cos \theta_2 < \sqrt{2} \quad (6)$$

In a symmetric design all four ring arms are identical. In such a case Eqs. (4) and (5) reduces to [7]:

$$Z_c = Z_0 \sqrt{2} \sqrt{1 - \cot^2 \theta} \quad (7)$$

An experimental reduced-size magic T [6,7] realized with symmetric coplanar striplines is shown in Fig. 6a. Coplanar striplines are chosen because they allow easy crossover of the two strips to realize the 180° phase shifter needed at the *E* arm. The crossover may be placed at any position along the arm or at the T junction as shown in Fig. 6b.

In Ref. 7 θ is equal to 60° and for Z_0 equal to 50Ω, Z_c from (7) is equal to 57.6Ω. This design results in a ring circumference of 0.67 guide wavelength. The magic T is fabricated on a 254-μm-thick alumina substrate ($\epsilon_r = 9.9$),

Table 1. Reduced-Size 3-dB Ring Magic T

<i>Circuit Parameters and Measured Characteristics</i>	
Substrate (alumina) ϵ_r	9.9
Thickness (μm)	254
Metallization thickness (μm)	4.0
<i>Coplanar Waveguide</i>	
Strip width S_1 (μm)	50
Slot width W_1 (μm)	30
Z_0 (Ω)	50
<i>Coplanar Stripline</i>	
Strip width S_1 (μm)	300
Slot width S_2 (μm)	60
Z_c (Ω)	57.6
θ (deg)	60
Circumference λ_g	0.67
Ring radius (μm)	3478
Crossover gap g (μm)	100
<i>Measured Performance</i>	
Center frequency f_0 (GHz)	6
Frequency range (GHz)	4.5–9.2
Transmission when fed at <i>H</i> -arm mag (S_{21}), mag (S_{31}) (dB)	4.3 ± 0.3
Transmission when fed at <i>E</i> -arm mag (S_{24}), mag (S_{34}) (dB)	4.3 ± 0.3
Output magnitude balance when fed at <i>H</i> -arm mag (S_{21}/S_{31}) (dB)	0.3 ± 0.05
Output phase balance when fed at <i>H</i> -arm phase (S_{21}/S_{31}) (deg)	0 ± 4
Output magnitude balance when fed at <i>E</i> -arm mag (S_{24}/S_{34}) (dB)	0.4 ± 0.25
Output phase balance when fed at <i>E</i> -arm phase (S_{24}/S_{34}) (deg)	180 ± 4
Return loss mag (S_{22}) and mag (S_{33}) (dB)	< -10.0
Isolation mag (S_{EH}), mag (S_{32}) (dB)	< -23.0

and the conductor thickness is $4\mu\text{m}$. The geometric parameters and the measured performance of the magic T are summarized in Table 1. The magic T has a bandwidth slightly larger than 1 octave.

As a concluding remark, it may be mentioned that other designs for magic Ts can be found in Refs. 8–11 in the literature.

5. COPLANAR WAVEGUIDE APERTURE-COUPLED PATCH ANTENNA

Aperture-coupled feeding is attractive because of certain advantages, such as lack of physical contact between the feed and radiator, wider bandwidth, and better isolation between antennas and the feed network. Furthermore, aperture-coupled feeding allows independent optimization of antennas and feed networks by using substrates of different thickness or permittivity. A grounded coplanar waveguide (GCPW) aperture-coupled patch antenna is schematically illustrated in Fig. 7. In the experimental

Figure 7. Grounded coplanar waveguide aperture-coupled patch antenna: $S = 0.076$ cm, $W = 0.025$ cm, $L = 0.711$ cm, $L_1 = 0.025$ cm, $L_2 = 0.205$ cm, $W_2 = 0.69$ cm, $a = 0.76$ cm, $b = 1.14$ cm, $h_1 = 0.051$ cm, $\epsilon_{r1} = 2.2$, $h_2 = 0.025$ cm, $\epsilon_{r2} = 2.2$, $L_t = 0.711$ cm, $S_1 = 0.355$ cm, $R = 0.0843$ cm.

antenna [12], the patch and the GCPW feed structure, with a series gap L_1 in the center conductor, are fabricated on separate substrates, and the aperture is etched in the common ground plane. The aperture is located directly

(a)

(b)

Figure 8. Measured radiation patterns for the grounded coplanar waveguide aperture-coupled patch antenna: (a) *E* plane; (b) *H* plane.

above the series gap. Thus, microwave power is coupled from the GCPW feedline to the patch through the aperture. In the experimental antenna, the patch is displaced by ~ 0.32 cm from the center of the aperture and the GCPW stub length L is adjusted to provide the best impedance match to the feedline. The radiation from the antenna is linearly polarized with the plane of polarization parallel to the patch side of dimension a .

The measured return loss is about -16.9 dB at the design frequency of 12.65 GHz as reported in Ref. 12. Typical measured E - and H -plane radiation patterns [12] for the GCPW aperture-coupled patch antenna are shown in Figs. 8a and 8b, respectively. The patterns look fairly symmetric and exhibit a 3 dB beamwidth of about 60° and 50° in the E and H planes, respectively. The measured front-to-back ratio is ~ 14.0 dB, which is typical for an aperture-coupled patch antenna. Finally, in Ref. 13 an aperture-coupled patch antenna with series slotline stubs in the CPW ground planes, instead of a series gap in the CPW center strip conductor, is demonstrated. The characteristics of this antenna are similar to those presented above.

COPLANAR WAVEGUIDE (CPW) TRANSMISSION LINES

LEI ZHU
Nanyang Technological
University
Singapore

1. INTRODUCTION

The coplanar waveguide (CPW) was invented by Wen [1] in 1969 as a novel surface strip transmission line fabricated on a dielectric substrate. As the strip conductor is deposited on the same surface as the two ground planes in close proximity, the CPW transmission line has demonstrated several advantageous features over the conventional microstrip line, for instance, easy surface mounting of external devices, easy fabrication of both shunt and series passive elements, low-frequency dispersion, and easy adjustment of desirable characteristic impedance. Since its proposal, the CPW technology has been progressively gaining a tremendous application in exploration of advanced RF and microwave integrated circuits, modules, and subsystems. For this purpose, much effort has been carried out to construct a new variety of modified CPW transmission lines with varied cross-sectional configurations and accurately characterize their propagation performance in theory and experiment, as summarized in two relevant books [2,3]. In particular, various static and full-wave methods have been effectively developed to deal with these inhomogeneous transmission lines and derive the two per unit length transmission parameters, i.e., effective dielectric constant and characteristic impedance.

This article focuses on the fundamentals of various CPW transmission lines developed so far, including their geometric schematics, transmission characteristics, modeling techniques, and closed-form design formulas:

1. The three most popular CPW lines with infinite and finite ground widths as well as the backed conductor are comprehensively described to exhibit their transmission performance versus strip/slot dimension ratios, operating frequency, and strip conductor profile.
2. Low-transmission-loss shielded CPW, suspended CPW, nonleaky CPW, micromachined CPW, and cavity-assisted CPW are briefly investigated.
3. Various coupled CPW transmission lines and the extent of their weak and tight parallel coupling are discussed.

4. Various periodic slow-wave CPW transmission lines with series inductive and/or shunt capacitive loading in periodical intervals with the objective of miniaturization of CPW circuits are discussed, and their complete propagation characteristics in terms of effective per unit length transmission parameters are demonstrated.

2. BASIC CPW: GEOMETRY AND ANALYSIS

The conventional CPW transmission line [1] consists of the central strip conductor and the two infinite-width ground planes on two sides that are formed in close proximity on the same surface of a dielectric substrate with finite height, as illustrated in Fig. 1a. By equalizing the electric potentials at the two ground planes, only the even symmetric dominant CPW mode can be excited. At high frequencies, this CPW mode becomes non-TEM with a longitudinal component of magnetic field. In such a case, the tangential magnetic field, on the surface of the coupled slots between the strip conductor and two ground planes, becomes elliptically polarized. This conventional CPW was developed by Wen [1] for suitable applications in nonreciprocal ferrite devices. However, the CPW has been extensively utilized as a quasi-TEM transmission-line candidate for exploration of a variety of MMIC's circuits

Figure 1. Schematic of infinite-ground coplanar waveguide (CPW) transmission line and distribution profiles of electromagnetic field and current density in cross section: (a) 3D schematic; (b) electric and magnetic field lines; (c) electric current density.

and modules. In this way, the cross-sectional dimensions, such as slot and strip widths, are readily selected electrically short in the frequency region of operation, so as to minimize the longitudinal magnetic field component.

Figure 1b shows the cross-sectional configurations of the electric and magnetic fields of the dominant quasi-TEM mode. The electric field lines start from the central conductor and then are symmetrically expanded with respect to the central plane toward the ground planes at two sides, whereas the magnetic field lines are perpendicular to their electric counterparts at any given location and surround the central conductor in terms of closed loops. Figure 1c illustrates the distribution of electric current densities on the strip conductor and ground planes, respectively, that are longitudinally oriented in an antiparallel pattern. The current density strength inherently tends to increase and then approach the infinity in an exponential function as the observed point moves to the metallic edges, regardless of either strip conductor or ground sides.

In Wen's work [1], the relative permittivity is assumed much larger than the unity ($\epsilon_r \gg 1$) so that the finite height of a substrate can be reasonably treated as the infinity ($h \rightarrow \infty$) for simplifying the theoretical analysis. But, in practice, ϵ_r and h have to be finite as shown in Fig. 2a. Also, the actual ground width of this CPW is usually finitely wide so as to formulate the call finite-ground CPW or FGCPW as shown in Fig. 2b. Further, an additional conductor plate is often formed on the opposite surface of a finite-height substrate in order to improve both the mechanical strength and power-handling capability, thus constructing the conductor-backed CPW (CBCPW) as illustrated in Fig. 2c. Moreover, many other modified CPW structures with dielectric multilayers and/or upper/lower

Figure 2. Cross-sectional view of three typical CPW transmission lines: (a) infinite-ground CPW; (b) finite-ground CPW; (c) conductor-backed CPW.

shielding conductors [2,3,5–7] are built on the basis of these three basic CPW in order to meet various requirements in realizing the preferred electrical performance and employing advanced fabrication techniques.

So far, extensive work in theory has been done to characterize a variety of CPW transmission lines in terms of per unit length characteristic impedance and propagation constants by developing the quasistatic and full-wave analysis approaches [2,3]. Assumption of quasi-TEM mode at low frequencies, the quasistatic conformal mapping technique was initially utilized to model the CPW line with infinite dielectric thickness [1] and then was significantly extended to consider a number of CPW structures with shielded and multilayered configurations [4–7]. In this way, the total per unit length capacitance can be derived as the algebraic sum of all the partial line capacitances [4–7] and separately calculated both above and below the slot interface. Generally speaking, this technique is strictly valid for the hypothesis that the interface of a substrate is considered as the magnetic wall or electric field lies on the dielectric interface. However, an accuracy of $>1\%$ for a wide range of physical dimensions and dielectric permittivity is achieved as compared with that of the full-wave spectral-domain method [6]. Of vital importance, this technique gives rise to analytical expressions for effective dielectric constants and characteristic impedance in terms of the ratio of complete elliptic integral of the first kind and its complement, $K(k)/K'(k)$, where k is the variable.

The detailed mathematics of this procedure can be found in the literature [e.g., 1–7] and are not discussed here. In this section, the three sets of closed-form design formulas are used to characterize three basic CPW structures in Figs. 2a–2c with respect to various physical dimensions. For the reader's convenience, the analytical expressions of the ratio $K(k)/K'(k)$, are provided below in two different regions of the variable k for infinite- and finite-width-ground CPWs:

$$\frac{K(k)}{K'(k)} = \frac{\pi}{\ln[2(1 + \sqrt[4]{1-k^2})/(1 - \sqrt[4]{1-k^2})]} \quad (0 \leq k \leq 0.707) \quad (1a)$$

$$\frac{K(k)}{K'(k)} = \frac{\ln[2(1 + \sqrt{k})/(1 - \sqrt{k})]}{\pi} \quad (0.707 \leq k \leq 1) \quad (1b)$$

2.1. Infinite-Ground CPW

For conventional CPW with infinite-width ground as in Fig. 2a, the two variables k_1 and k_2 are defined in terms of the dimensions a , b , and h , respectively, where the strip width $W = 2a$ and $S = b - a$:

$$k_1 = \frac{a}{b} \quad (2a)$$

$$k_2 = \frac{\sinh(\pi a/2h)}{\sinh(\pi b/2h)} \quad (2b)$$

As such, the per unit length effective dielectric constant and characteristic impedance can be deduced:

$$\epsilon_{re} = 1 + \frac{\epsilon_r - 1}{2} \frac{K(k_2) K'(k_1)}{K'(k_2) K(k_1)} \quad (3)$$

$$Z_0 = \frac{30\pi K'(k_1)}{\sqrt{\epsilon_{re}} K(k_1)} \quad (4)$$

Figures 3a and 3b show simulated results from Eqs. (3) and (4), respectively, with respect to the ratio of slot to strip widths (S/W in Fig. 3) under different h/W (height/width ratios). The impedance (Z_0) definitely increases as the slot is widened for all the four listed h/W because of reduced capacitive coupling between the strip conductor and two ground planes. As h/W increases, the Z_0 curve converges to that with very thick thickness ($h/W = 20$). Meanwhile, the effective dielectric constant (ϵ_{re}) falls down

Figure 3. Per unit length transmission parameters of the infinite-ground CPW transmission line as a function of slot width (S/W) with varying substrate thickness (h/W): (a) characteristic impedance (Z_0); (b) effective dielectric constant (ϵ_{re}).

as the slot width is enlarged under the fixed finite thickness (h/W) and it eventually becomes almost independent of h if h/W is larger than 20 as can be seen in Fig. 3b. It can be further deduced from these results that the effect of finite dielectric substrate is almost ignorable if h exceeds $2b = W + 2S$.

2.2. Finite-Ground CPW

Practical CPW has finite-width ground planes as illustrated in Fig. 2b. In order to factor in the effect of finite ground, the two modified variables, k_3 and k_4 , are defined as below; thus Eqs. (3) and (4) are still valid for this finite-ground CPW by using k_3 and k_4 instead of k_1 and k_2 :

$$k_3 = \frac{a}{b} \sqrt{\frac{1 - b^2/c^2}{1 - a^2/c^2}} \quad (5a)$$

$$k_4 = \frac{\sinh(\pi a/2h)}{\sinh(\pi b/2h)} \sqrt{\frac{1 - \sinh^2(\pi b/2h)/\sinh^2(\pi c/2h)}{1 - \sinh^2(\pi a/2h)/\sinh^2(\pi c/2h)}} \quad (5b)$$

The calculated results are depicted in Figs. 4a and 4b, in which $W_1 = 2a$, $S = b - a$, and $W_2 = c - b$ indicate the strip, slot, and finite-ground widths, respectively. As the ground-to-strip width ratio of W_2/W_1 is reduced, Z_0 tends to increase and the effective ϵ_{re} also goes up slowly. This may be attributed to the weakened strip-to-ground coupling and partial transfer of field energy from the free space to dielectric substrate. Moreover, we can find that the effect of the two lateral finite grounds becomes much smaller as W_2 is widened beyond $2W_1$, especially for the narrow slot width (S).

2.3. Conductor-Backed CPW

An additional conductor plate is put on the lower interface of a substrate to form the *conductor-backed-CPW* (CBCPW) as shown in Fig. 2c. This CBCPW resembles a mixed coplanar-microstrip structure, thus supporting a parasitic microstriplike mode in addition to the dominant CPW mode. The CPW-mode characteristic impedance may be considerably reduced by the shunt connection of the two per unit length capacitances between strip and lateral ground as well as the strip and backed conductor. The performance of this CBCPW can also be characterized using the conformal mapping technique [2,3]. For this purpose, an alternative variable k_5 is defined as follows:

$$k_5 = \frac{\tanh(\pi a/2h)}{\tanh(\pi b/2h)} \quad (6)$$

As such, the two per unit length parameters can be calculated in terms of the two closed-form equations:

$$\epsilon_{re} = 1 + (\epsilon_r - 1) \frac{K(k_5)/K'(k_5)}{K(k_1)/K'(k_1) + K(k_5)/K'(k_5)} \quad (7)$$

$$Z_0 = \frac{60\pi}{\sqrt{\epsilon_{re}}} \frac{1}{K(k_1)/K'(k_1) + K(k_5)/K'(k_5)} \quad (8)$$

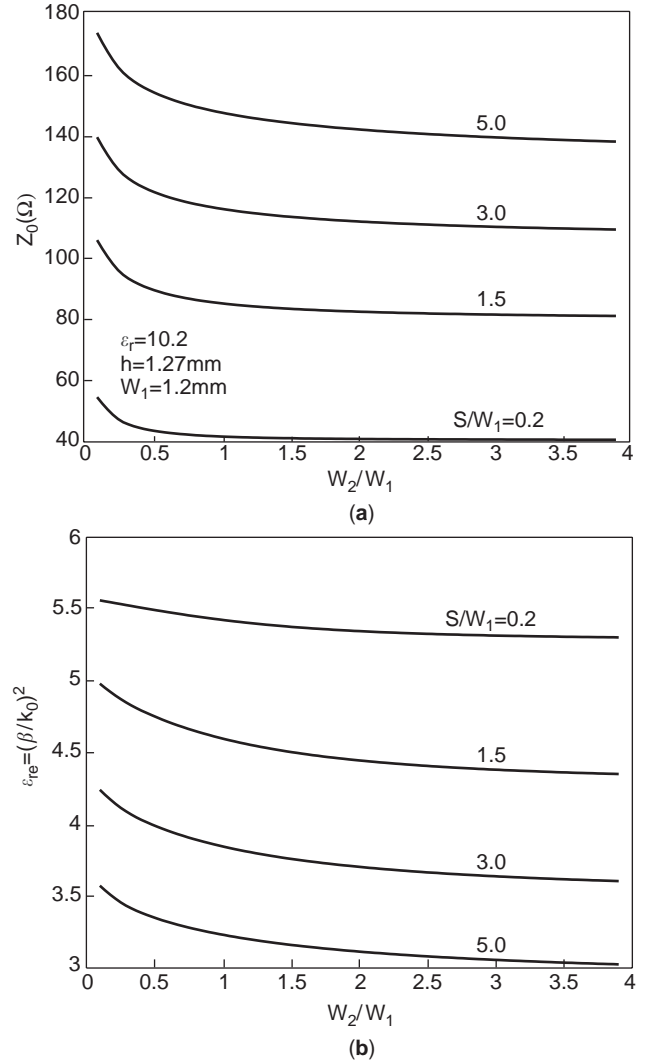

Figure 4. Per unit length transmission parameters of finite-ground CPW transmission line as a function of finite-ground width (W_2/W_1) with varying slot width (S/W_1): (a) characteristic impedance (Z_0); (b) effective dielectric constant (ϵ_{re}).

Figures 5a and 5b show the results of these two parameters versus the thickness-to-strip aspect ratio (h/W) under varied slot-to-strip aspect ratios (S/W). When the substrate is thin (i.e., with small h/W), the capacitive coupling between the strip and backed conductor is significantly tightened, causing this CBCPW to operate like a microstrip line with decreased characteristic impedance (Z_0), as can be observed in Fig. 5a. Meanwhile, the electromagnetic field is moved to the substrate region underneath the strip conductor, thereby enlarging the effective dielectric constant (ϵ_{re}) toward the dielectric permittivity (ϵ_r), as illustrated in Fig. 5b. At a narrow slot width of $S/W \leq 0.5$, the backed-conductor effect becomes negligibly small if the thickness (h) exceeds the strip width (W), implying that this CBCPW operates as a conventional CPW as in Fig. 2a. For the wide slot width ($S/W > 1.0$), both Z_0 and ϵ_{re} seem to depend on the substrate thickness (h/W) to some extent because of the concurrent existence of the strip-to-ground and strip-to-conductor coupling.

Figure 5. Per unit length transmission parameters of conductor-backed CPW transmission line as a function of substrate thickness (h/W) with varying slot width (S/W): (a) characteristic impedance (Z_0); (b) effective dielectric constant (ϵ_{re}).

Until now, the three basic CPW transmission lines have been characterized under the quasistatic assumption. The formulas presented above are well verified at low frequencies in comparison with the spectral-domain approach as discussed in Ref. 6. However, because of the inhomogeneous layers in these CPW, the two per unit length parameters become frequency-dispersive as the operating frequency increases as demonstrated extensively in the literature [2,3,8]. In addition, the higher-order modes may operate above their relevant cutoff frequencies and their parasitic effects cannot be taken into account in the design formulas above. Also, many other factors, such as the strip/ground conductor thickness and cross-sectional profiles, may seriously affect these two parameters. In order to rigorously model these CPW structures, a number of full-wave numerical approaches, such as the mode-matching method, spectral-domain method, method of lines, and the finite-element method, were successfully developed in

the 1970s–1990s. As the detailed procedures of these methods can be found in a contributed book [8], a lengthy and complicated formulation of these approaches in mathematics would be beyond the main objectives of this article and is not included here.

We nevertheless include some typical results using these full-wave approaches to demonstrate the electrical performance of CPW transmission lines with varied strip/conductor configurations [9,10]. Figures 6a and 6b show the calculated frequency-dispersive effective dielectric constants (ϵ_{re}) of the conductor-backed CPW, CBCPW, with rectangular or trapezoidal conductor configurations. In all these structures, ϵ_{re} seems to be frequency-independent at low frequencies ($f < 20 \text{ GHz}$) with a substrate thickness of $h = 100 \mu\text{m}$. This parameter increases sharply at the beginning and then more gradually as f increases, and eventually reaches to the relative permittivity of this substrate (i.e., $\epsilon_r = 12.9$), as f is beyond 100 GHz. In fact,

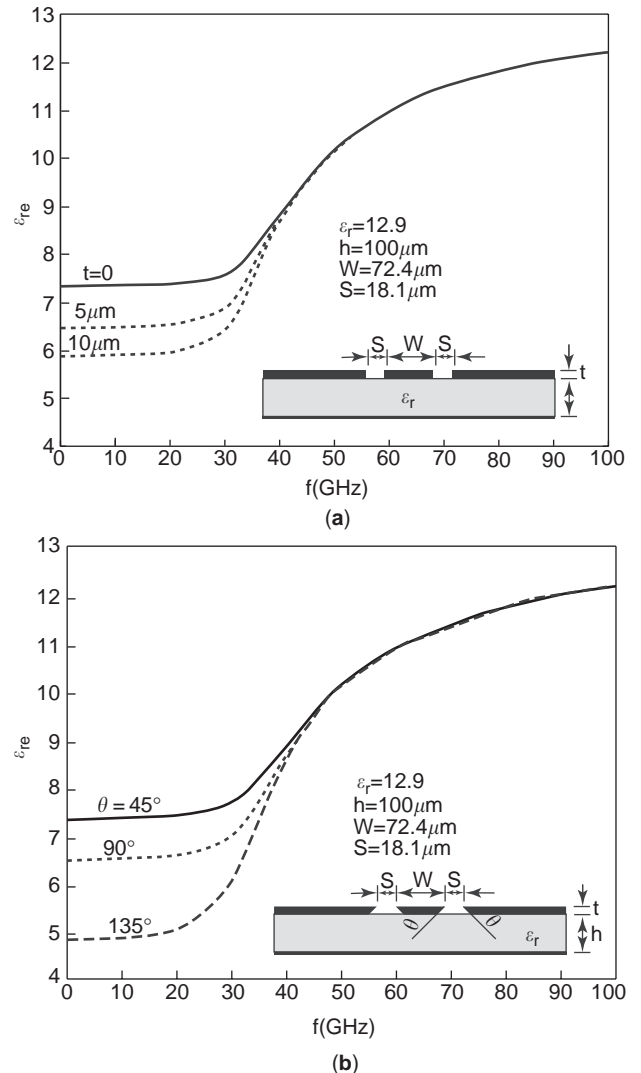

Figure 6. Frequency-dependent effective dielectric constant (ϵ_{re}) of conductor-backed CPW transmission line with rectangular or trapezoidal edge profile versus (a) conductor thickness (h) and (b) edge angle (θ).

all the electromagnetic (EM) fields definitely tend to be moved into the substrate region with high permittivity at high frequencies, thus causing the slow-wave propagation behavior with reduced velocity, which is the common frequency-dispersive feature for all CPW transmission lines. As can be observed in Fig. 6a, ϵ_{re} at low frequencies gradually decreases as the strip/ground thickness (t) increases from 0 to 10 μm . Because of tightened coupling between the central strip and two-side grounds for nonzero t , a small portion of EM fields in the substrate is moved to the free-space slot region. Figure 6b shows us that the varied angle (θ) of conductor edge wall affects the transmission properties. As θ increases, ϵ_{re} at low frequencies appears to drop because of the upward-oriented EM fields between the strip and ground.

3. MODIFIED CPW WITH ENHANCED PERFORMANCE

In this section, a variety of modified CPW transmission lines that have many promising features for applications in high-performance and millimeter-wave circuits will be overviewed. Figure 7a is the cross-sectional view of an initial CPW with metallic enclosure. This shielded CPW can completely avoid the unexpected radiation loss that occurs in the unbounded CPW discussed above. However, because of the high conductivity loss and serious frequency dispersion, the preferred construction for the CPW is suspension in a metallic enclosure as shown in Fig. 7b. This type of CPW was originally reported by Hatsuda [11], and the dominant-mode performance for this CPW is analyzed approximately using the relaxation method under the quasistatic assumption. To facilitate the mechanical installation, an improved CPW, the nonsymmetrically shielded CPW (NSCPW) [12] is shown in cross section Fig. 7c. This NSCPW is constructed by mounting the CPW in a nonsymmetric enclosure with respect to the upper and lower regions through the grooves. In addition to the low transmission loss and low frequency dispersion, this shielded NSCPW is best suited for mounting solid-state devices, constructing matching elements in series and shunt, and formulating the biasing circuits [12]. The propagation characteristics of the dominant and high-order modes are theoretically studied using full-wave methods [12,13], and the predicted phase constants of these modes are experimentally verified [12] by measuring the multiple transmission peaks of the two-port NSCPW resonator with coaxial launchers at two ends.

The theoretical characteristics of multilayered CPW transmission lines have been reported in the literature [5–7]. Three of these CPW structures that exhibit enhanced electrical performance, namely, elevated, insulated, and nonleaky CPW, are discussed here (see cross-sectional views in Fig. 8). The elevated CPW in Fig. 8a is proposed [14] for construction of a nonlinear transmission line fabricated with Schottky diodes on GaAs substrate. This CPW has several attractive features such as low loss, high wave velocity, and broad frequency bandwidth. Its propagation performance is characterized with respect to varied elevated heights [15] using the full-wave approach. The CPW is fabricated on silicon substrate for low-cost

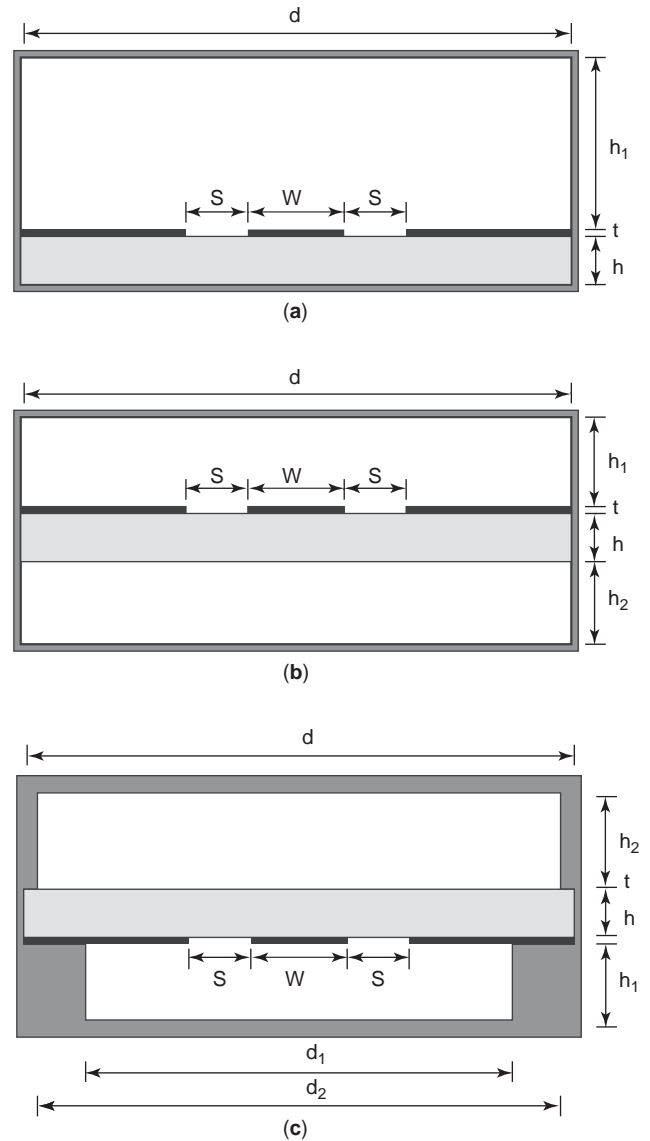

Figure 7. Cross-sectional view of enclosed CPW transmission lines: (a) shielded CPW; (b) suspended CPW; (c) suspended CPW with pedestal.

application in radiofrequency integrated circuits (RFICs). Due to high attenuation, the CPW is usually constructed by forming an insulated layer, such as low-loss polyimide [16] or SiO_2 [17], above the silicon substrate, as shown in Fig. 8b. The measured results show that attenuation can be reduced if the insulated layer is thick relative to the strip and slot widths [16]. Figure 8c shows the multilayered CBCPW with the upper metallic cover, and this CBCPW is one of two possible nonleaky CPW structures [18]. As demonstrated in the early literature, the presence of the backed conductor in the CBCPW causes unexpected power leakage into transverse directions in the form of a parallel-plate wave. As discussed by Liu et al. [18], this nonleaky CPW is established by forming an additional upper layer or insulated layer with higher permittivity above or below the strip/slot interface. Simulated results

Figure 8. Cross-sectional view of unbounded CPW transmission lines: (a) elevated CPW; (b) insulated CPW; (c) nonleaky CPW.

show that the dominant CPW mode is purely bound without leakage over certain frequency ranges as verified by experiment [18].

Microshield line originated with Dib et al. [19] as a new type of monolithic transmission line. Figure 9a shows its cross-sectional geometry, in which the ground plane is deformed to totally or partially surround the inner conductor. By using the membrane technology, the inner conductor can be suspended in air, thus eliminating dielectric loss even at high frequencies. This line may be considered as an enhancement of the CPW or microstrip-line structure. As compared with the conventional CPW investigated above, this microshield line may have several advantages, such as no requirement for via holes or airbridges for ground equalization, reduced radiation loss, reduced electromagnetic interference, and a wide impedance range [19]. Since then, various types of microshield lines have been developed and analyzed using the efficient static or accurate full-wave methods. The V-shaped microshield line with triangular cavity profile is illustrated in Fig. 9b. Using the conformal mapping technique under the static assumption [20], a set of closed-form expressions is derived for characterization of symmetric and asymmetric V-shaped lines. In addition, Figs. 9c and 9d show the microshield lines with upward- and downward-oriented trapezoidal shapes, respectively, which may be the practical shape in fabrication. Their performances are studied in [21] with respect to positive or negative sidewall slope [i.e., angle (ϕ)], implying that the effect of these nonvertical sidewalls can be minimized by keeping these sidewalls away from the slot edges.

The silicon micromachining technique has been developed to effectively remove the lossy dielectric material below, above, or around the coupled apertures in CPW in an effort to minimize propagation loss and reduce frequency dispersion. Figure 10a shows the micromachined CPW

Figure 9. Cross-sectional view of microshielded CPW transmission lines with various cavity profiles: (a) rectangular shape; (b) triangular shape; (c,d) trapezoidal shape.

[22], where the material underneath the coupled apertures is partially removed for construction of the free-space V-shaped grooves. This resulting line minimizes the total propagation loss since the EM fields are distributed mainly in the lossless V-shaped region and current density flow on the conductor is reduced. Figure 10b shows a practical microshielded membrane CPW that is fabricated by attaching two silicon wafers together [3,22]. The upper wafer, with a metallized cavity, supports a membrane with the CPW. Because of an extremely thin electric membrane, the overlapping capacitances between the top ground planes and cavity sidewalls are very large in the microwave region, thus virtually short-circuiting the overlapped region. The lower wafer is metallized on the top surface and provides the bottom wall of the cavity. Figure 10c shows a micromachined overlay CPW [23]. By partially elevating the edges of the central conductor and further overlaying them with the two outer ground planes, this CPW has a lower propagation loss because the current density is redistributed on the conductors and the impedance range widens.

In practice, the CPW is usually placed on a ground plane for mechanical support, inadvertently giving rise to

Figure 10. Cross-sectional view of silicon-based low-loss CPW transmission lines: (a) micromachined CPW with V-shaped groove; (b) microshielded membrane CPW; (c) micromachined overlay CPW; (d) Si-layer submounted CPW.

the conductor-backed CPW. In this CBCPW, the dominant CPW mode may be coupled to the parallel waveguide mode, which propagates transversally, causing the unwanted power leakage [24,25]. In addition, the substrate and side ground planes are always finitely widened, and this transversal leakage leads to substrate resonance and multiple-mode interference. In order to address this issue, the highly lossy silicon-doped substrate is inserted between the CPW and backed conductor as illustrated in Fig. 10d. This silicon submount layer operates as the absorbing layer to absorb this transversal leakage and eventually suppress the potentially harmful resonance. This suppression method is examined in numerical simulation and also verified by experimental characterization of the fabricated GaAs CBCPW [25]. Tien et al. [24] have shown that by laterally short-circuiting the side grounds with the lower ground, the electromagnetic field of the dominant CPW mode can be confined mostly within the surrounded conductor, thus alternatively suppressing this parasitic resonance.

4. COUPLED CPW

The traditional coupled CPW was originally presented [26] for design of directional couplers with improved isolation due to smaller difference between the even- and

Figure 11. Cross-sectional view of various coupled CPW transmission lines: (a) edge-coupled; (b) backed-conductor-coupled; (c) broadside-coupled; (d) parallel-coupled.

odd-mode propagation velocities. As shown in Fig. 11a, it is constructed by placing the two parallel strip conductors in close proximity. Due to strong interaction between these two conductors, the EM power is coupled from one line to the other, and the amount of coupling depends mainly on the distance of separation $2a$ and longitudinal length of the coupling section. Under the approximate assumption of infinitely thick substrate, the static conformal mapping technique is applied to characterize the two per unit length capacitances in conjunction with the even and odd dominant modes. As a result, the two sets of closed-form formulas can be derived to calculate the characteristic impedance values and effective dielectric constants. Because the substrate is always electrically finite, the even- and odd-mode transmission parameters of the coupled CPW in Fig. 11a with finite thickness are obtained using the same static technique as employed by Wen [26]. The relevant analytical formulas can be found in Ref. 27. In the even-mode case, the two transmission parameters, $\epsilon_{re,e}$ and $Z_{0,e}$, can be obtained

$$\epsilon_{re,e} = 1 + \frac{\epsilon_r - 1}{2} \frac{K(k_{e2})K'(k_{e1})}{K'(k_{e2})K(k_{e1})} \quad (9)$$

$$Z_{0,e} = \frac{60\pi}{\sqrt{\epsilon_{re,e}}} \frac{K'(k_{e1})}{K(k_{e1})} \quad (10)$$

where

$$k_{e1} = \sqrt{\frac{b^2 - a^2}{c^2 - a^2}} \quad (11a)$$

$$k_{e2} = \sqrt{\frac{\sinh^2(\pi b/2h) - \sinh^2(\pi a/2h)}{\sinh^2(\pi c/2h) - \sinh^2(\pi a/2h)}} \quad (11b)$$

In the odd-mode case, the two corresponding parameters, $\epsilon_{re,o}$ and $Z_{0,o}$, can be given as

$$\epsilon_{re,o} = 1 + \frac{\epsilon_r - 1}{2} \frac{K'(k_{o1})}{K(k_{o1})} \left(\frac{K(k_{o2})}{K'(k_{o2})} + \frac{K(k_{o3})}{K'(k_{o3})} \right) \quad (12)$$

$$Z_{0,o} = \frac{60\pi}{\sqrt{\epsilon_{re,o}}} \frac{K'(k_{o1})}{K(k_{o1})} \quad (13)$$

in which the three variables k_{o1} , k_{o2} and k_{o3} can be analytically expressed as a function of the incomplete elliptical integral of the first kind with respect to all transverse dimensions [27]. These formulas are effectively verified by Cheng [27] in comparison with the results from the full-wave method.

In fact, the traditional coupled CPW in Fig. 11a usually has weaker coupling due to edge coupling, thus resulting in a limited operating bandwidth. In order to tighten the coupling to a certain degree, an extra finite-extent backed conductor is formed on the opposite surface of a dielectric substrate underneath the coupled strip conductors [28], as shown in Fig. 11b. This backed conductor is strongly coupled with each upper strip conductor in a surface-to-surface format, thus increasing the degree of coupling between the two strip conductors. Figure 11c shows the cross-sectional view of a broadside-coupled CPW [29], in which the two CPW lines are formed at the upper and lower surfaces of a thin substrate. Under the assumed upper and lower shielding covers, the even- and odd-mode characteristics of this substrate are studied using the quasi-static technique. Numerical results [29] demonstrate a significant increase in the ratio of the two impedances, causing the coupling enhancement. However, as was the case in the CBCPW, the parallel-plate mode may be excited in such a broadside-coupled CPW to transversally propagate in the substrate between the two ground planes. This unexpected mode raises some problematic issues, such as power leakage, EM interference, and increased power loss. Thus, this broadside-coupled CPW should be constructed in a metallic enclosure that maintains electrical contact with all the ground planes. In addition, a triple-line-coupled CPW has been characterized by Cheng [30], and its cross-sectional geometry is drawn in Fig. 11d. By equalizing the electrical potential in the central strip with those in the two side ground planes, this arrangement can effectively suppress spurious coupling between the two CPW lines so as to avoid any signal distortion. Also, this triple line constitutes a basic block for the parallel-coupled bandpass filter. Its coupling performance is

investigated using static and full-wave approaches such as conformal mapping [30].

5. PERIODIC SLOW-WAVE CPW

An infinite-extended CPW structure, loaded with identical obstacles at each periodic interval, may be considered as an effective uniform CPW transmission line [31]. This periodic CPW exhibits two fundamental properties: passband-stopband selectivity and slow-wave propagation. The passband performance is basically realized by periodically interrupting the uniform CPW with series capacitive or shunt inductive elements, in which the periodicity is comparable to the guided-wavelength operation in the passband. However, because of the unexpected occurrence of multiple ripples within the passband, this periodic CPW has rarely been studied for practical design of CPW circuits. On the contrary, various periodic CPW transmission lines with slow-wave and bandstop behaviors [32–40], have generated increasing interest since the early 1980s. Regardless of the various configurations and different terminologies, to my best knowledge, this class of periodic CPW commonly has two distinct features for the dominant mode: slow-wave propagation at low frequencies and stopband attenuation in the midfrequency range.

In order to reduce the loss in uniform slow-wave CPW with metal-insulator-semiconductor (MIS) and Schottky contact configurations, a crosstie conductor grating with a periodic pattern [32] is embedded underneath the uniform CPW surface to make up the initial periodic slow-wave CPW transmission line, as shown in Fig. 12a. Then, a modified crosstie overlay slow-wave CPW [33] is constructed by swapping the crosstie conductor with the CPW layer, as illustrated in Fig. 12b. Observing the cross section of the crosstie conductor in Fig. 12a or 12b, we see that the capacitive coupling between the central strip conductor and the two outer ground planes are significantly increased, thus reducing the characteristic impedance at this section. Actually, this crosstie conductor grating can be equivalently treated as extra shunt capacitive elements that are periodically loaded on the uniform CPW without a crosstie layer [40]. Alternatively, a slow-wave CPW is formed on periodically doped semiconductor substrate. Its schematic is shown in Fig. 12c, and Wang and Itoh [34] have shown that it can reduce the attenuation. In Refs. 32–34, these periodic CPW lines are approximately characterized by the well-known Floquet theorem as well as the approximation that the effects of each junction discontinuity between two constituent sections with and without crossties are neglected [32–34]. After these two sections are analyzed using the two-dimensional (2D) numerical technique, two effective per unit length transmission parameters of these periodic CPW lines are derived to explicitly demonstrate the fundamental guided-wave characteristics, namely, slow wave at low frequencies and bandstop or band rejection at certain midfrequencies.

To satisfy the requirements in miniaturizing millimeter-wave integrated circuits (MMICs), in a novel class of periodic slow-wave CPW lines [35–38], the strip conductor and/or ground-plane configurations are irregularly

Figure 12. Schematic of traditional periodic slow-wave CPW transmission lines with (a) embedded crosstie grating; (b) overlaid crosstie grating; and (c) periodically doped substrate.

rearranged with periodically varied patterns. Figure 13a shows the periodic CPW with the central conductor in the form of a meanderline [35]. Because of an increased inductance per unit length, the slow-wave factor in the periodic CPW is at least twofold greater than that in the uniform CPW, resulting in a reduction in the longitudinal length. Figure 13b shows the shunt-capacitive-loaded slow-wave CPW [36] with interdigitated capacitors between the inner strip conductor and outer ground planes. Experimental study is performed to extract its complex propagation constant and characteristic impedance, thereby confirming the theoretically predicted slow-wave behaviors. By forming the periodic fingers in the two grounds and inserting them into the transversal slits of a central meander strip, a modified meanderline CPW [37] is constructed as illustrated in Fig. 13c. Its enhanced capacitance per unit lengths results in further lowering the velocity of propagation as exhibited in experiment. The work [38] describes the slow-wave CPW with periodic slots in the ground plane as shown in Fig. 13d. Since the uniform CPW is periodically loaded by these short-end slot-line stubs, the extra series inductance per unit length is increased so as to raise the slow-wave factor involved here. The calibration method in experiment has been utilized [38] to extract the velocity and characteristic impedance from the measured S parameters.

Figure 13. Top view of uniplanar slow-wave CPW transmission lines with series inductive and/or shunt inductive loading: (a) meanderline; (b) interdigitated capacitor; (c) modified meanderline; (d) periodically slotted ground.

The terms, *photonic* and *electromagnetic bandgap CPW*, introduced in 1999 [39], have again aroused significant interest in characterizing periodically loaded CPW transmission lines with nonuniform patterns on the backed conductor or CPW central strip/ground surface. In this aspect, the periodicity is selected to be electrically comparable to the CPW guided wavelength at high frequencies, thus inducing wave attenuation within a certain frequency range referred to as the *bandstop* [31], *band-reject* [33], or *bandgap* characteristic [39]. Extensive work has been undertaken in theory and experiment to characterize a large number of finite extended periodic CPW structures with varied unit configurations in terms of S parameters, thus illustrating the bandstop behavior of a two-port device [39]. Following the results in much of the

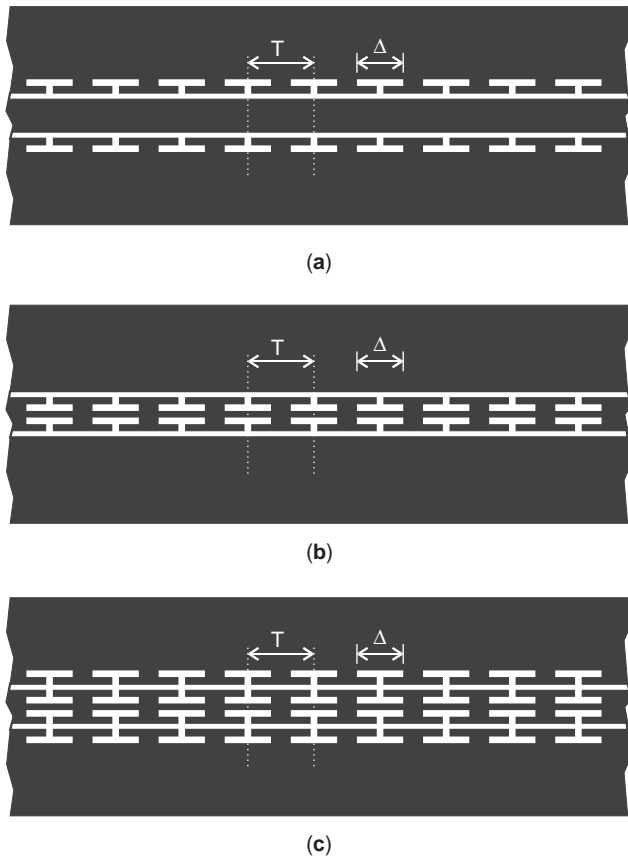

Figure 14. Top view of series inductively periodic CPW transmission lines with slow-wave and bandstop transmission behaviors: (a) T-slotted ground; (b) T-slotted strip; (c) T-slotted strip and ground.

early literature [31–38], one can deduce that the two per unit length transmission parameters are critically important in exposing the complete guided-wave characteristics of various periodic CPW transmission lines with infinite extension. Figure 14 illustrates the three modified periodic CPW transmission lines reported in Ref. 40, extended from the original structure described in Ref. 38. They are constructed by etching a pair of transverse slots on the ground planes and/or strip conductor so as to enhance the shunt inductive loading with low radiation loss.

With no hypothesis in theoretical modeling, the two per unit length transmission parameters of these infinite-extended periodic CPW lines [40] are directly extracted using the full-wave self-calibrated method of moments. Figure 15a plots the three relevant sets of extracted complex propagation constants (γ) normalized to the free-space wavenumber (k_0), specifically, $\gamma/k_0 = \alpha + j\beta$, where α and β are the attenuation and phase constants, respectively. Initially, the nonzero β/k_0 increases slowly and then rises rapidly while α/k_0 remains zero at low frequencies, regardless of the (varied) configurations. As the frequency further increases, β/k_0 begins to fall after peaking and α/k_0 appears, increasing and decreasing until it disappears again. These frequency ranges with nonzero α/k_0 are the so-called bandstop, band rejection, or bandgap for the guided wave propagating in these periodic CPW trans-

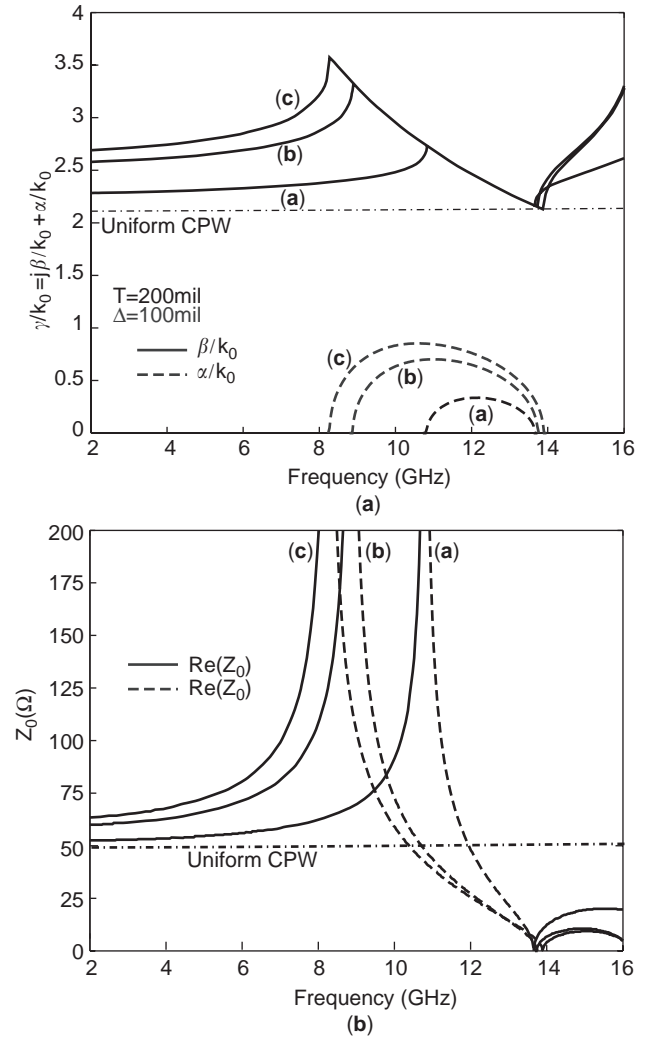

Figure 15. Per unit length transmission parameters of the three T-slotted periodic CPW transmission lines in Fig. 16: (a) complex propagation constant; (b) complex characteristic impedance.

mission lines. One of these lines, the periodic CPW (Fig. 15c) has the largest slow-wave factor at low frequencies and achieves the widest stop bandwidth because of inductive loading of paired slots on both inner and outer conductors. Figure 15b shows three sets of complex characteristic impedances, $Z_0 = \text{Re}(Z_0) + j \text{Im}(Z_0)$. In the lowpass frequency region, the real $\text{Re}(Z_0)$ tends to increase slowly and then exponentially rapidly to infinity, while the imaginary $\text{Im}(Z_0)$ remains zero. Then, $\text{Re}(Z_0)$ suddenly disappears and is converted to its infinity imaginary counterpart, $\text{Im}(Z_0)$, and this $\text{Im}(Z_0)$ drops off very quickly to zero. These nonzero $\text{Im}(Z_0)$ and zero $\text{Re}(Z_0)$ within the whole stopband provide an alternative physical view on the guided-wave bandstop behaviors of all the periodic slow-wave CPW transmission lines discussed here.

6. CONCLUSIONS

This article systematically describes the fundamental geometries and propagation characteristics of various

uniform CPW and periodic slow-wave CPW transmission lines. First, the three basic CPW lines with infinite or finite ground width and backed conductor are discussed, including detailed design formulas. Then, a variety of modified CPW lines, namely, shielded, suspended, and micromachined CPW, including their performance advantages such as low conductivity and low material and radiation losses, are briefly discussed. Next, four coupled CPW lines are roughly investigated in terms of relative coupling. Finally, several typical infinitely extended periodic CPW lines are characterized as an effective uniform CPW transmission line and their complete guided-wave performance, such as slow-wave propagation and stop-band attenuation, are demonstrated in terms of dispersive and complex propagation constants and characteristic impedance per unit length.

1. INTRODUCTION

Corrugated horns are microwave antennas commonly used as feeds for high-performance reflector antenna systems. Although rectangular corrugated horns have been successfully used, circular corrugated horns are used more frequently, and this type of radiation device is treated in detail in this article.

Corrugated horns are attractive as feeds as they possess several unique properties:

1. They have high beam symmetry and low sidelobes.
2. They show very low cross-polarization.
3. They exhibit high return loss over a quite broad band (30–40%).

Corrugated horn properties have been investigated since the 1950s, and the book by Clarricoats and Olver [1] gives an accurate analytical description of their electromagnetic features, introducing simple and powerful design tools, and thus so far is the major reference text on the subject of corrugated horn antennas.

These antennas are widely used in the field of radio astronomy, remote sensing, and telecommunications on both ground-based and satellite platforms, whenever simple and easy-to-fabricate solutions to efficiently feed reflector antennas are required.

More recently, research activity on corrugated horns has been devoted mainly to studying complex profiles for the corrugations. The effects of profiling the horns using an exponential taper are accurately described in Ref. 2, an exhaustive description of different methods for profiling the horn corrugations is given in Ref. 3, a profile specific for the electrical requirements typical of radio astronomy applications with reduced size and weight is shown in Ref. 4, and the effects of tuning the phase center position by shaping the exponential profile, without changing in practice other features such as beam size, sidelobe levels, return loss, and cross-polarization, have also been investigated [5].

This work is intended to give the reader a brief introduction to corrugated circular horns highlighting their electromagnetic features, analysis tools, and design aspects.

2. ELECTROMAGNETIC PROPERTIES OF CORRUGATED WAVEGUIDES

In this section we attempt to explain the theory of electromagnetic propagation in circular corrugated waveguides, with a short but thorough characterization of corrugated waveguides, highlighting their main aspects, as this knowledge is of great importance in understanding the features of corrugated horns.

Figure 1 shows a longitudinal section of a circular corrugated waveguide in a cylindrical coordinate system (O, ρ, φ, z) . The metallic corrugated boundary extends between an inner radius a and an outer radius b and is described in terms of a slot depth s , a slot width g , and a tooth width t , for a total longitudinal periodicity of period w . On the basis of this periodicity, the Floquet theorem ensures that if one knows the field within the period

$$[\mathbf{E}_{(p)}(\rho, \varphi, z), \mathbf{H}_{(p)}(\rho, \varphi, z)] \neq 0, \quad \text{for } z \in [0, w) \quad (1)$$

it is possible to obtain an arbitrary field configuration in the whole domain, $(0 \leq \rho < b, 0 \leq \varphi < 2\pi, -\infty < z < \infty)$, whose wave nature is characterized by means of a propagation constant β , as follows (propagation is assumed,

Figure 1. Corrugated waveguide geometry.

without loss of generality, in the +z-axis direction):

$$\begin{aligned} & [\mathbf{E}(\rho, \varphi, z), \mathbf{H}(\rho, \varphi, z)] \\ &= [\mathbf{E}_{(p)}(\rho, \varphi, z), \mathbf{H}_{(p)}(\rho, \varphi, z)]e^{-j\beta z} \end{aligned} \tag{2}$$

The periodical part of the field can be expanded in a Fourier series:

$$\begin{aligned} & [\mathbf{E}_{(p)}(\rho, \varphi, z), \mathbf{H}_{(p)}(\rho, \varphi, z)] \\ &= \sum_{n=0}^{\infty} [\mathbf{E}_n(\rho, \varphi), \mathbf{H}_n(\rho, \varphi)]e^{-j\beta_n z}, \end{aligned} \tag{3}$$

$$\beta_n = \frac{n\pi}{w}$$

From now on a series of assumptions will be performed largely to simplify the treatment. These assumptions are, however, justified as they relate to physical features of corrugated horns.

The first simplification is that the corrugation period is supposed to be very small compared to the wavelength, $w \ll \lambda$, so that in the Fourier spatial harmonic expansion (3) the term $n = 0$ is predominant and can be the only one considered. So the total field in the corrugated waveguide is reduced to the following:

$$\begin{aligned} & [\mathbf{E}(\rho, \varphi, z), \mathbf{H}(\rho, \varphi, z)] \\ &= [\mathbf{E}_0(\rho, \varphi), \mathbf{H}_0(\rho, \varphi)]e^{-j\beta z} \end{aligned} \tag{4}$$

The transverse function of the field representation in (4) $[\mathbf{E}_0(\rho, \varphi), \mathbf{H}_0(\rho, \varphi)]$ is assumed to be valid in the cylinder ($0 \leq \rho < a, 0 \leq \varphi < 2\pi$); the general form of the field solution is obtained by imposing the boundary condition in $\rho = a$. For the sake of simplicity, the subscript 0 will be omitted in the following equations. The solution appears to be similar to the one in the circular waveguide [6], but substantial differences emerge, especially for the eigenmode functions, due to the presence of the corrugations.

As in the more general case, such as, for example, optical fibers, in corrugated waveguides the boundary conditions at $\rho = a$ cannot be reduced to a perfect electric conductor or a perfect magnetic conductor; hence the field cannot be expanded in terms of only TE or only TM modes of a circular waveguide of radius a , but rather by a couple

of TE and TM modes. Such a combination can be seen as another couple of modes, which are called *hybrid modes*, each of which can propagate individually.

Thus, searching for the generic eigenmode solution, we proceed in a classical way [7] by considering the longitudinal components of the fields as scalar potentials; they have to satisfy the Helmholtz equation:

$$(\nabla_t^2 + k_t^2)[E_z(\rho, \varphi), H_z(\rho, \varphi)] = 0 \tag{5}$$

In this expression ∇_t^2 is a 2D operator on the variables (ρ, φ) and the transverse eigenvalue k_t is introduced; at this point it is unknown but must satisfy the relation

$$\left(\frac{2\pi}{\lambda}\right)^2 = k_0^2 = k_t^2 + \beta^2 \tag{6}$$

in which λ is the wavelength and k_0 is the free-space propagation factor; each eigenvalue will thus produce a different propagation constant β .

One should observe that the eigenvalue k_t in Eq. (5) is the same for both E_z and H_z , so that each mode of the associated pair TE and TM exhibits the same phase velocity and group velocity, hence producing a hybrid mode that is able to satisfy boundary conditions.

From a mathematical point of view, since the problem shows azimuthal symmetry, the solution to the Helmholtz equation (5) is the same as in a circular waveguide:

$$\left\{ \begin{aligned} E_z(\rho, \varphi) &= \sum_{m=0}^{\infty} J_m(k_t \rho) \\ [A_m \cos(m\varphi) + C_m \sin(m\varphi)] \\ H_z(\rho, \varphi) &= \sum_{m=0}^{\infty} J_m(k_t \rho) \\ \left[\frac{B_m}{Z_0} \sin(m\varphi) + \frac{D_m}{Z_0} \cos(m\varphi) \right] \end{aligned} \right. \tag{7}$$

where J_m is the m th-order first-kind Bessel function; A_m, B_m, C_m, D_m , are complex constants; and the characteristic impedance of the medium $Z_0 = \sqrt{\mu/\epsilon}$ is introduced, where μ is the magnetic permeability and ϵ is the electric permittivity of the medium. We must now point out the following observations:

- Equation (7) represents essentially the Fourier expansion of the potential in the azimuth coordinate φ for a given transverse eigenvalue k_t that has still to be determined by imposing boundary conditions.
- If a mode has no azimuth variation ($m = 0$), then it has a single polarization state, but, for each mode having $m > 0$, two linear polarizations exist and are associated to the two terms in the bracket on the right side of (7). Thus, given a generic mode with $m > 0$ (the eigenvalue k_t is also fixed), if $A_m = B_m = 0$, then one has one of the two possible field polarizations while if $C_m = D_m = 0$, one has the other one; the fields associated with each of these two polarization states are orthogonal, as can be easily seen by

computing the flux of the coupled Poynting vector $\mathbf{S} = \frac{1}{2} \mathbf{E}_{(A_m=B_m=0)} \times \mathbf{H}_{(C_m=D_m=0)}^*$ over an arbitrary circular section and verifying that it gives zero as result.

- Radial-type discontinuities excite modes having the same azimuth variation; thus the harmonic number m is preserved in a field propagating in a corrugated waveguide. We can also state that, in this kind of structure, there is no power transfer between fields characterized by a different harmonic number m .

Considering a corrugated waveguide excited by the circular waveguide TE₁₁ fundamental mode and choosing one of the two polarization states, a generic couple of hybrid mode potentials can be expressed as follows:

$$[E_z(\rho, \varphi), H_z(\rho, \varphi)] = J_1(k_t \rho) \left[A \cos(\varphi), \frac{B}{Z_0} \sin(\varphi) \right] \quad (8)$$

Before applying the boundary conditions, it is now useful to write the electromagnetic field generated by the potentials in (8), also expressing the z -variation terms:

$$\left\{ \begin{array}{l} E_z(\rho, \varphi, z) = A J_1(k_t \rho) \cos(\varphi) e^{-j\beta z} \\ H_z(\rho, \varphi, z) = \frac{B}{Z_0} J_1(k_t \rho) \sin(\varphi) e^{-j\beta z} \\ E_\varphi(\rho, \varphi, z) = j \frac{k_0}{k_t} \left[A \frac{\beta J_1(k_t \rho)}{k_0} + B J_1'(k_t \rho) \right] \sin(\varphi) e^{-j\beta z} \\ H_\varphi(\rho, \varphi, z) = -j \frac{k_0}{k_t Z_0} \left[A J_1'(k_t \rho) + B \frac{\beta J_1(k_t \rho)}{k_0} \right] \cos(\varphi) e^{-j\beta z} \\ E_\rho(\rho, \varphi, z) = -j \frac{k_0}{k_t} \left[A \frac{\beta J_1(k_t \rho)}{k_0} + B \frac{J_1(k_t \rho)}{k_t \rho} \right] \cos(\varphi) e^{-j\beta z} \\ H_\rho(\rho, \varphi, z) = -j \frac{k_0}{k_t Z_0} \left[A \frac{J_1(k_t \rho)}{k_t \rho} + B \frac{\beta J_1'(k_t \rho)}{k_0} \right] \sin(\varphi) e^{-j\beta z} \end{array} \right. \quad (9)$$

This set of expressions is a generic hybrid mode-field configuration with azimuth harmonic $m = 1$, in which the TM part ($A \neq 0, B = 0$) and the TE part ($A = 0, B \neq 0$) can be noted.

We now return to the particular problem under consideration here, namely, the corrugated waveguide geometry of Fig. 1. As already mentioned, in corrugated horns a small corrugation period, compared to the wavelength, is assumed; this fact allows us to further assume that inside the grooves of the corrugations ($a \leq \rho < b$) only a TEM wave propagating in the radial direction exists, with all higher-order modes in cutoff. In such a TEM wave (which is rigorously the exact solution in the asymptotic limit as the frequency and/or the radial co-ordinate approach infinity) all the field components are equal to zero except the z component of the electric field and the φ component of the magnetic field. Since the walls are perfect electric conductors, no power loss is present and the Poynting

vector in $\rho = a$ must be imaginary; hence

$$\frac{H_\varphi(a, \varphi)}{E_z(a, \varphi)} = -\frac{1}{jX_s} \quad (10)$$

where X_s assumes the meaning of a reactance.

The reactance of the total field at $\rho = a$ is given by two main contributions:

1. A contribution that holds for the portion of w of length g associated to the slot can be obtained by considering that the corrugation slot behaves like a transmission line of length s closed with a short circuit, thus having at the section $\rho = a$ a reactance value given by

$$X = Z_0 \tan(k_0 s) \quad (11)$$

2. A contribution that holds for the width t associated with the tooth is given by a short circuit at $\rho = a$, producing $X = 0$.

As a first approximation, the total reactance of the field at $\rho = a$ is given by considering both contributions according to their respective lengths of action. We can therefore apply the following boundary condition:

$$X_s = Z_0 \tan(k_0 s) \left(1 - \frac{t}{w} \right) \quad (12)$$

Thus, substituting (10) and (12) in the field representation (9) and also taking into account the following condition

$$E_\varphi(a, \varphi) = 0 \quad (13)$$

we obtain the following relations

$$\left\{ \begin{array}{l} \gamma = \frac{A}{B} = -\frac{k_0 u J_1'(u)}{\beta J_1(u)} \\ y \equiv -\frac{Z_0}{X_s} = \frac{k_0 J_1'(u)}{k_t J_1(u)} + \frac{\beta}{\gamma k_t u} \\ u \equiv k_t a \end{array} \right. \quad (14)$$

where γ is the hybrid factor, y represents the normalized susceptance, a new variable u is introduced, and $J_1'(u) = (d/du)J_1(u)$. Substituting these relations in (9), using some algebraic and trigonometric formulas, and neglecting the z dependence, a very interesting representation is found for the transverse component \mathbf{E}^t of the electric field, which is useful for analyzing the properties of corrugated waveguides:

$$\mathbf{E}^t(\rho, \varphi) = -j \frac{k_0 B}{k_t} \cdot \left\{ \left(\gamma \frac{\beta}{k_0} + 1 \right) J_0(k_t \rho) \hat{\mathbf{x}} + \left(1 - \gamma \frac{\beta}{k_0} \right) J_2(k_t \rho) [\cos(2\varphi) \hat{\mathbf{x}} + \sin(2\varphi) \hat{\mathbf{y}}] \right\} \quad (15)$$

Eliminating the hybrid factor γ in (14), the characteristic equation is obtained as follows:

$$\frac{y}{k_0 a} = \frac{J_1(u)}{u^3 J_1'(u)} \left[\left(u \frac{J_1'(u)}{J_1(u)} \right)^2 - \left(\frac{\beta}{k_0} \right)^2 \right] \quad (16)$$

Thus, solving this equation for the variable u , the eigenvalues k_t of the hybrid modes can be obtained. A detailed analysis of (16) is beyond the scope of this work; the reader is referred to the text by Clarricoats and Olver [1] for a more in-depth treatment of this topic. Here we are interested only in some cases of practical interest:

1. If we assume that the slot length s is a quarter-wavelength, then the normalized susceptance y is zero, and using the asymptotic limit $\beta \rightarrow k_0$, where the frequency is much greater than the cutoff frequency of the mode ($f \gg f_c$), we can approximate (16) by

$$\left(u \frac{J_1'(u)}{J_1(u)} \right)^2 - 1 = 0 \Rightarrow u \frac{J_1'(u)}{J_1(u)} = \pm 1 \quad (17)$$

2. In the same asymptotic limit $\beta \rightarrow k_0$, Eq. (17) is also obtained as an approximation of (16) independently from the slot length s , assuming that the radius a is large enough that the first side of (16) tends to zero.

These two cases are important in practice because in the region close to the throat (small a), corrugations are designed in order to satisfy condition 1, while condition 2 is satisfied in the region close to the aperture (large a).

Equation (17) can be easily solved using the recurrence formulas for Bessel functions

$$\begin{aligned} J_n(u) &= -J_{n-1}'(u) + \frac{(n-1)J_{n-1}(u)}{u} \\ &= J_{n+1}'(u) + \frac{(n+1)J_{n+1}(u)}{u} \end{aligned} \quad (18)$$

thus giving

$$\begin{cases} J_0(u) = 0 \\ J_2(u) = 0 \end{cases} \quad (19)$$

As can be noted from the first line of (14), in the asymptotic limit $\beta \rightarrow k_0$, the first line of (19) is equivalent to $\gamma = 1$ and the second, to $\gamma = -1$. The dual condition $\gamma = \pm 1$ is termed the *balanced hybrid condition*. If this condition is satisfied, the right side of (16) is always zero, thus producing a more general solution in the case in which the left side of (16) is zero.

In this particular case two sets of hybrid modes, *HE* and *EH*, corresponding to, respectively, $\gamma = 1$ and $\gamma = -1$, are simply given by analytical formulas.

The eigenvalues of these modes are

$$\begin{cases} HE_{1n} \Rightarrow k_t = k_{1n}^{HE} = \frac{u_{0n}}{a} \\ EH_{1n} \Rightarrow k_t = k_{1n}^{EH} = \frac{u_{2n}}{a} \end{cases} \quad (20)$$

where u_{0n} and u_{2n} are the well-known and tabulated zeros of the first-kind Bessel functions, the zero-order J_0 and the second-order J_2 , respectively.

Although these modes are approximated solutions of corrugated waveguides, in the sense explained above, they accurately describe wave propagation with the major advantage of a relatively simple analytical form.

Using solutions (20) in the electric field expression (15), with the asymptotic approximation $\beta \rightarrow k_0$, we obtain

- For the *EH*_{1n} modes ($\gamma = -1$) the transverse electric field is given by

$$\begin{aligned} \mathbf{E}_{1n}^t(\rho, \varphi) &\cong -j \frac{k_0 a}{u_{2n}} B J_2\left(\rho \frac{u_{2n}}{a}\right) \\ &[\cos(2\varphi)\hat{\mathbf{x}} + \sin(2\varphi)\hat{\mathbf{y}}] \end{aligned} \quad (21)$$

- For the *HE*_{1n} modes ($\gamma = 1$), we can use the following approximation for (16)

$$\begin{aligned} \frac{y}{k_0 a} &= \frac{1}{u^2} \frac{\beta}{k_0} \frac{1}{\gamma} (1 - \gamma^2) \\ &\cong \frac{2}{u^2} \left(1 - \gamma \frac{\beta}{k_0} \right) \\ &\Rightarrow \left(1 - \gamma \frac{\beta}{k_0} \right) = \frac{yu^2}{2k_0 a} \end{aligned} \quad (22)$$

thus leading to

$$\begin{aligned} \mathbf{E}_{1n}^t(\rho, \varphi) &\cong -j \frac{k_0 a}{u_{0n}} B \times \\ &\left\{ J_0\left(\frac{u_{0n}}{a} \rho\right) \hat{\mathbf{x}} + \frac{yu_{0n}^2}{4k_0 a} J_2\left(\frac{u_{0n}}{a} \rho\right) \right. \\ &[\cos(2\varphi)\hat{\mathbf{x}} + \sin(2\varphi)\hat{\mathbf{y}}] \left. \right\} \end{aligned} \quad (23)$$

While *EH* modes show undesired field configuration features, since there is no preferential direction for field polarization, as can be noted in the electric field configuration of the *EH*₁₁ mode of Fig. 2b, this is not the case for the *HE* modes. In fact, regarding the *HE*₁₁ fundamental hybrid mode, one should note that, in the case in which the first term inside the braces predominates over the second one, the field is essentially linearly polarized, as can be seen in Fig. 2a, and shows high azimuthal symmetry in amplitude. These features are of prime importance because they yield high beam symmetry and very low cross-polarization.

The second term inside the braces is highly undesired as it has the same negative polarization features as do *EH* modes. Its contribution should be as low as possible, and this may be achieved, as mentioned above, by keeping the susceptance y very small using quarter-wavelength slots.

Figure 2. Corrugated waveguide—electric field distribution of hybrid modes: (a) HE_{11} ; (b) EH_{11} .

3. RADIATION PROPERTIES OF CORRUGATED CONICAL HORNS

A very useful method for accurate analytical description of the radiation properties of corrugated horns is the Gaussian beam approach, using the Gauss–Laguerre expansion of the electromagnetic field [8]. Although this approach is valid in the paraxial beam approximation [9] (i.e., for narrow beams), it is a very good tool for fast analysis and design of all the corrugated horns of practical interest. It enables accurate description of the main lobe shape, up to approximately -20 dB relative to the maximum, and accurate prediction of the phase center position. As a drawback sidelobes are not characterized and there is only a lower bound limit estimate for the cross-polarization level. These features can be taken into account, together with flange effects and other second-order phenomena, by resorting to numerical methods, as described later.

Referring to Fig. 3, let's consider a corrugated horn of conical shape excited by a perfectly azimuth symmetric fundamental HE_{11} hybrid mode that is assumed to be polarized in the y -axis direction. Thus the electric field contribution due to J_0 in (23) gives the amplitude distribution at the horn aperture, where it is also possible to accurately estimate the phase distribution. Indeed, using the same approximation usually applied to common conical waveguides, the radius of curvature of the aperture phase distribution is assumed equal to the height L of the

Figure 3. Conical corrugated horn geometry.

ideal triangle formed by the corrugated wall envelope and the aperture diameter (Fig. 3), which is approximately the horn length. This results in the following analytical expression for the field:

$$\mathbf{E}_{1n}^t(\rho, \varphi) \cong A_0 J_0\left(\rho \frac{u_{01}}{R}\right) e^{-j(k_0 \rho^2/2L)} \hat{\mathbf{y}} \quad (24)$$

The constant A_0 may be given an explicit value if, on the horn aperture surface S , the following power normalization rule is adopted:

$$\iint_S \mathbf{E}_{1n}^t(\rho, \varphi) \cdot [\mathbf{E}_{1n}^t(\rho, \varphi)]^* dS = 1 \quad (25)$$

leading to

$$A_0 = \frac{1}{\sqrt{\pi R J_1(u_{01})}} \quad (26)$$

The successive step is to expand the field in the space of the Gauss–Laguerre complete set ($0 \leq \rho < \infty$) of orthonormalized functions:

$$\begin{aligned} & \left[\frac{J_0\left(\frac{u_{01}}{R} \rho\right)}{\sqrt{\pi R J_1(u_{01})}} \right] e^{-j(k_0 \rho^2/2L)} \\ &= \left[\sum_{n=0}^{\infty} a_n \sqrt{\frac{2}{\pi w}} L_n^0\left(\frac{2\rho^2}{w^2}\right) \cdot e^{-(\rho^2/w^2)} \right] e^{-j(k_0 \rho^2/2L)} \end{aligned} \quad (27)$$

where a_n are the expansion coefficients and L_n^0 is the Laguerre zero-order n th polynomial. Of particular interest is the zero term of the expansion

$$G(\rho) = a_0 \sqrt{\frac{2}{\pi w}} \cdot e^{-(\rho^2/w^2)} e^{-j(k_0 \rho^2/2L)} \quad (28)$$

which represents the normalized fundamental *Gaussian beam mode*.

Neglecting a detailed analysis of the Gaussian beam, which can be found in Ref. 10, it is important to highlight that, in the expansion (27), w is an arbitrary parameter that can be chosen according to different objectives, each corresponding to different expansions. The most convenient choice for our purposes is the one maximizing the a_0 coefficient; thus, by taking the fundamental Gaussian beam mode only, the horn aperture field is already nicely approximated. Then, the expression

$$0 \leq a_0 = 2\sqrt{2} \int_0^1 \left[\frac{J_0(u_{01}u)}{p J_1(u_{01})} \right] e^{-(u^2/p^2)} u du \leq 1 \quad (29)$$

in which $p = w/R$ and $u = \rho/R$, must be maximized with respect to p .

Figure 4 shows the a_0 coefficient as a function of p . It has a maximum at $p = 0.6435$, with $a_0 = 0.99$, corresponding to a power coupling between the HE_{11} mode and the Gaussian beam mode (28) of $\sim 98\%$.

Figure 4. Coupling between the HE_{11} mode and the Gaussian beam mode.

Once the best-coupled Gaussian beam has been completely determined on the aperture ($z = 0$), the electromagnetic field is known, in our case, on the infinite half-space $z > 0$, thanks to the Gaussian beam propagation formula:

$$G(\rho, z') = \frac{w_0}{w(z')} \cdot e^{-[\rho^2/w^2(z')]} e^{-j[k_0 \rho^2/2H(z')]} e^{-jk_0 z'} \quad (30)$$

where a new coordinate $z' = z + z_a$ is introduced for convenience (Fig. 3), where z_a gives the horn aperture position with respect to z' . The term w_0 , termed “beam waist,” is a fundamental parameter governing all features of the Gaussian beam according to what is demonstrated in the following points:

1. The function $w(z')$ determines the transverse size of the beam; for each z' it gives the radial coordinate ρ at which the field has a e^{-1} ratio with the on-axis maximum. This size has a minimum value that is exactly w_0 at $z' = 0$, and its general expression is given analytically by

$$w(z') = w_0 \sqrt{1 + \left(\frac{z'}{z_c}\right)^2} \quad (31)$$

where z_c , the confocal distance, may be interpreted as the limit between near-field and far-field regions and is given by

$$z_c = \frac{\pi w_0^2}{\lambda} \quad (32)$$

where λ is the wavelength. From (31) we can see that in (30), the amplitude factor

$$A(z') = \frac{w_0}{w(z')} \quad (33)$$

decreases with a $1/z'$ law for large on-axis distances from the waist.

2. The term $H(z')$ gives the radius of curvature of the wavefronts and is a function of the beam waist, through the confocal distance z_c , according to

$$H(z') = \left(z' + \frac{z_c^2}{z'}\right) \quad (34)$$

This equation gives very important insights on Gaussian beam behavior. The radius of curvature is infinite in two cases: (1) in the near-field region at $z' = 0$, which means that the field has a planar phase front exactly at the waist, which is on the horn axis, commonly located in the inner corrugated region of the horn; and (2) while approaching infinity as z' tends to infinity, meaning that, since this occurs in the far region, the field has a spherical phase front. It must, however, be noted that the radius of curvature tends to infinity as z' , implying that the far-field phase center of the Gaussian beam is the beam waist position $z' = 0$. An even more important fact is that Eq. (34) gives the radius of curvature of the beam at every distance from the waist, so that, to the extent that the Gaussian beam is a good approximation of the field radiated by a corrugated horn, the phase center position of the horn is known simply and accurately everywhere, including the near-field region, with dramatic simplification in the design task of the optics of reflector antenna systems fed by corrugated horns.

It is now possible to characterize both phase center position and radiation patterns of corrugated horns. By considering the phase center position, the problem is to determine the horn aperture abscissa z_a , where the field expansion is completely known as a consequence of having determined the waist $w(z_a) = pR$, with $p = 0.6435$, and the radius of curvature $H(z_a) = L$.

To do this, the following inverse formulas, obtained by manipulating (31) and (34), are useful:

$$\begin{aligned} w_0 &= \frac{pR}{\sqrt{1 + \left(\frac{\pi(pR)^2}{\lambda L}\right)^2}}; \\ z_a &= \frac{L}{1 + \left(\frac{\lambda}{\pi(pR)^2}\right)^2} \end{aligned} \quad (35)$$

The relations in (35) are very important because they give analytically both the far-field phase center position with respect to the horn aperture (z_a from the aperture toward the throat) and the waist w_0 , which governs, as mentioned above, the Gaussian beam propagation. Thus, the field radiated by the horn ($z' > z_a$) can be analytically evaluated everywhere.

As a consequence, we can also characterize the corrugated horn radiation pattern. To do this, we approximate, in the far field, the expression (30) as follows:

$$w(z') \cong w(z) \cong w_0 \frac{z}{z_c} \quad (36)$$

Remembering the confocal distance expression (32) and passing to a spherical coordinate system

$$z = r \cos(\vartheta); \quad \rho = r \sin(\vartheta) \quad (37)$$

it is possible to rewrite the field radiated by the aperture distribution (24) with the Gaussian beam approximation (28) as follows

$$|E(r, \vartheta)| \cong \alpha_0 \sqrt{\frac{2}{\pi}} \left(\frac{\pi w_0^2}{\lambda} \right) \frac{1}{r \cos(\vartheta)} e^{-\tan^2(\vartheta)(\pi w_0/\lambda)^2} \quad (38)$$

which is assumed to be valid for $r > 0$ and $0 \leq \vartheta < \pi/2$.

Moreover, it is possible to use the inverse formulas (35) to express the radiated field in terms of the geometric parameters R and L and expand the $\hat{\mathbf{y}}$ versor in spherical coordinates, neglecting the radial component. Proceeding in this way, we have a full characterization of the radiated field, including its polarization, and obtain the following expression

$$\mathbf{E}(r, \vartheta, \varphi) = \frac{\alpha_0}{r} \exp \left[-\tan^2(\vartheta) \frac{1}{\left(\frac{\lambda}{R} \right)^2 \frac{1}{(\pi \cdot p)^2} + p^2 \left(\frac{R}{L} \right)^2} \right] \left[\sin(\varphi) \hat{\mathbf{i}}_\vartheta + \frac{\cos(\varphi)}{\cos(\vartheta)} \hat{\mathbf{i}}_\varphi \right]. \quad (39)$$

where

$$\alpha_0 = a_0 \sqrt{\frac{2}{\pi}} \left(\frac{\pi w_0^2}{\lambda} \right) \quad (40)$$

Figure 5 shows the accuracy that can typically be achieved with the Gaussian beam approximation. The plot gives the $\varphi = 45^\circ$ plane radiation pattern of a corrugated horn obtained by a full-wave analysis, which is assumed to be the reference, and by its best-fit Gaussian beam. The cut

Figure 5. Corrugated horn radiation pattern at $\varphi = 45^\circ$: $L = 44\lambda$; $R = 3.4\lambda$.

chosen is representative of every φ cut, at least up to a level of approximately -35 dB, because of the high azimuthal symmetry of the horn. Thus we are led to the conclusion, which is more or less valid in general for standard corrugated horns, that the Gaussian beam approach gives high accuracy with respect to the beam pattern up to about -15 dB below the on-axis maximum.

4. DESIGN ASPECTS OF CORRUGATED HORNS

Thus far we have presented a quite general theory to help the reader understand the electromagnetic properties of corrugated horns. This knowledge is, however, sufficient only to a first step and rough design; for accurate design, further aspects are needed and are developed in the following paragraphs.

In particular, we intend to focus on arguments that constitute requirements for most applications. As seen above in (39), the mainbeam radiation is controlled by the aperture size and the horn length. A very important task is the design of the throat region because it controls primarily the input return loss and the proper excitation of the HE_{11} fundamental hybrid mode. Another important feature of corrugated horns is the cross-polarization, which is of importance mainly in modern dual-polarization applications. When the horn is used as a feed for a reflector, the phase center position must be accurately known; this, according to the Gaussian beam approximation, coincides in the far field with the waist position (35), while in near field it is given by the center of curvature of the phase front according to (34).

For a very accurate characterization of the properties mentioned above, numerical techniques are needed. A very accurate full-wave analysis method is presented below.

4.1. MainBeam Radiation of Corrugated Horns

As stated above, an accurate analytical characterization of the mainbeam pattern is given in (39). In practice, typical specifications related to the mainbeam are given in terms of *gain*, *edge taper*, or sometimes the *waist*, each of which may be used to determine the geometric parameters R and L of the horn.

When complex reflector arrangements are to be fed by a corrugated horn, the waist is typically given as a requirement because the design of the optics is efficiently done using the Gaussian beam approach.

If a waist w_0 is given, then the mainlobe can be determined. In particular, we can define the $1/e$ *half-beamwidth* as the angle at which the field intensity is $1/e$ down from the on-axis maximum. Neglecting the $\cos(\vartheta)$ term, from (38) we have the following approximation:

$$\vartheta_{1/e} = \tan^{-1} \left(\frac{\lambda}{\pi w_0} \right) \quad (41)$$

To obtain the geometric parameters of the horn, it is possible to proceed by fixing the phase shift on the horn

aperture

$$\beta = \frac{\pi R^2}{\lambda L} \tag{42}$$

to a maximum allowed value β_0 , where $\beta_0 = \pi/16$ is a practical choice.

Proceeding this way, it is possible to use the inverse formulas (35) to simply have

$$R = \frac{w_0}{p} \sqrt{1 + p^4 \beta_0^2};$$

$$L = \frac{\pi R^2}{\lambda \beta_0} \tag{43}$$

As already mentioned, the Gaussian model is valid in the paraxial beam approximation and, in practice, the wavelength can be regarded as the lower limit for the waist ($w_0 > \lambda$) in a design approach of this kind.

It is interesting to note that fixing the phase shift β is equivalent to fixing the wavelength-normalized radius R_λ and the half-flare angle α defined by

$$R_\lambda = \frac{R}{\lambda}; \quad \alpha = \tan^{-1} \left(\frac{R}{L} \right) \tag{44}$$

The *edge taper* is the level, relative to the on-axis maximum, at which the horn illuminates a certain elevation angle, usually individuated by the edge of the reflector that is fed directly.

For example, an edge taper of X dB at an angle ϑ_t may be necessary. This information may be used to directly obtain the waist by using (38), neglecting the $\cos(\vartheta)$ term again, yielding

$$10^{X/20} = e^{\tan^2(\vartheta_t)(\pi w_0/\lambda)^2} \tag{45}$$

leading to

$$w_0 = \frac{\lambda}{2.95\pi} \cdot \frac{\sqrt{X}}{\tan(\vartheta_t)} \tag{46}$$

Once the waist has been calculated, it is possible to proceed in the same way as in the previous case with the waist given directly.

In practice, because of the approximation in the Gaussian beam model, this method gives accurate results for edge taper levels X up to 20–25 dB and taper angles ϑ_t not greater than 30° .

If the gain is given as specification, an efficient way to proceed for simple, accurate, and fast design is as follows. First, it is more convenient to refer to the gain G_0 in the on-axis direction of the horn and, due to the high return loss and the low ohmic losses of corrugated horns, to approximate the gain with the

directivity D_0 :

$$G_0 \cong D_0 = 4\pi \frac{\text{power density in } \vartheta = 0}{\text{horn aperture outgoing power}} \tag{47}$$

$$= 4\pi \frac{U(\vartheta = 0)}{P_{\text{rad}}}$$

The power out from the aperture can be written as the flux of the real part of the Poynting vector:

$$P_{\text{rad}} = \frac{1}{2} \text{Re} \iint_S \mathbf{E} \times \mathbf{H}^* \cdot \hat{\mathbf{z}} dS$$

$$= \frac{1}{2} \text{Re}(Y_m) \iint_S |\mathbf{E}_t|^2 dS \tag{48}$$

where \mathbf{E}_t indicates the tangential component of the electric field, S is the horn aperture surface, and Y_m is the field admittance on the aperture. In the case of the hybrid HE_{11} fundamental mode, under the balanced hybrid condition (19), introducing the field impedance $Z_m = 1/Y_m$, we have $Z_m = \zeta$, the characteristic impedance of the medium.

The power density radiated in the free space on-axis direction is given by

$$U(\vartheta = 0) = \frac{r^2}{2\zeta} |\mathbf{E}_{\text{rad}}(\vartheta = 0)|^2 \tag{49}$$

The radiated electric field \mathbf{E}_{rad} in the far-field approximation (> 1) may be given as a function of the tangential electric field distribution \mathbf{E}_t on the horn aperture. This can be simply obtained by using the field expansion as a spectrum of plane waves, and this method is outlined in detail in Ref. 11.

Essentially, the far-field approximation can be obtained as the plane-wave spectrum

$$\mathbf{E}_{\text{rad}}(r, \vartheta, \varphi) = 2\pi j \frac{e^{-jk_0 r}}{r} k_0 \cos(\vartheta) \hat{\mathbf{E}}(\xi, \eta) \tag{50}$$

asymptotically evaluated at the stationary point $\xi = \sin(\vartheta) \cos(\varphi)$, $\eta = \sin(\vartheta) \sin(\varphi)$, where the spectrum is the 2D Fourier transform of the tangential electric field \mathbf{E}_t on the aperture:

$$\hat{\mathbf{E}}(u, v) = \frac{1}{(2\pi)^2} \iint_S \mathbf{E}_t(x, y) e^{-jux} e^{-jvy} dx dy \tag{51}$$

In the on-axis direction $\vartheta = 0$, we have

$$\hat{\mathbf{E}}(0, 0) = \frac{1}{(2\pi)^2} \iint_S \mathbf{E}_t dS \tag{52}$$

$$\mathbf{E}_{\text{rad}}(r, \vartheta = 0, \varphi) = j \frac{1}{\lambda} \frac{e^{-jk_0 r}}{r} \iint_S \mathbf{E}_t dS \tag{53}$$

$$U(\vartheta = 0) = \frac{1}{2\zeta} \frac{1}{\lambda^2} \left| \iint_S \mathbf{E}_t dS \right|^2 \tag{54}$$

Obviously, the traditional approach based on the auxiliary potential formulation according to the theory developed in Ref. 12 can be used, leading to the same results. It is thus possible to rewrite the on-axis gain expression (47) as a function of the tangential electric field distribution \mathbf{E}_t on the horn aperture alone

$$G_0 = \frac{4\pi}{\lambda^2} \frac{\left| \iint_S \mathbf{E}_t dS \right|^2}{Z_m \iint_S |\mathbf{E}_t|^2 dS} \quad (55)$$

where, in our case, $Z_m = \zeta$, as already stated.

We can use the *effective area* concept, in this case given by

$$A_e = \frac{\left| \iint_S \mathbf{E}_t dS \right|^2}{\iint_S |\mathbf{E}_t|^2 dS} \quad (56)$$

for

$$G_0 = 4\pi^2 R_\lambda^2 \eta_A \quad (57)$$

where the aperture radius normalized to the wavelength R_λ is as defined in (44) and $\eta_A = A_e/A$ is the *aperture efficiency*, where $A = \pi R^2$ is the geometric area of the aperture. The aperture efficiency, which is a measure of how much of the aperture is effectively used, can be expressed in a more useful way by using (24) (omitting the amplitude $A_0 = 1$)

$$\iint_S |\mathbf{E}_t|^2 dS = 2\pi \int_0^R J_0^2\left(u_{01} \frac{\rho}{R}\right) \rho d\rho \quad (58)$$

$$= \pi R^2 J_1^2(u_{01})$$

$$\left| \iint_S \mathbf{E}_t dS \right|^2 = 4\pi^2 R^4 \quad (59)$$

$$\left| \int_0^1 J_0(u_{01}x) e^{-j(\pi R_\lambda \tan(\alpha))x^2} x dx \right|^2$$

where we use the relation $\tan(\alpha) = R/L$.

Thus we obtain a useful aperture efficiency expression as a function only of the geometric parameters R and L :

$$\eta_A = \frac{4}{J_1^2(u_{01})} \left| \int_0^1 J_0(u_{01}x) e^{-j(\pi R_\lambda \tan(\alpha))x^2} x dx \right|^2 \quad (60)$$

This function is plotted against the parameter $R_\lambda \tan(\alpha)$ in Fig. 6. We observe that it has a maximum $\eta_A = 0.69$ in the origin, corresponding to the case of a corrugated waveguide with a null half-flare angle α . It has to be noticed that, in order to have the same efficiency, if we enlarge the aperture radius R , the horn length also has to be increased so that $R_\lambda \tan(\alpha)$ remains constant.

Figure 6. Corrugated feed horn aperture efficiency.

Concluding, according to (57) and (60), it is possible to express the on-axis gain as a function only of the geometric parameters R and L , which is the desired form, analogously to the other cases of the waist and edge taper specifications, in order to design corrugated horns. Together with the curve in Fig. 6, another useful design chart is given in Fig. 7, where parametric curves based on the on-axis gain expression (57), with the aperture efficiency given by (60), are plotted against R_λ , with the flare angle α used as a parameter. Given a particular on-axis gain specification, it is thus possible, both analytically and graphically, to obtain the most convenient solution in terms of R and L .

4.2. Design of the Throat Transition Region

The initial part of the corrugated horn, the throat region, is of primary importance because it directly determines the input matching and the excitation of the HE_{11} fundamental hybrid mode.

Because circular waveguides are the most convenient solutions to feed corrugated horns, the design of the throat is not straightforward. As mentioned previously, the ideal condition to support the propagation of the HE_{11} mode is that the widths of both the tooth and the slot be much smaller than the wavelength and that the slot depth be a quarter-wavelength. This latter condition would produce very poor input matching if applied directly to the initial corrugations connected to the circular waveguide. This is because a perfect magnetic wall results at a quarter-wavelength distance (the slot depth) from the metallic enclosure, constituting, with respect to the wave coming from the circular waveguide, an equivalent open circuit as a boundary condition at $\rho = a$. This produces abrupt discontinuities at the boundary, which presents, alternately, short circuits (tooth sections) and open circuits (groove sections) within a small fraction of the wavelength. This is the required boundary condition for the desired HE_{11} mode but is incompatible with the fundamental TE_{11} mode of the feeding circular guide; hence high reflection coefficients would be present.

Figure 7. Corrugated horn gain versus aperture radius and half-flare angle.

The solution is a transition region where the corrugations begins with approximately half-wavelength slot depths and with the teeth thicker than the slots; the steady-state geometry is gradually reached with a few corrugations. Proceeding this way, two important objectives are obtained:

1. The equivalent boundary conditions for a half-wavelength-depth slot is a short circuit at $\rho = a$, and hence there is no abrupt discontinuity, with a gradual variation giving a good input matching.
2. A half-wavelength slot also ensures the proper propagating condition for the circular waveguide TM_{11} mode, thus producing an adequate condition to excite the hybrid HE_{11} mode of the corrugated waveguide (formed by the TM_{11} and TE_{11} modes).

This type of solution is given in Fig. 8, where typical values for the transition region geometry are explicitly given. In practice transition regions may be formed by 10–20 corrugations.

Problems associated with the design of the transition region have been encountered in the literature. Only an intuitive explanation of the proposed solution has been

Figure 8. Corrugated horn throat: transition region typical geometry.

given here; a very detailed theoretical approach on this can be found, for example, in Ref. 13.

4.3. Cross-Polarization

A large part of modern applications is based on dual-polarization channels, where two channels exist at the same frequency in the same medium (free space or waveguide). This means that the transmitter and receiver subsystems, carrying the dual-polarized signal, need to keep the two polarizations separate, introducing negligible coupling between them.

Thus, a related figure of merit here is the extent to which the two polarizations may be kept uncoupled. With respect to corrugated horns, this parameter is given by the cross-polarization level and, instead of the ordinary ϑ and φ components of the radiated field, in these applications a more useful characterization is given in terms of copolar (CP) and cross-polar (XP) components.

According to the Ludwig definition [14], a Huygens source, (one electric and one magnetic elementary dipole, mutually orthogonal, in phase and whose amplitudes are in a ratio equal to the characteristic impedance of the medium) radiates a pure copolar field with null *cross-polarization*. Thus this source is taken as a reference, and the CP or XP pattern of any antenna is defined by projecting the antenna’s radiated field on the fields generated by two mutually orthogonal Huygens sources. The Huygens source reference for the copolar field is oriented so as to produce an electric field that is parallel to the one generated by the antenna in the far field and in the direction of maximum radiation. According to this definition, it is possible to demonstrate that, given the spherical coordinate components $E_\vartheta(\vartheta, \varphi)$, $E_\varphi(\vartheta, \varphi)$ of the radiated field, the copolar (E_{CP}) and cross-polar (E_{XP}) components are given by

$$\begin{bmatrix} E_{CP}(\vartheta, \varphi) \\ E_{XP}(\vartheta, \varphi) \end{bmatrix} = \underline{\underline{M}}(\varphi) \begin{bmatrix} E_\vartheta(\vartheta, \varphi) \\ E_\varphi(\vartheta, \varphi) \end{bmatrix} \quad (61)$$

where the conversion matrix $\underline{\underline{M}}(\varphi)$ depends on the direction of the far-region electric field vector; in the case of an y -directed or x -directed electric field, we have, respectively

$$\begin{aligned} \underline{\underline{M}}(\varphi) = \underline{\underline{M}}^y(\varphi) &= \begin{bmatrix} \sin(\varphi) & \cos(\varphi) \\ \cos(\varphi) & -\sin(\varphi) \end{bmatrix}, \\ \underline{\underline{M}}(\varphi) = \underline{\underline{M}}^x(\varphi) &= \begin{bmatrix} \cos(\varphi) & -\sin(\varphi) \\ \sin(\varphi) & \cos(\varphi) \end{bmatrix} \end{aligned} \quad (62)$$

As in a more general case of azimuth-symmetric feed, for a corrugated horn producing a field with a first-order harmonic variation in the azimuth coordinate ($m = 1$), the radiated field may be obtained once the E -plane and H -plane cut patterns, respectively $C_E(\vartheta)$ and $C_H(\vartheta)$, are given.

For example, in the case of an antenna radiating an y -polarized far-region electric field, the following relation

can be verified:

$$\begin{aligned} E_{\vartheta}(\vartheta, \varphi) &= C_E(\vartheta) \sin(\varphi); \\ E_{\varphi}(\vartheta, \varphi) &= C_H(\vartheta) \cos(\varphi) \end{aligned} \tag{63}$$

Combining these relations with (61), using the first row of (62), the following results are obtained

$$\begin{cases} E_{CP}(\vartheta, \varphi) = C_E(\vartheta) \sin^2(\varphi) + C_H(\vartheta) \cos^2(\varphi) \\ E_{XP}(\vartheta, \varphi) = [C_E(\vartheta) - C_H(\vartheta)] \sin(\varphi) \cos(\varphi) \\ = \frac{1}{2} [C_E(\vartheta) - C_H(\vartheta)] \sin(2\varphi) \end{cases} \tag{64}$$

and the same expression can be verified analogous [$C_E(\vartheta)$ and $C_H(\vartheta)$ are exchanged in the first expression] in the case of an x -axis polarization. From (64) it should be noted that, in general, the cross-polar component of the field has a maximum in the 45° plane cut.

Usually the level of cross-polarization is given as a level with respect to the maximum of the copolar; if we assume the copolar maximum in the direction $\vartheta = 0$, we can give the cross-polarization pattern, in decibels, as

$$XP(\vartheta) = 10 \log_{10} \frac{\frac{1}{4}|C_E(\vartheta) - C_H(\vartheta)|^2}{|C_E(\vartheta=0)|^2} \tag{65}$$

and the cross-polarization maximum can be found by searching for the maximum of this expression for all the allowed values of ϑ :

$$XP_{\max} = \max_{\vartheta \in (0, 180^\circ)} \left\{ 10 \log_{10} \frac{\frac{1}{4}|C_E(\vartheta) - C_H(\vartheta)|^2}{|C_E(\vartheta=0)|^2} \right\} \tag{66}$$

To obtain the cross-polarization characterization of corrugated horns, we can use the field expression (39).

Proceeding this way, we have the cross-polar features of the perfectly balanced hybrid HE_{11} mode that radiates unperturbed, according to the Gaussian beam model, thus neglecting contributions to cross-polarization coming from the nonideality of the fundamental mode itself, higher-order modes and flange effects.

From (39), we can readily find that

$$\begin{aligned} C_E(\vartheta) &= \exp \left[-\tan^2(\vartheta) \frac{1}{\left(\frac{1}{R_\lambda}\right)^2 \frac{1}{(\pi p)^2} + p^2 \tan^2(\alpha)} \right]; \\ C_H(\vartheta) &= \frac{C_E(\vartheta)}{\cos(\vartheta)} \end{aligned} \tag{67}$$

where $p = 0.6435$ and the wavelength-normalized aperture radius R_λ and the half-flare angle α are as already defined in (44), giving the following expression for the

cross-polarization pattern:

$$XP(\vartheta) = 10 \log_{10} \left\{ \frac{\left| 1 - \frac{1}{\cos(\vartheta)} \right|^2}{4} \exp \left[-\tan^2(\vartheta) \frac{2}{\left(\frac{1}{R_\lambda}\right)^2 \frac{1}{(\pi p)^2} + p^2 \tan^2(\alpha)} \right] \right\}. \tag{68}$$

This expression is plotted in Fig. 9, with R_λ as a parameter, for a corrugated waveguide ($\alpha = 0$).

Curves related to the maximum of cross-polarization are given in Fig. 10 as a function of R_λ , with α as a parameter.

Results shown in Figs. 9 and 10, even if obtained from an approximate theory, provide an important insight into the behavior of the cross-polar field of a corrugated horn, also giving the optimum limit for achievable cross-polarization performances. As we can see from both plots, the cross-polarization is only very slightly affected by R_λ and α , which, on the contrary, significantly influence the mainbeam pattern.

In fact, the geometry of the corrugations is of prime importance in maintaining the cross-polarization down at the levels given in Figs. 9 and 10. The corrugations must give the appropriate boundary conditions for propagation of the HE_{11} mode. As already stated regarding the transition region, typical optimum values, coming from a mix between theory and experimental data, are those given in the right side of Fig. 8, which are practically used for the steady-state corrugation geometry from the end of the transition region to the radiating aperture, consisting of a 0.25λ slot depth, a 0.1λ tooth width, and a 0.2λ slot width. These values, in practice, guarantee a cross-polarization level better than ~ 35 dB down the co-polar maximum, for bandwidth of about 30–40%.

Figure 9. Corrugated waveguide cross-polar pattern for different values of the wavelength normalized aperture radius.

Figure 10. Cross-polarization maximum parametric curves for corrugated horns.

4.4. Phase Center

The *phase center* is theoretically defined as the origin in space of the spherical phase fronts of the radiated field. In general, for practical antennas, the definition holds only approximately, but corrugated horns are radiating structures for which a rather well-defined phase center exists.

In the Gaussian beam model, as we have seen, it is possible to predict the phase center position in both the near and far regions, by using (34) and (35). However, it is sometimes important to estimate a more accurate phase center position as a function of the radiating pattern. In particular, in the design of a corrugated horn, it is important to minimize the phase shift of the radiated field on a given spherical surface subregion (e.g., as delimited by the edges of the illuminated reflector). Thus the center of curvature of the phase-shift-minimized wavefront on that surface can be defined as the operative phase center of the antenna. Knowledge of this point is important in optimizing the position of a feed in a system of reflectors, to produce the best optical design.

Computation of the phase center, given the radiated phase pattern, can be carried out in different ways leading to different degrees of approximation in the evaluation. The one here shown is based on the minimization of a given phase pattern in the far-field region.

To better explain this method, we refer to Fig. 11, showing the geometry of a horn feeding a reflector antenna. The aim is to minimize the phase variation of the radiated far field inside the solid angle delimited by the elevation angle ϑ_0 (for sake of simplicity, a symmetric configuration is assumed), which is generally not necessarily associated with the reflector edges. Let's suppose that O and O' are two points separated by a distance d on the axis of the horn (where, by symmetry, the phase center is located); it can be shown that, in the far-field approximation, the phase patterns having the above mentioned points as phase reference are related by

$$\phi_{O'}^{P(\vartheta,\varphi)}(d) = \phi_O^{P(\vartheta,\varphi)} - k_0 d \cos(\vartheta) \quad (69)$$

Figure 11. Reference geometry for phase center numerical evaluation.

in which $\phi_C^{P(\vartheta,\varphi)}$ is the phase at the observation point P with respect to the generic point C and k_0 is the wave-number. The right hand side of (69) can be seen as a function of the variable d ; thus the computation of the phase center can be mathematically formulated as the minimization of the function

$$f(d) = \sum_i \sum_j W_{ij} |\phi_{O'}^{P(\vartheta_i,\varphi_j)}(d) - \phi_O^{P(\vartheta=0)}(d)|^n \quad (70)$$

in which the absolute value of the phase shift, eventually powered to an arbitrary value n , is suitably weighted by W_{ij} coefficients, with the double summation extended over the samples (ϑ_i, φ_j) of the angular region of interest.

4.5. Profiled Horns

As stated in the introduction (Section 1), corrugated horns possessing profiles of corrugations consisting of complex curves have been studied extensively.

The effect of the curved profile is to excite an appropriate higher-order set of modes to add degrees of freedom with respect to standard linear profiled horns. These additional parameters can be used to control electrical requirements (the radiation pattern and the phase center location) or mechanical requirements (space occupation and weight reduction). In fact, using higher-order modes, it is possible to modify the standard corrugated horn aperture field in order to obtain a radiated mainbeam a bit closer to a rectangle, which is the optimum shape when feeding reflector antenna systems because both aperture and spillover efficiency are maximized. The same approach is also valid if low sidelobe levels are required, and in this case an exponential taper ending section is most appropriate to excite the correct set of higher-order modes; the longer is the exponential section, the lower is the sidelobe level. The property of exciting higher-order modes by varying the profile can be also used to satisfy requirements on the horn mainbeam and at the same time to reduce as much as possible the horn dimensions, which is an attractive feature especially in spacecraft applications. A further advantage of adopting curved profiles is

the possibility of controlling the phase center position and its stability versus frequency; for example, if the profile is quite flat in the region near the radiating aperture, resembling an open corrugated waveguide, the phase center is very close to the aperture itself, and is also very stable with respect to frequency. Thus phase center position and stability can be controlled by properly designing the slope and the shape of the end part of the profile. When dealing with optical systems, especially in those applications in which feed clusters are required, this feature gives some degree of freedom to the design of the geometric configuration of the feeds, which can be very critical because of mutual coupling, for example.

Typically, the design of profiled horns begins with the design of a standard linear horn, matching as closely as possible the specifications. Then, using numerical techniques performing the electromagnetic analysis and the optimization, the design is refined to fully satisfy all the requirements.

Here we discuss in analytical detail the so-called dual profile [5]. As shown in Fig. 12, it is formed by two elementary curves, the sine square r_s at the beginning and the exponential r_e at the end, according to the following rule

$$r_s(z) = R_i + (R_s - R_i) \left[(1 - A_s) \frac{z}{L_s} + A_s \sin^2 \left(\frac{\pi z}{2L_s} \right) \right], \quad 0 \leq z \leq L_s \quad (71)$$

$$\begin{aligned} r_e(z) &= R_s + e^{\alpha(z-L_s)} - 1, \\ L_s \leq z &\leq L_e + L_s, \\ \alpha &= \frac{1}{L_e} \ln(1 + R - R_s) \end{aligned} \quad (72)$$

where $0 \leq A_s \leq 1$ modulates the first region profile between a straight line and a pure sine square.

The principal effect of the sine square profile is the shaping of the mainlobe by properly exciting higher-order modes, while the exponential taper controls mainly the phase center position and the sidelobe levels.

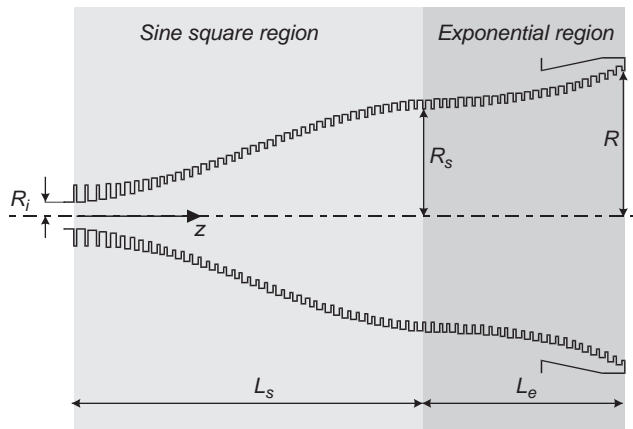

Figure 12. Dual-profile corrugated horn.

A more flexible version for the shaping of the horn corrugation profile can be obtained by using parametric curves. Among these the nonuniform rational B-splines (NURBS) are particularly versatile [15]. NURBS curves are generated by an ordered set of points $\{P_i\}$, $i=0, \dots, n$, defining the control polygon, through a function expressed as a ratio of vector-valued polynomials

$$\mathbf{P}(u) = \frac{\sum_{i=0}^n q_i \mathbf{P}_i N_{i,p}(u)}{\sum_{i=0}^n q_i N_{i,p}(u)} \quad (73)$$

where q_i are an assigned set of weights and $N_{i,p}(u)$ are the normalized B-spline basis functions of degree p . Design methods based on NURBS have already been successfully used [16], and a typical corrugated horn NURBS profile is shown in Fig. 13, where the upper part of the horn longitudinal cut is given and the control polygon is highlighted.

4.6. Numerical Techniques for Corrugated Horns

Thus far theoretical aspects of corrugated horns have been discussed on the basis of simple models. Formulas and graphs derived in this way are very useful in the design and, in general, are also sufficient if requirements are not too stringent. This is seldom the case in many modern applications, where high levels of accuracy are required in the design phase. Taking advantage of the computational power of modern computers, numerical techniques for the analysis of electromagnetic problems are now used successfully in microwave applications as a refinement of the simple design approach described above.

Regarding the analysis of circular corrugated horns, a hybrid numerical technique is the most efficient, using a combination of different methods according to their ability to accurately analyze different regions. This technique is presented in Ref. 17 and is based on the mode-matching method (MM) [18] and the method of moments (MoM) [19]. The internal part of the horn is best analyzed with MM

Figure 13. NURBS-profile corrugated horn.

making use of the generalized scattering matrix (GSM) concept. The horn can be seen as a cascade of single-step discontinuities in circular waveguide for which the MM method allows computation of the GSM. The overall horn geometry is analyzed by respectively cascading all the GSMs of the steps to find the overall GSM of the corrugated structure. MM is convenient for these structures because of its efficiency and small storage demand. In fact, whenever a new step is solved, it is immediately cascaded with the following step to form a partial GSM that includes all the steps solved thus far.

In the corrugated horn analysis only a particular subset of modes may be chosen. In the case of a circular waveguide TE_{11} excitation, the subset of TE_{1n}/TM_{1n} modes is sufficient to fully represent the field inside the horn if the azimuth symmetry is preserved everywhere. The rule for choosing the number N of modes in a single circular waveguide section for accurate numerical results and computation efficiency depends on the wavelength-normalized radius of the waveguide; typically, this is about $N=20R/\lambda$. The outer part of the horn, including the radiating aperture and the external metallization, is analyzed with the application of MoM to a combined field integral equation (CFIE). Formulating an equivalent problem in which the horn aperture and the external feed shape form a closed metallic surface, the CFIE enforces the boundary conditions for both the electric and magnetic fields. The axial symmetry of the structure is used to apply the body of revolution (BoR) formulation [20] to the MoM, so that an efficient expansion for electromagnetic sources and fields is possible. In particular, a subsectional basis function expansion is applied only along the generating curve of the BoR surface, while expansion in entire domain harmonic-type basis functions is used along the azimuth angle. In this way, CFIE may be solved easily for an unknown set of amplitudes of the basis functions used to expand electric surface current density on the external horn surface.

Finally, to complete the analysis, the coupling between the inner and the outer parts of the horn must be taken into account. This is done by applying the tangential field continuity over the horn aperture leading to a magnetic field integral equation (MFIE), which is solved by MoM.

Combination of MM and MoM allows us to compute the GSM of the horn in the presence of the actual outer feed shape. This also enables us, given the excitation, to estimate the input matching and calculate the external horn surface equivalent sources, allowing an easy computation of the radiated fields by means of the well-known free-space Green function. In conjunction with analysis techniques, numerical optimization procedures have been developed to produce complete tools for corrugated horn design.

Optimization techniques search for the optimum geometry satisfying a given set of specifications. Typically a cost is defined as a function of a particular set of electromagnetic performances so that the optimum solution is an extreme point of the cost function (a minimum or a maximum). Then the optimization procedure searches in the space of the allowed geometry parameters of the structure to be optimized to find this extreme point.

The existing used methods to search for the optimum geometry may be grouped into two categories: deterministic and stochastic.

A commonly used deterministic technique is the quasi-Newton method [21], while genetic algorithms [22] are an example of the stochastic type. The quasi-Newton method searching for the optimum value is governed mathematically by computing the differentiation, up to the second order, of the cost function. This is an iterative procedure where, at each computation step, the higher-order derivative information is used to directly evaluate the next point, in the space of the geometry to be optimized. Such a point is a potential candidate to be the optimum. This is quite a fast optimization method, performing very well if the iteration starting point is already within the basin of attraction of the optimum point itself; otherwise, as is well known, it remains confined to the nearest local minima.

Genetic algorithms are an evolutionary method producing successive populations of individuals according to their capabilities to adapt themselves to the environment. This capability is expressed in terms of a cost function, where individuals represent the codification of the space of the allowed geometric parameters. Individuals with higher capabilities (better cost functions) have a greater probability of reproducing themselves in successive generations (new sets of geometric parameters). In the genetic algorithm scheme, each successive generation is produced with genetic laws of crossover and mutation, yielding individuals that may have better capabilities, that is better cost functions.

From a practical point of view, genetic algorithms, like other stochastic methods, have complementary features with respect to direct searching techniques. They are generally more CPU-demanding and slower, but have the advantage of performing global searches for the optimum point without being trapped in local minima. A hybrid method based on genetic algorithms and the Quasi-Newton method has been successfully applied to corrugated horn design [23].

Artificial neural networks [24] (ANNs) are another useful approach for corrugated horn design. ANNs can be considered as universal approximators with the ability to model any given transfer function if properly instructed. On the basis of a given set of data related to horn geometry and performance, the network is able to "learn" how the horn operates. This learning process matures, generating an evolving model of the horn that may be perceived as a blackbox having geometric parameters such as input and electromagnetic performance such as output. The accuracy of the ANN model is refined by using the information coming from a cost function evaluating the distance, in terms of the performances, between the model and the real horn. The major advantage of this method is that, once the learning phase has produced, an accurate ANN model, the ANN-based horn analysis, is very fast, and thus is of prime interest in the horn design phase, where a very large number of simulations are commonly required. Examples of ANN applications to horn design can be found in Ref. 25.

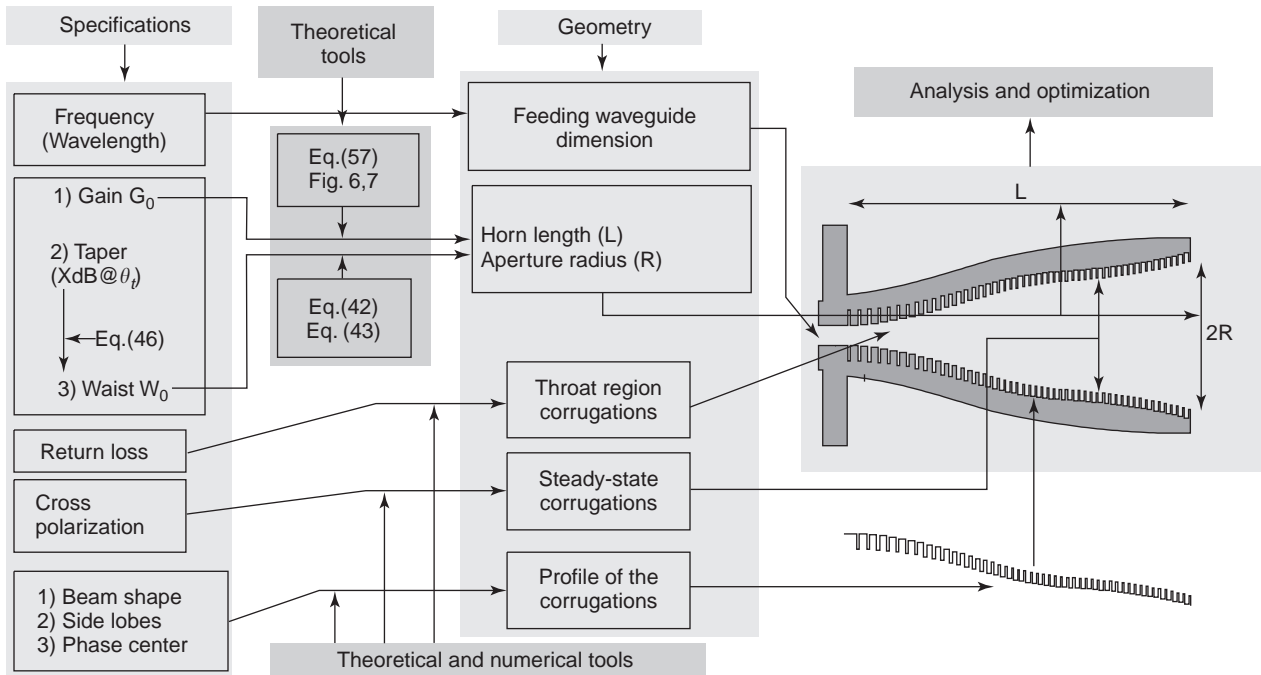

Figure 14. Schematic flow chart for corrugated horn design.

4.7. Summary of Corrugated Horn Design

To summarize the previous concepts, a practical design procedure is outlined, following the sketch in Fig. 14, showing a flowchart for corrugated horn design.

In the flowchart the design should be seen as a process linking a set of specifications (grouped under “specifications”) to a set of geometric parameters (geometry) that

Figure 15. High-gain feed horn at 32 GHz (Courtesy of the Institute of Radioastronomy of the Italian National Research Council.)

completely characterize the fundamental aspects of horn mechanics, at least from an electromagnetic perspective.

The frequency is the fundamental specification involved (by means of the wavelength) in all the horn geometry; however, from a design perspective, it directly fixes the dimension of the input waveguide feeding the horn once single fundamental mode propagation is imposed in the operative band.

Three equivalent specifications can be used to theoretically determine the horn length L and the aperture radius R ; if the horn gain G_0 is given, it is possible to use (57) and the graphs of Figs. 6 and 7 for best choice of L and R ; if the waist w_0 is given, then (42) and (43) can be

Figure 16. E -plane pattern cut of the 32-GHz high-gain corrugated horn.

used; if the taper X dB at θ_t is given, then the equivalent waist specification can be obtained from (46), proceeding as in the previous case.

Both theoretical and numerical tools should be used for the other specifications. Return loss is related mainly to the geometry of the throat region corrugations; cross-polarization affects the geometry of the steady-state region corrugations; and mainbeam shape, sidelobe, and phase center specifications should be used to design the curvature of the corrugation profile. The electromagnetic phenomena governing the preceding relations between specifications and horn geometry have been explained in the text above and values have been suggested to quantify these relations since this would be of greater help to the designer. However, those quantitative values should not be taken as an arbitrary rule; rather, they require further verification by analytical simulations according to the particular application, and this is the meaning of the term “numerical tools” introduced here. Once the horn geometry has been determined, analysis and optimization routines should be used to verify and refine the design.

5. CORRUGATED HORN DESIGN EXAMPLES

To give the reader an idea of the performances of corrugated horns, two examples are presented here.

Example 1. Assume a high-gain corrugated horn operating in Ka band at 32 GHz with gain of ~ 28 dB. Thus, according to the graph of Fig. 7, a 6λ aperture radius with an half-flare angle of $\sim 8^\circ$ has been chosen, leading to the prototype of Fig. 15 with an aperture diameter of ~ 11 cm and an overall length of ~ 38 cm.

The gain was verified to be correct by full-wave simulations, showing a ~ 1 dB variation in a 20% band, while the copolar radiation pattern is given in Fig. 16, highlighting results close to measurement data.

Particular attention in the design has been devoted to keep both the input reflection coefficient and the

Figure 18. Dual-profile corrugated horn at 22 GHz (Courtesy of the Institute of Radioastronomy of the Italian National Research Council.)

cross-polarization maximum as low as possible. As is shown in the plots of Fig. 17, the measured reflection coefficient is less than -30 dB with very good agreement with simulation data.

Example 2. Given a dual-profile corrugated horn at 22 GHz for use as a feed for a reflector antenna illuminated with an edge taper of 12 dB at 9.5° . The horn, whose prototype is given in Fig. 18, has been optimized for compactness, reducing about 20% space occupation with respect to a standard horn. It is interesting to observe the measured beam pattern of the horn that is compared in the plot of Fig. 19 with the results of the full-wave simulation.

Comparing the dual-profile horn pattern with the one of the standard horn in Fig. 16, we note the differences in the shape of the mainbeam and the secondary lobe due to the contribution to the radiation of higher-order modes, excited by the curved profile.

COULOMB GAUGE IN ELECTROMAGNETICS, THE

ROBERT D. NEVELS

 Texas A&M University
 College Station, Texas

1. INTRODUCTION

Problems in high-frequency electromagnetic scattering and diffraction, where the fields are expressed in terms of magnetic vector (\mathbf{A}) and scalar (V) potentials, have in the past been solved almost exclusively with the Lorentz¹ gauge. However, in this article it will be shown that any wave guidance or scattering problem that can be found through an application of the Lorentz gauge can as well be solved subject to the Coulomb gauge. It will be shown that the Coulomb gauge formulation displays some unique mathematical characteristics that provide insight into the meaning and structure of potentials [1]. Also, the component parts of the mathematical expressions for the field arising from an application of the Coulomb gauge provide a way of directly determining how the field changes with a change in frequency.

The fact that the Lorentz and Coulomb gauges possess unique properties that correspond to physical aspects of the electromagnetic field suggests that the choice of gauge should depend on the kind of problem being solved or the physical parameters that are being sought. However, although gauge methods have existed for over 150 years, mathematical solutions for the electromagnetic field that include the region of the source current have been obtained only with these two gauges. Other gauges have been explored, but, without a solution that is valid in the source region, problems of practical interest, where objects can have any general shape, cannot be solved.

A comparison of the Lorentz and Coulomb gauges can best be displayed by incorporating the effects of some object such as a cylinder or wedge in the problem definition, thereby leaving the current distribution on a nearby arbitrary surface as the only unknown to be found. This approach is sometimes referred to as the “hybrid method

¹According to E. Whittaker’s *A History of the Theories of Aether and Electricity*, this gauge was first derived by L. Lorenz and not H. A. Lorentz. The interested reader is referred to Refs. 11 and 12 for more background on this historical oversight. Here we choose to continue to use the name by which the gauge has been known for over a century.

of moments (MM) Green's function method" [2,3]. From a purely mathematical point of view, a change in gauge means that the vector and scalar potentials will have Green functions [4,5] that differ significantly from those of the familiar Lorentz gauge. An important consequence of the hybrid MM/Green function method presented here is that the Green functions are in their most general dyadic form, incorporating all coordinate components in a few compact mathematical expressions. The advantage of the dyadic Green function formulation is that it provides a procedure for handling general three-dimensional boundary value problems in the Lorentz gauge, and yet it is uniquely suited for the Coulomb gauge owing to the particular solenoidal nature of the Coulomb vector potential and lamellar nature of the Coulomb scalar potential.

2. THE ELECTROMAGNETIC FIELD IN TERMS OF POTENTIALS

Maxwell's equations in time harmonic form are

$$\nabla \times \mathbf{E} = -j\omega \mathbf{B} \quad (1)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + j\omega \mathbf{D} \quad (2)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (3)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (4)$$

where \mathbf{E} and \mathbf{H} are the electric and magnetic field intensities and \mathbf{D} and \mathbf{B} are the electric and magnetic field flux densities and ω is the radian frequency. Equation (3), when substituted into the divergence of (2), gives the continuity equation

$$\nabla \cdot \mathbf{J} = -j\omega \rho \quad (5)$$

a useful relationship between the electric current \mathbf{J} and charge ρ densities.

In this article all regions are assumed to be homogeneous, linear, and isotropic, which means that the permittivity ϵ and permeability μ of space are constant and the relationships between field intensities and the flux densities are given by the simple expressions

$$\mathbf{D} = \epsilon \mathbf{E} \quad \text{and} \quad \mathbf{B} = \mu \mathbf{H} \quad (6)$$

which are known as the *constitutive relations*. Also, in the mathematics of this article the time convention $\exp(j\omega t)$ is suppressed.

Because magnetic charge has never been observed, the right-hand side of the magnetic field divergence equation (4) is always zero. It also happens that the divergence of the curl of any vector \mathbf{U} is also always zero. This identity, expressed mathematically by $\nabla \cdot (\nabla \times \mathbf{U}) = 0$, when compared to (4) suggests the possibility that the flux density \mathbf{B} can be found by taking the curl of some other vector. In electromagnetism this vector has been assigned the sym-

bol \mathbf{A} and termed the *magnetic vector potential*:

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (7)$$

At this point \mathbf{A} is not known, nor do we have an equation for it, but we do know a couple of facts. First, if the magnetic vector potential were known, then the magnetic field could be easily found with (7); second, because the electromagnetic fields must satisfy Maxwell's equations, it follows that the magnetic vector potential must also satisfy Maxwell's equations. The latter condition can be exploited in order to find the relationship between the vector potential \mathbf{A} and the electric field. To do this, Eq. (7) is substituted into (1) and the terms under the curl operation are collected, giving

$$\nabla \times (\mathbf{E} + j\omega \mathbf{A}) = 0 \quad (8)$$

By comparing (8) with another vector identity, $\nabla \times \nabla \psi = 0$, where ψ is any scalar function of position, it can be hypothesized that the term in the parenthesis can be expressed as the gradient of a scalar:

$$\mathbf{E} + j\omega \mathbf{A} = -\nabla V \quad (9)$$

The scalar, V , is referred to as the *electric scalar potential*. Equation (9) can be rearranged to display the electric field equivalent of (7):

$$\mathbf{E} = -j\omega \mathbf{A} - \nabla V \quad (10)$$

One obvious question to ask is why a negative sign is chosen in front of the gradient operation in (9) when an always less troublesome positive sign appears to be equally valid. One answer is that since the gradient produces a vector that is in the direction of increasing potential value, then the Lorentz force law, $\mathbf{F} = q\mathbf{E}$, holds true when $\omega = 0$ only if a negative sign is placed in front of the gradient of the potential.

2.1. Justification for Using Potentials

The fact that potentials save considerable effort when solving Maxwell's equations may not be immediately obvious. To see that potentials do indeed simplify electromagnetic field calculations, let us investigate what would happen if we were to attempt to directly solve for the electric or magnetic field. Taking the curl of Faraday's law (1) and substituting Ampere's law (2) into the result gives

$$\nabla \times \nabla \times \mathbf{E} + k^2 \mathbf{E} = j\omega \mu \mathbf{J} \quad (11)$$

or, with the vector identity

$$\nabla \times \nabla \times \mathbf{U} = -\nabla^2 \mathbf{U} + \nabla \nabla \cdot \mathbf{U} \quad (12)$$

and the continuity equation (5), Eq. (11) can be reduced to the Helmholtz equation

$$\nabla^2 \mathbf{E} + k^2 \mathbf{E} = \frac{j}{\omega \epsilon} (\nabla \nabla \cdot \mathbf{J} + k^2 \mathbf{J}) \quad (13)$$

Also, by taking the curl of (2), a similar set of vector operations leads to a Helmholtz equation for the magnetic field

$$\nabla^2 \mathbf{H} + k^2 \mathbf{H} = -\nabla \times \mathbf{J} \quad (14)$$

Although in some cases it is possible to find a Green function by directly solving Eqs. (11), (13), and (14), it is the complexity of these equations that encourages the use of potentials. For example, the $\nabla \times \nabla \times$ operator in (11) produces a set of three scalar equations in which E_x , E_y , and E_z are coupled. Similarly the $\nabla \nabla \cdot$ operator on the right-hand side of (13) leads to three scalar equations for the electric field, and $\nabla \times$ in (14) results in three scalar equations for the magnetic field that are in each of these cases coupled in terms of the current density components J_x , J_y , and J_z . It is very difficult to solve coupled sets of equations. However, it will be shown below that a mathematical relationship called a “gauge” can produce from one to three uncoupled equations from which all six electric and magnetic field components can be found. The use of gauges is therefore said to reduce the number of degrees of freedom, thereby simplifying the problem solution.

2.2. Nonuniqueness of Potentials

A potential is not unique even though it satisfies Maxwell’s equations and a given set of boundary conditions. However, potentials that satisfy the same boundary conditions differ from one another in definable ways. For instance, if the gradient of any scalar ψ is subtracted from a vector potential \mathbf{A} , then the result

$$\mathbf{A}' = \mathbf{A} - \nabla\psi \quad (15)$$

produces a different magnetic potential \mathbf{A}' , although the magnetic field will be the same as that obtained with the original \mathbf{A} . This can be shown by substituting (15) into (7)

$$\begin{aligned} \mathbf{B} &= \nabla \times \mathbf{A} + \nabla \times \nabla\psi \\ &= \nabla \times \mathbf{A}' \end{aligned} \quad (16)$$

and (15) into (4)

$$\nabla \cdot \mathbf{B} = \nabla \cdot \nabla \times \mathbf{A}' = 0 \quad (17)$$

and by observing, with the aid of (16), that

$$\nabla \times \mathbf{B} = \nabla \times \nabla \times \mathbf{A}' = \nabla \times \nabla \times \mathbf{A} \quad (18)$$

In other words, the magnetic flux density \mathbf{B} , as well as its divergence (17) and curl (18), are the same regardless of whether the vector potential used to define \mathbf{B} is \mathbf{A} or \mathbf{A}' , two expressions that differ by $\nabla\psi$. Equation (15) is referred to as a *vector potential gauge transformation*. The magnetic flux density \mathbf{B} is therefore said to be preserved under the gauge transformation between \mathbf{A} and \mathbf{A}' given in (15).

If the electric field is to be preserved under the gauge transformation, then the scalar potential in (10) must be modified so as to compensate for a change in the vector

potential. The electric field in terms of the new vector and scalar potentials is

$$\mathbf{E} = -j\omega \mathbf{A}' - \nabla V' \quad (19)$$

By substituting (15) into (19) it is clear that the electric field

$$\mathbf{E} = -j\omega \mathbf{A} - \nabla(-j\omega\psi + V') \quad (20)$$

will not change if the term in parentheses is equal to the original scalar potential V , that is

$$V' = V + j\omega\psi \quad (21)$$

This equation is known as the scalar potential gauge transformation.

The gauge transformations in (15) and (21) create a new set of potentials (\mathbf{A}', V') , yet the electric and magnetic fields produced with these new potentials are the same as those calculated with the original set (\mathbf{A}, V) . The fact that the electric and magnetic fields are the same, regardless of which set of potentials is used, is described as the gauge invariance property of the fields. From a historical prospective it is interesting that gauge transformations, after they were first discovered for the electromagnetic field, were incorporated into the mathematical description of many physical phenomena, which was a key to finding of a relationship between some of the fundamental forces of nature [12].

Although sets of potentials for a particular problem configuration are always related through the transformations in (15) and (21), the mathematical expression for ψ is seldom obvious. Each new set of potentials will give rise to a new ψ that, through (15) and (21), determines the relationship between the new potentials and the original set. An important use of the gauge transformations is suggested by rearranging (21) as follows:

$$\psi = \frac{V' - V}{j\omega} \quad (22)$$

This equation shows that the difference between the scalar potentials found with two different gauges produces ψ , which through (15) yields the remaining vector potential. This observation provides a valuable tool when deriving a new set of potentials since the equations from which scalar potentials are derived can be solved without resorting to complicated vector procedures. Once ψ is found we are relieved of the necessity of independently deriving the vector potential.

In the sections that follow the goal will not be to find the relationship between different sets of potentials, but rather to determine the link between a particular vector and scalar potential that form a single set. This relationship, called a “gauge”, leads to differential equations for the vector and scalar potentials and ultimately, by applying boundary conditions, to the potentials themselves.

2.3. Dyadic Green's Functions

In order to solve problems that involve current distributions or scattering structures that are encountered in practice, it is necessary to develop the dyadic Green function approach. Green's method is a systematic procedure for obtaining a mathematical expression in which the potential due to an elemental source is convolved with a particular current distribution in order to determine the potential caused by that current. The dyadic Green function method is the simplest method for finding the electromagnetic fields produced by a general-shaped structure via the Coulomb gauge. Here, as in most cases of practical interest, the potential is found first and then, by an application of Eqs. (7) and (10), the magnetic and electric fields. Limited space prevents a more thorough discussion of the topic of dyadics, so it is assumed that the reader has a working knowledge of the subject. If not, please refer to Appendix A for a brief introduction. Also the authors highly recommend the excellent text by Tai [4].

The vector potential is obtained in terms of a dyadic Green's function as follows. The current density forcing function on the right-hand side of Helmholtz potential equation

$$\nabla^2 \mathbf{A} + k^2 \mathbf{A} = -\mu \mathbf{J} \quad (23)$$

which will be derived later in this article, is replaced by a dyadic delta forcing function, resulting in

$$\nabla^2 \overline{\mathbf{G}} + k^2 \overline{\mathbf{G}} = -\overline{\delta}(\mathbf{r} - \mathbf{r}') \quad (24)$$

where $\overline{\mathbf{G}}$ is Green's function for an elemental source oriented in an arbitrary direction in free space and $\overline{\delta} = \overline{\mathbf{I}}\delta(\mathbf{r} - \mathbf{r}')$. $\overline{\mathbf{I}} = \hat{\mathbf{x}}\hat{\mathbf{x}} + \hat{\mathbf{y}}\hat{\mathbf{y}} + \hat{\mathbf{z}}\hat{\mathbf{z}}$ is the identity dyadic and $\delta(\mathbf{r} - \mathbf{r}')$ is the Dirac delta function. Equation (23) is postmultiplied by $\overline{\mathbf{G}}$ and (24) premultiplied by \mathbf{A} as follows:

$$(\nabla^2 \mathbf{A} + k^2 \mathbf{A} = -\mu \mathbf{J}) \cdot \overline{\mathbf{G}} \quad (25)$$

$$\mathbf{A} \cdot (\nabla^2 \overline{\mathbf{G}} + k^2 \overline{\mathbf{G}} = -\overline{\delta}(\mathbf{r} - \mathbf{r}')) \quad (26)$$

These two equations are subtracted and then integrated over a volume of space, yielding

$$\int_{\text{vol}} (\nabla^2 \mathbf{A} \cdot \overline{\mathbf{G}} - \mathbf{A} \cdot \nabla^2 \overline{\mathbf{G}}) dv = \int_{\text{vol}} (\mathbf{A} \cdot \overline{\delta}(\mathbf{r} - \mathbf{r}') - \mu \mathbf{J} \cdot \overline{\mathbf{G}}) dv \quad (27)$$

The volume integral on the left in (27) can be rewritten in terms of a surface integral bounding the volume as follows [6]

$$\begin{aligned} & \int_{\text{vol}} (\nabla^2 \mathbf{A} \cdot \overline{\mathbf{G}} - \mathbf{A} \cdot \nabla^2 \overline{\mathbf{G}}) dv \\ &= \int_{\text{surf}} [\nabla \cdot \mathbf{A}(\hat{\mathbf{n}} \cdot \overline{\mathbf{G}}) - (\hat{\mathbf{n}} \cdot \mathbf{A})\nabla \cdot \overline{\mathbf{G}} \\ &+ \nabla \times \mathbf{A} \cdot (\hat{\mathbf{n}} \times \overline{\mathbf{G}}) - (\hat{\mathbf{n}} \times \mathbf{A}) \cdot \nabla \times \overline{\mathbf{G}}] ds \end{aligned} \quad (28)$$

where $\hat{\mathbf{n}}$ is a unit vector normal to the bounding surface. If the surface extends to infinity, then this integral is zero due to the Sommerfeld radiation condition, which says that at infinity all fields, and therefore the potentials, must go to zero. If the bounding surface is a perfect conductor, then the conditions [7]

$$\hat{\mathbf{n}} \times \mathbf{A} = 0 \quad \nabla \cdot \mathbf{A} = 0 \quad \text{on surface} \quad (29)$$

hold for the vector potential and similarly for the vector potential Green's function $\overline{\mathbf{G}}$, so again the right hand side of (28) is zero. Equation (27) therefore reduces to

$$\mathbf{A}(\mathbf{r}') = \mu \int_{\text{vol}} \mathbf{J}(\mathbf{r}) \cdot \overline{\mathbf{G}}(\mathbf{r}|\mathbf{r}') dv \quad (30)$$

Interchanging \mathbf{r} and \mathbf{r}' and using the reciprocity theorem [7] of Green's functions $\overline{\mathbf{G}}(\mathbf{r}|\mathbf{r}') = \overline{\mathbf{G}}(\mathbf{r}'|\mathbf{r})$ gives

$$\mathbf{A}(\mathbf{r}) = \mu \int_{\text{vol}} \mathbf{J}(\mathbf{r}') \cdot \overline{\mathbf{G}}(\mathbf{r}|\mathbf{r}') dv' \quad (31)$$

A similar set of operations leads to the scalar potential equation

$$V(\mathbf{r}) = \frac{-1}{j\omega\epsilon} \int_{\text{vol}} G_V(\mathbf{r}|\mathbf{r}') \nabla' \cdot \mathbf{J}(\mathbf{r}') dv' \quad (32)$$

3. FREE-SPACE LORENTZ AND COULOMB GAUGE GREEN FUNCTION

In this section the scalar and vector potential Green functions for a general directed source in free space are derived in both the Lorentz and Coulomb gauges. It is shown that the Coulomb gauge vector potential Green function can be extracted from the well-known free-space Lorentz gauge vector potential Green function by taking advantage of a set of dyadic identities. The method presented here avoids the difficulties inherent in the vector eigenfunction approach, which will be used in the next section to derive Green's functions for a boundary value problem. In order to confirm the correctness of our expressions, the electric field mixed potential integral equation (MPIE) for the current on a straight finite-length wire scatterer is derived and solved by the method of moments [8]. The numerically computed Coulomb gauge current and an equation for the scattered far field are presented and compared in terms of numerical computation time and programming difficulty with that obtained via Lorentz for gauge potentials.

3.1. Analysis

The time-harmonic electric and magnetic fields are related to the magnetic vector potential \mathbf{A} and scalar potential V :

$$\mathbf{E} = -j\omega \mathbf{A} - \nabla V \quad (33)$$

$$\mathbf{H} = \frac{1}{\mu} \nabla \times \mathbf{A} \quad (34)$$

The differential equations that define the potentials and thereby give rise to Green's functions are obtained by

combining (33) and (44) with Maxwell's equations. For example (33) and (44) substituted into Maxwell's equation $\nabla \times \mathbf{H} = \mathbf{J} + j\omega\epsilon\mathbf{E}$, results in

$$\nabla^2 \mathbf{A} + k^2 \mathbf{A} = -\mu \mathbf{J} + \nabla(\nabla \cdot \mathbf{A} + j\omega\mu\epsilon V) \quad (35)$$

and (3) and (5) substituted into the divergence of (33) gives

$$\nabla^2 V + j\omega \nabla \cdot \mathbf{A} = \frac{\nabla \cdot \mathbf{J}}{j\omega\epsilon} \quad (36)$$

Equations (35) and (36) are as far as we can go in obtaining equations for the vector and scalar potentials without some additional information. This information is provided by the Helmholtz theorem, according to which a vector is completely specified by its divergence and curl. Another way of stating this is that if $\nabla \cdot \mathbf{A}$ and $\nabla \times \mathbf{A}$ are known, then there is an equation, the mathematical form of Helmholtz's equation, into which both can be placed that, when evaluated, will give \mathbf{A} . This equation, which is not necessary for our analysis because we will determine \mathbf{A} and V in a direct manner, can be found in many texts on vector analysis and field theory, for example, Collin [9]. The curl of the vector \mathbf{A} has already been defined in (34), so the determination of the divergence of \mathbf{A} is left entirely to our discretion. Does this mean that $\nabla \cdot \mathbf{A}$ can be defined to be any mathematical expression that can be written down? The answer is yes, but care must be taken to choose a divergence of \mathbf{A} that, when placed in (35) or (36), will lead to a differential equation that is solvable. Otherwise the vector potential and therefore the field given by (7) and (10) may not be found.

Two choices for the divergence of \mathbf{A} are presented in Sections 3.2 and 3.3, the first resulting in the Lorentz gauge and the second in the Coulomb gauge. The discovery of the vector potential is accredited to Franz Neumann; however, it was James Clerk Maxwell who first obtained a solution for \mathbf{A} by applying what is now known as the Coulomb gauge [10]. Although the difficulties presented by the Coulomb gauge vector potential differential equation prevented its general solution until recently, it is apparent that Maxwell distained the use of the Lorenz (please see footnote 1 on the first page of this article) gauge, for which a solution for the potentials already existed [11,12]. Likely Maxwell's reluctance to accept the Lorenz gauge arose because it produced what was thought to be nonphysical "retarded" fields. However, H. A. Lorentz rediscovered this gauge around the beginning of the twentieth century at a time when the concept of the retarded field was beginning to gain wide acceptance [11]. The simplicity of the Lorenz gauge vector potential differential equation and the fact that the Lorenz potentials are relativistically covariant led to its widespread use. The electromagnetic field has not been solved in general, including the source region, with any gauge other than these two.

3.2. Lorentz Gauge Green's Functions

With the definitions ($\mathbf{A} \equiv \mathbf{A}^L$) and ($V \equiv V^L$) we define the Lorentz gauge

$$\nabla \cdot \mathbf{A}^L = -j\omega\mu\epsilon V^L \quad (37)$$

where $k^2 = \omega^2\mu\epsilon$. Substitution of Eq. (37) in (35) and Eq. (37) in (36) leads to a set of decoupled potential equations:

$$\nabla^2 \mathbf{A}^L + k^2 \mathbf{A}^L = -\mu \mathbf{J} \quad (38)$$

$$\nabla^2 V^L + k^2 V^L = \frac{\nabla \cdot \mathbf{J}}{j\omega\epsilon} \quad (39)$$

As described above, Eq. (38) motivates the dyadic Green function equation

$$\nabla^2 \overline{\mathbf{G}}^L + k^2 \overline{\mathbf{G}}^L = -\overline{\delta}(\mathbf{r} - \mathbf{r}') \quad (40)$$

Equation (39) suggests a similar scalar Green function equation:

$$\nabla^2 G_V^L + k^2 G_V^L = -\delta(\mathbf{r} - \mathbf{r}') \quad (41)$$

Equations (40) and (41) have familiar solutions [13], respectively

$$\overline{\mathbf{G}}^L(\mathbf{r}|\mathbf{r}') = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \frac{e^{-jkR}}{4\pi R} = \overline{\mathbf{I}}G(\mathbf{r}|\mathbf{r}') \quad (42)$$

$$G_V^L(\mathbf{r}|\mathbf{r}') = \frac{e^{-jkR}}{4\pi R} = G(\mathbf{r}|\mathbf{r}') \quad (43)$$

with $R = [(x - x')^2 + (y - y')^2 + (z - z')^2]^{\frac{1}{2}}$.

3.3. Coulomb Gauge Green's Functions

The Coulomb gauge

$$\nabla \cdot \mathbf{A}^C = 0 \quad (44)$$

in (35) and in (36) along with the definitions ($\mathbf{A} \equiv \mathbf{A}^C$) and ($V \equiv V^C$) leads to the set of Coulomb gauge potential equations

$$\nabla^2 \mathbf{A}^C + k^2 \mathbf{A}^C = -\mu \mathbf{J} + j\omega\mu\epsilon \nabla V^C \doteq -\mu \mathbf{J}^s \quad (45)$$

$$\nabla^2 V^C = \frac{1}{j\omega\epsilon} \nabla \cdot \mathbf{J} \quad (46)$$

At the beginning of this section we used the property of Helmholtz theorem that states that a vector is completely determined by its divergence and curl. The Helmholtz theorem in its mathematical form can also be viewed as expressing a vector \mathbf{J} solely in terms of its solenoidal (divergenceless) \mathbf{J}^s and lamellar (zero curl) \mathbf{J}^l parts [14]. Mathematically the properties of these two parts of a vector can be described by $\nabla \times \mathbf{J}^s \neq 0$, $\nabla \cdot \mathbf{J}^s = 0$, $\nabla \times \mathbf{J}^l = 0$, $\nabla \cdot \mathbf{J}^l \neq 0$. The superscript "s" in (45) which designates a solenoidal current density \mathbf{J}^s , results when the lamellar current \mathbf{J}^l is removed from the total current density $\mathbf{J} = \mathbf{J}^s + \mathbf{J}^l$. That $\mathbf{J}^l = j\omega\epsilon \nabla V^C$ can be shown by taking the

divergence of (45) and then applying the Coulomb condition (34).

It is important to note that the definition of the Coulomb gauge used here allows for $(\nabla \cdot \mathbf{A} = 0, V \neq 0)$, which encompasses far more territory than does that of a small but important class of problems where the divergences of both the magnetic vector potential \mathbf{A} and the current density \mathbf{J} are zero. In that case it is convenient to use what is commonly referred to as the “radiation gauge” [15].

The Green function equations pertaining to the Coulomb potential equations (45) and (46) respectively are

$$\nabla^2 \bar{\mathbf{G}}^C(\mathbf{r}|\mathbf{r}') + k^2 \bar{\mathbf{G}}^C(\mathbf{r}|\mathbf{r}') = -\bar{\delta}^s(\mathbf{r} - \mathbf{r}') \quad (47)$$

$$\nabla^2 G_V^C(\mathbf{r}|\mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \quad (48)$$

Note that because the dyadic delta function $\bar{\delta}^s$ is solenoidal, the Coulomb Green function $\bar{\mathbf{G}}^C$ must also be solenoidal. Equation (48) is simply the Poisson equation for a source in free space. The solution to (48) is

$$G_V^C(\mathbf{r}|\mathbf{r}') = \frac{1}{4\pi R} \quad (49)$$

As described in the introduction (Section 1), the vector eigenfunction method for solving (47) is in general formidable but in this particular case, where the source resides in free space, we can make some observations that will lead to a method for finding the Coulomb gauge Green function that is understandable to those readers with a basic knowledge of dyadic vector operations. First we observe that the solenoidal part of the Lorentz gauge vector potential Green function is equal to the Coulomb gauge vector potential Green function. This can be shown by first decomposing the dyadics on the left- and right-hand sides of (40) into solenoidal and lamellar parts and then equating just the solenoidal components. The result is Eq. (47). Therefore, since the Lorentz gauge Green function is already available (42), our strategy is to extract its solenoidal part. This can be done by first using the identity (12) in (40), which, on rearrangement of terms, becomes

$$\bar{\mathbf{G}}^L = \frac{1}{k^2} (\nabla \times \nabla \times \bar{\mathbf{G}}^L - \nabla \nabla \cdot \bar{\mathbf{G}}^L - \bar{\delta}(\mathbf{r} - \mathbf{r}')) \quad (50)$$

Identity (12) is next substituted into a second identity [13]

$$\bar{\delta}(\mathbf{r} - \mathbf{r}') = -\frac{1}{4\pi} \nabla^2 \left(\frac{\bar{\mathbf{I}}}{R} \right) \quad (51)$$

to get

$$\bar{\delta}(\mathbf{r} - \mathbf{r}') = \frac{1}{4\pi} \left[-\nabla \nabla \cdot \left(\frac{\bar{\mathbf{I}}}{R} \right) + \nabla \times \nabla \times \left(\frac{\bar{\mathbf{I}}}{R} \right) \right] \quad (52)$$

Finally, (52) is substituted into (50), yielding

$$\bar{\mathbf{G}}^L = \frac{-1}{k^2} \nabla \nabla \left(\frac{e^{-jkR} - 1}{4\pi R} \right) + \frac{1}{k^2} \nabla \times \nabla \times \bar{\mathbf{I}} \left(\frac{e^{-jkR} - 1}{4\pi R} \right) \quad (53)$$

The right-hand sides of (52) and (53) contain respectively the lamellar and solenoidal delta functions $\bar{\delta}^l$ and $\bar{\delta}^s$ and vector potential Green’s functions $\bar{\mathbf{G}}^l$ and $\bar{\mathbf{G}}^s$. The solenoidal term $\bar{\mathbf{G}}^s$ has been identified above as the Coulomb Green function $\bar{\mathbf{G}}^s = \bar{\mathbf{G}}^C$, which, by rearranging (53), can be written in a convenient form:

$$\bar{\mathbf{G}}^C = \bar{\mathbf{I}}G + \frac{1}{k^2} \nabla \nabla \left(\frac{e^{-jkR} - 1}{4\pi R} \right) \quad (54)$$

When the differentiation in (54) is performed, the result is

$$\bar{\mathbf{G}}^C(\mathbf{r}|\mathbf{r}') = \begin{bmatrix} S_{xx} & S_{xy} & S_{xz} \\ S_{yx} & S_{yy} & S_{yz} \\ S_{zx} & S_{zy} & S_{zz} \end{bmatrix} \frac{e^{-jkR}}{4\pi R} = \bar{\mathbf{S}}G(\mathbf{r}|\mathbf{r}') \quad (55)$$

$$\bar{\mathbf{S}} = \left[(1 - Q)\bar{\mathbf{I}} - (1 - 3Q)\frac{\mathbf{R}\mathbf{R}}{R^2} \right] \quad (56)$$

$$Q = \frac{1 + jkR - e^{jkR}}{(kR)^2} \quad (57)$$

$$\mathbf{R} = (x - x')\hat{\mathbf{x}} + (y - y')\hat{\mathbf{y}} + (z - z')\hat{\mathbf{z}} \quad (58)$$

This completes our presentation of the free-space Coulomb and Lorentz gauge Green functions. The potentials are found by employing Green’s method [13] as discussed above. Ordinarily, for a coordinate space (Euclidean) vector, one thinks of orthogonality as a property that requires the vector components to be mutually perpendicular. However, the solenoidal and lamellar parts of a vector can be shown to exhibit function orthogonality (see Appendix B). This property is used to resolve one of the apparent dilemmas of the Coulomb gauge integral equation formulation presented above, namely, that when Green’s method is applied to (45) and (47) the resulting vector potential integral contains a solenoidal current \mathbf{J}^s , rather than the desired surface current \mathbf{J} . This problem is resolved by simply replacing the solenoidal current with the total current:

$$\begin{aligned} \mathbf{A}^C(\mathbf{r}) &= \mu \int_{v'} \bar{\mathbf{G}}^C(\mathbf{r}|\mathbf{r}') \cdot \mathbf{J}^s(\mathbf{r}') dv' \\ &= \mu \int_{v'} \bar{\mathbf{G}}^C(\mathbf{r}|\mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dv' \end{aligned} \quad (59)$$

The replacement $\mathbf{J}^s(\mathbf{r}) \rightarrow \mathbf{J}(\mathbf{r})$ is allowed because solenoidal and lamellar vectors are orthogonal and since the Coulomb Green function is solenoidal, the integration process in (59) will automatically remove the lamellar part of the surface current. We emphasize that one can numerically solve only for the total current because the nonphysical solenoidal and lamellar currents cannot be numerically quantified since they exist throughout space. By analogy this last point is illustrated with Eq. (52), where the two terms on the right-hand side are respectively the lamellar and solenoidal delta functions. These terms are everywhere nonzero functions of position,

but together they collapse to a function that is nonzero only at $\mathbf{r} = \mathbf{r}'$.

Perhaps one of the most interesting controversies concerning the Coulomb gauge is the apparent instantaneous propagation of the scalar potential. Note that both the Lorentz and Coulomb gauge scalar potentials in (43) and (49) have the same static scalar potential owing to the fact that $k = \omega\sqrt{\mu\epsilon} = \omega/c \rightarrow 0$ as the frequency $\omega = 2\pi f \rightarrow 0$. However, the propagation factor $\exp(-jkr)$ that governs the velocity at which a wave propagates is absent from the Coulomb scalar potential (49). This seems to suggest that as soon as the source is turned on, the Coulomb scalar potential exists instantaneously throughout space. Although much has been written on this subject [16,17], it is important only that the electromagnetic field obey the speed-of-light law, which it does when the Coulomb vector and scalar potentials are combined in (33) to calculate the field. A summary of much of the literature on this subject is that, when a field is decomposed into component parts, there is no reason to expect that these components should each individually satisfy all the rules of physics. On the other hand, there is some interesting evidence, primarily associated with the Aharonov–Bohm experiment, that potentials may have some physical significance. However, these discussions are outside the context of this presentation and will not be pursued further.

The gauge invariance property of the electromagnetic field [15] ensures us that the fields given by (33) and (34) are unique, that is, independent of the choice of gauge. The equivalent current appearing in Eqs. (31) and (32) is also unique and can be used as a basis for comparing the Coulomb and Lorentz gauges. Below we present a method for solving for the current obtained with these two gauges.

3.4. Example: Scattering from a Straight Thin Wire

Some contrasting aspects of Eqs. (42) and (55) clearly indicate that the Lorentz gauge has a computational advantage over the Coulomb gauge. For example, the Coulomb gauge Green function contains a fully populated dyadic coefficient matrix $\bar{\mathbf{S}}$ while the Lorentz gauge coefficient is simply the diagonal identity dyadic $\bar{\mathbf{I}}$. This means, for example, that current flowing in the z direction will produce three (x , y , and z) dissimilar Coulomb vector potential components while the same z -directed current will produce only a single (z) Lorentz vector potential component. A general bent-wire scatterer solved by the method of moments MPIE technique would, for most of the moment matrix, require three calculations (a column of the $\bar{\mathbf{S}}$ dyadic) per matrix element with the Coulomb gauge and only one calculation with the Lorentz gauge.

On the other hand, for a straight wire, a Coulomb gauge analysis appears at first glance to have some advantages over the Lorentz gauge because of the simple mathematical form of the Coulomb scalar potential. Although this will not prove to be the case, we present below an MPIE analysis of a straight finite-length wire scatterer illuminated by a plane wave because it is a simple instructive problem for comparing our gauge formulations.

A straight wire of radius $a \ll \lambda$, length ℓ and lying along the z axis is illuminated by a plane wave with an electric field z component given by $E_z^i = E_0 \sin \theta e^{jkz \cos \theta}$ in a homogeneous free-space region (see Fig. 1). By enforcing the condition that the tangential component of the total electric field is zero on the wire surface one gets the MPIE

$$j\omega A_z^L + \frac{\partial}{\partial z} V^C = E_z^i \quad (60)$$

where in the Lorentz and Coulomb gauges the potentials are

$$A_z^L = \frac{\mu}{2\pi} \int_{z'} I(z') \int_{\phi'} \left\{ \begin{array}{l} G(z, z', \phi') \\ S_{zz} G(z, z', \phi') \end{array} \right\} d\phi' dz' \quad (61)$$

$$V^C = \frac{j}{2\pi\omega\epsilon} \int_{z'} \frac{d}{dz'} I(z') \int_{\phi'} \left\{ \begin{array}{l} G(z, z', \phi') \\ 1/4\pi R \end{array} \right\} d\phi' dz' \quad (62)$$

with

$$G(z, z', \phi') = \frac{e^{-jkR}}{4\pi R} \quad (63)$$

and $R = [(z - z')^2 + 2a^2 \sin^2 \phi']^{1/2}$.

3.5. Numerical Method

The method-of-moments (MM) procedure [8] is applied to solve Eqn. (60) for the unknown current $I(z)$ on a straight thin wire scatterer. The straight wire lying along the z axis is subdivided into N segments of length $\Delta z = \ell/N$. The

Figure 1. Plane wave incident on a thin straight wire.

current I is expanded as

$$I(z) = \sum_{n=1}^N I_n \Lambda_n(z) \quad (64)$$

where Λ_n are piecewise linear expansion functions defined as

$$\Lambda_n(z) = \begin{cases} \frac{z - z_{n-1}}{\Delta z}, & z_{n-1} \leq z \leq z_n \\ \frac{z_{n+1} - z}{\Delta z}, & z_n \leq z \leq z_{n+1} \\ 0, & \text{otherwise} \end{cases} \quad (65)$$

Note that (65) is piecewise differentiable, so the derivative with respect to z in (62) can be performed analytically. When the expansion (65) is used in (60) and the result “tested” with piecewise linear functions Λ_m , we arrive at a set of N simultaneous equations with N unknowns I_n expressed in matrix form:

$$[Z_{mn}][I_n] = [V_m], \quad m = 1, 2, \dots, N \quad (66)$$

The impedance matrix $[Z_{mn}]$ is inverted and multiplied by the voltage vector $[V_m]$. The resulting current amplitudes I_n are substituted into (64) giving the final current approximation. In our procedure we employed 21 rectangular basis and 21 testing functions.

3.6. Results

Figure 2 shows the current distributions on a three-quarter-wavelength (0.75λ) wire with a plane-wave excitation angle of incidence $\theta = 60^\circ$. The solid lines depict real and imaginary parts of the current due to a Coulomb gauge formulation while the overlying circles are from the Lorentz gauge analysis. The results for the two gauges are numerically indistinguishable. The computation time difference for each of these two results was 15% in favor of the Lorentz gauge.

A difference between the two gauges does emerge in the vector and scalar potential ϕ' integrations. The dyadic component S_{zz} is a regular non-singular function that presents no numerical difficulties. The singularity in $G(z, z', \phi')$ is evaluated by subtracting and adding $1/R$ as follows:

$$\int_{\phi'} G(z, z', \phi') d\phi' = \frac{1}{4\pi} \int_{\phi'=-\pi}^{\pi} \frac{e^{-jkR} - 1}{R} d\phi' + \frac{1}{4\pi} \int_{\phi'=-\pi}^{\pi} \frac{1}{R} d\phi' \quad (67)$$

Evaluation of the Lorentz scalar potential requires both integrals on the right-hand side (RHS) of (67) while only the second RHS integral is required for the Coulomb scalar potential. This advantage gained with the Coulomb gauge scalar potential calculation is not enough to

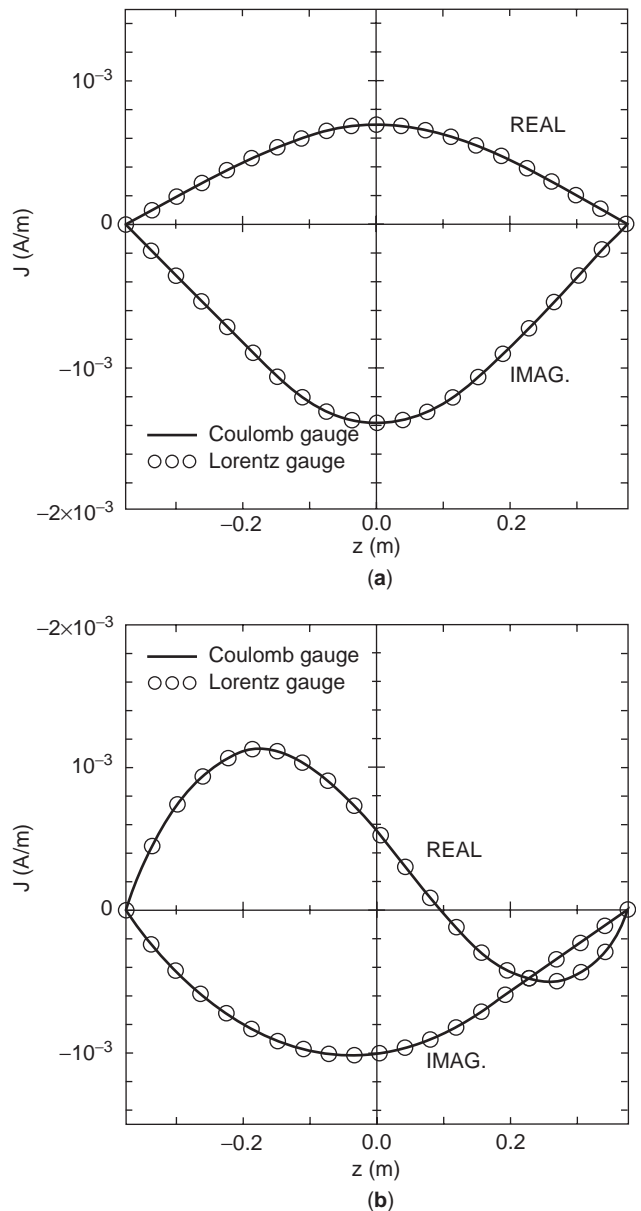

Figure 2. Comparison of Lorentz and Coulomb gauge current distributions on a $3/4$ dipole with plane-wave excitation at $\theta = 60^\circ$. The incident electric field amplitude is set to unity and $ka = 0.04$.

overcome the fact that the ϕ' integration in the Lorentz gauge can be carried out once and the result used in both the scalar and vector potentials [cf. (61) and (62)]. We can then conclude that the Lorentz gauge potentials can be computed more rapidly than the Coulomb gauge potentials for all thin-wire configurations and, it is safe to say, in any case for which a Green function can be derived. It should be pointed out, however, that the Coulomb scalar potential contains the static limit portion of the electromagnetic field. One can therefore isolate and observe the physical behavior of that part of the field (the Coulomb vector potential portion) that approaches zero as the excitation frequency decreases.

3.7. Far Field

The far-zone electric field can be found by letting $r \rightarrow \infty$ in (61) and (62) and then substituting the result into (10). The far electric field is

$$\mathbf{E}_\theta(\mathbf{r}) = j\omega\mu \frac{e^{-jkr}}{r} \int_{C'} I(z') e^{jkz' \cos\theta} dz' \sin\theta \quad (68)$$

in both gauges. Because, as was shown above, the currents and the far field expressions are the same, there is no difference in the far fields obtained by the two gauge formulations.

4. OPEN-REGION BOUNDARY VALUE PROBLEMS

As an example of a Coulomb gauge solution for an open-region boundary value problem, we present a two-dimensional surface of arbitrary shape in the presence of an infinite perfectly conducting wedge, subject to transverse electric excitation. The wedge/scatterer is analyzed by comparing mixed potential integral equations (MPIEs) that are constructed based on the Coulomb and Lorentz gauges. In each case the effect of the wedge is incorporated in the integral equation by means of the appropriate Green's functions, leaving the current distribution on the arbitrary surface as the only unknown. The Green functions are derived by the eigenfunction expansion technique [4]. A well-established moment method (MM) procedure [8] is adapted to numerically solve both gauge forms of the MPIE. Computed results are presented and the relative merits of the Coulomb and Lorentz gauge MPIEs are discussed. Zheng et al. [18] have provided more detailed presentation of this problem.

4.1. General Formulation of Integral Equations

Consider an infinitesimally thin surface that is in infinite extent and invariant along the z axis, but has an arbitrary (open or closed) cross-sectional profile C , and which resides near the edge of an infinite, perfectly conducting wedge of angle α , whose upper surface coincides with the ($x \geq 0, y = 0$) half-plane (see Fig. 3). The surrounding medium is homogeneous and is characterized by permittivity ε and permeability μ . The structure is illuminated by a plane-wave transverse electric (TE) to the z axis. Once the current distribution induced on the object C is found, other quantities of interest, such as the far field pattern, are easily determined.

In the case considered here (Fig. 3), \mathbf{J} is the unknown current induced on the perfectly conducting surface C by a known "incident" field $\mathbf{E}^i, \mathbf{H}^i$, which exists in the presence of the wedge. Enforcing the condition that the total tangential electric field, \mathbf{E} plus \mathbf{E}^i , is zero on C leads to the EFIE

$$\hat{\mathbf{t}} \times (j\omega\mathbf{A} + \nabla V) = \hat{\mathbf{t}} \times \mathbf{E}^i \quad (69)$$

where $\hat{\mathbf{t}}$ is a unit vector normal to C at $\boldsymbol{\rho}$, a position vector from the coordinate origin to a point on C . This equation is then solved for \mathbf{J} by the MM procedure.

Figure 3. Scatterer of arbitrary cross-sectional profile C in the presence of an infinite wedge.

4.2. Lorentz Gauge Integral Equation

Choosing the Lorentz gauge

$$\nabla \cdot \mathbf{A} = -j\omega\mu\varepsilon V \quad (70)$$

in (35) leads to

$$\mathbf{A}(\boldsymbol{\rho}) = \mu \int_C \overline{\mathbf{G}}_A(\boldsymbol{\rho}|\boldsymbol{\rho}') \cdot \mathbf{J}(\boldsymbol{\rho}') dl' \quad (71)$$

where $\overline{\mathbf{G}}_A$ is the vector potential dyadic Green function, which satisfies

$$(\nabla^2 + k^2)\overline{\mathbf{G}}_A(\boldsymbol{\rho}|\boldsymbol{\rho}') = -\overline{\boldsymbol{\delta}}(\boldsymbol{\rho} - \boldsymbol{\rho}') \quad (72)$$

subject to the conditions $\hat{\mathbf{n}} \times \overline{\mathbf{G}}_A = 0, \nabla \cdot \overline{\mathbf{G}}_A = 0$ on the PC wedge, the radiation condition at infinity, and the edge condition [9]. In (72), $\overline{\boldsymbol{\delta}}$ is the dyadic delta function [19]. For later reference, we observe that \mathbf{A} , and thus $\overline{\mathbf{G}}_A$, can in general be represented as sums of their respective lamellar (irrotational) and solenoidal (divergenceless) parts. Hence, we may write

$$\overline{\mathbf{G}}_A(\boldsymbol{\rho}|\boldsymbol{\rho}') = \overline{\mathbf{G}}_A^l(\boldsymbol{\rho}|\boldsymbol{\rho}') + \overline{\mathbf{G}}_A^s(\boldsymbol{\rho}|\boldsymbol{\rho}') \quad (73)$$

It follows from (70) and (71) that V can be expressed as

$$V(\boldsymbol{\rho}) = \frac{1}{\varepsilon} \int_C G_V(\boldsymbol{\rho}|\boldsymbol{\rho}') q(\boldsymbol{\rho}') dl' \quad (74)$$

in which the scalar potential kernel G_V is related to $\bar{\mathbf{G}}_A^1$ through

$$\nabla \cdot \bar{\mathbf{G}}_A^1(\boldsymbol{\rho}|\boldsymbol{\rho}') = -\nabla' G_V(\boldsymbol{\rho}|\boldsymbol{\rho}') \quad (75)$$

where ∇' acts on the primed (source) coordinates.

When \mathbf{A} given by (71) and V given by (74) are used in (69), the Lorentz gauge MPIE is obtained.

4.3. Coulomb Gauge Integral Equation

In the Coulomb gauge $\nabla \cdot \mathbf{A} = 0$; hence the vector potential is solenoidal and may be obtained from (71) if $\bar{\mathbf{G}}_A^s$ is used in place of $\bar{\mathbf{G}}_A$. The Coulomb scalar potential can be found from (74), where G_V satisfies the Poisson equation

$$\nabla^2 G_V(\boldsymbol{\rho}|\boldsymbol{\rho}') = -\delta(\boldsymbol{\rho} - \boldsymbol{\rho}') \quad (76)$$

subject to the condition that $G_V = 0$ on the PC wedge, the edge condition, and the boundedness condition at infinity. As was already mentioned, (76) has a closed-form solution for the geometry of Fig. 3. When the Coulomb vector and scalar potentials are used in (69), the Coulomb gauge MPIE is obtained.

4.4. Green's Function Potentials

We begin by constructing two scalar eigenfunctions, $\psi_{n\kappa}$ and $\dot{\psi}_{n\kappa}$, which satisfy the equation

$$(\nabla_t^2 + \kappa^2) \begin{Bmatrix} \psi_{n\kappa}(\boldsymbol{\rho}) \\ \dot{\psi}_{n\kappa}(\boldsymbol{\rho}) \end{Bmatrix} = 0 \quad (77)$$

subject to, respectively, the Dirichlet and Neumann boundary conditions on the PC wedge. They must also satisfy the edge condition and be bounded as $\rho \rightarrow \infty$. In (77), ∇_t^2 is the transverse Laplacian in cylindrical coordinates (no z dependence). These eigenfunctions are easily obtained by, for example, the characteristic Green's function procedure [20]. For the problem of Fig. 3, the normalized eigenfunctions are

$$\begin{Bmatrix} \psi_{n\kappa}(\boldsymbol{\rho}) \\ \dot{\psi}_{n\kappa}(\boldsymbol{\rho}) \end{Bmatrix} = \sqrt{\frac{\varepsilon_n}{\beta}} J_{v_n}(\kappa\rho) \begin{Bmatrix} \sin v_n \varphi \\ \cos v_n \end{Bmatrix} \quad (78)$$

where ε_n is the Neumann number ($\varepsilon_n = 1$ for $n = 0$ and $\varepsilon_n = 2$ for $n > 0$), J_{v_n} is the Bessel function of fractional order $v_n = n\pi/\beta$, $\beta = 2\pi - \alpha$, $0 \leq \kappa < \infty$, and $n = 0, 1, 2, \dots$. These eigenfunctions possess the orthogonality properties

$$\int_0^\beta \int_0^\infty \begin{Bmatrix} \psi_{n\kappa} \\ \dot{\psi}_{n\kappa} \end{Bmatrix} \begin{Bmatrix} \psi_{n'\kappa'} \\ \dot{\psi}_{n'\kappa'} \end{Bmatrix} \rho d\rho d\varphi = \delta_{nn'} \frac{\delta(\kappa - \kappa')}{\kappa'} \quad (79)$$

where $\delta_{nn'}$ is the Kronecker delta ($\delta_{nn'} = 1$ when $n = n'$ and zero otherwise).

We now construct three species of vector eigenfunctions, $\mathbf{L}_{n\kappa}$, $\mathbf{M}_{n\kappa}$, and $\mathbf{N}_{n\kappa}$, as [4]

$$\mathbf{L}_{n\kappa} = \nabla \psi_{n\kappa} \quad (80)$$

$$\mathbf{M}_{n\kappa} = \nabla \times \hat{\mathbf{z}} \dot{\psi}_{n\kappa} = -\hat{\mathbf{z}} \times \nabla \dot{\psi}_{n\kappa} \quad (81)$$

$$\mathbf{N}_{n\kappa} = \frac{1}{\kappa} \nabla \times \nabla \times \hat{\mathbf{z}} \dot{\psi}_{n\kappa} = \hat{\mathbf{z}} \kappa \psi_{n\kappa} \quad (82)$$

Clearly, the $\mathbf{L}_{n\kappa}$ functions are lamellar and the $\mathbf{M}_{n\kappa}$ and $\mathbf{N}_{n\kappa}$ functions are solenoidal. It is easily confirmed that all of them satisfy (77) and the required boundary conditions. It also follows from (79) that the vector eigenfunctions possess the orthogonality properties

$$\int_0^\beta \int_0^\infty \begin{Bmatrix} \mathbf{L}_{n\kappa} \\ \mathbf{M}_{n\kappa} \\ \mathbf{N}_{n\kappa} \end{Bmatrix} \cdot \begin{Bmatrix} \mathbf{L}_{n'\kappa'} \\ \mathbf{M}_{n'\kappa'} \\ \mathbf{N}_{n'\kappa'} \end{Bmatrix} \rho d\rho d\varphi = \delta_{nn'} \kappa \delta(\kappa - \kappa') \quad (83)$$

We now expand $\bar{\mathbf{G}}_A$ in (72) in terms of the vector eigenfunctions and employ (77) and (83) to obtain

$$\bar{\mathbf{G}}_A^1(\boldsymbol{\rho}|\boldsymbol{\rho}') = \sum_{n=0}^{\infty} \int_0^\infty \frac{d\kappa}{\kappa(\kappa^2 - k^2)} \mathbf{L}_{n\kappa}(\boldsymbol{\rho}) \mathbf{L}_{n\kappa}(\boldsymbol{\rho}') \quad (84)$$

and

$$\bar{\mathbf{G}}_A^s(\boldsymbol{\rho}|\boldsymbol{\rho}') = \sum_{n=0}^{\infty} \int_0^\infty \frac{d\kappa}{\kappa(\kappa^2 - k^2)} [\mathbf{M}_{n\kappa}(\boldsymbol{\rho}) \mathbf{M}_{n\kappa}(\boldsymbol{\rho}') + \mathbf{N}_{n\kappa}(\boldsymbol{\rho}) \mathbf{N}_{n\kappa}(\boldsymbol{\rho}')] \quad (85)$$

Noting that the term in (85) comprising the $\mathbf{N}_{n\kappa}$ functions contributes only the $\hat{\mathbf{z}}\hat{\mathbf{z}}$ component of $\bar{\mathbf{G}}_A^s$, we separate it by writing

$$\bar{\mathbf{G}}_A^s = \bar{\mathbf{G}}_{At}^s + \hat{\mathbf{z}}\hat{\mathbf{z}} \bar{G}_{Azz}^s \quad (86)$$

where only $\bar{\mathbf{G}}_{At}^s$, the transverse part of $\bar{\mathbf{G}}_A^s$, is of consequence to the TE problem considered here.

Using (84) in (75), we easily find the Lorentz scalar potential Green's function as

$$G_V(\boldsymbol{\rho}|\boldsymbol{\rho}') = \sum_{n=1}^{\infty} \int_0^\infty \psi_{n\kappa}(\boldsymbol{\rho}) \psi_{n\kappa}(\boldsymbol{\rho}') \frac{\kappa d\kappa}{\kappa^2 - k^2} \quad (87)$$

(which, incidentally, is identical with G_{Azz}^s).

The eigenfunction expansion method can also be used to solve (76) for the Coulomb scalar potential Green function, with the result

$$G_V(\boldsymbol{\rho}|\boldsymbol{\rho}') = \sum_{n=1}^{\infty} \int_0^\infty \psi_{n\kappa}(\boldsymbol{\rho}) \psi_{n\kappa}(\boldsymbol{\rho}') \frac{d\kappa}{\kappa} \quad (88)$$

The integrations over the radial spectral variable κ in (84), (85) and in (87), (88) can be evaluated using

$$\int_0^\infty J_\nu(\kappa\rho)J_\nu(\kappa\rho')\frac{d\kappa}{\kappa} = \frac{1}{2\nu}\left(\frac{\rho_{<}}{\rho_{>}}\right)^\nu, \quad \nu > 0 \quad (89)$$

$$\begin{aligned} & \int_0^\infty J_\nu(\kappa\rho)J_\nu(\kappa\rho')\frac{\kappa d\kappa}{\kappa^2 - k^2} \\ &= -\frac{\pi j}{2} J_\nu(k\rho_{<})H_\nu^{(2)}(k\rho_{>}), \quad \nu \geq 0 \end{aligned} \quad (90)$$

and

$$\begin{aligned} & \int_0^\infty J_\nu(\kappa\rho)J_\nu(\kappa\rho')\frac{d\kappa}{\kappa(\kappa^2 - k^2)} \\ &= -\frac{\pi j}{2k^2} \left[J_\nu(k\rho_{<})H_\nu^{(2)}(k\rho_{>}) - \frac{j}{v\pi} \left(\frac{\rho_{<}}{\rho_{>}}\right)^\nu \right], \quad \nu > 0 \end{aligned} \quad (91)$$

where $\rho_{>}$ denotes the greater, and $\rho_{<}$ the lesser, of ρ and ρ' , and $H_\nu^{(2)}$ is the Hankel function of the second kind and order ν . In the above and henceforth, we omit the subscript n on ν for notational simplicity.

Using (91) in (86) and the notation

$$c_n^\pm = \cos \nu(\varphi - \varphi') \pm \cos \nu(\varphi + \varphi') \quad (92)$$

$$s_n^\pm = \sin \nu(\varphi - \varphi') \pm \sin \nu(\varphi + \varphi') \quad (93)$$

$$b_n^{\rho\rho'} = \frac{\nu}{k^2\rho\rho'} J_\nu(k\rho_{<})H_\nu^{(2)}(k\rho_{>}) - \nu\Omega_n \quad (94)$$

$$b_n^{\rho\rho'} = \begin{cases} \frac{\nu}{k\rho} J'_\nu(k\rho')H_\nu^{(2)}(k\rho) - \nu\Omega_n, & \rho > \rho' \\ \frac{\nu}{k\rho} J_\nu(k\rho)H_\nu^{(2)'}(k\rho') + \nu\Omega_n, & \rho < \rho' \end{cases} \quad (95)$$

$$b_n^{\varphi\rho'} = \begin{cases} -\frac{\nu}{k\rho'} J_\nu(k\rho')H_\nu^{(2)'}(k\rho) - \nu\Omega_n, & \rho > \rho' \\ -\frac{\nu}{k\rho'} J'_\nu(k\rho)H_\nu^{(2)}(k\rho') + \nu\Omega_n, & \rho < \rho' \end{cases} \quad (96)$$

$$b_n^{\varphi\rho'} = J'_\nu(k\rho_{<})H_\nu^{(2)'}(k\rho_{>}) + \nu\Omega_n \quad (97)$$

where J'_ν and $H_\nu^{(2)'}$ denote derivatives with respect to the arguments of the respective functions and

$$\Omega_n = \frac{j}{\pi k^2 \rho \rho'} \left(\frac{\rho_{<}}{\rho_{>}}\right)^\nu \quad (98)$$

we can express the elements of $\bar{\mathbf{G}}_{At}^s$ as

$$G_{A\rho\rho'}^s = \frac{\pi}{2j\beta} \sum_{n=1}^\infty c_n^- b_n^{\rho\rho'} \quad (99)$$

$$G_{A\rho\varphi'}^s = \frac{\pi}{2j\beta} \sum_{n=1}^\infty s_n^+ b_n^{\rho\varphi'} \quad (100)$$

$$G_{A\varphi\rho'}^s = \frac{\pi}{2j\beta} \sum_{n=1}^\infty s_n^- b_n^{\varphi\rho'} \quad (101)$$

$$G_{A\varphi\varphi'}^s = \frac{\pi}{4j\beta} \sum_{n=0}^\infty \varepsilon_n c_n^+ b_n^{\varphi\varphi'} \quad (102)$$

Finally, using (89) in (88) and summing the resulting series, we can express the Coulomb scalar potential as

$$G_V = -\frac{1}{2\pi} (\ln R^- - \ln R^+) \quad (103)$$

where

$$R^\pm = (1 - 2\xi \cos \zeta^\pm + \xi^2)^{1/2} \quad (104)$$

with

$$\zeta^\pm = \frac{\pi}{\beta} (\varphi \pm \varphi'), \quad \xi = \left(\frac{\rho_{<}}{\rho_{>}}\right)^{\pi/\beta} \quad (105)$$

The lamellar part of $\bar{\mathbf{G}}_A$ can also be transformed by a procedure analogous to that used to obtain Eqs. (99)–(102). When the corresponding components of $\bar{\mathbf{G}}_A^i$ and $\bar{\mathbf{G}}_{At}^s$ are added to form the transverse part of the Lorentz vector potential Green function, cancellations occur, resulting in the relatively simple expressions

$$G_{A\rho\rho'} = \frac{\pi}{2j\beta} \sum_{n=1}^\infty c_n^- a_n^+ \quad (106)$$

$$G_{A\rho\varphi'} = \frac{\pi}{2j\beta} \sum_{n=1}^\infty s_n^+ a_n^- \quad (107)$$

$$G_{A\varphi\rho'} = -\frac{\pi}{2j\beta} \sum_{n=1}^\infty s_n^- a_n^- \quad (108)$$

$$G_{A\varphi\varphi'} = \frac{\pi}{4j\beta} \sum_{n=0}^\infty \varepsilon_n c_n^+ a_n^+ \quad (109)$$

where

$$a_n^\pm = \frac{1}{2} [J_{\nu-1}(k\rho_{<})H_{\nu-1}^{(2)}(k\rho_{>}) \pm J_{\nu+1}(k\rho_{<})H_{\nu+1}^{(2)}(k\rho_{>})] \quad (110)$$

Finally, using (90) in (87), we express the Lorentz scalar potential as

$$G_V = \frac{\pi}{2j\beta} \sum_{n=1}^{\infty} c_n^- J_v(k\rho_<) H_v^{(2)}(k\rho_>) \quad (111)$$

4.5. Incident Field and Far-Field Pattern

The TE plane wave with amplitude E_0 impinging on the wedge at an angle φ_i (Fig. 3) produces in the absence of the arbitrary scatterer C the “incident” field \mathbf{E}^i, H_z^i . The components of \mathbf{E}^i , which appear as the driving function in the integral equation (69), are easily found as [21]

$$\begin{aligned} E_{\varphi}^i &= E_0 \frac{\pi}{\beta} \sum_{n=0}^{\infty} \varepsilon_n e^{j(v+1)\pi/2} J'_v(k\rho) \\ &\times [\cos v(\varphi - \varphi_i) + \cos v(\varphi + \varphi_i)] \end{aligned} \quad (112)$$

$$\begin{aligned} E_{\rho}^i &= E_0 \frac{\pi}{\beta} \sum_{n=1}^{\infty} \frac{2v}{k\rho} e^{j(v+1)\pi/2} J_v(k\rho) \\ &\times [\sin v(\varphi - \varphi_i) + \sin v(\varphi + \varphi_i)] \end{aligned} \quad (113)$$

When the scatterer is introduced near the wedge, the field \mathbf{E}^i, H_z^i is modified by the “scattered” field \mathbf{E}^s, H_z^s , whose source is the surface current (of density \mathbf{J}) induced on C . It can be shown that far from the edge

$$H_z^s = \left(\frac{2j}{\pi k\rho} \right)^{1/2} e^{-jk\rho} P(\varphi) \quad (114)$$

where

$$P(\varphi) = \frac{\pi k}{4\beta j} \int_C \mathbf{F}(\boldsymbol{\rho}', \varphi) \cdot \mathbf{J}(\boldsymbol{\rho}') d\ell' \quad (115)$$

is the far-field pattern, in which

$$\begin{aligned} F(\boldsymbol{\rho}', \varphi) &= \hat{\boldsymbol{\rho}}' \sum_{n=1}^{\infty} \frac{2v}{k\rho'} s_n^- e^{jv\pi/2} J_v(k\rho') \\ &- \hat{\boldsymbol{\phi}}' \sum_{n=0}^{\infty} \varepsilon_n c_n^+ e^{jv\pi/2} J'_v(k\rho') \end{aligned} \quad (116)$$

4.6. Numerical Method

To numerically solve the MPIEs in both gauges, we adapt the MM procedure developed in Ref. 22 for objects in free space. In this approach, the arbitrary contour C is modeled in terms of straight-line segments, as illustrated in Fig. 4, and the current \mathbf{J} is expanded as

$$\mathbf{J}(\rho) = \sum_{n=1}^N J_n \Lambda_n(l) \quad (117)$$

where Λ_n are piecewise linear expansion functions defined as

$$\Lambda_n(l) = \begin{cases} \frac{\boldsymbol{\rho}_n^+}{h_n^+} & l \text{ in } C_n^+ \\ \frac{\boldsymbol{\rho}_n^-}{h_n^-} & l \text{ in } C_n^- \\ 0, & \text{otherwise} \end{cases} \quad (118)$$

Here, l is the arclength along the contour approximating C , C_n^{\pm} denote segments which meet at the n th node, h_n^{\pm} are their respective lengths, $\boldsymbol{\rho}_n^+$ is a vector from the free node of C_n^+ to an arbitrary point on the segment, and $\boldsymbol{\rho}_n^-$ is a vector from an arbitrary point on segment C_n^- to its free node, as shown in Fig. 4. Observe that Λ_n is piecewise differentiable, so that we may take divergence of (117) to form an expansion for the charge density q , as dictated by (5).

When the expansion (117) is used in (69) and the resulting equation is “tested” with Λ_m , an algebraic system of simultaneous equations for the current expansion coefficients J_n is obtained, which may be written in matrix form:

$$[Z_{mn}][J_n] = [\Phi_m], \quad m = 1, 2, \dots, N \quad (119)$$

In (119), the elements of the $N \times N$ “impedance matrix” $[Z_{mn}]$ can be expressed as

$$Z_{mn} = j\omega\mu(A_{mn}^+ + A_{mn}^-) + \frac{1}{j\omega\varepsilon}(V_{mn}^+ - V_{mn}^-) \quad (120)$$

where

$$A_{mn}^{\pm} = \int_C \boldsymbol{\rho}_m^{\pm} \cdot \bar{\mathbf{G}}_{Ai}(l_m^{\pm}|l') \cdot \Lambda_n(l') dl' \quad (121)$$

and

$$V_{mn}^{\pm} = \int_C G_{\Phi}(l_m^{\pm}|l') \nabla' \cdot \Lambda_n(l') dl' \quad (122)$$

while the elements of the forcing vector are given as

$$\Phi_m = \boldsymbol{\rho}_m^{c+} \cdot \mathbf{E}^i(l_m^{c+}) + \boldsymbol{\rho}_m^{c-} \cdot \mathbf{E}^i(l_m^{c-}) \quad (123)$$

in which $\boldsymbol{\rho}_m^{c+}$ is a vector from the free node of segment C_m^+ to its midpoint and $\boldsymbol{\rho}_m^{c-}$ is a vector from the midpoint of segment C_m^- to its free node. The arclength coordinates of the middle points of C_m^{\pm} are denoted by l_m^{\pm} .

4.7. Sample Results

In this section we present sample numerical results for a simple structure near a wedge with an arbitrarily chosen angle α (see Fig. 5). In this case, $f = 300$ MHz, which corresponds to free-space wavelength $\lambda = 1$ m. The structure considered was that of a circular cylinder of radius $a = \lambda/2\pi$, enclosing the edge of a wedge with $\alpha = 30^\circ$, thus simulating a cylindrically tipped wedge, for which an exact solution is available [23]. The circular profile C of the cylinder was approximated by 30 straight-line segments. The current distribution on C for $\varphi_i = 45^\circ$ is shown in

Figure 4. Contour C approximated by straight-line segments and local coordinates associated with the n th node.

Fig. 5a and the corresponding far-field pattern, in Fig. 5b. Since the Coulomb and Lorentz gauge-based programs produced graphically indistinguishable results, only the Lorentz gauge data are displayed here.

5. SUMMARY

Green's functions for the scalar and vector potentials are derived employing the Lorentz and Coulomb gauges. The two sets of gauge potentials are compared by constructing and solving integral equations for a straight wire in free space and for the two-dimensional problem of a conducting surface of arbitrary shape near an infinite wedge illuminated by a transverse electric plane wave. The attractive feature of the latter is the fact that the Coulomb scalar potential is available in closed form (rather than in series form, as in the Lorentz gauge) for the geometries considered here. However, this advantage of the Coulomb gauge formulation is offset by the fact that the resulting series converge slower than the corresponding series of the Lorentz gauge MPIE, and their acceleration is more involved. In the case of scattering from a wedge, we have observed on average a 15% savings in the impedance matrix fill time when the Lorentz gauge was used instead of the Coulomb gauge. However, the opposite is true in the case of the wire. Another advantage of the Coulomb gauge is that the scalar potential is identical to the static potential. This being the case, in the near zone the scalar potential entirely dominates the field, whereas in the far zone the vector potential dominates and the effect of the scalar potential can be neglected.

6. APPENDIX A

Dyadics are an alternative to the more usual matrix operations. For example, the matrix expression

$$\underline{\mathbf{B}} = \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} \tag{A.1}$$

Figure 5. (a) Normalized current density on C and (b) far-field pattern for a cylindrically tipped wedge ($\alpha = 30^\circ$) illuminated by a plane wave with $\phi_i = 45^\circ$.

in dyadic notation becomes

$$\underline{\mathbf{B}} = b_{11}\hat{\mathbf{x}}\hat{\mathbf{x}} + b_{12}\hat{\mathbf{x}}\hat{\mathbf{y}} + b_{21}\hat{\mathbf{y}}\hat{\mathbf{x}} + b_{22}\hat{\mathbf{y}}\hat{\mathbf{y}} \tag{A.2}$$

where the product of two unit vectors, for example, $\hat{\mathbf{x}}\hat{\mathbf{y}}$, is a dyad and the sum of dyads, $\underline{\mathbf{B}}$ in this case, is a dyadic.

In this chapter the main operation that takes place between a vector and a dyadic is the dot product. The product of a vector and a matrix follows the usual rules of matrix multiplication; for example, multiplication of the vector $\mathbf{A} = a_{11}\hat{\mathbf{x}} + a_{12}\hat{\mathbf{y}}$ by the matrix $\underline{\mathbf{B}}$ in vector-matrix

notation is

$$\begin{aligned} \underline{\mathbf{A}}\underline{\mathbf{B}} &= [a_{11} \ a_{12}] \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} \\ &= [(a_{11}b_{11} + a_{12}b_{21}) \ (a_{11}b_{12} + a_{12}b_{22})] \end{aligned}$$

or

$$\underline{\mathbf{A}}\underline{\mathbf{B}} = (a_{11}b_{11} + a_{12}b_{21})\hat{\mathbf{x}} + (a_{11}b_{12} + a_{12}b_{22})\hat{\mathbf{y}} \quad (\text{A.3})$$

The vector-dyadic dot product follows the rule that the dot product is taken between the two unit vectors in closest proximity to the dot. For example, $\hat{\mathbf{x}} \cdot \hat{\mathbf{x}}\hat{\mathbf{y}} = (\hat{\mathbf{x}} \cdot \hat{\mathbf{x}})\hat{\mathbf{y}} = \hat{\mathbf{y}}$, whereas $\hat{\mathbf{x}}\hat{\mathbf{y}} \cdot \hat{\mathbf{x}} = \hat{\mathbf{x}}(\hat{\mathbf{y}} \cdot \hat{\mathbf{x}}) = 0$. So, equivalent to the vector-matrix product (A.3) is the vector-dyadic dot product

$$\begin{aligned} \underline{\mathbf{A}} \cdot \underline{\mathbf{B}} &= a_{11}[b_{11}(\hat{\mathbf{x}} \cdot \hat{\mathbf{x}})\hat{\mathbf{x}} + b_{12}(\hat{\mathbf{x}} \cdot \hat{\mathbf{x}})\hat{\mathbf{y}} \\ &\quad + b_{21}(\hat{\mathbf{x}} \cdot \hat{\mathbf{y}})\hat{\mathbf{x}} + b_{22}(\hat{\mathbf{x}} \cdot \hat{\mathbf{y}})\hat{\mathbf{y}}] \\ &\quad + a_{12}[b_{11}(\hat{\mathbf{y}} \cdot \hat{\mathbf{x}})\hat{\mathbf{x}} + b_{12}(\hat{\mathbf{y}} \cdot \hat{\mathbf{x}})\hat{\mathbf{y}} \\ &\quad + b_{21}(\hat{\mathbf{y}} \cdot \hat{\mathbf{y}})\hat{\mathbf{x}} + b_{22}(\hat{\mathbf{y}} \cdot \hat{\mathbf{y}})\hat{\mathbf{y}}] \\ &= (a_{11}b_{11} + a_{12}b_{21})\hat{\mathbf{x}} \\ &\quad + (a_{11}b_{12} + a_{12}b_{22})\hat{\mathbf{y}} \end{aligned} \quad (\text{A.4})$$

Equations (A.3) and (A.4) show that the vector-matrix product is exactly equivalent to the vector-dyadic dot product.

Dyadic operations tend to be easier to perform and more systematic than operations with matrices. For example, it is not necessary to retain a dyad with a zero coefficient as must be done with terms of a matrix. More importantly, the fact that a dyadic can be readily decomposed into solenoidal and lamellar components is a crucial advantage in solving problems in the Coulomb gauge. For a more detailed discussion of dyadic operations the reader is referred to Tai [4].

7. APPENDIX B

The following example demonstrates function orthogonality between solenoidal and lamellar components of two dyadics, in which a dyadic delta function can be used to extract the solenoidal (or lamellar) component of a dyadic, and an alternative method can be employed to obtain the Coulomb gauge vector potential Green function. We evaluate [19]

$$\begin{aligned} \bar{\mathbf{G}}^{\text{C}}(\mathbf{r}|\mathbf{r}') &= \int_{v''} \bar{\delta}^{\text{S}}(\mathbf{r} - \mathbf{r}'') \cdot \bar{\mathbf{G}}^{\text{L}}(\mathbf{r}'' - \mathbf{r}') dv'' \\ &= \frac{1}{4\pi} \nabla \times \nabla \times \bar{\mathbf{I}} \int_{v''} \frac{\mathbf{G}(\mathbf{r}'' - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}''|} dv'' \end{aligned} \quad (\text{B.1})$$

Figure 6. Coordinate transformation for volume integration.

The Lorentz gauge Green function $\bar{\mathbf{G}}^{\text{L}}$ contains both solenoidal and lamellar components while $\bar{\delta}^{\text{S}}$ is entirely solenoidal. An evaluation of this integral should yield the solenoidal component of $\bar{\mathbf{G}}^{\text{L}}$, which has been shown in the text to be the Coulomb Green function $\bar{\mathbf{G}}^{\text{C}}$.

Since the integration in (B.1) is over all space, the coordinate transformation shown in Fig. 6 can be made where \mathbf{r}' designates the new coordinate origin and

$$\begin{aligned} R &= |\mathbf{r} - \mathbf{r}'| \\ S &= |\mathbf{r}'' - \mathbf{r}'| \end{aligned} \quad (\text{B.2})$$

$$T^2 = S^2 + R^2 - 2SR \cos \gamma$$

giving

$$\begin{aligned} I &= \int_{v''} \frac{e^{-jk|\mathbf{r}'' - \mathbf{r}'|}}{|\mathbf{r}'' - \mathbf{r}'||\mathbf{r} - \mathbf{r}''|} dv'' \\ &= \int_{\psi=0}^{2\pi} \int_{\gamma=0}^{\pi} \int_{S=0}^{\infty} \frac{e^{-jkS}}{T} S \sin \gamma dS d\gamma d\psi \end{aligned} \quad (\text{B.3})$$

Integration in ψ is performed and a change of variables

$$U = (S^2 + R^2 - 2SR \cos \gamma)^{1/2} \quad (\text{B.4})$$

results in

$$\begin{aligned} I &= \frac{2\pi}{R} \int_{S=0}^{\infty} e^{-jkS} dS \int_{U=|R-S|}^{R+S} dU \\ &= \frac{4\pi}{R} \left\{ \int_{S=0}^R S e^{-jkS} dS + R \int_{S=R}^{\infty} e^{-jkS} dS \right\} \end{aligned} \quad (\text{B.5})$$

The first integral in (B.5) is evaluated by integration by parts. The second integral is evaluated by assuming that k contains a small loss factor so that as $S \rightarrow \infty$, $e^{-jkS} \rightarrow 0$.

Finally we arrive at

$$I = \frac{4\pi}{k^2} \left(\frac{e^{-jkR} - 1}{R} \right) \quad (\text{B.6})$$

which, when substituted into (B.1) yields the solenoidal part of the Lorentz gauge Green function given in (53).

COUPLED TRANSMISSION LINES

CLAYTON R. PAUL
Mercer University
Macon, Georgia

Two transmission lines whose electromagnetic fields are coupled induce signals from one line into the other. This coupling is either intentional as in directional couplers or unintentional, producing unwanted responses in the other line, which is referred to as *crosstalk*. This discussion of coupled transmission lines will concentrate on the analysis of coupled lines and can be used to design intentional coupling or to assess unintentional coupling as in crosstalk.

The study of two-conductor lines is standard in undergraduate electrical engineering courses [1]. The equations governing two-conductor lines and most of their properties have direct parallels in the case of multiconductor transmission lines (MTLs), which consist of $n + 1$ conductors, where $n > 1$. The equations and properties of the two-conductor line can be written for MTLs in a virtually identical form using matrix notation. We will focus on those parallels throughout this article in order to facilitate an understanding of MTLs. For a complete discussion of two-conductor lines and their properties, see Ref. 1. For a complete discussion of MTLs, see Ref. 2, which contains a large number of references on MTLs and their properties. See also Ref. 3 for an extensive list of references on MTLs.

Although a MTL can have any number of conductors (greater than two), we will concentrate here on a three-conductor line, $n = 2$. This will simplify the detail, and virtually all the discussion can be extended in a simple fashion to MTLs consisting of more than three conductors using matrix notation. Practical lines have losses in the finite, nonzero conductivities of the line conductors and in the losses in the surrounding dielectric medium. These losses complicate the analysis considerably. Their incorporation will be briefly discussed in Section 7, and the reader is referred to Ref. 2 for a more complete discussion.

In Section 1 we will investigate the transverse electromagnetic (TEM) mode of propagation on transmission lines. Although higher-order modes can exist at the higher frequencies, the dominant TEM mode has been shown to be sufficient for the analysis of transmission-line structures up to the low-gigahertz frequency range. As

digital clock speeds and the frequencies of analog systems continue to increase, seemingly without bound, the TEM-mode assumption will provide a simple but effective analysis tool for electronic systems in the near future. We will derive the MTL equations and discuss some general features of the problem.

In Section 2 we will briefly consider the all-important per unit length (PUL) parameters of inductance and capacitance through which the unique features that distinguish one specific type of line from another are contained. The MTL equations are the same for all MTLs, but these PUL parameters contain all the structural dimensions that distinguish one line from another. Without the ability to compute these PUL parameters for a specific line, solving the MTL equations would be fruitless.

In Section 3 we will investigate the time-domain solution of the MTL equations. We will show a useful SPICE model for coupled lines that allows complicated lines and terminations to be analyzed. The heart of the analysis is the ability to decouple the MTL equations. This separates the coupled lines into two uncoupled two-conductor lines for which we know the simple solution. Decoupling the MTL equations is discussed extensively in Refs. 2 and 3.

In Section 4 we will investigate the solution of the MTL equations in the frequency domain (single frequency, sinusoidal, steady state). Again, the heart of this solution process is the decoupling of the MTL equations.

In Section 5 we will present an approximate, lumped-circuit model of an MTL. This model is valid for lines that are electrically short, specifically, whose total length is less than, say, one-tenth of a wavelength at the highest significant frequency of the source. This approximate, lumped-circuit model bypasses the need to solve the MTL equations and is amenable to use in lumped-circuit analysis programs such as SPICE.

There are a few important classes of three-conductor MTLs for which a closed-form solution can be obtained. These are discussed in Section 6. For a three-conductor line in a homogeneous medium, the exact solution in the frequency domain can be readily obtained and shows considerable insight into its behavior, which is obscured in the numerical solution of the MTL equations. In some important instances, the line is electrically short, much less than a wavelength. In addition, the lines are not tightly coupled. This is said to be *weak coupling*. For a weakly coupled, electrically short line the solution reduces to the simple inductive-capacitive coupling model from which great insight and numerical results can be easily obtained. For lines in an inhomogeneous medium that are electrically long, the general solutions have not been obtained in closed form. However, for weak coupling a closed-form solution can be obtained, and the reader is referred to Ref. 5 for that solution.

1. THE MTL EQUATIONS

A generic three-conductor line ($n=2$) is shown in Fig. 1a. The line is parallel to the z axis. It consists of a total of

three ($n+1=3$) conductors. One conductor is chosen as the reference conductor to which the line voltages are referenced and through which the currents of the other two conductors “return.” The reference conductor is shown as a “ground plane” for illustration. However, the reference conductor can be of any type (wires, PCB lands, etc.). The dominant mode of propagation (extending from DC to the low-gigahertz frequency range) is the transverse electromagnetic (TEM) mode, wherein the electric and magnetic fields lie in the transverse or xy plane and are denoted by E^t , H^t , respectively. This assumption of the TEM field structure allows the unique definition of voltages and currents [1,2]. The line consists of a generator conductor that connects a source, characterized by an open-circuit voltage $V_S(t)$ and its source resistance R_S and a load characterized by a load resistance R_L . A receptor conductor connects two loads characterized by resistors R_{NE} and R_{FE} . The subscripts refer to “near end” and “far end,” respectively, with reference to the driving source of the generator line. Although we use resistive terminations, the analysis can be extended to dynamic and nonlinear terminations with the SPICE model to be developed. The voltages are defined with respect to the reference conductor and are functions of line position z and time t as $V_G(z, t)$ and $V_R(z, t)$. Similarly, the line currents are denoted as $I_G(z, t)$ and $I_R(z, t)$. We will assume throughout that the line is a *uniform* line wherein the conductors have uniform cross sections along their length and all conductors are parallel. The task will be to solve for the terminal voltages and currents of the line. The line is of total length L and extends from $z=0$ to $z=L$.

We next derive the differential equations governing these line voltages and line currents. We will use a lumped-circuit model to obtain these equations. The lumped-circuit model is not the only method for obtaining the governing equations. See Ref. 2 for alternative derivations directly from the electromagnetic field equations. Consider a differentially small section of length Δz as shown in Fig. 1b. Per unit length parameters of inductance and capacitance contain the structural dimensions of a particular line and will be discussed later. The PUL parameters of self-inductance are denoted as l_G , l_R , and the PUL parameters of self-capacitance are denoted as c_G , c_R . The PUL parameters of mutual inductance and capacitance are denoted by l_{GR} , c_{GR} , respectively. The inductance parameters have units of henries per meter (H/m), and the capacitance parameters have units of Farads per meter (F/m). We will assume that the line is lossless, that is, that the conductors are perfect conductors and the surrounding medium has zero conductivity. Hence the PUL parameters of conductor resistance and internal inductance as well as the conductance of the surrounding medium are absent from this PUL model. For a discussion of incorporating losses, see Section 7 and Ref. 2. Writing Kirchhoff’s voltage law around the loop consisting of the generator conductor and the reference conductor yields

$$V_G(z + \Delta z, t) = V_G(z, t) - l_G \Delta z \frac{\partial I_G(z, t)}{\partial t} - l_{GR} \Delta z \frac{\partial I_R(z, t)}{\partial t}$$

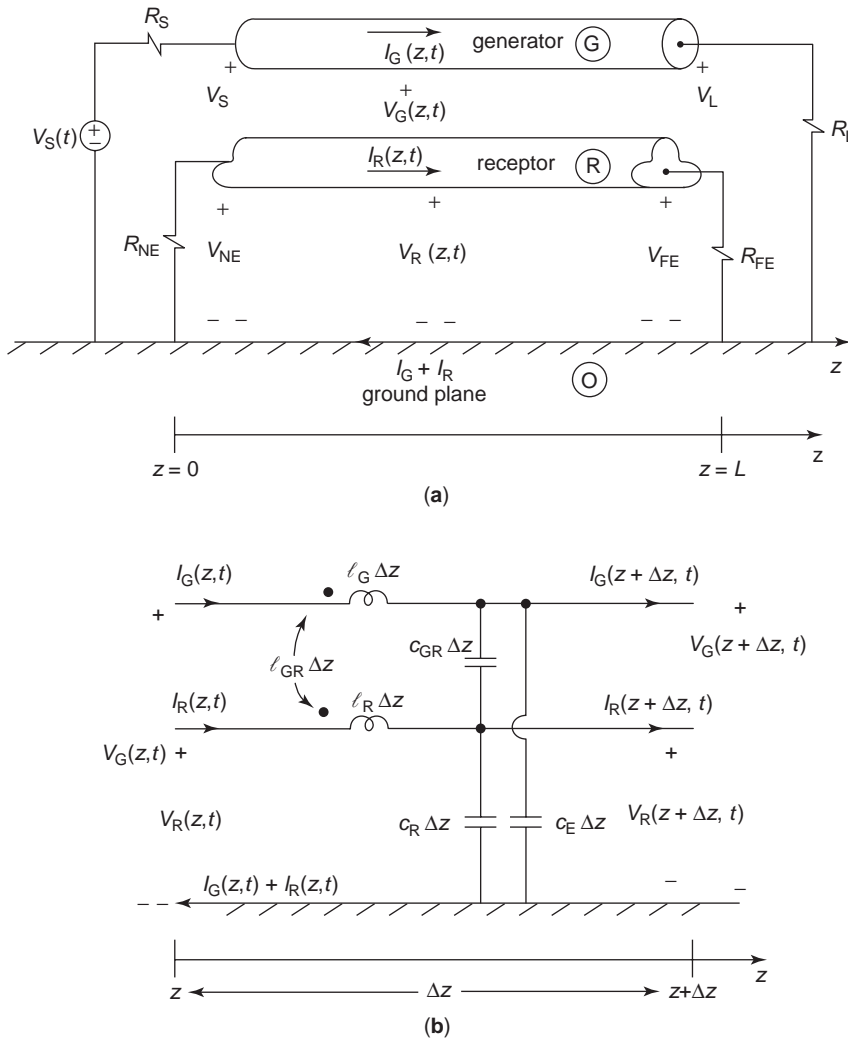

Figure 1. Illustration of coupled transmission lines; (a) the physical line with terminations, and (b) the per unit length equivalent circuit.

Similarly, writing Kirchhoff's current law at the node to the right of the inductor $l_G \Delta z$ yields

$$\begin{aligned} I_G(z + \Delta z, t) &= I_G(z, t) - c_G \Delta z \frac{\partial V_G(z + \Delta z, t)}{\partial t} \\ &\quad - c_{GR} \Delta z \frac{\partial (V_G(z + \Delta z, t) - V_R(z + \Delta z, t))}{\partial t} \end{aligned}$$

Dividing both sides by Δz and taking the limit as $\Delta z \rightarrow 0$ yield

$$\frac{\partial V_G(z, t)}{\partial z} = -l_G \frac{\partial I_G(z, t)}{\partial t} - l_{GR} \frac{\partial I_R(z, t)}{\partial t} \quad (1a)$$

$$\frac{\partial I_G(z, t)}{\partial t} = -(c_G + c_{GR}) \frac{\partial V_G(z, t)}{\partial t} + c_{GR} \frac{\partial V_R(z, t)}{\partial t} \quad (1b)$$

Similarly, for the receptor circuit we obtain

$$\frac{\partial V_R(z, t)}{\partial z} = -l_{GR} \frac{\partial I_G(z, t)}{\partial t} - l_R \frac{\partial I_R(z, t)}{\partial t} \quad (2a)$$

$$\frac{\partial I_R(z, t)}{\partial t} = c_{GR} \frac{\partial V_G(z, t)}{\partial t} - (c_R + c_{GR}) \frac{\partial V_R(z, t)}{\partial t} \quad (2b)$$

Combining (1) and (2) and writing them in matrix form yields the MTL equations to be solved as

$$\frac{\partial}{\partial z} \mathbf{V}(z, t) = -\mathbf{L} \frac{\partial}{\partial t} \mathbf{I}(z, t) \quad (3a)$$

$$\frac{\partial}{\partial z} \mathbf{I}(z, t) = -\mathbf{C} \frac{\partial}{\partial t} \mathbf{V}(z, t) \quad (3b)$$

where

$$\mathbf{V}(z, t) = \begin{bmatrix} V_G(z, t) \\ V_R(z, t) \end{bmatrix} \quad (4a)$$

$$\mathbf{I}(z, t) = \begin{bmatrix} I_G(z, t) \\ I_R(z, t) \end{bmatrix} \quad (4b)$$

and the PUL inductance and capacitance matrices are

$$\mathbf{L} = \begin{bmatrix} l_G & l_{GR} \\ l_{GR} & l_R \end{bmatrix} \quad (5a)$$

$$\mathbf{C} = \begin{bmatrix} (c_G + c_{GR}) & -c_{GR} \\ -c_{GR} & (c_R + c_{GR}) \end{bmatrix} \quad (5b)$$

The PUL parameter matrices \mathbf{L} and \mathbf{C} are symmetric, which is proved in Ref. 2. The MTL equations in (3) have considerable similarity to those for the two-conductor line, which is studied in all undergraduate electrical engineering curricula, where the quantities are scalars [1]. In fact, we will show that for a MTL the corresponding solutions and properties will have direct parallels to those for the two-conductor line but with matrix notation. Although we are studying a special case of the more general $(n+1)$ conductor MTL where $n=2$, the corresponding MTL equations for $n>2$ are in exactly the same form as in (3) [2]. The important point here is that if we can solve the MTL equations in (3) for a two-conductor line, we can readily obtain the solution for a general MTL where $n>2$.

Finally, the line is said to be a *uniform line* wherein the conductor cross sections and the cross sections of any inhomogeneous media surrounding the conductors are independent of z , and the line conductors are parallel to each other and the z axis. A *nonuniform line* would have the PUL parameter matrices as a function of z : $\mathbf{L}(z)$ and $\mathbf{C}(z)$. In this case the MTL equations would be quite difficult to solve except in certain special cases such as a line with exponential taper. Although there are several important cases of nonuniform lines, we will restrict our discussion to uniform lines, which represent the majority of the applications.

2. THE PER UNIT LENGTH PARAMETERS

The reader is once again reminded that all cross-sectional structural dimensions are contained in the PUL parameters in \mathbf{L} and \mathbf{C} . The MTL equations in (3) are identical for all lines. Hence, determining these parameters for a particular line is essential to the complete solution; solving the MTL equations would do little good without knowledge of the values of the PUL parameters for the specific line.

Because of the TEM mode assumption, the transverse electric and magnetic fields satisfy a static distribution in the two-dimensional (2D) xy cross-sectional plane [2]. In other words, the transverse electric and magnetic fields are the same as static field distributions in the xy plane

even though they vary with time. Hence a wide variety of commercially available 2D electrostatic and magnetostatic field solvers can be used to determine these PUL parameters. These field solvers use numerical solutions of Laplace's equation via the method of moments (MoM) or the finite-element method (FEM) [2].

Definition of these PUL parameters is very similar to the two-conductor case ($n=1$). Again, the TEM field structure is assumed to be present where the electric field intensity vector E^t and the magnetic field intensity vector H^t lie solely in the *transverse* or xy plane. There are two "circuits"; one is the loop formed between the generator conductor and the reference conductor, and the other loop is formed between the receptor conductor and the reference conductor. The PUL inductance matrix in (5a) relates the magnetic flux ψ penetrating these loops to the line currents as

$$\psi_G = l_G I_G + l_{GR} I_R \quad (6a)$$

$$\psi_R = l_{GR} I_G + l_R I_R \quad (6b)$$

In matrix form, these relations become

$$\Psi = \mathbf{L} \mathbf{I} \quad (7a)$$

where

$$\Psi = \begin{bmatrix} \psi_G \\ \psi_R \end{bmatrix} \quad (7b)$$

Each PUL parameter in (9) can be found in a fashion similar to that employed for two-port parameters, as follows:

$$l_G = \left. \frac{\psi_G}{I_G} \right|_{I_R=0} \quad (8a)$$

$$l_R = \left. \frac{\psi_R}{I_R} \right|_{I_G=0} \quad (8b)$$

$$l_{GR} = \left. \frac{\psi_G}{I_R} \right|_{I_G=0} = \left. \frac{\psi_R}{I_G} \right|_{I_R=0} \quad (8c)$$

This is illustrated in Fig. 2a. Similarly, the PUL capacitance matrix in (5b) relates the PUL charge on the conductors Q to the line voltages as

$$Q_G = (c_G + c_{GR})V_G - c_{GR}V_R \quad (9a)$$

$$Q_R = -c_{GR}V_G + (c_R + c_{GR})V_R \quad (9b)$$

In matrix form, these relations become

$$\mathbf{Q} = \mathbf{C} \mathbf{V} \quad (10a)$$

where

$$\mathbf{Q} = \begin{bmatrix} Q_G \\ Q_R \end{bmatrix} \quad (10b)$$

Each PUL parameter in (9) can be found in a fashion similar to that used for two-port parameters, as follows:

$$c_G + c_{GR} = \frac{Q_G}{V_G} \Big|_{V_R=0} \quad (11a)$$

$$c_R + c_{GR} = \frac{Q_R}{V_R} \Big|_{V_G=0} \quad (11b)$$

$$-c_{GR} = \frac{Q_G}{V_R} \Big|_{V_G=0} = \frac{Q_R}{V_G} \Big|_{V_R=0} \quad (11c)$$

This is illustrated in Fig. 2b.

There are several important properties of the PUL parameter matrices (see Ref. 2 for proofs of these properties):

1. The PUL parameters matrices \mathbf{L} and \mathbf{C} are real and symmetric, specifically, $\mathbf{L} = \mathbf{L}^t$ and $\mathbf{C} = \mathbf{C}^t$, where the superscript “t” on a matrix denotes its transpose.
2. The PUL parameter matrices \mathbf{L} and \mathbf{C} are positive-definite, meaning, among other things, that all their eigenvalues are nonzero and positive.

These important results will be used in the solution of the MTL equations.

We now discuss the important classes of lines seen in practice. First we consider typical lines in *homogeneous media* shown in Fig. 3. Figure 3a shows three bare wires

Figure 2. Illustration of the determination of the per unit length parameters of (a) mutual inductance, and (b) mutual capacitance.

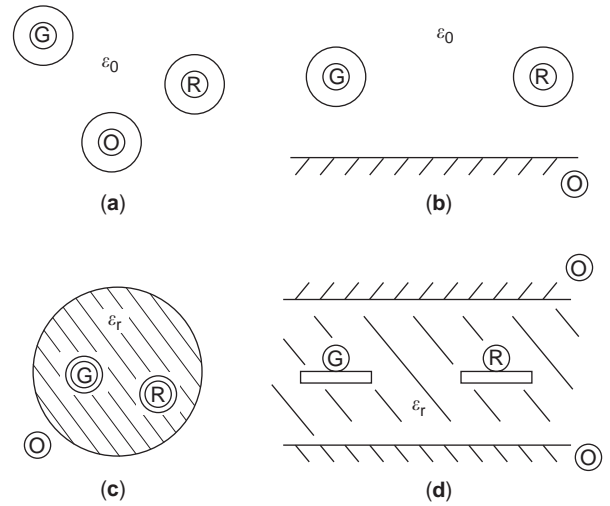

Figure 3. Cross sectional dimensions of lines in a homogeneous medium; (a) a three-wire line, (b) two wires above a ground plane, (c) two wires within an overall cylindrical shield, and (d) a coupled stripline.

(circular cross section conductors) immersed in free space. Wires typically have dielectric insulation such that the surrounding medium is inhomogeneous. In this illustration, we have removed (ignored) those insulations in order to make this a homogeneous medium problem. High-voltage transmission lines typically are bare. Figure 3b shows two bare wires above an infinite ground plane. Figure 3c shows two wires within a surrounding shield. The medium internal to the shield has a relative permittivity of ϵ_r . Figure 3d shows a typical structure occurring in printed circuit boards (PCBs): the coupled stripline. Two “lands” (rectangular cross section conductors) lie between two ground planes. This is typical of PCBs that have inner planes. The medium between the planes has a relative permittivity of ϵ_r where $\epsilon_r = 4.7$ for typical glass-epoxy (resin) (FR4) boards.

For the lines in a homogeneous medium having permeability $\epsilon = \epsilon_0 \epsilon_r$ and permeability μ_0 in Fig. 3, the velocity of propagation of the voltage and current waves is

$$v = \frac{1}{\sqrt{\mu\epsilon}} = \frac{v_0}{\sqrt{\epsilon_r}} \quad (12)$$

where $v_0 = 2.99792458 \times 10^8$ m/s is the speed of light. Perhaps the most important property of lines in a homogeneous medium is that the PUL parameter matrices are related as [2]

$$\mathbf{LC} = \mathbf{CL} = \mu\epsilon \mathbf{1}_2 = \frac{1}{v^2} \mathbf{1}_2 \quad (13)$$

where $\mathbf{1}_2$ is the 2×2 identity matrix:

$$\mathbf{1}_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

For the general $n + 1$ conductor MTL in a homogeneous medium, the PUL parameter matrices satisfy (13), where the identity matrix is $n \times n$ with ones on the main diagonal and zeros elsewhere. The property in (13) is the matrix counterpart to the familiar scalar result for two-conductor lines ($n = 1$) [1].

In general, numerical methods must be used to solve the 2D static field problem here. However, there exist some closed-form approximate solutions for these PUL parameters [2]. For the case of wires in a homogeneous medium as in Figs. 3a-c, these results can be obtained for wide separations. If the wires are sufficiently spaced so that the charge distributions around the peripheries of the wires are essentially uniform, simple formulas are obtainable [2].

Figure 4 shows several important cases of an *inhomogeneous surrounding medium*. Figure 4a shows the common case of a ribbon cable where wires with dielectric insulations are arranged in a linear array. Figure 4b shows the common coupled microstrip where two lands are etched on one side of a substrate and a ground plane on the other side constitutes the reference conductor. This commonly occurs in the outer layers of a PCB having innerplanes. Figure 4(c) shows a case where the three conductors lie on one side of the substrate. This occurs in PCBs that are single- or double-sided without inner planes.

For all these cases of an inhomogeneous medium surrounding the conductors, the electric field lies partly in the dielectric and partly in air. Hence the velocity of propagation is no longer given by (12). Furthermore, there are two velocities of propagation of the two “modes” on the line. In addition, the simple relation between the PUL \mathbf{L} and \mathbf{C} matrices given for a homogeneous medium in (13) no longer holds for an inhomogeneous medium.

Figure 4. Cross sectional dimensions of lines in inhomogeneous media; (a) a three-wire ribbon cable, (b) a coupled microstrip, and (c) a printed circuit board (PCB).

For these cases of an inhomogeneous medium, numerical methods must be used to solve the electrostatic 2D problem. Reference 2 contains descriptions of several FORTRAN computer programs that can be used to compute, via numerical methods, the PUL parameter matrices \mathbf{L} and \mathbf{C} . Once the PUL capacitance matrix \mathbf{C} is determined, we can determine the PUL inductance matrix \mathbf{L} by first determining the PUL capacitance matrix *with the dielectric removed* \mathbf{C}_0 . Then the inductance matrix can be determined from the homogeneous medium relation in (13) as

$$\mathbf{L} = \frac{1}{v_0^2} \mathbf{C}_0^{-1} \tag{14}$$

Hence we only need to obtain the PUL capacitance matrix with the dielectric present and with the dielectric removed (and replaced with free space).

First consider the numerical solution of the ribbon cable in Fig. 4a. The solution method relies on the solution of a fundamental subproblem shown in Fig. 5a. A wire (cylindrical cross section conductor) of radius r_w is surrounded by a cylindrical dielectric insulation having permittivity ϵ . At the air-dielectric interface there is a bound charge distribution that we represent with a Fourier series in the angular variation θ as

$$\rho_b' = a_0' + \sum_{k=1}^{A'} a_k' \cos(\theta) + \sum_{k=1}^{B'} b_k' \sin(\theta) \text{ C/m}^2 \tag{15a}$$

Similarly, at the wire-dielectric interface there is a charge distribution consisting of a combination of free charge and a bound charge, which we represent with a Fourier series

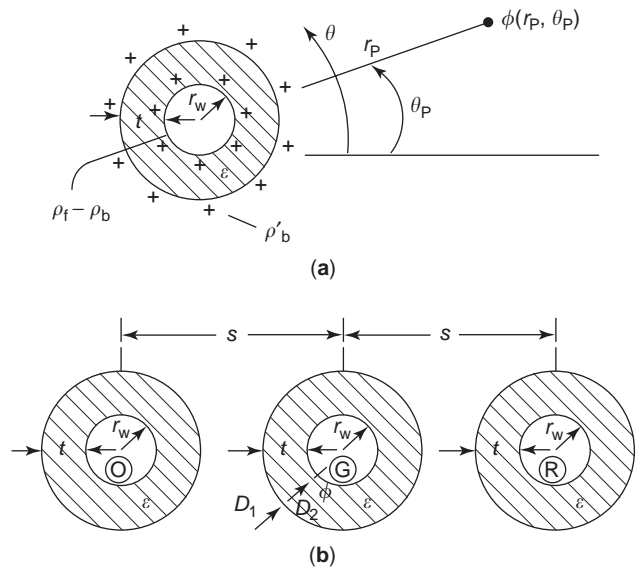

Figure 5. Illustration of the determination of capacitances of a ribbon cable; (a) illustrations of the expansion of charge distributions into bound and free charge, and (b) the physical dimensions of a three-wire ribbon cable.

in the angular variation θ as

$$\rho_f - \rho_b = a_0 + \sum_{k=1}^A a_k \cos(\theta) + \sum_{k=1}^B b_k \sin(\theta) \text{ C/m}^2 \quad (15b)$$

The constants in these expressions ($a'_0, a'_k, b'_k, a_0, a_k, b_k$) will be determined in the problem solution in order to satisfy the boundary conditions. We desire the potential $\phi(r_P, \theta_P)$ due to these charge distributions at a point that is a distance r_P from the wire center and an angle θ_P . Solutions for the potential and electric fields for this basic subproblem are given in Ref. 2. The total PUL charge distribution along the line is obtained from the constant terms in these distributions as

$$Q_f - Q_b = 2\pi r_w a_0 \text{ C/m} \quad (16a)$$

and

$$Q_b = 2\pi(r_w + t)a'_0 \text{ C/m} \quad (16b)$$

where the dielectric insulation is of thickness t . Hence the total PUL free charge distribution is

$$Q_f = 2\pi r_w a_0 + 2\pi(r_w + t)a'_0 \text{ C/m} \quad (17)$$

from which the PUL capacitances of the line can be found. For the three-wire ribbon cable in Fig. 5a, we choose the number of expansion terms around the wire–dielectric interface ($1 + A + B$), and around the air–dielectric interface ($1 + A' + B'$), and apply the boundary conditions. These are to match the potential at sufficient points on each wire (that is due to all charge distributions), and ensure continuity of the components of the electric flux density D_n that are normal to the air–dielectric interface at sufficient points around this interface (due to all charge distributions). This generates simultaneous equations of the form

$$\Phi = \mathbf{D}_{11}\mathbf{A} + \mathbf{D}_{12}\mathbf{A}' \quad (18a)$$

$$\mathbf{0} = \mathbf{D}_{21}\mathbf{A} + \mathbf{D}_{22}\mathbf{A}' \quad (18b)$$

Vector \mathbf{A} contains the expansion coefficients in (15b) for the bound plus free charge at the wire–dielectric interface, while \mathbf{A}' contains the expansion coefficients in (15a) for the bound charge at the air–dielectric interface. Equations (18a) enforce the potential at matchpoints on the wire surfaces, and equations (18b) enforce continuity of the normal components of the electric flux density vector across the air–dielectric interface at matchpoints on that surface. Putting these in matrix form gives

$$\begin{bmatrix} \Phi \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{D}_{11} & \mathbf{D}_{12} \\ \mathbf{D}_{21} & \mathbf{D}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{A} \\ \mathbf{A}' \end{bmatrix} \quad (19)$$

Inverting this gives the solution for the expansion coefficients:

$$\begin{bmatrix} \mathbf{A} \\ \mathbf{A}' \end{bmatrix} = \begin{bmatrix} \mathbf{D}_{11} & \mathbf{D}_{12} \\ \mathbf{D}_{21} & \mathbf{D}_{22} \end{bmatrix}^{-1} \begin{bmatrix} \Phi \\ \mathbf{0} \end{bmatrix} \quad (20)$$

Once the expansion coefficients $a'_0, a'_k, b'_k, a_0, a_k, b_k$ are found from (20), the total free charge on each wire is obtained from (17), and hence we obtain the PUL capacitance matrix [2].

Reference 2 describes this process in greater detail and provides the implementation of the method in a FORTRAN computer code, RIBBON.FOR, which can be obtained from ftp://ftp.wiley.com/public/sci_tech_med/multiconductor_transmission/. As an example, consider the typical three-wire ribbon cable shown in Fig. 5b, where $s = 50$ mils (1.27 mm), the wires are AWG (American Wire Gauge) 28-gauge stranded having a radius of $r_w = 7.5$ mils (0.19 mm), an insulation thickness of $t = 10$ mils (0.254 mm), and PVC insulation having a relative permittivity of $\epsilon_r = 3.5$; we then obtain (with the reference conductor chosen as an outer wire)

$$\mathbf{C} = \begin{bmatrix} 37.432 & -18.716 \\ -18.716 & 24.982 \end{bmatrix} \text{ pF/m}$$

$$\mathbf{C}_0 = \begin{bmatrix} 22.494 & -11.247 \\ -11.247 & 16.581 \end{bmatrix} \text{ pF/m}$$

$$\mathbf{L} = \frac{1}{v_0^2} \mathbf{C}_0 = \begin{bmatrix} 0.7485 & 0.5077 \\ 0.5077 & 1.0154 \end{bmatrix} \mu\text{H/m}$$

and we used 10 expansion coefficients (the constant and 9 cosine terms) around the conductor–dielectric interface and around the dielectric–air interface for each of the three wires. Hence, the matrix to be inverted in Eq. (19) is 60×60 .

For conductors of rectangular cross section (lands) such as the coupled microstrip in Fig. 4b and the PCB in Fig. 4c, we use a similar numerical method. We first obtain the solution for the basic subproblem in Fig. 6a for the potential due to an infinitely long strip of width w along which the charge has a constant distribution ρ C/m². The solution of this basic subproblem is given in Ref. 2. For the coupled microstrip we divide each land into N subsections as shown in Fig. 6b. Instead of representing the free and bound charge as in the ribbon cable problem, we determine the subproblem potential by simply imaging across the air–dielectric interface and across the dielectric–ground plane interface and hence remove the dielectric and the ground plane (see Ref. 2 for details of this imaging). Then we choose N matchpoints at the center of each land subsection and determine the potential at that point due to all charge distributions of all the other subsections to yield

$$\Phi = \mathbf{D}\mathbf{A} \quad (21)$$

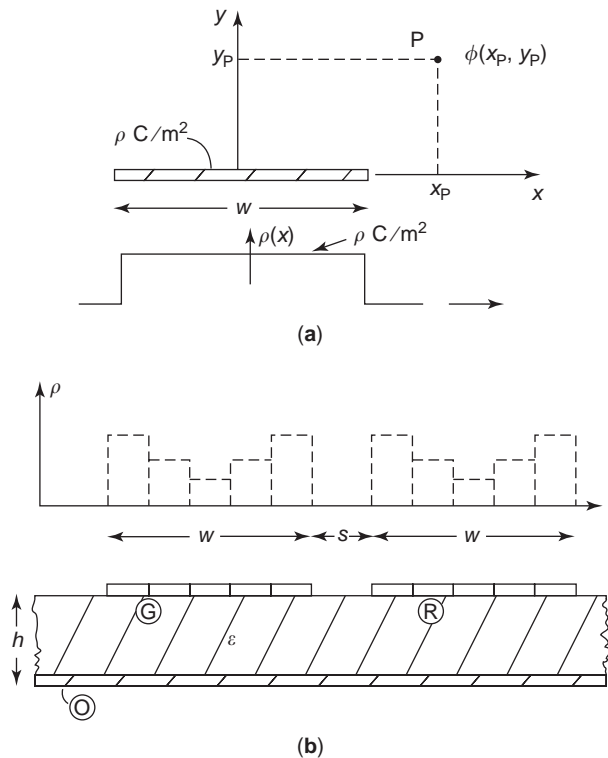

Figure 6. Illustration of the determination of capacitances of a coupled microstrip; (a) the basic subproblem of determining the potential due to a constant charge distribution, and (b) representation of the charge distribution on a coupled microstrip.

where **A** contains the (constant) charge distributions along the land subsections. Inverting this yields the charge distributions on each subdivision of each land. Once these charge distributions are obtained, the total PUL free charge distribution on each land is obtained by multiplying the charge distributions of each subdivision by the subdivision width and adding them for each land. The PUL capacitance matrix is then obtained [2].

Throughout this discussion we will show typical computed and experimental results confirming this theory. The structure to be used is a three-conductor ($n = 2$) coupled microstrip shown in Fig. 6b having dimensions $s = 100$ mils (2.54 mm) and $w = 100$ mils (2.54 mm) and a dielectric having a thickness of $h = 62$ mils (1.57 mm) and a relative permittivity of $\epsilon_r = 4.7$ (glass-epoxy or FR4). The method described above is implemented for the coupled microstrip in a FORTRAN computer program, MSTRP.FOR, described in Ref. 2, obtainable from ftp://ftp.wiley.com/public/sci_tech_med/multiconductor_transmission/. For this line we obtain the following equations, dividing each land into 30 subdivisions [hence the matrix in (21) is 60×60]:

$$\mathbf{C} = \begin{bmatrix} 115.511 & -4.927 \\ -4.927 & 115.511 \end{bmatrix} \text{ pF/m}$$

$$\mathbf{C}_0 = \begin{bmatrix} 33.593 & -3.722 \\ -3.722 & 33.593 \end{bmatrix} \text{ pF/m}$$

$$\mathbf{L} = \frac{1}{v_0^2} \mathbf{C}_0^{-1} = \begin{bmatrix} 335.327 & 37.153 \\ 37.153 & 335.327 \end{bmatrix} \text{ nH/m}$$

A FORTRAN code, PCB.FOR, for the PCB in Fig. 4c is also described in Ref. 2 and can be obtained from ftp://ftp.wiley.com/public/sci_tech_med/multiconductor_transmission/.

3. THE TIME-DOMAIN SOLUTION

The key to solving the coupled MTL equations in (3) is to transform the actual voltages and currents to “mode” voltages and currents with similarity transformations

$$\mathbf{V} = \mathbf{T}_V \mathbf{V}_m \tag{22a}$$

$$\mathbf{I} = \mathbf{T}_I \mathbf{I}_m \tag{22b}$$

where the real matrices \mathbf{T}_V and \mathbf{T}_I are 2×2 ($n \times n$ for the general $n + 1$ conductor MTL) with entries

$$\mathbf{T}_V = \begin{bmatrix} T_{VGG} & T_{VGR} \\ T_{VRG} & T_{VRR} \end{bmatrix} \tag{23a}$$

$$\mathbf{T}_I = \begin{bmatrix} T_{IGG} & T_{IGR} \\ T_{IRG} & T_{IRR} \end{bmatrix} \tag{23b}$$

and the 2×1 vectors \mathbf{V}_m and \mathbf{I}_m contain the mode voltages and currents, respectively, as

$$\mathbf{V}_m = \begin{bmatrix} V_{mG} \\ V_{mR} \end{bmatrix} \tag{24a}$$

$$\mathbf{I}_m = \begin{bmatrix} I_{mG} \\ I_{mR} \end{bmatrix} \tag{24b}$$

Substituting (22) into (3) yields

$$\frac{\partial}{\partial z} \mathbf{V}_m(z, t) = \underbrace{-\mathbf{T}_V^{-1} \mathbf{L} \mathbf{T}_I}_{\mathbf{L}_m} \frac{\partial}{\partial t} \mathbf{I}_m(z, t) \tag{25a}$$

$$\frac{\partial}{\partial z} \mathbf{I}_m(z, t) = \underbrace{-\mathbf{T}_I^{-1} \mathbf{C} \mathbf{T}_V}_{\mathbf{C}_m} \frac{\partial}{\partial t} \mathbf{V}_m(z, t) \tag{25b}$$

If transformations \mathbf{T}_V and \mathbf{T}_I can be found such that the mode PUL parameter matrices are diagonalized as

$$\begin{aligned} \mathbf{L}_m &= \mathbf{T}_V^{-1} \mathbf{L} \mathbf{T}_I \\ &= \begin{bmatrix} l_{mG} & 0 \\ 0 & l_{mR} \end{bmatrix} \end{aligned} \quad (26a)$$

$$\begin{aligned} \mathbf{C}_m &= \mathbf{T}_I^{-1} \mathbf{C} \mathbf{T}_V \\ &= \begin{bmatrix} c_{mG} & 0 \\ 0 & c_{mR} \end{bmatrix} \end{aligned} \quad (26b)$$

then the equations in terms of mode quantities in (25) are uncoupled. We will show methods of determining the transformations \mathbf{T}_V and \mathbf{T}_I that will simultaneously diagonalize \mathbf{L} and \mathbf{C} for any MTL.

The importance of this result is that the MTL equations in terms of the mode quantities are now uncoupled and consist of two uncoupled two-conductor lines:

$$\frac{\partial V_{mG}}{\partial z} = -l_{mG} \frac{\partial I_{mG}}{\partial t} \quad (27a)$$

$$\frac{\partial I_{mG}}{\partial z} = -c_{mG} \frac{\partial V_{mG}}{\partial t} \quad (27b)$$

$$\frac{\partial V_{mR}}{\partial z} = -l_{mR} \frac{\partial I_{mR}}{\partial t} \quad (28a)$$

$$\frac{\partial I_{mR}}{\partial z} = -c_{mR} \frac{\partial V_{mR}}{\partial t} \quad (28b)$$

The two-conductor line equations in (27) represent a two-conductor line with velocity of propagation

$$v_{mG} = \frac{1}{\sqrt{l_{mG} c_{mG}}} \quad (29a)$$

and characteristic impedance

$$Z_{CmG} = \sqrt{\frac{l_{mG}}{c_{mG}}} \quad (29b)$$

Similarly, the equations in (28) represent a two-conductor line with velocity of propagation

$$v_{mR} = \frac{1}{\sqrt{l_{mR} c_{mR}}} \quad (30a)$$

and characteristic impedance

$$Z_{CmR} = \sqrt{\frac{l_{mR}}{c_{mR}}} \quad (30b)$$

The solutions to the uncoupled-mode transmission-line equations in (27) are well known [1]:

$$V_{mG}(z, t) = V_G^+ \left(t - \frac{z}{v_{mG}} \right) + V_G^- \left(t + \frac{z}{v_{mG}} \right) \quad (31a)$$

$$\begin{aligned} I_{mG}(z, t) &= \frac{1}{Z_{CmG}} V_G^+ \left(t - \frac{z}{v_{mG}} \right) \\ &\quad - \frac{1}{Z_{CmG}} V_G^- \left(t + \frac{z}{v_{mG}} \right) \end{aligned} \quad (31b)$$

Similarly the solutions to the transmission line equations in (28) are:

$$V_{mR}(z, t) = V_R^+ \left(t - \frac{z}{v_{mR}} \right) + V_R^- \left(t + \frac{z}{v_{mR}} \right) \quad (32a)$$

$$\begin{aligned} I_{mR}(z, t) &= \frac{1}{Z_{CmR}} V_R^+ \left(t - \frac{z}{v_{mR}} \right) \\ &\quad - \frac{1}{Z_{CmR}} V_R^- \left(t + \frac{z}{v_{mR}} \right) \end{aligned} \quad (32b)$$

The functions V_G^+ , V_G^- , V_R^+ , V_R^- will be determined by the time history of the driving source, $V_S(t)$.

Hence, the original problem is transformed into two uncoupled two-conductor mode lines as shown in Fig. 7 with transformation networks representing the transformations \mathbf{T}_V and \mathbf{T}_I at the endpoints that transform out to the original line voltages and currents. We will show a simple SPICE implementation of Fig. 7.

Although we have two transformation matrices \mathbf{T}_V and \mathbf{T}_I , it can be shown that these can be chosen such that they are related as [3]

$$\mathbf{T}_V^t \mathbf{T}_I = \mathbf{1}_2 \quad (33)$$

where the superscript “t” denotes the transpose of the matrix $\mathbf{1}_2$ is the 2×2 identity matrix. Hence these transformation matrices are also related as

$$\mathbf{T}_V^t = \mathbf{T}_I^{-1} \quad (34)$$

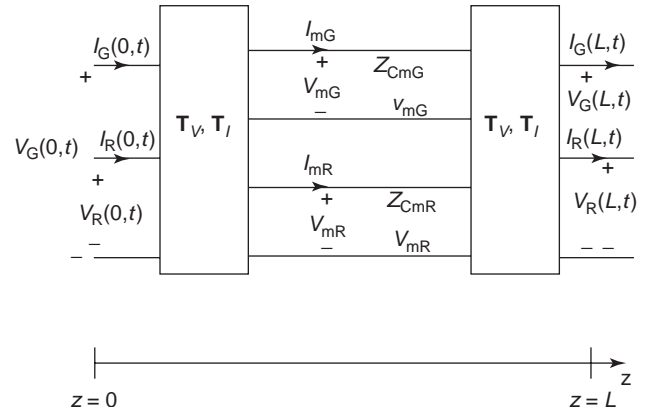

Figure 7. Illustration of the basic method for decoupling the MTL equations.

The implementation of the transformation networks in Fig. 7 is quite simple. Writing out the relation between the voltages and the mode voltages in (22a) and using (23a) gives

$$V_G = T_{VGG} V_{mG} + T_{VGR} V_{mR} \quad (35a)$$

$$V_R = T_{VRG} V_{mG} + T_{VRR} V_{mR} \quad (35b)$$

If we invert the relation between the currents and the mode currents in (22b) we obtain

$$\mathbf{I}_m = \mathbf{T}_I^{-1} \mathbf{I} \quad (36)$$

which becomes

$$\begin{bmatrix} I_{mG} \\ I_{mR} \end{bmatrix} = \underbrace{\begin{bmatrix} T_{IGG}^{-1} & T_{IGR}^{-1} \\ T_{IRG}^{-1} & T_{IRR}^{-1} \end{bmatrix}}_{\mathbf{T}_I^{-1}} \begin{bmatrix} I_G \\ I_R \end{bmatrix} = \underbrace{\begin{bmatrix} T_{VGG} & T_{VGR} \\ T_{VGR} & T_{VRR} \end{bmatrix}}_{\mathbf{T}_V^t} \begin{bmatrix} I_G \\ I_R \end{bmatrix} \quad (37)$$

where we have denoted the entries in the inverse of \mathbf{T}_I as T_{IXX}^{-1} . (The inverse of a matrix is not simply the inverse of each of its components. This notation for the entries in the inverse of \mathbf{T}_I was chosen for simplicity of notation.) Writing out (37) gives

$$I_{mG} = T_{IGG}^{-1} I_G + T_{IGR}^{-1} I_R = T_{VGG} I_G + T_{VGR} I_R \quad (38a)$$

$$I_{mR} = T_{IRG}^{-1} I_G + T_{IRR}^{-1} I_R = T_{VGR} I_G + T_{VRR} I_R \quad (38b)$$

The relations between the actual line voltage and the mode voltage in Eqs. (35) can be implemented using voltage-controlled voltage sources as shown in Fig. 8. The relations between the mode currents and the actual line currents in Eqs. (38) can be implemented using current-controlled current sources as shown in Fig. 8.

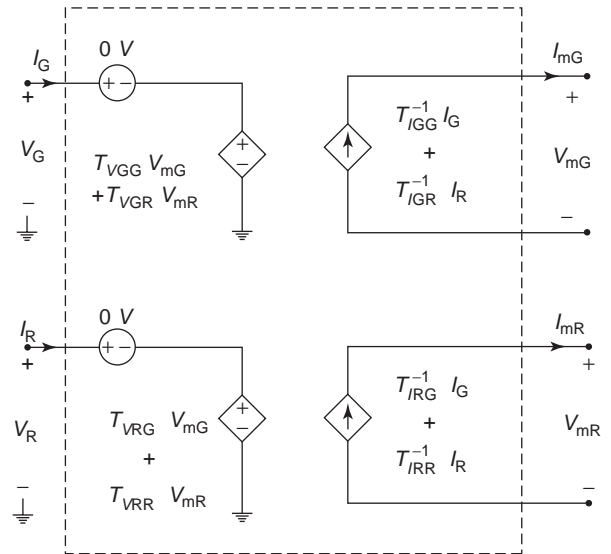

Figure 8. Implementation of the mode transformations in SPICE using controlled sources.

A SPICE (or the personal computer version, PSPICE) subcircuit model for transformations and mode transmission lines as shown in Fig. 9 can be generated by the FORTRAN program SPICEMTL.FOR that is described in Ref. 2 and can be obtained from ftp://ftp.wiley.com/public/sci_tech_med/multiconductor_transmission/. All that remains is to attach the terminations to that subcircuit model in order to give a complete SPICE solution model.

We will show results for a coupled microstrip shown in cross section in Fig. 10a. The PUL parameter matrices for this structure were computed in the previous section. The line is terminated in 50-Ω loads at each port, and the open-circuit voltage source is a 10-MHz, periodic, trapezoidal pulsetrain (representing a digital clock) having a voltage

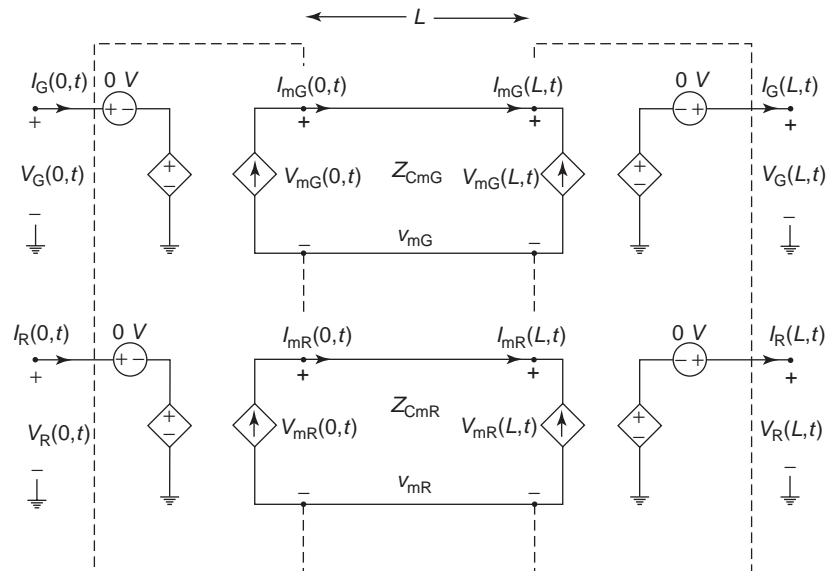

Figure 9. A complete SPICE model for a three-conductor coupled MTL.

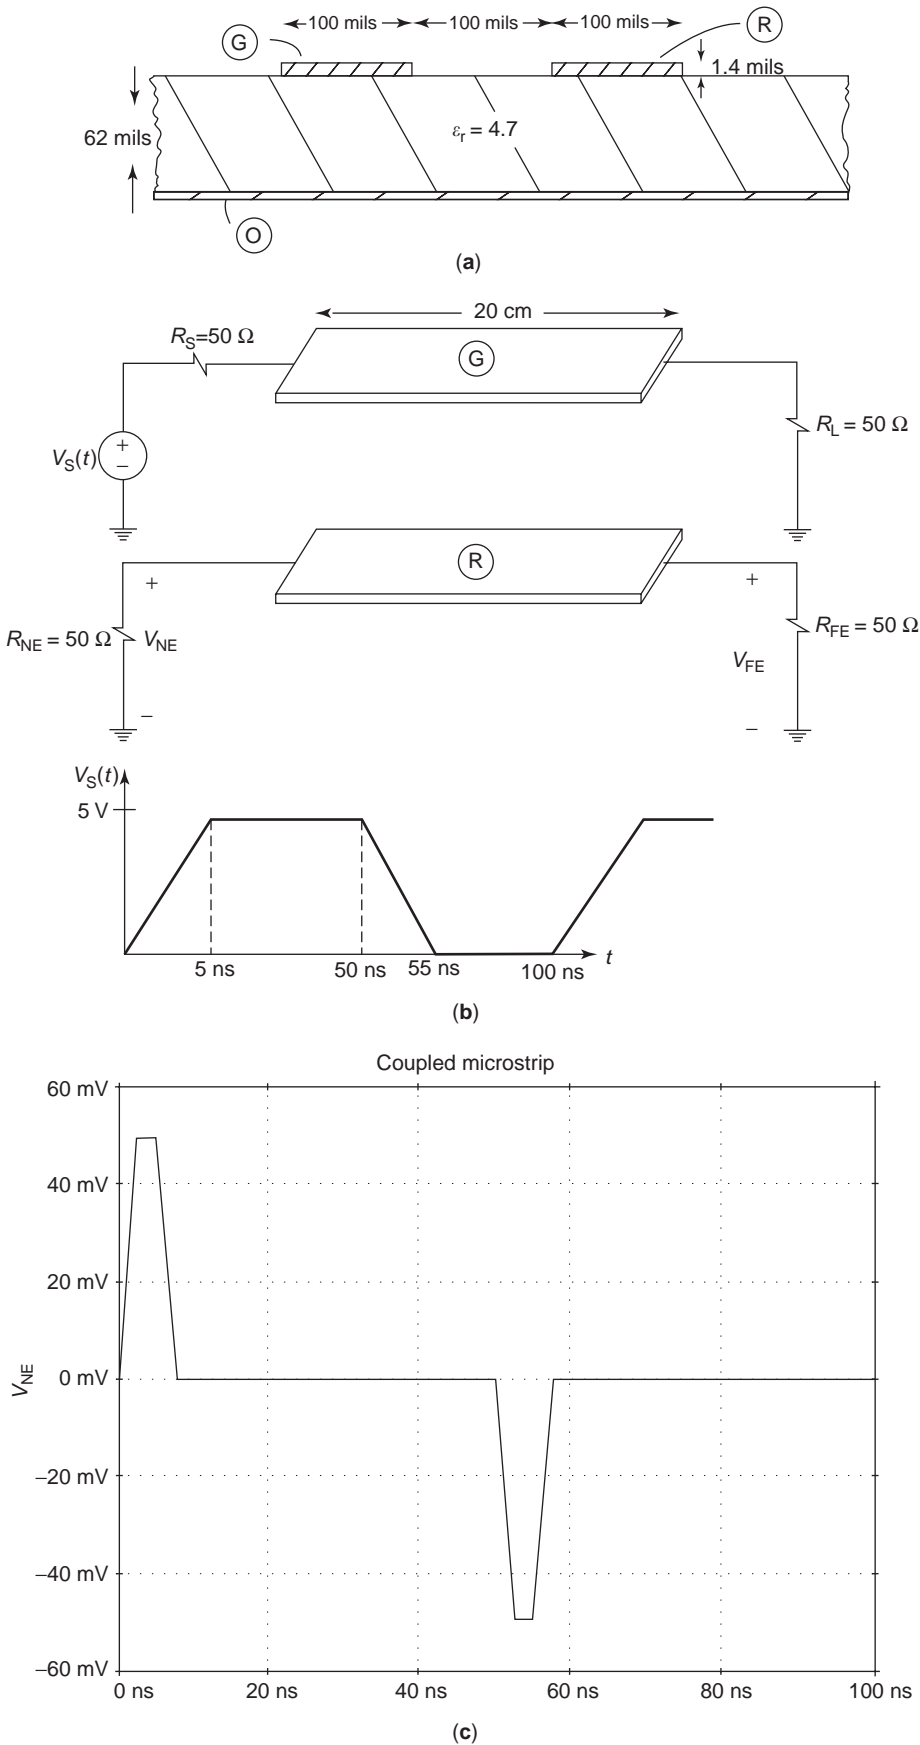

Figure 10. Illustration of a computational example; (a) the cross sectional dimensions of the coupled microstrip, (b) the longitudinal dimensions, terminations and source waveform, and (c) the SPICE predicted near-end cross-talk.

of 5 V, a rise/falltime of 5 ns, and a 50% duty cycle. The results of this PSPICE generated output for the near-end crosstalk voltage is shown in Fig. 10c. See Ref. 1 for experimental confirmation of these results.

For the coupled microstrip investigated, the transformations and mode velocities and characteristic impedances are

$$\mathbf{T}_V = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}$$

$$\mathbf{T}_I = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}$$

$$\mathbf{T}_I^{-1} = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ -1 & 1 \end{bmatrix}$$

Observe that (33) and (34) are satisfied. Because of the physical symmetry of this coupled microstrip (both lands have identical width and are at the same height above the ground plane), the transformations are simple. Inverting the voltage transformation to give \mathbf{T}_V^{-1} and writing out the transformation gives

$$V_{mG} = \frac{1}{\sqrt{2}} (V_G + V_R)$$

$$V_{mR} = \frac{1}{\sqrt{2}} (-V_G + V_R)$$

This is often referred to in the literature as the *even-mode/odd-mode transformation*. The characteristic impedances and one-way delays of the modes (the total line length is 20 cm) are

$$Z_{CmG} = 58.037 \Omega \quad T_{mG} = \frac{L}{v_{mG}} = 1.2836 \text{ ns}$$

$$Z_{CmR} = 49.757 \Omega \quad T_{mR} = \frac{L}{v_{mR}} = 1.1985 \text{ ns}$$

3.1. Determining the Mode Transformations

We now show how to determine the transformations \mathbf{T}_V and \mathbf{T}_I such that they simultaneously diagonalize the per unit parameter matrices, \mathbf{L} and \mathbf{C} , as in (26). We consider two separate cases: homogeneous media and inhomogeneous media.

3.1.1. Homogeneous Media. For the case of a homogeneous medium, we have the important identity

$$\mathbf{LC} = \mathbf{CL} = \frac{1}{v^2} \mathbf{1}_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad (39)$$

where $v^2 = v_0^2/\epsilon_r$. Because \mathbf{L} is real and symmetric, there always exists a transformation \mathbf{T} , such that [2]

$$\mathbf{T}^t \mathbf{L} \mathbf{T} = \mathbf{L}_m \quad (40a)$$

where \mathbf{L}_m is diagonal as

$$\mathbf{L}_m = \begin{bmatrix} l_{mG} & 0 \\ 0 & l_{mR} \end{bmatrix} \quad (40b)$$

and the inverse of \mathbf{T} is its transpose [2]:

$$\mathbf{T}^{-1} = \mathbf{T}^t \quad (41)$$

This diagonalization of a real, symmetric matrix is said to be an orthogonal transformation and is numerically accomplished with the stable and efficient Jacobi method [2]. In fact, for the special case of the three-conductor line considered here, we obtain

$$\mathbf{T} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \quad (42a)$$

where

$$\tan 2\theta = \frac{2l_{GR}}{l_G - l_R} \quad (42b)$$

For MTLs with $n > 2$, a FORTRAN subroutine, JACOBI.SUB described in Ref. 2, is available to determine this orthogonal transformation in a stable and efficient manner. From the identity in (39), we obtain

$$\mathbf{C} = \frac{1}{v^2} \mathbf{L}^{-1} \quad (43)$$

Forming

$$\begin{aligned} \mathbf{T}^{-1} \mathbf{C} (\mathbf{T}^t)^{-1} &= \mathbf{T}^t \mathbf{C} \mathbf{T} \\ &= \frac{1}{v^2} \mathbf{T}^t \mathbf{L}^{-1} \mathbf{T} \\ &= \frac{1}{v^2} \mathbf{L}_m^{-1} \end{aligned} \quad (44)$$

Comparing (40a) and (44) to (26a) and (26b), we identify

$$\mathbf{T}_I = \mathbf{T} \quad (45a)$$

$$\mathbf{T}_V^{-1} = \mathbf{T}^t \quad (45b)$$

$$\mathbf{T}_V = \mathbf{T} \quad (45c)$$

Hence the mode characteristic impedances are

$$Z_{CmG} = vl_{mG} \quad (46a)$$

$$Z_{CmR} = vl_{mR} \quad (46b)$$

and all mode velocities are the same:

$$v_{mG} = v_{mR} = v \quad (47)$$

3.1.2. Inhomogeneous Media. For inhomogeneous media we no longer have the identity in (39). However, the transformations that simultaneously diagonalize \mathbf{L} and \mathbf{C} can still be obtained in a stable and numerically efficient manner. Since \mathbf{C} is real and symmetric, we can find an orthogonal transformation \mathbf{U} that diagonalizes it as [2]

$$\mathbf{U}^t \mathbf{C} \mathbf{U} = \theta^2 \quad (48a)$$

where θ^2 is diagonal as

$$\theta^2 = \begin{bmatrix} \theta_{mG}^2 & 0 \\ 0 & \theta_{mR}^2 \end{bmatrix} \quad (48b)$$

Because \mathbf{C} is also positive definite, its eigenvalues, θ_{mG}^2 and θ_{mR}^2 are real, positive, and nonzero [2]. In addition, since the transformation is an orthogonal one, we obtain

$$\mathbf{U}^{-1} = \mathbf{U}^t \quad (49)$$

Since the eigenvalues of \mathbf{C} in (48b) are real, positive, and nonzero, we can form the square root of θ^2 , θ , and form the product $\theta \mathbf{U}^t \mathbf{L} \mathbf{U} \theta$, which is real and symmetric. Hence we can obtain an orthogonal transformation that diagonalizes it as

$$\mathbf{S}^t (\theta \mathbf{U}^t \mathbf{L} \mathbf{U} \theta) \mathbf{S} = \Lambda^2 \quad (50a)$$

where Λ^2 is diagonal having real, positive, and nonzero eigenvalues on its diagonal as

$$\Lambda^2 = \begin{bmatrix} \Lambda_{mG}^2 & 0 \\ 0 & \Lambda_{mR}^2 \end{bmatrix} \quad (50b)$$

and

$$\mathbf{S}^{-1} = \mathbf{S}^t \quad (50c)$$

Define a transformation matrix as

$$\mathbf{T} = \mathbf{U} \theta \mathbf{S} \quad (51)$$

In order to minimize numerical errors, we normalize the columns of \mathbf{T} to a Euclidean length of unity as

$$\mathbf{T}_{\text{norm}} = \mathbf{T} \alpha \quad (52a)$$

where α is a 2×2 diagonal matrix:

$$\alpha = \begin{bmatrix} \alpha_{mG} & 0 \\ 0 & \alpha_{mR} \end{bmatrix} \quad (52b)$$

The desired transformations are

$$\mathbf{T}_I = \mathbf{U} \theta \mathbf{S} \alpha \quad (53a)$$

$$\mathbf{T}_V = \mathbf{U} \theta^{-1} \mathbf{S} \alpha^{-1} \quad (53b)$$

In addition, these transformations have the properties

$$\begin{aligned} \mathbf{T}_I^{-1} &= \alpha^{-1} \mathbf{S}^t \theta^{-1} \mathbf{U}^t \\ &= \mathbf{T}_V^t \end{aligned} \quad (54a)$$

$$\begin{aligned} \mathbf{T}_V^{-1} &= \alpha \mathbf{S}^t \theta \mathbf{U}^t \\ &= \mathbf{T}_I^t \end{aligned} \quad (54b)$$

To show that these in fact do simultaneously diagonalize \mathbf{L} and \mathbf{C} , we form

$$\begin{aligned} \mathbf{T}_V^{-1} \mathbf{L} \mathbf{T}_I &= \alpha \mathbf{S}^t \theta \mathbf{U}^t \mathbf{L} \mathbf{U} \theta \mathbf{S} \alpha \\ &= \alpha \Lambda^2 \alpha \end{aligned} \quad (55a)$$

$$\begin{aligned} \mathbf{T}_I^{-1} \mathbf{C} \mathbf{T}_V &= \alpha^{-1} \mathbf{S}^t \theta^{-1} \mathbf{U}^t \mathbf{C} \mathbf{U} \theta^{-1} \mathbf{S} \alpha^{-1} \\ &= \alpha^{-2} \end{aligned} \quad (55b)$$

Comparing (55) to (26) shows that

$$l_{mG} = \alpha_{mG}^2 \Lambda_{mG}^2 \quad (56a)$$

$$l_{mR} = \alpha_{mR}^2 \Lambda_{mR}^2 \quad (56b)$$

$$c_{mG} = \alpha_{mG}^{-2} \quad (56c)$$

$$c_{mR} = \alpha_{mR}^{-2} \quad (56d)$$

Hence the mode characteristic impedances and velocities of propagation become

$$Z_{CmG} = \alpha_{mG}^2 \Lambda_{mG}, \quad v_{mG} = \frac{1}{\Lambda_{mG}} \quad (57a)$$

$$Z_{CmR} = \alpha_{mR}^2 \Lambda_{mR}, \quad v_{mR} = \frac{1}{\Lambda_{mR}} \quad (57b)$$

4. THE FREQUENCY-DOMAIN SOLUTION

We now consider driving the line with a single-frequency, sinusoidal source: $V_S(t) = V_S \cos(\omega t + \theta)$. It is also assumed that the line is in steady state. The solution method is the phasor method used in the analysis of electric circuits where we replace the actual source with $\hat{V}_S = V_S e^{j\theta} = V_S \angle \theta$. We will denote all complex-valued phasor quantities with a caret ($\hat{\cdot}$) over them. This phasor method stems from the fact that, according to Euler's identity [1] $V_S(t) = \text{Re}[\hat{V}_S e^{j\omega t}] = \text{Re}[V_S e^{j(\omega t + \theta)}] = V_S \cos(\omega t + \theta)$. All time derivatives are replaced by $j\omega$ since $(d/dt) \Leftrightarrow j\omega$. Hence the

time-domain MTL equations in (3) become

$$\frac{d}{dz} \hat{\mathbf{V}}(z) = -j\omega \mathbf{L} \hat{\mathbf{I}}(z) \quad (58a)$$

$$\frac{d}{dz} \hat{\mathbf{I}}(z) = -j\omega \mathbf{C} \hat{\mathbf{V}}(z) \quad (58b)$$

We can once again transform to (phasor) mode quantities as

$$\hat{\mathbf{V}} = \mathbf{T}_V \hat{\mathbf{V}}_m \quad (59a)$$

$$\hat{\mathbf{I}} = \mathbf{T}_I \hat{\mathbf{I}}_m \quad (59b)$$

We showed that transformations can be found that simultaneously diagonalize \mathbf{L} and \mathbf{C} as in (26). Substituting the transformations into (58) again yields uncoupled, first-order differential equations as in (25). Hence little has changed from the time-domain case. We can use the SPICE model employed earlier with only a change in some control statements in order to solve for the magnitude and phase of the line phasor terminal voltages and currents [1,2]. In fact, for the coupled microstrip problem in Figs. 10a and 10b, we may use the SPICE code (developed with the FORTRAN code SPICEMTL.FOR [2]) to obtain the subcircuit model of the line. Changing the source to a 1-V sinusoid and running SPICE in the AC mode yields the magnitude plot for the near-end crosstalk voltage \hat{V}_{NE} (which is the transfer function since the source value is 1V) shown in Fig. 11.

An alternative to using SPICE to generate the frequency response, referred to as the *direct method*, is as follows. First we generate second-order differential equations from (58) by differentiating one and substituting the other to yield

$$\frac{d^2}{dz^2} \hat{\mathbf{V}}(z) = \hat{\mathbf{Z}} \hat{\mathbf{Y}} \hat{\mathbf{V}}(z) \quad (60a)$$

$$\frac{d^2}{dz^2} \hat{\mathbf{I}}(z) = \hat{\mathbf{Y}} \hat{\mathbf{Z}} \hat{\mathbf{I}}(z) \quad (60b)$$

Figure 11. Predicted and experimentally measured frequency response of the near-end crosstalk.

where we have written the PUL impedance and admittance matrices compactly as

$$\hat{\mathbf{Z}} = j\omega \mathbf{L} \quad (61a)$$

$$\hat{\mathbf{Y}} = j\omega \mathbf{C} \quad (61b)$$

Again we seek to uncouple these equations by simultaneously diagonalizing the products $\hat{\mathbf{Z}} \hat{\mathbf{Y}}$ and $\hat{\mathbf{Y}} \hat{\mathbf{Z}}$. To do so, we arbitrary choose to diagonalize $\hat{\mathbf{Y}} \hat{\mathbf{Z}}$ as

$$\hat{\mathbf{T}}^{-1} \hat{\mathbf{Y}} \hat{\mathbf{Z}} \hat{\mathbf{T}} = \hat{\gamma}^2 = \begin{bmatrix} \hat{\gamma}_{mG}^2 & 0 \\ 0 & \hat{\gamma}_{mR}^2 \end{bmatrix} \quad (62)$$

Note that for a lossless line where $\hat{\mathbf{Z}}$ and $\hat{\mathbf{Y}}$ are as given by (61)

$$\hat{\mathbf{T}}^{-1} \hat{\mathbf{Y}} \hat{\mathbf{Z}} \hat{\mathbf{T}} = -\omega^2 \hat{\mathbf{T}}^{-1} \mathbf{C} \mathbf{L} \hat{\mathbf{T}} \quad (63)$$

and hence $\hat{\mathbf{T}} = \mathbf{T}_I$ and

$$\begin{aligned} \hat{\gamma}^2 &= \begin{bmatrix} -\omega^2 c_{mG} l_{mG} & 0 \\ 0 & -\omega^2 c_{mR} l_{mR} \end{bmatrix} \\ &= \begin{bmatrix} -\omega^2 / v_{mG}^2 & 0 \\ 0 & -\omega^2 / v_{mR}^2 \end{bmatrix} \end{aligned} \quad (64)$$

However, for the second-order equations in (60) there are many more choices for this transformation. For example, for a homogeneous medium, $\mathbf{L}\mathbf{C} = \mathbf{C}\mathbf{L} = (1/v^2)\mathbf{1}_2$ and the product is already uncoupled; hence we could choose $\hat{\mathbf{T}} = \mathbf{1}_2$.

Substituting the transformation

$$\hat{\mathbf{I}} = \hat{\mathbf{T}} \hat{\mathbf{I}}_m \quad (65)$$

into (60b) we obtain

$$\begin{aligned} \frac{d^2}{dz^2} \hat{\mathbf{I}}_m(z) &= \hat{\mathbf{T}}^{-1} \hat{\mathbf{Y}} \hat{\mathbf{Z}} \hat{\mathbf{T}} \hat{\mathbf{I}}_m(z) \\ &= \hat{\gamma}^2 \hat{\mathbf{I}}_m(z) \end{aligned} \quad (66)$$

whose general solution is

$$\hat{\mathbf{I}}_{mG} = \hat{\mathbf{I}}_{mG}^+ e^{-j\omega z/v_{mG}} - \hat{\mathbf{I}}_{mG}^- e^{j\omega z/v_{mG}} \quad (67a)$$

$$\hat{\mathbf{I}}_{mR} = \hat{\mathbf{I}}_{mR}^+ e^{-j\omega z/v_{mR}} - \hat{\mathbf{I}}_{mR}^- e^{j\omega z/v_{mR}} \quad (67b)$$

where the $\hat{\mathbf{I}}_{mG,R}^\pm$ are undetermined coefficients. These will be determined by the terminations of the line. Transforming to the total line currents, we obtain

$$\hat{\mathbf{I}} = \mathbf{T} (e^{-\hat{\gamma}z} \hat{\mathbf{I}}_m^+ - e^{\hat{\gamma}z} \hat{\mathbf{I}}_m^-) \quad (68a)$$

where

$$\hat{\mathbf{I}}_m^\pm = \begin{bmatrix} \hat{I}_{mG}^\pm \\ \hat{I}_{mR}^\pm \end{bmatrix} \quad (68b)$$

$$\mathbf{e}^{\pm\hat{\gamma}z} = \begin{bmatrix} e^{\pm j\omega z/v_{mG}} & 0 \\ 0 & e^{\pm j\omega z/v_{mR}} \end{bmatrix} \quad (68c)$$

The solution for the mode voltages can be obtained by substituting this into (58b):

$$\begin{aligned} \hat{\mathbf{V}}(z) &= -\hat{\mathbf{Y}}^{-1} \frac{d}{dz} \hat{\mathbf{I}}(z) \\ &= \underbrace{(\hat{\mathbf{Y}}^{-1} \hat{\mathbf{T}} \hat{\gamma} \hat{\mathbf{T}}^{-1})}_{\hat{\mathbf{Z}}_C} \hat{\mathbf{T}} (\mathbf{e}^{-\hat{\gamma}z} \hat{\mathbf{I}}_m^+ + \mathbf{e}^{\hat{\gamma}z} \hat{\mathbf{I}}_m^-) \end{aligned} \quad (69)$$

where the matrix of propagation constants is

$$\hat{\gamma} = \begin{bmatrix} j\omega/v_{mG} & 0 \\ 0 & j\omega/v_{mR} \end{bmatrix} \quad (70)$$

Note the definition of the characteristic impedance matrix $\hat{\mathbf{Z}}_C = \hat{\mathbf{Y}}^{-1} \hat{\mathbf{T}} \hat{\gamma} \hat{\mathbf{T}}^{-1}$ in (69). The characteristic impedance matrix is not diagonal. Hence, in order to “match” a MTL, we must obtain termination networks that represent this matrix rather than individually matching each line [2]. In other words, to match a MTL, we must have termination impedances between each line and the reference conductor and between each line.

The advantage of the direct method is that frequency-dependent losses can be readily incorporated into the solution. This will be discussed in Section 7. Losses cannot be readily incorporated into the SPICE model.

Alternatively, we may write the first-order equations in (58) in the form of state-variable equations commonly found in automatic control systems as well as the mathematical texts on the solution of ordinary differential equations. Hence we can draw from that enormous body of knowledge to obtain immediate solutions. We write the first-order equations in (58) as

$$\frac{d}{dz} \hat{\mathbf{X}}(z) = \hat{\mathbf{A}} \hat{\mathbf{X}}(z) \quad (71a)$$

where

$$\hat{\mathbf{X}}(z) = \begin{bmatrix} \hat{\mathbf{V}}(z) \\ \hat{\mathbf{I}}(z) \end{bmatrix} \quad (71b)$$

and

$$\hat{\mathbf{A}} = \begin{bmatrix} 0 & -\hat{\mathbf{Z}} \\ -\hat{\mathbf{Y}} & 0 \end{bmatrix} \quad (71c)$$

These are in identical form to state-variable equations [2]. The solution is well known:

$$\hat{\mathbf{X}}(L) = \hat{\Phi}(L) \hat{\mathbf{X}}(0) \quad (72a)$$

for a line of total length L that extends from $z = 0$ to $z = L$. Expanding (72a) gives

$$\begin{bmatrix} \hat{\mathbf{V}}(L) \\ \hat{\mathbf{I}}(L) \end{bmatrix} = \underbrace{\begin{bmatrix} \hat{\Phi}_{11} & \hat{\Phi}_{12} \\ \hat{\Phi}_{21} & \hat{\Phi}_{22} \end{bmatrix}}_{\hat{\Phi}(L)} \begin{bmatrix} \hat{\mathbf{V}}(0) \\ \hat{\mathbf{I}}(0) \end{bmatrix} \quad (72b)$$

This is said to be the *chain parameter matrix* of the line or the *ABCD* parameters. The chain parameter matrix $\hat{\Phi}(L)$ relates the voltages and currents at one end of the line to the voltages and currents at the other end. It is so called because a line can be broken into contiguous sections, and the overall chain parameter matrix of the entire line is the product of the chain parameter matrices of the adjacent sections (in the proper order). This is one way to represent a nonuniform line [2]. The chain parameter submatrices for a uniform line are [2]

$$\hat{\Phi}_{11}(L) = \frac{1}{2} \hat{\mathbf{Y}}^{-1} \hat{\mathbf{T}} (\mathbf{e}^{\hat{\gamma}L} + \mathbf{e}^{-\hat{\gamma}L}) \hat{\mathbf{T}}^{-1} \hat{\mathbf{Y}} \quad (73a)$$

$$\hat{\Phi}_{12}(L) = -\frac{1}{2} \hat{\mathbf{Z}}_C \hat{\mathbf{T}} (\mathbf{e}^{\hat{\gamma}L} - \mathbf{e}^{-\hat{\gamma}L}) \hat{\mathbf{T}}^{-1} \quad (73b)$$

$$\hat{\Phi}_{21}(L) = -\frac{1}{2} \hat{\mathbf{T}} (\mathbf{e}^{\hat{\gamma}L} - \mathbf{e}^{-\hat{\gamma}L}) \hat{\mathbf{T}}^{-1} \hat{\mathbf{Z}}_C^{-1} \quad (73c)$$

$$\hat{\Phi}_{22}(L) = \frac{1}{2} \hat{\mathbf{T}} (\mathbf{e}^{\hat{\gamma}L} + \mathbf{e}^{-\hat{\gamma}L}) \hat{\mathbf{T}}^{-1} \quad (73d)$$

In the general form of the solution in (68) and (69) there are four ($2n$ for a general MTL) undetermined constants in $\hat{\mathbf{I}}_m^+$ and $\hat{\mathbf{I}}_m^-$. In order to determine these undetermined constants, we need to apply the terminal constraints. With reference to Fig. 1a these are

$$\hat{\mathbf{V}}(0) = \hat{\mathbf{V}}_S - \hat{\mathbf{Z}}_S \hat{\mathbf{I}}(0) \quad (74a)$$

$$\hat{\mathbf{V}}(L) = \hat{\mathbf{Z}}_L \hat{\mathbf{I}}(L) \quad (74b)$$

where

$$\hat{\mathbf{V}}_S = \begin{bmatrix} \hat{V}_S \\ 0 \end{bmatrix} \quad (75a)$$

$$\hat{\mathbf{Z}}_S = \begin{bmatrix} R_S & 0 \\ 0 & R_{NE} \end{bmatrix} \quad (75b)$$

$$\hat{\mathbf{Z}}_L = \begin{bmatrix} R_L & 0 \\ 0 & R_{FE} \end{bmatrix} \quad (75c)$$

Substituting (68) and (69) into (74) yields [2]

$$\begin{bmatrix} (\hat{\mathbf{Z}}_C + \hat{\mathbf{Z}}_S) \hat{\mathbf{T}} & (\hat{\mathbf{Z}}_C - \hat{\mathbf{Z}}_S) \hat{\mathbf{T}} \\ (\hat{\mathbf{Z}}_C - \hat{\mathbf{Z}}_L) \hat{\mathbf{T}} \mathbf{e}^{-\hat{\gamma}L} & (\hat{\mathbf{Z}}_C + \hat{\mathbf{Z}}_L) \hat{\mathbf{T}} \mathbf{e}^{\hat{\gamma}L} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{I}}_m^+ \\ \hat{\mathbf{I}}_m^- \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{V}}_S \\ 0 \end{bmatrix} \quad (76)$$

Solving (76) for the four undetermined constants and substituting into (68) and (69) gives the solution for the line voltages and currents at any point along the line.

Reference 2 contains a description of the FORTRAN code MTL.FOR, which (1) diagonalizes $\hat{\mathbf{Y}}\hat{\mathbf{Z}}$ according to Eq. (62), (2) forms and solves Eq. (76), and (3) substitutes into Eqs. (68) and (69) to obtain the phasor terminal voltages. This code can be obtained from ftp://ftp.wiley.com/public/sci_tech_med/multiconductor_transmission/.

5. APPROXIMATE, LUMPED-CIRCUIT MODELS OF MTLs

If the line is electrically short at the highest frequency of the source, say, $L < \frac{1}{10}\lambda$, where $\lambda = v/f$ denotes a wavelength, then the line can be approximated with a lumped-circuit model and the solution of the MTL equations is bypassed. A useful such model is the so-called lumped- π model shown in Fig. 12. This name is in reference to its resemblance to the symbol π . The capacitances are split to give the circuit a reciprocal property. For the periodic, trapezoidal waveform with rise/falltimes τ_r/τ_f representing a digital signal, the highest significant frequency is approximately [2] $f_{\max} = 1/\tau_r$, where we assume the rise/falltimes to be equal. For example, for the 10-MHz pulsetrain with 5-ns rise/falltimes, which we have been investigating and shown in Fig. 10b, the maximum frequency is approximately 200 MHz. The total line length of 20 cm is $\frac{1}{4.44}\lambda$, where we have calculated the velocity of propagation as 1.777×10^8 m/s using an effective relative permittivity as the average of the board ($\epsilon_r = 4.7$) and air giving $\epsilon'_r = 2.85$. Figure 13a shows a comparison between the SPICE model and this lumped- π model for the source waveform in Fig. 10b. Some inaccuracy is caused by the inability of the lumped- π model to correctly process the high-frequency components of the source waveform. Figure 13b shows a similar comparison for the frequency response. Here we again see that the comparison is good up to only about 100 MHz, where the line length of 20 cm is about $\frac{1}{9}\lambda$.

Figure 12. The lumped- π approximate model of the MTL.

6. CLOSED-FORM SOLUTIONS

In the previous discussions, the solution of the MTL equations in the time and frequency domains was obtained via numerical solution. There are some important cases where the solution of the MTL equations can be obtained in literal form (with symbols as opposed to numbers). These are (1) a three-conductor line ($n=2$) in a homogeneous medium and (2) a three-conductor line in an inhomogeneous medium assuming weak coupling.

For the case of a three-conductor line ($n=2$) in a homogeneous medium, the chain parameter submatrices in (73) simplify to [2]

$$\hat{\Phi}_{11}(L) = C\mathbf{1}_2 \tag{77a}$$

$$\hat{\Phi}_{12}(L) = -j\omega S\mathbf{L}\mathbf{L} \tag{77b}$$

Figure 13. Comparison of the exact SPICE predictions to those of the lumped- π approximate model for the near-end crosstalk of the configuration of Figure 10; (a) time domain crosstalk, and (b) frequency response of the crosstalk.

$$\hat{\Phi}_{21}(L) = -j\omega SCL \quad (77c)$$

$$\hat{\Phi}_{22}(L) = C\mathbf{1}_2 \quad (77d)$$

where $\mathbf{1}_2$ is the 2×2 identity matrix and

$$C = \cos\left(2\pi \frac{L}{\lambda}\right) \quad (78a)$$

$$S = \frac{\sin\left(2\pi \frac{L}{\lambda}\right)}{2\pi \frac{L}{\lambda}} \quad (78b)$$

The velocity of propagation in this homogeneous medium is

$$v = \frac{1}{\sqrt{\mu\epsilon}} \quad (79)$$

and a wavelength is defined by

$$\lambda = \frac{v}{f} \quad (80)$$

The terminal conditions in (74) were incorporated, and the exact literal solutions for the near-end and far-end phasor voltages are [2]

$$\hat{V}_{NE} = \frac{S}{Den} [j\omega M_{NE}C + (j\omega)^2 TK_{NE}S] \hat{V}_S \quad (81a)$$

$$\hat{V}_{FE} = \frac{S}{Den} [j\omega M_{FE}] \hat{V}_S \quad (81b)$$

where

$$Den = C^2 + (j\omega)^2 S^2 \tau_G \tau_R P + j\omega CS(\tau_G + \tau_R) \quad (81c)$$

The various quantities in these expressions are defined by

$$M_{NE} = M_{NE}^{IND} + M_{NE}^{CAP} \quad (82a)$$

$$M_{FE} = M_{FE}^{IND} + M_{FE}^{CAP} \quad (82b)$$

$$M_{NE}^{IND} = \frac{R_{NE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L} \quad (82c)$$

$$M_{FE}^{IND} = -\frac{R_{FE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L} \quad (82d)$$

$$M_{NE}^{CAP} = M_{FE}^{CAP} = \frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_{GR} L \frac{R_L}{R_S + R_L} \quad (82e)$$

and

$$K_{NE} = M_{NE}^{IND} \frac{1}{\sqrt{1-k^2}} \frac{1 + \Gamma_{LG}}{1 - \Gamma_{LG}} \quad (82f)$$

where the superscripts ‘‘IND’’ and ‘‘CAP’’ denote inductive and capacitive, respectively, since those terms involve mutual inductance and mutual capacitance. The coupling coefficient between the two circuits is defined as

$$k = \frac{l_{GR}}{\sqrt{l_G l_R}} \quad (83)$$

the line one-way time delay is

$$T = \frac{L}{v} \quad (84)$$

and the reflections coefficients are

$$\Gamma_{SG} = \frac{R_S - Z_{CG}}{R_S + Z_{CG}} \quad (85a)$$

$$\Gamma_{LG} = \frac{R_L - Z_{CG}}{R_L + Z_{CG}} \quad (85b)$$

$$\Gamma_{SR} = \frac{R_{NE} - Z_{CR}}{R_{NE} + Z_{CR}} \quad (85c)$$

$$\Gamma_{LR} = \frac{R_{FE} - Z_{CR}}{R_{FE} + Z_{CR}} \quad (85d)$$

and the circuit characteristic impedances are defined by

$$Z_{CG} = v l_G \sqrt{1 - k^2} \quad (86a)$$

$$Z_{CR} = v l_R \sqrt{1 - k^2} \quad (86b)$$

The factor P in Den defined by

$$P = \left[1 - k^2 \frac{(\Gamma_S + \Gamma_{FE})(\Gamma_L + \Gamma_{NE})}{(1 + \Gamma_S \Gamma_L)(1 + \Gamma_{NE} \Gamma_{FE})} \right] \quad (87)$$

The circuit time constants are defined by

$$\tau_G = \frac{T}{\sqrt{1-k^2}} \frac{1 + \Gamma_S \Gamma_L}{1 - \Gamma_S \Gamma_L} \quad (88a)$$

$$\tau_R = \frac{T}{\sqrt{1-k^2}} \frac{1 + \Gamma_{NE} \Gamma_{FE}}{1 - \Gamma_{NE} \Gamma_{FE}} \quad (88b)$$

6.1. The Inductive/Capacitive Coupling Model

If the line is electrically short ($L \ll \lambda$), the terms C and S in (78) reduce to unity: $C \cong S \cong 1$. In addition, if the line is weakly coupled ($k \ll 1$), then P in Den becomes unity, $P = 1$.

These results simplify to [4]

$$\hat{V}_{NE} = j\omega \left[\underbrace{\frac{R_{NE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L}}_{\text{inductive coupling}} + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_{GR} L \frac{R_L}{R_S + R_L}}_{\text{capacitive coupling}} \right] \hat{V}_S \quad (89a)$$

$$\hat{V}_{FE} = j\omega \left[\underbrace{-\frac{R_{NE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L}}_{\text{inductive coupling}} + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_{GR} L \frac{R_L}{R_S + R_L}}_{\text{capacitive coupling}} \right] \hat{V}_S \quad (89b)$$

Observe that the frequency response has a phase of $\pm 90^\circ$ and the magnitude increases linearly with frequency (20 dB/decade). This behavior is evidenced in the lower frequencies of the transfer function in Figs. 11 and Fig. 13b. These results can be derived from the simple equivalent circuit shown in Fig. 14.

A simple time-domain extension of these results can be obtained by noting the equivalence

$$j\omega \Leftrightarrow \frac{d}{dt} \quad (90)$$

Hence the frequency-domain results in (89) become, in the time domain

$$V_{NE}(t) = \left[\underbrace{\frac{R_{NE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L}}_{\text{inductive coupling}} + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_{GR} L \frac{R_L}{R_S + R_L}}_{\text{capacitive coupling}} \right] \frac{dV_S(t)}{dt} \quad (91a)$$

$$V_{FE}(t) = \left[\underbrace{-\frac{R_{FE}}{R_{NE} + R_{FE}} l_{GR} L \frac{1}{R_S + R_L}}_{\text{inductive coupling}} + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_{GR} L \frac{R_L}{R_S + R_L}}_{\text{capacitive coupling}} \right] \frac{dV_S(t)}{dt} \quad (91b)$$

Hence the time-domain crosstalk voltages depend on the instantaneous slope of the source voltage waveform.

Figure 14. The inductive-capacitive coupling model for weakly coupled, electrically short lines.

Hence, the crosstalk occurs during the transition (rise/falltimes) of the pulse waveform as illustrated in Fig. 15. For the situation in Fig. 10, this model predicts that the crosstalk pulses would have magnitude of 49 mV and the full SPICE exact model predicts a level of 50 mV. Hence, the structure in Fig. 10a is evidently “weakly coupled.”

This previous exact literal solutions were for a homogeneous medium. If we relax this requirement, we can obtain the literal solution for an inhomogeneous medium. However, the solution is quite complicated, and in order to make it feasible, we must assume weak coupling from the outset. The reader is referred to Ref. 5 for the details of that solution.

7. INCORPORATION OF LOSSES

The previous results have ignored losses. Losses occur in the finite, nonzero conductor resistance and in the nonzero conductivity of the surrounding medium. Typically at frequencies in the low-GHz range, the losses in the surrounding dielectric are negligible. As operating frequencies of digital and analog systems continue to increase, this may no longer be true. The losses in the conductors are due to the finite nonzero conductivity of the conductor material. In addition, when the conductor cross-sectional dimensions become on the order of a skin depth, the current crowds to the conductor surfaces and the PUL resistance increases as the square root of frequency, \sqrt{f} (see Ref. 2 for computed resistances vs. frequency for wires and PCB lands). The conductors possess, in addition to a PUL resistance r , an internal PUL inductance l_{int} , due to magnetic flux internal to the conductor, which decreases as the square root of frequency.

Figure 15. Time-domain crosstalk predictions of the inductive-capacitive coupling model for weakly coupled, electrically short lines.

The MTL equations with losses included can be written in the frequency domain as

$$\frac{d}{dz} \hat{\mathbf{V}}(z) = -\hat{\mathbf{Z}}(\omega) \hat{\mathbf{I}}(z) \quad (92a)$$

$$\frac{d}{dz} \hat{\mathbf{I}}(z) = -\hat{\mathbf{Y}}(\omega) \hat{\mathbf{V}}(z) \quad (92b)$$

where

$$\hat{\mathbf{Z}}(\omega) = \mathbf{R}(\omega) + j\omega \mathbf{L}_{\text{int}}(\omega) + j\omega \mathbf{L} \quad (93a)$$

$$\hat{\mathbf{Y}}(\omega) = \mathbf{G}(\omega) + j\omega \mathbf{C} \quad (93b)$$

The matrices \mathbf{R} and \mathbf{L}_{int} contain the conductor losses, while the matrix \mathbf{G} contains the losses in the surrounding medium. The PUL parameter matrices \mathbf{L} and \mathbf{C} remain as before. The frequency-domain or phasor solution for sinusoidal steady-state excitation of the line can be solved using the direct method of Section 4. Those results were written in terms of a general $\hat{\mathbf{Z}}$ and $\hat{\mathbf{Y}}$, and the method is unchanged when losses are added to the MTL equations as in (92) and (93). We must now find a transformation that diagonalizes the product $\hat{\mathbf{Y}}(\omega)\hat{\mathbf{Z}}(\omega)$ as in (62). This is a straightforward problem and is computed in the FORTRAN code MTL.FOR described in Ref. 2. However, here the diagonalization is frequency-dependent [$\hat{\mathbf{T}}(\omega)$] and must be repeated at each frequency. Nevertheless, the re-

maining solution process is identical to that described in Section 4.

Incorporation of losses into the time-domain solution is much more difficult and is the subject of much present research. If we represent (92) via the Laplace transform, where s represents the Laplace transform variable, we have

$$\frac{d}{dz} \mathbf{V}(z, s) = -\mathbf{Z}(s) \mathbf{I}(z, s) \quad (94a)$$

$$\frac{d}{dz} \mathbf{I}(z, s) = -\mathbf{Y}(s) \mathbf{V}(z, s) \quad (94b)$$

If we can find the inverse Laplace transform of $\mathbf{Z}(s)$ and $\mathbf{Y}(s)$ as $\mathbf{z}(t)$ and $\mathbf{y}(t)$, then Eqs. (94) become, in the time domain

$$\frac{d}{dz} \mathbf{V}(z, t) = -\mathbf{z}(t) * \mathbf{I}(z, t) \quad (95a)$$

$$\frac{d}{dz} \mathbf{I}(z, t) = -\mathbf{y}(t) * \mathbf{V}(z, t) \quad (95b)$$

where $*$ denotes convolution. The requirement for performing convolution in the time domain can be mathematically intensive. A method known as *recursive convolution* provides a computationally efficient implementation [2]. One of the more popular ways of inc-

orporating losses into the time-domain solution is to use the finite-difference, time-domain (FDTD) method [2]. The MTL equations are discretized in space and time, and a bootstrapping method of solution is implemented [2]. The recursive convolution method for implementing losses fits the FDTD method very well. See Ref. 2 for a description of this method.

8. SUMMARY

We have investigated the solution of the transmission-line equations for multiconductor transmission lines (MTLs). The discussion concentrated on lossless lines. Numerical methods for determining the per unit length (PUL) parameter matrices \mathbf{L} and \mathbf{C} , which contain the line PUL inductances and capacitances were discussed. All cross-sectional dimensions that distinguish one line from another are contained in these parameter matrices. Solution of the MTL equations without the solution for the PUL parameter matrices would be a waste of time. An exact time-domain SPICE model for lossless MTLs was developed according to the ability to decouple the MTL equations. This SPICE model could also be used to compute the frequency-domain solution for the terminal voltages and currents. The frequency-domain solution can also be directly obtained by decoupling the MTL equations. Finally, some important classes of weakly coupled lines allow closed-form, literal solutions. These literal solutions allow considerable insight into the coupling mechanism, whereas a numerical solution does not give this insight.

1. INTRODUCTION

Integration of cryogenic electronics involving high-temperature superconductor (HTS) technology or low-temper-

ature superconductor (LTS) technology in conjunction with microstrip circuit technology has created a new class of low-loss microwave, MM-wave, and infrared (IR) components for possible applications in high-performance commercial, industrial, military, and space systems. Planar microstrip HTS circuits and cryogenically cooled microwave and MM-wave devices have demonstrated significant performance improvements in insertion loss, reliability, power consumption, and packaging. A variety of HTS and LTS microwave and MM-wave components such as thin-film bandpass filters (BPFs), high- Q resonators, high-quantum-efficiency laser diodes, precision solid-state phase shifters, low-noise GaAs MESFET and HEMT amplifiers, low-phase-noise solid-state MM-wave sources, and IR focal planar arrays (FPAs) have been developed with minimum power consumption, high reliability, high device efficiency, and stable performance over wide instantaneous bandwidth. Significant performance improvement in widely used cryogenic electronic and RF components or devices will be identified with particular emphasis on reliability, power consumption, and cost. Integration of cryogenic electronic technology will result in cost-effective design of satellite communication systems, terrestrial communication equipment, missile guidance sensors, unmanned air vehicles (UAVs), high-altitude reconnaissance drones, underwater sonar transmitters, high-power missile tracking radars, and space-based IR surveillance sensors.

Studies performed by the author indicate that integration of cryogenic electronic (CE) technology offers the potential of a 10-fold miniaturization of payload electronic equipment, leading to significant reduction in cost and rapid development of small or microsatellite systems. The studies further indicate that the major system cost is due to the cryogenic cooler required to maintain a specified operating temperature within the system. Performance capabilities and limitations of potential cryogenic coolers and microcoolers are briefly summarized. Applications of cryogenic electronics in various commercial, industrial, military, and space systems will be described identifying significant performance improvements. Performance capabilities and limitations of CE devices are identified wherever applicable.

2. CE TECHNOLOGY FOR COMMUNICATION AND SPACE SYSTEMS

Recent (as of 2004) studies indicate that record-level performance improvements have been observed in cryogenically cooled electronic switches, laser diodes, RF/IR detectors, GaAs amplifiers, Josephson driver circuits, ADCs, low-noise mixers, thin-film tunable filters, and other RF and MM-wave devices. Furthermore, research and development (R&D) activities are vigorously pursued to demonstrate the feasibility of cryogenic electronics, including both HTS and LTS devices, in satellite communication systems, base transceiver stations (BTSs) for terrestrial mobile communication, medical diagnostic equipment, and space sensors. Deployment of noise reduction filter technology for spatial and spectral filtering and

input multiplexing channel filters in the front end of the multicarrier BTS receiver (Fig. 1) will result in significant improvement in power consumption, channel isolation, skirt selectivity, insertion loss, and overall system reliability. Integration of fast switching filters in the system will introduce the antijam capability to a satellite communication (satcom) system, thereby providing the most effective and secured communication capability required by law enforcement agencies.

Cryogenic electronic (CE) components or devices have been deployed in a 60-channel HTS multiplexer that duplicates the requirements of the Intelsat-8 satellite communication system and in a Ka-band beam link subsystem that defines the critical requirements of the multimedia satellite communication system. In addition, the use of CE components in the HTS-satellite communication system provides reduction in launch cost, increase in payload capacity, improvement in noise figure and receiver figure-of-merit (G/T), increase in ground station effective radiated power, reduction in antenna size, improved gain margin

needed under rainy and fading conditions, reduction in prime power requirements, and smaller satellite bus architecture due to miniaturization provided by the cryogenic electronic technology. These CE components are best suited for deployment in second- and third-generation BTS-based digital mobile communication systems capable of providing GSM and wideband CDMA (WCDMA) capabilities. The BTS transceiver architecture shown in Fig. 1 permits several cryogenic electronic components including the ADC devices, BPFs, preselectors, preamplifiers (LNAs), and mixers to share a common cooling system, leading to significant reduction in operating cost and system weight.

2.1. Cryogenically Cooled Analog-to-Digital Converter (ADC) Devices

Superconducting ADC architectures using rapid single-quantum-flux (RSQF) technology are best suited for military systems that demand excellent linearity of 16 bits or

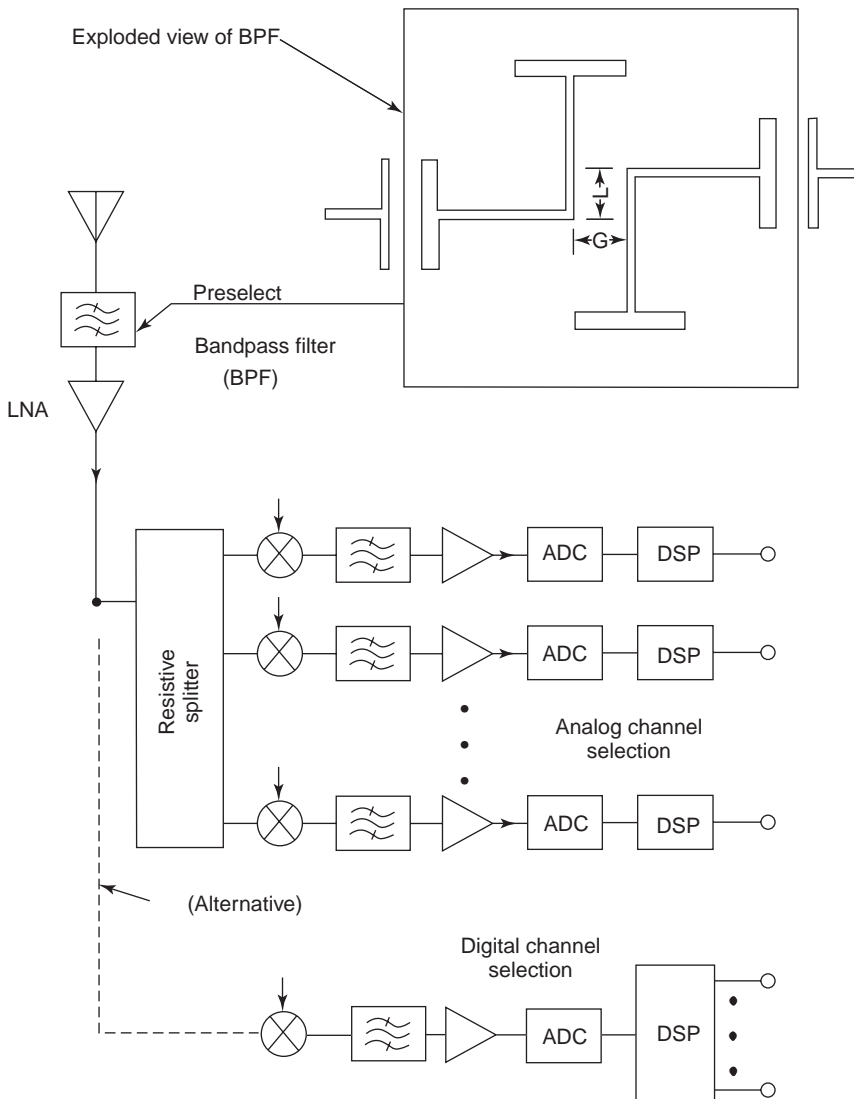

Figure 1. Cryogenic electronic components for applications in communication satellites and base transceiver stations (BTSs) for terrestrial mobile communications.

more, spurious-free dynamic range greater than 78 dB, and third-order intermodulation products better than 65 dB. An innovative ADC design developed by Hpress Corp. (NY) for a 10-bit ADC unit consisting of more than 800 Josephson junction (JJ) devices has demonstrated a dynamic range equivalent to that of a 14-bit ADC, while operating at a cryogenic temperature of 4.2 K. An ADC design with LTS microelectronic technology offers high sensitivity, improved reliability, high resolution, wide instantaneous bandwidth, and power consumption as low as 5 mW/chip at 4.2 K. Further improvement in dynamic range and instantaneous bandwidth in an ADC can be achieved through a combination of oversampling and flux quantization feedback techniques. It is important to point out that superconducting ADC design based on LTS technology at 4.2 K appears to be the only way to achieve simultaneously low aperture time, high internal clock frequency, high data rate, lowest power consumption, and optimum accuracy.

2.2. Cryogenically Cooled Microwave and MM-Wave Mixers

Superconducting microwave and MM-wave mixers using JJ devices and stable solid-state sources have demonstrated sensitivities better than -90 dBm/MHz over a 10–13 GHz frequency range, including the losses in the microwave structures. Performance requirements for microwave mixers are not stringent compared to those for MM-wave mixers. Lower noise figure, conversion loss, and LO (local-oscillator) power requirement are possible only at lower cryogenic temperatures. Typical noise figure and LO power requirements for MM-wave mixers as a function of cryogenic temperature are summarized in Table 1.

The data in Table 1 indicate that the LO power requirement is reduced by a factor of 3 and the noise figure (NF) is reduced close to 2 dB when the mixer is operated at 77 K. It is important to mention that lower noise figure and higher gain are possible from superconductor–insulator–superconductor (SIS) mixers employing LTS Nb-based tunnel junctions in waveguide cavities integrated with SIS chips. SIS mixers are widely used at sub-millimeter-wave frequencies exceeding 200 GHz. Note that an SIS mixer using Josephson junction (JJ) devices has to be biased above a specified threshold voltage to avoid instabilities caused by the Josephson currents at low bias levels. Furthermore, lowest LO power (~ 1 nW) is required for a single-junction SIS mixer, thereby making this mixer design most cost-effective. SIS mixers are limited to small-signal applications and have instantaneous bandwidth of < 3 GHz, which is adequate for astronomic applications but insufficient for radar and communications systems.

Table 1. Noise Figure and LO Power as a Function of Cryogenic Temperature

Frequency (GHz)	300 K		77 K	
	NF (dB)	LO Power (dBm)	NF (dB)	LO Power (dBm)
75–110	5.08	0.60	2.68	0.20
90–140	5.51	0.62	3.06	0.22
110–170	6.12	0.73	3.44	0.25
140–220	6.45	0.92	4.10	0.32

2.3. Cryogenically Cooled Low-Noise Amplifier (LNA)

Significant performance improvements have been achieved by lowering the operating temperature (T) of the RF and MM-wave amplifiers, regardless of whether the amplifiers use GaAs MESFET or AlGaAs HEMT or Si HBT devices. Optimum improvement in performance has been observed at lower cryogenic temperatures as illustrated by data summarized in Tables 2–4.

All the data summarized in Tables 2–4 demonstrate that lower operating temperatures yield significant improvement in gain, noise figure (NF), power-added efficiency, and power consumption. Note the gain of the amplifier is also dependent on the bias level. Furthermore, in all solid-state amplifiers higher gain is possible with higher values of transconductance and lower gate and source resistances. Furthermore, integration of feedback technique tends to minimize gain fluctuations over the band of interest. In a C-band GaAs LNA, significant improvement is observed when the operating temperature is reduced to 4.2 K. In a C-band amplifier operating over the 3200–4200 MHz region, noise figures as low as 1.2, 0.62, and 0.32 dB have been observed at operating temperatures of 300, 77, and 4.2 K, respectively.

2.4. Cryogenically Cooled Microwave Filters and Their Applications

In all satellite communications systems, channel filters play a key role in performance optimization. These filters are required to meet stringent passband and stopband performance requirements. In these filters, sharp skirt selectivity is of critical importance. The multipole self-equalized, quasielliptic HTS planar filter configuration is best suited to satisfy the required performance specifications. The most efficient and cost-effective way to realize both the elliptic function response and the self-realization is to use a dual-mode resonator configuration as shown in

Table 2. Performance Improvement in GaAs MESFET Amplifiers

T (K)	Wideband Amplifier (8–18 GHz)		Narrowband Amplifier (9.5–10.5 GHz)	
	Gain (dB)	NF (dB)	Gain (dB)	NF (dB)
300	22	2.08	23	1.25
200	24	1.59	26	0.98
77	27	0.87	29	0.35
10	29	0.73	32	0.26

Table 3. Performance Improvement in Pseudomorphic HEMT Amplifiers

Parameter	12 GHz Amplifier		18 GHz Amplifier	
	300 K	20 K	300 K	20
Gain (dB)	7	12	5	11
Noise figure (dB)	2.8	0.59	3.7	0.97
Power required (mw)	68	45	93	63

Fig. 1. This resonator configuration allows coupling between the nonadjacent resonators with minimum complexity. Dual-mode patch resonators have been used to design HTS filters with elliptic response in the passband. However, elimination of undesired coupling between the various resonator elements is a serious design problem. This problem can be overcome by using a lumped-element HTS filter with a basic resonator configuration as illustrated in Fig. 1. This resonator configuration permits easy control of coupling between the two modes by adjusting the spacing G and the offset parameter L . In brief, this resonator configuration allows ease of realization and controlling the cross-coupling between the resonators, which is necessary to achieve both the quasielliptic and self-equalization functions with minimum cost and complexity. The 10-pole self-equalized input channel filter using the dual-mode resonator configuration is an integral part of the multichannel HTS multiplexer subsystem. This filter design can be integrated with an input circulator for channel dropping and output isolator to isolate the filter from backreflections. The drop-in ferrite components are fully qualified to operate at cryogenic temperatures. Such a filter designed for operation in a C-band satellite communication system exhibited low insertion loss, symmetric bandpass response, and sharp skirt selectivity.

Significant improvement in mass reduction of electronics payload and satellite mission life has been observed due to integration of cryogenic electronic technology in the satellite communication systems. In a 60-channel multimedia satellite design, a mass reduction of 10 kg and mission life extension of 2 years are noted because of the integration of cryogenic electronic technology-based components.

It is important to mention that performance requirements such as insertion loss, instantaneous bandwidth, stopband rejection, and in-band phase linearity for microwave filters vary from application to application. In general, filter performance requirements for military and space systems are more stringent in terms of weight, size, and reliability. These requirements dictate the filter design parameters for the architecture and resonators

Table 4. Power-Added Efficiency (%) for HBT Amplifiers Operating at X Band

T (K)	Common-base Design	Common-Emitter Design
300	31	43
77	43	55

best suited for the architecture selected. In case of satellite communications filters, microstrip or stripline or coplanar waveguide resonator structures could meet the performance requirements with minimum cost and complexity. Long-dispersive-HTS, tapped-delay-line chirp filters are most attractive for use in wideband compressive receivers. Long-dispersive-HTS, tapped-delay-line chirp filters fabricated from HTS thin films of yttrium barium calcium oxide (YBCO) on magnesium oxide (MgO) substrate or lanthanum aluminate (LaAlO_3) are best suited for military warfare applications, where high sensitivity is of critical importance for spectral analysis and remote sensing. In case of satellite communications and terrestrial mobile communications, miniature superconducting filters with unique filter geometry, minimum size, low insertion loss, excellent skirt selectivity, linear phase response over wideband, and maximum stopband rejection are considered the most desirable features.

Optimum filter performance requires low insertion loss and high resonator Q_0 (unloaded Q), which are possible only at lower cryogenic operations. A superconducting filter design using a thin film of YBCO on MgO substrate demonstrated a stopband rejection of -40 dB at 86 K, -60 dB at 77 K, and -80 dB at 15 K. The same filter while operating at 5 GHz demonstrated a reduction in insertion loss by 2% at 77 K, 16% at 15 K, and 35% at 4.2 K operation. A 60-channel superconducting multiplexer integrated with pulsetube cryocooler and 10-pole channel filters using HTS planar structures has demonstrated a reduction in mass of $>50\%$ and in size of $>65\%$ using HTC YBCO film on LaAlO_3 substrate.

2.4.1. Resonator Requirements for Nb-Based and YBCO-Based Filters. Printed circuit resonator, microstrip resonator, and coplanar technologies will provide significant reduction in insertion loss, weight, and size when cooled down to lower cryogenic temperatures. Studies performed by the author on microwave filters indicate that significant reduction in insertion loss can be realized using HTS YBCO-based (77-K) or LTS Nb-based (4.2-K) filter elements. Resonator parameters can be selected to meet specific system performance requirements. The resonators described above have demonstrated unloaded Q (Q_0) greater than 150,000 at 10 GHz, a bandwidth in excess of 10,000 MHz, amplitude accuracy of 0.05 dB, and filter passband loss of <1.65 dB at 77 K temperature. Filter performance characteristics are strictly dependent on resonator type and its unloaded Q , substrate parameters, and the operating temperature. Resonators with higher electrical conductivity, with polished and even surfaces tend to offer higher unloaded Q_0 . Higher the Q_0 , the lower will be the insertion loss and the sharper will be the skirt selectivity. However, all these benefits come with additional cost, size, weight, and complexity.

2.4.1.1. Unloaded Q for Resonators. Superconducting filter resonators must use appropriate substrate technology for the deposition of the thin film of superconducting compound materials, namely, yttrium barium calcium oxide (YBCO) compound on low-loss magnesium oxide (MgO) or lanthanum aluminate substrate (LaAlO_3) for

77 K operation. Nb-based alloy films must be deposited on sintered-alumina substrate (Al_2O_3) to achieve best performance at 4.2 K operation. The low-temperature Nb-based resonators demonstrated a Q close to 10^6 at 14.5 GHz frequency when operating at a cooling temperature between 4.2 and 1.8 K. Computed values of unloaded Q of resonators made from YBCO thin films on lanthanum aluminate substrate and Nb-based films on alumina substrate as a function of frequency are summarized in Table 5.

The computations listed in Table 5 indicate that the higher the operating frequency, the lower will be the unloaded Q and the lower the cryogenic temperature, the higher will be the Q_0 . Unloaded Q_0 of the resonator is dependent on the operating frequency, cryogenic temperature, superconductor film properties, substrate thickness, surface conditions of the film, and RF surface resistance of the film. The unloaded Q of a superconducting microstrip is dependent on the operating frequency and cryogenic temperature and can be defined as

$$Q_0 = [(0.00395)(f)(h)/R_s] \quad (1)$$

where f is the operating frequency (GHz), h is the dielectric substrate thickness (μm), and R_s is the surface resistance of the superconducting thin film (Ω). Assuming a surface resistance of $10^{-7} \Omega$ at 4.2 K for a 10- μm LTS niobium (Nb) film deposited on silicon substrate, the unloaded Q comes to 3.9×10^5 at 1 GHz frequency. HTS resonators have potential applications in fixed-tune filters, tunable filters, oscillators, and tuners. A HTS tunable filter using an LC circuit with a Q factor in excess of 10^5 at 77 K demonstrated a tuning range of 17–1, while operating over the frequency range of 1–23 GHz. A solid-state source using a high- Q superconductor resonator will exhibit significantly improved frequency stability at lower cryogenic temperatures.

2.4.1.2. Insertion Loss in Resonators. The insertion loss (IL) in a superconducting microstrip resonator can be given as

$$\text{IL} = [20 \log(1 + Q_{\text{ex}}/Q_0)] \quad (2)$$

where Q_{ex} is the Q for the external circuit with typical values generally less than 1000 and Q_0 is the unloaded Q as defined by Eq. (1), whose value can run into a few million at higher frequencies and lower cryogenic temperatures. The insertion loss for the HTS YBCO microstrip resonator on LaAlO_3 substrate at 77 K cryogenic temperature can be computed using an empirical formula given

as

$$\text{IL} = [1.59 \times 10^{-5} f^2] \text{ dB/mm} \quad (3)$$

where the frequency is expressed in GHz.

2.4.1.3. RF Surface Resistance of Superconductor Films. The RF surface resistance of a superconductor film is the most important parameter, which determines the unloaded Q and insertion loss in the resonator. As stated earlier, the lower the surface resistance, the higher will be the unloaded Q and the lower will be the insertion loss. It is important to mention that the RF surface resistance is dependent on the operating frequency, cryogenic temperature, intensity of the RF field, properties of superconductor compound and dielectric substrate, and thickness and surface finish of the superconductor film. Furthermore, minimum film thickness must be used to allow a few RF penetration depths to shield the substrate from the RF field.

Studies performed by the author on a variety of high-temperature superconductors in bulk, single crystal, polycrystalline, and film indicate that the RF field intensity, operating frequency, and cryogenic temperature have significant impact on the RF surface resistance R_s . These studies further indicate that R_s increases monotonically with field amplitude through a transition region characterized by a strong field dependence, and then saturates to a value of a few percentage of the normal state surface resistance just above the critical temperature T_c . Lower surface resistance is possible only at low cryogenic temperatures and low RF surface fields ($< 0.1 \text{ G}$). The same studies also reveal that at high fields ($> 30 \text{ G}$) the R_s values of polycrystalline samples can increase by several orders of magnitude, although the samples remain in the superconducting state up to the highest fields. In the presence of low RF field, the frequency dependence of R_s in the transition region is approximately quadratic, but at high fields R_s shows only a weak dependence on frequency and temperature. Specifically, f^2 scaling is not universally valid under high field conditions. More recent studies on superconductor-oriented films and single crystals show a significant improvement in RF properties, leading to achievement of lower R_s values under similar operating parameters.

2.4.1.3.1. Surface Resistance Computation for Normal Conductor Film. The RF surface resistance of a normal conductor film at cryogenic temperatures can be expressed

Table 5. Unloaded Q Values for Superconducting Resonators as a Function of Frequency and Cryogenic Temperature (Millions, M)

Frequency α (GHz)	Nb-Based Resonators		YBCO-Based Resonators		
	$T = 4.2 \text{ K}$		$T = 90 \text{ K}$	$T = 77 \text{ K}$	$T = 50 \text{ K}$
1	0.08 M		0.7 M	1.8 M	3.9 M
10	0.05 M		0.08 M	0.5 M	1 M
100	0.04 M		0.07 M	0.4 M	0.8 M

as

$$R_s = [\pi \rho f \mu_0]^{0.5} \quad (\Omega) \quad (4)$$

where ρ is the resistivity ($\Omega \cdot \text{cm}$), f is the frequency (Hz/s), and μ_0 is the permeability of the medium, with a value of 1.258×10^{-8} (H/cm). For the copper film, the resistivity is $1.72 \mu\Omega \cdot \text{cm}$ at 300 K, $0.8 \mu\Omega \cdot \text{cm}$ at 77 K, and $0.25 \mu\Omega \cdot \text{cm}$ at 4.2 K. Computed values of surface resistance for the copper film at 4.2 K temperature are 0.0028Ω at 1 GHz, 0.0088Ω at 10 GHz, and 0.028Ω at 100 GHz. These computations indicate that the surface resistance for normal conductor films is proportional to the square root of the RF frequency.

2.4.1.3.2. Surface Resistance Computation for Superconductor Films. The surface resistance for the superconductor films, including HTS-based YBCO and TBCCO films and LTS-based Nb alloy films, is a function of operating frequency, intensity of RF field, cryogenic temperature, properties of superconductor material, film thickness, and surface conditions of the film. Several empirical formulas exist to compute the surface resistance under low RF field environments. The most accurate expression for computation of surface resistance can be written as

$$R(f, T) = [Cf^n \exp(-E_g/kT)] \quad (\Omega) \quad (5)$$

where C is a constant function of frequency, f is the operating frequency (Hz), T is the cryogenic temperature (K), n is the exponent parameter (which varies from 1 to 2 depending on the RF field intensity), E_g is the energy gap ($1.76 \times kT_c$), T_c is the critical temperature for the superconductor (111 K for TBCCO film, 91 K for YBCO film, and 9.4 K for Nb alloy film), and k is Boltzmann's constant. The exact value of constant C is dependent on the RF field intensity and is not readily available.

However, the most practical and reliable expression for the surface resistance, which is widely used by the research scientists, can be given as

$$R(f, T) = [(0.5)(\omega^2)(\mu_0)^2 \lambda(T)] \quad (\Omega) \quad (6)$$

where ω is the angular frequency ($2\pi f$) and $\lambda(T)$ is the London penetration depth for the superconductor film, which is a function of operating frequency and critical temperatures and can be written as

$$\lambda(T) = [\lambda_0 / 1 - (T/T_c)^4] \quad (7)$$

For a LTS-Nb-based film (4.2 K), the surface resistance comes to about $10^{-7} \Omega$ at 1 GHz, $10^{-5} \Omega$ at 10 GHz, and $10^{-3} \Omega$ at 100 GHz. Surface resistance values for HTS YBCO films as a function of temperature and frequency have been computed and are summarized in Table 6. These computed values [which agree with those in *Proc. IEEE* 1252 (Aug. 1989)] show the surface resistance dependence as the square of the frequency for the superconductor films under low RF fields. As stated earlier, this

Table 6. Values of Surface Resistance for Various Superconductor Films (Ω)

Frequency (GHz)	Nb Film ($T=4.2$ K)	YBCO Film ($T=4.2$ K)	YBCO Film ($T=77$ K)
1	10^{-7}	2×10^{-6}	8×10^{-6}
10	10^{-5}	2×10^{-4}	8×10^{-4}
100	10^{-3}	2×10^{-2}	8×10^{-2}

square law may not be valid under high RF field environments.

A superconductor oxypolished cavity employing thin films offers much higher values of unloaded Q and lower values of surface resistance. The surface resistance for a cavity-based superconductor films can be written as

$$R(f, T) = [G/Q_0(f, T)] \quad (\Omega) \quad (8)$$

where G is a constant that has a value of 780Ω for a TE_{011} mode cavity and Q_0 is the quality factor for the cavity function frequency (f) and temperature (T).

3. CRYOGENIC ELECTRONIC COMPONENTS FOR MILITARY SYSTEMS

Cryogenic electronic technology has potential applications in missile electronics, high-performance radar systems, electronic countermeasure systems (ECMs), UAVs, reconnaissance drones, battlefield sensors, transmit/receive (T/R) modules, battlefield aerial surveillance sensors, electronically steerable phased-array antennas, and electronic support measure (ESM) receivers. Superconducting signal processing components such as tapped-delay-line structures for matched filtering, convolution, correlation, and Fourier analysis are best suited for precision tracking radars, satellite communication systems, and space surveillance sensors with stringent performance specifications. Microwave delay lines using superconducting meanderline structures are most attractive for deployment in electronic warfare (EW) systems.

3.1. Digital Radiofrequency Memory (DRFM) using cryogenically-cooled devices

Cryogenically cooled components including ADCs, DACs, mixers, solid-state LOs, and stripline technology-based delay lines with meanderline configuration are best suited for effective integration in the design of DRFM, which offers real-time performance simulation of high-performance radars using complex waveforms and sophisticated EW systems incorporating advanced ECM techniques. Simulation techniques such as these will be able to define the requirements for a EW system capable of providing effective ECM capability against enemy radars without undertaking extensive field tests. It is important to mention that low spurious levels over wide instantaneous bandwidth is the principal requirement for a DRFM-based system, a condition that cannot be met by uncooled

microwave components. The ADC device is the heart of the DRFM system, and an uncooled ADC will not be able to meet stringent system requirements. Studies performed by the author indicate that incorporating an Nb-based RSQF superconductive logic in the ADC architecture will meet these stringent performance requirements. The high-resolution requirements can be satisfied only with cryogenically cooled electronic circuits with ultralow time constants and with the correct threshold levels. Cryogenically cooled devices and components used in the DRFM system can be enclosed in a common cryogenic chamber shown by the dotted rectangle in Fig. 2. In this way only one cryogenic cooler can provide cooling to all the cryogenic electronics involved with minimum cost.

Design of the meanderline delay line requires the use of a London two-fluid model to derive the slow mode propagation velocity in the meanderline structure, which is dependent on the ratio of dielectric substrate thickness to superconductor film thickness to penetrate the depth. The propagation velocity in the delay medium is strictly dependent on the coherence length, mean-free path, surface reflection, cryogenic temperature, and magnetic field. However, the effective penetration depth is given by the modified London penetration depth (λ_L), which takes into account the superconductor Nb-based or YBCO-based film thickness. The phase velocity of the dominant slow-wave E mode is a function of velocity of light in the dielectric and the penetration depth in the superconductor thin film. Any superconductor alloy impurity will increase the delay per unit length without increasing the insertion loss or degrading the pulse shape. A delay line using a superconductor meanderline structure offers significant improvements in size, weight, and insertion loss over a conventional uncooled delay line made from coaxial transmission lines. It is important to mention that the wave interaction produces slight nonlinear dispersion; therefore, both the linear and nonlinear dispersive performance levels are possible with this unique delay-line structure.

This geometry is very useful as a dispersive delay-line element for a pulse compression filter widely used in high-performance, long-range missile detection radars.

3.2. Cryogenically Cooled Local-Oscillator (LO) or Solid-State RF Source

A stable solid-state RF source with low phase noise can be used as a LO source to provide power to RF mixers shown in Fig. 2. Phase noise and frequency stability are the most critical performance parameters for a LO. Small LO power requirements can be met with a solid-state source comprising of one or two solid state devices such as HBTs or MESFETs or HEMTs or Gunn diodes. The frequency stability of such sources is dependent on bias level, fluctuation in supply voltage, and operating environments. In cases where frequency stability is of paramount importance, thermal stabilization circuit, regulated voltage power supply, and cryogenic cooling must be considered for the LO design. An X-band superconducting oscillator using lead-plated cavity with $Q = 10,000$ demonstrated a frequency stability of 10^{-8} at 6.7 K. A superconducting monotron oscillator using a reflex klystron stabilized with a superconducting cavity achieved a frequency stability of $> 10^{-12}$ at 10 K operating temperature. Of course, high stability sources do suffer slightly from higher weight and cost.

The solid-state sources are generally used to provide LO power in the microwave and MM-wave regions. However, when LO frequencies are in sub-millimeter-wave regions, frequency multipliers using varactors or step recovery diodes are used to achieve sufficient power levels. The conversion efficiencies of these frequency multipliers can be significantly improved using cryogenic cooling as shown in Table 7.

The phase noise of an uncooled frequency multiplier source is relatively high, as shown in Table 7, but it can be reduced at least by 20 dBc/Hz under CW operation

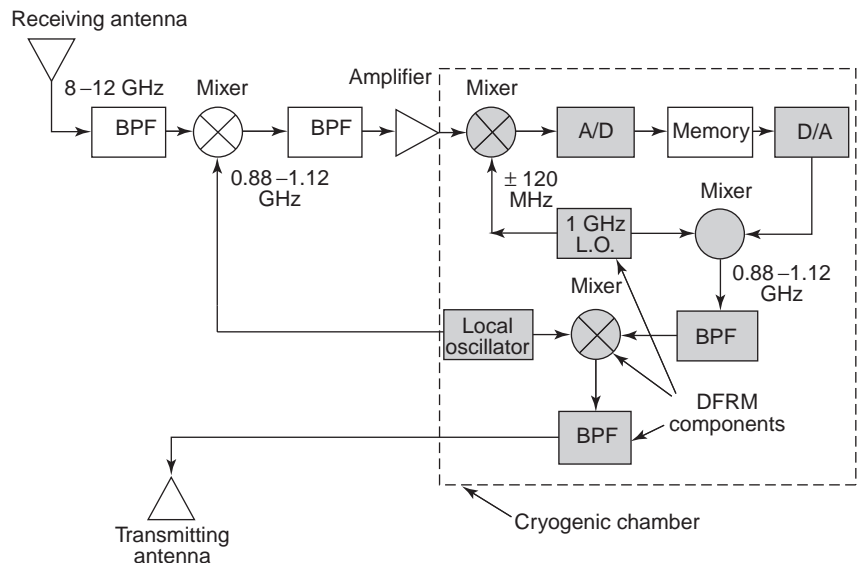

Figure 2. Cryogenic electronic components deployed by an electronic warfare system.

Table 7. Conversion Efficiency of Cryogenically Cooled Frequency Multipliers^a

Multiplier Type and Cutoff Frequency (GHz)	300 K	77 K
Doubler (1000 GHz)	39%	87%
Tripler (500 GHz)	32	54
Quadrupler (800 GHz)	23	42
Quintupler (1000 GHz)	9	21
Sextupler (1500 GHz)	18	29

^aAn input frequency of 10 GHz is assumed in each case.

through cryogenic cooling at 77 K. Cryogenic cooling also improves the conversion efficiency of the multiplier, thereby increasing the output power. Under pulse operations, the intrapulse phase change across a 10- μ s pulse is 2.5° at 300 K, which can be reduced well under 0.8° at 77 K. Studies performed by the author indicate that higher conversion efficiencies have been observed when integrated series IMPATT structure (ISIS) diodes are used in the design of microwave frequency multipliers. In brief, cryogenic cooling does improve the frequency stability and phase noise of the source irrespective of LO design.

3.3. Detectors and Focal Planar Arrays (FPAs) for Target Tracking and Imaging

High-performance detectors and cryogenically cooled FPAs are widely used by airborne IR sensors to track targets and by high-resolution digital cameras to achieve high quality of images of the objects. RF detectors are used to monitor microwave and MM-wave signals. Earlier bolometer IR detectors using temperature-dependent resistances were used to detect IR and MM-wave signals. Direct detectors are characterized in terms of dark current, noise equivalent power (NEP), responsivity, quantum efficiency, detectivity, and dynamic range. Significant improvement in dark current, responsivity, and detectivity is noticed at a cryogenic temperature optimized over a specific spectral region (see Tables 8 and 9 and Fig. 3). IR FPAs are widely used by military IR search-and-tracking (IRST) sensors for target tracking and IR line scanners (IRLSs) for battlefield thermal imaging with high resolution. Photoconductive (PC) and photovoltaic (PV) detectors using Hg:Te: Cd alloy structure when cooled to 77 K offer low dark current and high quantum efficiency at operating wavelengths up to 17 μ m. For an 8- μ m detector junction, the dark current is reduced from 700 nA at 77 K to much less than 1 nA at 40 K cryogenic temperature (Tables 8 and 9 and Fig. 3). Such detectors are best suited for detection and tracking of long-range ballistic missiles during launch, boost, and cruise phases.

Table 8. Performance of Hg:Te: Cd Detectors for Various IR Bands

Hg _{1-x} :Cd _x :Te	T (K)	Spectral Region (μ m)	Maximum Detectivity (cm Hz ⁻¹ W ⁻¹)
0.39	80	1.5–3.5	1.8×10^{11} at 1.8 μ m
0.27	80	4.5–5.0	5×10^{10} at 5 μ m
0.20	80	7–11	3×10^{11} at 11 μ m
0.18	80	14–17	5.6×10^{10} at 17 μ m

3.4. Microcooler Requirements for Military and Space Sensors

Cryogenic cooler requirements are more stringent at lower cryogenic temperatures. For cooling military and space system components and devices, lower weight, size, and power consumption and higher cooling efficiency and reliability are the most critical performance requirements. For certain military applications cooling time is of paramount importance to the life of the cooler. For space applications minimum weight, size, and power consumption are the principal requirements. The word greater reliability are the principal requirements. Studies performed by the author on various cooler configurations indicate that miniaturized microcoolers have potential applications to space sensors, IR missile seeker, airborne IR thermal imaging radiometers, and mini-IRST sensors. A microcooler using a stirling cycle engine takes less than 3 min to reach a liquid nitrogen temperature of 77 K. This type of cryocooler is deployed in military missions where short cooling time is the principal requirement. A microcooler designed for NASA thermal imaging sensor weighs only 15 oz, consumes power less than 3 W, has a shelf life more than 5 years, and has demonstrated a continuous operation over 8000 h with no compromise in reliability or cooling performance. High-reliability coolers require improved materials with self-lubrication features, very-low-friction clearance seals, and linear drive mechanisms. A microcooler can provide a cooling capacity of > 150 mW at 77 K with a heat load of 150 mW and a cooling time ranging from 1.5 min at 120 K to 4 min at 77 K from a room temperature of 25 °C. Research studies performed by the author on cryogenic coolers reveal that reduction in the Intelsat-8 multiplexer's mass and size by 50–65% is possible by using pulsetube cryocoolers. Research studies further reveal that closed-cycle cryocoolers are best suited for high-resolution imaging, MRI, and NMR applications.

4. APPLICATION OF CRYOGENIC ELECTRONIC TECHNOLOGY IN MEDICAL AND SCIENTIFIC RESEARCH FIELDS

Cryogenic electronic technology has played a key role in the development of medical diagnostic equipment and scientific research instrumentation. Integration of low-temperature superconductor (LTS) technology in early 1960s allowed the design and development of high-power magnetic resonance imaging (MRI) magnets to achieve high-resolution images of human organs. LTS technology has also played a key role in the design and development of

Table 9. Detector Dark-Current Levels as a Function of Temperature

^aWavelength 17 μm.

nuclear magnetic resonance (NMR) equipment best suited for medical diagnosis and scientific research.

4.1. Application of Cryogenic Electronic Technology for Medical Diagnosis

The MRI provides physicians, veterinarians, and surgeons with precision diagnostic tools to locate and diagnose medical problems in the body with high reliability. MRI demands superconducting windings of topological precision greater than that provided by crystalline conductors. Magnets with storage capacity of 40 MJ of energy can be developed with adiabatic windings, in which the conductors are locally uncooled. Availability of improved magnetic components and state-of-the art cryogenic electronic technology has significantly improved the design of the MRI equipment with major emphasis on enhanced resolution and patient comfort. The latest MRI equipment contains couple of openings in the cylindrical structure to eliminate patient fear.

The use of high-resolution nuclear magnetic resonance (NMR) in the critical medical analysis and diagnosis of human organs is now considered the state-of-the art technique involving proton frequencies exceeding 850 MHz, which is possible only with superconducting ribbons of high quality. LTS or HTS technology can be applied to the design and development of accelerators widely used in fusion and other scientific research activities. Both NMR

and accelerator magnets demand superconducting windings with high current density ratings. The magnet configuration can be optimized for high-resolution capability and to meet state-of-the art performance levels. The dipole magnets with superconducting windings are deployed in the design of superconducting supercollider (SSCs) for industrial, military, and space research applications. Niobium–titanium (4.2 K) filament wires with high current density are used in the SSC program to achieve exceptionally high performance capability.

4.2. Requirements for Superconducting Windings or Coils

Characterizations of superconductor materials and superconducting windings indicate that windings or coils must stringent requirements in terms of uniformity, pitch, and spacing between the layers. These superconducting windings or coils are designed to produce very high magnetic fields, which are necessary for high-energy physics experiments, controlled thermonuclear fusion, magnetohydrodynamic power generators, magnetic resonance imaging equipment, and levitated high-speed ground vehicles such as the bullet train in Japan with a speed capability of 550 km/h.

Winding or coil materials must be selected with lower critical temperatures (T_c) to meet the specified performance requirements for a particular system. Intermediate superconducting compounds such as Nb₃Sn, Nb₃Al, and Nb₃(Al_{0.8}, Ge_{0.2}) are best suited for high-magnetic-field applications because of their lower critical temperatures, ranging from 17 to 21 K. These coils use superconducting wires or filaments or multifilaments capable of generating high flux levels with minimum insertion loss and heat generation. Both MRI and NMR equipment require liquid helium (4.2 K) refrigeration systems using either rotary or reciprocating compressors and expansion engines to provide the required cooling capacity.

4.3. Josephson Junction (JJ) Devices for Medical and Scientific Applications

As stated earlier, JJ devices are widely used for detection and mixing at MM-wave and sub-millimeter-wave levels, but their potential application was first explored in the design and development of the magnetic sensors such as superconducting quantum interference devices (SQUIDS). JJ devices can be fabricated using various configurations, including tunnel junction, multijunction, bridge junction, and point contact. Selection of a particular configuration depends on the type of parameters to be detected and resolution accuracy requirements.

Figure 3. Quantum efficiency as a function of wavelength and temperature.

Critical elements of the magnetometer, the first-derivative gradiometer, and the second-derivative gradiometer with different pickup loop orientations are shown in Figs. 4a, 4b, and 4c, respectively. Noise energy levels for various DC and RF SQUID devices operating at different cryogenic temperatures are shown in Fig. 4d. A cooling temperature of 4.2 or lower is used for Nb-based thin films, while temperatures at 77 K and 28 K are preferred for YBCO thin films. The lowest noise energy levels occur for DC Nb-based SQUID devices operating at 4.2 K. It is evident from Fig. 4d that the noise energy level RF commercial SQUID devices remains flat at 4.2 K.

These devices are used to measure magnetic field with an accuracy of $10^{-14} \text{ T Hz}^{-1}$ (T stands for tesla, which is equal to 10,000 G) and magnetic field gradient with an accuracy of $10^{-12} \text{ T/m}^{-1} \text{ Hz}^{-1}$. Superconducting SQUID is widely used in the design of the magnetic anomaly detection (MAD) device, which is best suited for anti-submarine warfare (ASW) reconnaissance missions. Note the sensor resolution is limited by the Josephson noise developed in the low-temperature circuit resistance at 4.2 K.

4.4. Critical Elements of SQUID-Based Sensors

Cryogenically cooled flux transformers and pickup loops are used in the design of SQUID-based sensors. A pickup loop is connected across the input coil to fabricate a superconducting flux transformer, which is made from Nb wire. The orientation of the pickup loop and the number of loops deployed determine the type of SQUID-based sensor, namely, a magnetometer or first-derivative gradiometer or second-derivative gradiometer. The SQUID device and the

input coil are enclosed in a superconducting enclosure. A fraction of the applied magnetic energy in the pickup loop is transferred to the SQUID. Magnetometer loop has a typical sensitivity of 0.01 pT/Hz. Magnetometers are widely used in geophysics research applications such as active electromagnetic (EM) sounding, piezomagnetism, and tectonomagnetism. The axial first-derivative gradiometer with two pickup loops wound in opposite directions measures the quantity (dB/dz) along the z axis, where B is the magnetic flux density. The second-derivative gradiometer employs three pickup loops and measures the quantity (d^2B/dz^2) along the z axis. The first-derivative gradiometers are operated in a shielded room made from mumetal magnetic material that attenuates the ambient magnetic noise. However, the second-derivative gradiometer can be operated in an unshielded environment. In cases where ultrahigh sensitivity is required, an array containing 50–100 gradiometers incorporating integrated thin-film devices can be used to design a most sensitive clinical viable system.

4.5. Various Applications of SQUID-Based Gradiometers

The most important application of a gradiometer is in field of neuromagnetism. This sensor detects the weakest magnetic signals emanating from the human brain. Two basic kinds of measurements are made on human brain. In the first, the sensors detect spontaneous activity of the brain based on the magnetic pulses coming out of patient brain suffering from local epilepsy. The second kind of measurement involves evoked response of the brain such as the

Figure 4. Low-temperature Josephson junction devices used in a (a) SQUID magnetometer, (b) first-derivative gradiometer, and (c) second-derivative gradiometer and (d) noise energy levels in Nb-based (4.2 K) and YBCO-based (77 and 28 K) thin films (PC = pick coil or loop).

magnetic field from the auditory cortex generated by different frequency tones.

Besides medical diagnostic applications, SQUID gradiometers are widely employed in the research studies of corrosion and location of fractures in the underground pipelines and other structures not easily accessible. These gradiometers can be deployed to locate fine cracks in the building structures or metallic posts affected by earthquakes.

5. APPLICATION OF CRYOGENIC ELECTRONICS IN COMPUTER AND HIGH-SPEED SIGNAL PROCESSING

High-speed switching capability (1–5 ps), low power consumption (3–5 μ Watt/chip), and low dispersion feature of the JJ devices are the most desirable parameters to meet the operational requirements of the digital circuits for use in high-speed computing systems and complex signal processing equipment used by radar and ECM systems. Josephson digital logic circuits made from niobium alloy operating at 4.2 K have demonstrated improved process reliability, high-speed capability, and extremely low power consumption. These logic circuits are capable of meeting the performance requirements for large-scale integration (LSI) circuit and very-large-scale integrated (VLSI) circuit applications. Both the LSI and VLSI circuits are best suited for ultrafast Josephson microprocessors, which are the backbone of complex signal processors or supercomputers. The Josephson microprocessor is capable of operating at clock frequencies much greater than 800 MHz. Josephson circuits use a variety of cryogenic electronic integrated circuits as Josephson logic gates such as JJ tunnel logic, current injection device (CID) logic, resistive coupled JJ logic, and modified variable threshold logic (MVTL). Among all these logic devices, the fastest gate delay (<1.5 ps) is observed in the MVTL OR gate. The JJ shift register, OR gate, and AND gates are the critical components of the high-speed Josephson microprocessors and are widely used in the design of high-power computing systems. OR-type and AND-type decoders have been developed using Nb-based Josephson IC technology with access time far below 0.5 ns for 1–4-kb (kilobit) memories using improved architectures. A \geq 4-kb multiplier can be fabricated using LTS-Nb-based threshold logic circuits with multiplication time far below 150 ps and power consumption not exceeding 1 mW. A 16-bit multiplier consisting of 828 MVTL gates demonstrated a multiplication time of <1 ns with power consumption <25 mW and with a gate delay not exceeding 6 ps. Josephson logic gates made from

HTS YBCO films at 77 K can be as fast as Nb-based devices, but they suffer from power dissipation as high as 200 μ W/gate compared to 1–8 μ W/gate for Nb-based logic gates.

LSI and VLSI circuits are widely used in semiconductor chips to design very high-speed complex digital computers for possible applications in advanced radars with multiple target tracking capability, ECM systems to mitigate threats posed by hostile missiles, and space MM-wave radiometers for high-quality imaging. The use of these Josephson devices has also allowed several military and scientific research laboratories to maintain a primary Josephson voltage standard with high-speed instrumentation capability. In addition, JJ devices are best suited for high-performance waveform acquisition and display equipment, leading to development of precision measurement instruments for scientific and industrial research applications.

6. SUMMARY

This article is devoted to cryogenic electronics. Performance capabilities of most widely used cryogenic electronic components and devices using HTS and LTS technologies are summarized with emphasis on reliability, power consumption, and weight. Performance improvements due to integration of cryogenic electronic technology in RF, microwave, and millimeter-wave components, including RF detectors, ADCs, MESFET and HEMT amplifiers, mixers, filters, solid-state sources, frequency multipliers, and laser diodes are identified. Applications of cryogenic electronic technology in satellite communication systems, terrestrial mobile communication systems, space sensors, missile seeking systems, and long-range, missile tracking radars are discussed. Benefits due to deployment of cryogenic electronic components in the design and development of medical diagnostic equipment such as MRI and NMR, scientific and industrial instruments, space sensors, and battlefield systems are summarized. Performance requirements and applications of low-temperature SQUIDs and Josephson junction (JJ) devices such as JJ shift registers, decoders, and logic gates in high-speed computers and sophisticated digital signal processors generally used by missile tracking radar, ECM, and high-resolution imaging sensors are identified. Despite several benefits of cryogenic cooling technology, high-power cryocooler reliability and procurement cost remain the major drawbacks, which can be eliminated by using highly efficient pulsetube cryogenic cooler technology.

COMPUTATIONAL ELECTROMAGNETIC SCATTERING MODELS FOR MICROWAVE REMOTE SENSING

1. INTRODUCTION

Modeling of electromagnetic wave scatterings by random discrete scatterers and rough surfaces play an important role in geoscience and remote sensing research. Since the 1970s, considerable theoretical efforts have been made to elucidate and understand the scattering processes involved in such problems, and various models have been developed for microwave active and passive remote sensing applications [1–7]. With the rapid advances in computer technology and fast computational electromagnetics algorithms, numerical simulations of scattering by random media allow us to solve Maxwell's equations exactly without the limitations of analytical approximate models. The numerical models can provide a valuable means for evaluating the validity regimes of analytical scattering theories; in addition, they can potentially aid in the future development of extended analytical models. These theoretical and numerical models, which are commonly used for tackling electromagnetic wave scattering problems and for remote sensing applications, have been presented in three volumes of books [5–7]. In this article, we will update the development in the numerical scattering models for discrete random scatterers, with emphasis on the applications of microwave remote sensing in snowcover, seafoam, and vegetation canopy.

The frequency dependence of scattering by geophysical media at microwave frequencies is an important topic because multifrequency measurements are used in remote sensing applications. In Section 2, we investigate rigorously the frequency dependence of scattering by dense media [7–9]. The approach used is based on the Monte Carlo simulations where the three-dimensional solutions of Maxwell's equations are pursued [6]. The particle positions are generated by deposition and bonding techniques. The properties of absorption, scattering, and extinction are calculated for dense media consisting of sticky and nonsticky particles. Numerical solutions of Maxwell's equations indicate that the frequency dependence of densely packed sticky small particles is much weaker than that of independent scattering. Numerical results are illustrated using parameters of snow in microwave remote sensing. Comparisons are made with extinction measurements as a function of frequency.

In Section 3, polarimetric microwave emissions from foam-covered ocean surfaces are studied. The foam is

treated as densely packed air bubbles coated with thin seawater coating [10–12]. The absorption, scattering, and extinction coefficients are computed from the Monte Carlo solutions of Maxwell's equations for a collection of coated particles. These quantities are then applied in the dense media radiative transfer (DMRT) theory [2,7] to calculate the polarimetric microwave emissivities of ocean surfaces with foam cover. The theoretical results of Stokes brightness temperatures with typical parameters of foam in passive remote sensing at 10.8 and 36.5 GHz are illustrated and compared with experimental measurements [10–12].

We present an efficient computational model for computing tree scattering at VHF/UHF frequencies in Section 4. A structure model with dielectric cylinders is used to simulate trees with bare branches. The method of moments (MoM) is applied to solve the volume integral equation for the tree scattering signatures. An efficient numerical algorithm based on the sparse matrix iterative approach (SMIA) is applied in solving the matrix equation iteratively [13–15]. The SMIA decomposes the impedance matrix into a sparse matrix for the near interactions, and a complementary matrix for the far interactions among the cylindrical sub-cells of the tree structure. The SMIA tree scattering model is applied to calculate scattering from various simulated trees with up to several hundreds of branches using a laptop computer. Solutions obtained from the SMIA method agree very well with the solutions obtained using exact matrix inversion and the conjugate gradient method (CGM). The key feature of the SMIA approach is that very little iteration is required to obtain convergent solutions, compared to the CGM, the SMIA approach may reduce the number of iterations by a factor of >100 [16].

In Section 5, a UV multilevel partitioning (UV-MLP) method is presented for solving the volume scattering problem [17–20]. The method consists of setting up a rank table of transmitting and receiving block sizes and their separations. The table can be set up speedily using coarse-coarse sampling. For a specific scattering problem with given geometry, the scattering structure is partitioned into multilevel blocks. By looking up the rank in the pre-determined table, the impedance matrix for a given transmitting and receiving block is expressed by a product of U and V matrices. We demonstrate the method for two-dimensional volume scattering by discrete scatterers. Multiple scattering is cast into the Foldy-Lax equations of partial waves [2,5–7]. We show that the UV decomposition can be applied directly to the impedance matrix of partial waves of higher order than the usual lowest-order Green function. Numerical results are illustrated for randomly distributed cylinders with diameter of 1 wavelength. For scattering by 1024 cylinders on a single PC processor with 2.6-GHz CPU and 2 GB (gigabytes) of memory, only 14 CPU minutes is needed to obtain the numerical solution and, for 4096 cylinders, only 7.34 s is needed for one matrix-vector multiplication.

2. FREQUENCY DEPENDENCE OF SCATTERING BY DENSE MEDIA WITH APPLICATIONS TO SNOW

For remote sensing applications, the measurements are generally taken at multiple frequencies [21–25] because

each frequency contains information. For instance, the special sensor microwave/imager (SSM/I) radiometer measures at 19, 22, 37, and 85 GHz. Backscattering data are usually measured at L, C, and X bands in the active remote sensing case [1–4]. These multiple frequency measurements are used in many applications, such as the snow parameter retrievals, the surface type classification, and metamorphism signature of snow. Thus, the frequency dependence of scattering is an important issue for making a better use of multifrequency data in remote sensing. The extinction of dry snow is due primarily to scattering rather than absorption. Since the snow grain sizes are much smaller than wavelength, classical Rayleigh scattering theory indicates that the dependence on scattering is frequency to the fourth power. The important question of dense media is whether the scattering still exhibits frequency to the fourth power when these small particles are densely packed. Several approaches have been used in studying the frequency dependence of scattering. The first is based on experimental measurements and empirical fitting. Hallikainen et al. [22] measured the extinction coefficients of snow at 18, 35, 60, and 90 GHz. The second approach is based on analytical modeling using effective medium theories [2,7]. Analytical approaches that account for correlations between particles, such as the quasicrystalline approximation (QCA) and quasicrystalline approximation with coherent potential (QCA-CP) [2,7], have been used to simulate the densely packed media. The Percus–Yevick (PY) pair distribution functions are used to model the relative location of particles. The dense media radiative transfer equations have been derived based on QCA for sticky particles and found useful applications in microwave remote sensing of snow [7,26]. At higher frequencies, particles become comparable to wavelength and higher-order multipoles have to be included [27–29]. The third approach is a rigorous approach based on Monte Carlo (MC) simulations of exact solutions of Maxwell equations that govern microwave interactions exactly [6]. The method consists of generating the positions of the particles on a computer on the basis of prescribed rules. Once the positions are generated, the Maxwell equations are solved numerically. Numerical methods include the T -matrix method [2,7], the finite-difference time-domain (FDTD) method [30], and the volume integral equation method [6]. Monte Carlo simulations have been applied to study the extinction coefficients and the effective permittivities for dense media [27–35]. In 2001–2003, we conducted two- and three-dimensional Monte Carlo simulations to investigate the frequency dependence of scattering by dense media [7–9].

In this section, we describe the three-dimensional dense medium scattering simulations for media with small and moderate size particles. Particles with (sticky) and without interparticle force (nonsticky) are both used in simulations to study the frequency dependence of the extinction coefficient. The T -matrix method is used, and the effects of absorption are included. For typical snow grains, the diameters are in millimeter ranges, and the size parameter ka values are ranging from 0.2 to 1 depending on the frequencies. It is shown that densely

packed sticky particles exhibit a frequency dependence of scattering coefficient weaker than that of independent scattering. The methodology of dense media study consists of studying the pair distribution functions of particle positions, computer growth of dense media, and three-dimensional solutions of Maxwell equations for the computer-grown dense media. Section 2.1 briefly describes the pair distribution functions and the computer creation of discrete random media with sticky particles. The three types of formulations of Foldy–Lax multiple scattering equations, based on exciting field, scattered field, and internal field, for spheres are presented in Section 2.2. We also describe how to calculate scattering and absorption coefficients. Convergence tests are performed using various numerical parameters to show that the results are accurate. In Section 2.3, simulation convergence with respect to the number of particles used, the number of multipoles used, the box size used, and the number of realizations are demonstrated. In Section 2.4, we present results based on Monte Carlo simulations of densely packed sticky and nonsticky dielectric spheres. The Monte Carlo simulation results are compared with independent scattering and QCA results. The results of Monte Carlo simulations are in good agreement with QCA results. Simulated results are shown for various size parameter ka and stickiness parameter τ for the four microwave frequencies at 18, 35, 60, and 90 GHz using typical parameters in snow. Comparisons are also made with extinction measurements [22] as a function of frequency.

2.1. Pair Distribution Functions and Computer Generation of Ensemble of Particle Positions for Finite-Size Sticky Particles

The pair distribution functions for various types of materials, which can be classified as gas, crystal, and liquid/glass, are described in detail in three other texts [2,6,36]. The key observation is that liquid is a “dynamical” system with moving molecules while glass is amorphous solid that is “static.” Yet they have same probability density function (pdf) and joint pdf of particle positions. They both have short-range order with the same class of pair distribution functions. Another comparison is using the Bernal random closed-packed sphere model, which is a macroscopic “static” situation, because in this model the spheres are dropped into the container. On the other hand, the Percus–Yevick (PY) hard-sphere model is based on molecular “dynamics” of liquids using a hard-sphere potential. Yet the Bernal random closed-packed sphere model and the PY model give very similar pair distribution functions. In practice, the Bernal random packing is of limited use, due to its fixed volume fraction at about 63%. From these studies one can see that static situations can be generated from dynamic situations because one can view the dynamics as merely random walk or shuffling of particles to create realizations of random positions of particles. In other words, shuffling of particle positions creates the static situation of various statistical ensembles. The particles do not actually move in a natural snow medium.

To understand the scattering of waves by dense discrete random media, it is important to systematically

generate the ensemble of random positions of particles using the procedure of computer growth. To generate the “static” case of dense random media with fractional volume between 20% and 50%, we have been using shuffling, which is viewed as a means of creating different realizations rather than viewing particles as actually moving in real life. The particles are first placed periodically, which is possible up to 70%. Then the particles are shuffled, by random walk, to attain the random positions. The results of particle positions actually look quite realistic.

Aggregation is introduced by allowing particles to bond. The diffusion-limited aggregation methods [37] are not useful as they are limited to low fractional volume, and the structure created is quite sparse not dense as in snow grain. The fractional volume decreases as the number of particles increases for fractals generated by diffusion limited aggregation. The manner in which bonding is done is actually “static.” The probabilities are constructed based on the exposed surface area of the particles. Then bonding is decided on the basis of these probabilities [6,38–40]. We call these particles “sticky” because they bear similarities to the Percus–Yevick liquid model of a sticky potential; the pair functions are also similar.

Sticky particle models are used to consider cases when the particles can have surface adhesion [6]. This means that when the particles are randomly packed together, they tend to form clusters and bonds with each other. The adhesive force is parameterized using a variable τ that governs the degree of clustering. Analytic solutions of the pair distribution functions can be calculated for particles of the same size [41] and for medium with multiple sizes of particles [42]. They have distinct pair distribution functions that are different from those of nonsticky particles. To generate the positions of particles in the sticky particle model, a two-step procedure is used. First, the Metropolis shuffling technique is used to provide random positions of the particles in a box. Next we follow the work of Seaton and Glandt [38] and Kranendonk and Frenkel [39], to allow the particles to form bonds. There are four binding states for each particle: unbonded, single bond, double bond, and triple bond. Transition probabilities are calculated. The particles are then selected to form bonds on the basis of these transition probabilities [6,38–40]. The sequence of bonds can be formed by different particles resulting in aggregates.

The sticky particle model is useful to describe snow because the ice grains in snow are adhesive. Furthermore, as metamorphism occurs, the ice grains form bridges. The appropriateness of the sticky particle model can be verified by reexamining the pair distribution functions in snow and comparing them with the sticky particle model. It has been observed that grain size in snow follows a lognormal size distribution [43]. The large size grain can be viewed as a result of aggregates. The study of relation between particle size distribution and the alternative viewpoint of aggregation of small particles to form larger size grains will be studied in the future.

In the following simulations, all the particles are assumed to have the same size. However, since the particles can form bonds and aggregates, the effective sizes of the particles can be much larger. Furthermore, the aggregates consist of a varying number of particles. This gives an effective size distribution when the medium is viewed as aggregates of particles. The particle positions are generated for both nonsticky and sticky particles. After the particle positions are generated, the conjugate gradient method is used to solve the Foldy–Lax multiple scattering matrix equations described in Section 2.2.

2.2. Numerical Solution of Maxwell Equations Based on Foldy–Lax Formulation

The final step of simulation is to solve Maxwell equations of these realizations to study the coherent wave and incoherent waves by averaging the electromagnetic fields and intensities over realizations. In the dispersion relation for the coherent wave, the coherent wave has an effective propagation constant that has a real part and an imaginary part. The real part corresponds to effective permittivity. The imaginary part accounts for loss due to absorption and scattering. The scattering loss is due to the conversion of coherent waves to incoherent waves. It can be calculated by angular integration of the incoherent wave intensities. In the simulations, Maxwell equations are solved exactly. Then we calculate incoherent waves by subtracting the coherent wave from the scattered wave. Absorption is calculated by finding the absorption loss of each particle, based on the solution of internal fields of each particle. Combining scattering and absorption give the extinction of the dense random media. However, for dry snow, the extinction is crucial and the results of extinction are shown in Section 2.4. The procedures are used for the four frequencies: 18, 37, 60, and 90 GHz.

Consider a medium consisting of N spheres, with radii a and permittivities ϵ_p , centered at $\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N$. An incident wave with wavevector \vec{k}_i is impinging onto the medium. The solution of Maxwell’s equations can be cast into the Foldy–Lax multiple scattering equations. In matrix form [2,6,9]

$$\vec{w}^{(q)} = \sum_{p=1, p \neq q}^N \overline{\sigma}(k\vec{r}_q\vec{r}_p) \overline{T}^{(p)} \vec{w}^{(p)} + e^{i\vec{k}_i \cdot \vec{r}_q} \vec{a}_{\text{inc}} \quad (1)$$

where $\vec{w}^{(q)}$ are the exciting field coefficients, $q = 1, 2, \dots, N$, $\overline{\sigma}(k\vec{r}_q\vec{r}_p)$ is the vector spherical wave transformation matrix, $\overline{T}^{(p)}$ the T matrix representing scattering from the scatterer p , and \vec{a}_{inc} the incident field coefficients. The physical interpretation of Eq. (1) is that the exciting field at particle q is equal to the incident field plus the scattered fields from all other particles except itself.

The relationships between exciting field coefficients $w_{mn}^{(M)}$ and $w_{mn}^{(N)}$, scattered field coefficients $\alpha_{mn}^{S(M)}$ and $\alpha_{mn}^{S(N)}$,

and internal field coefficients $c_{mn}^{(M)}$ and $c_{mn}^{(N)}$ are as follows [6,9]

$$a_{mn}^{S(M)} = T_n^{(M)} w_{mn}^{(M)} \quad (2)$$

$$a_{mn}^{S(N)} = T_n^{(N)} w_{mn}^{(N)} \quad (3)$$

$$\begin{aligned} a_{mn}^{S(M)} &= S_n^{(M)} c_{mn}^{(M)} \\ a_{mn}^{S(N)} &= S_n^{(N)} c_{mn}^{(N)} \\ c_{mn}^{(M)} &= B_n^{(M)} w_{mn}^{(M)} \\ c_{mn}^{(N)} &= B_n^{(N)} w_{mn}^{(N)} \end{aligned} \quad (4)$$

with $T_n^{(M)}$, $T_n^{(N)}$, $S_n^{(M)}$, $S_n^{(N)}$, $B_n^{(M)}$, and $B_n^{(N)}$ as given by

$$T_n^{(M)} = -\frac{j_n(k_p a)[ka j_n(ka)]' - j_n(ka)[k_p a j_n(k_p a)]'}{j_n(k_p a)[ka h_n(ka)]' - h_n(ka)[k_p a j_n(k_p a)]'}$$

$$T_n^{(N)} = -\frac{(k_p a)^2 j_n(k_p a)[ka j_n(ka)]' - (ka)^2 j_n(ka)[k_p a j_n(k_p a)]'}{(k_p a)^2 j_n(k_p a)[ka h_n(ka)]' - (ka)^2 h_n(ka)[k_p a j_n(k_p a)]'} \quad (5)$$

$$\begin{aligned} S_n^{(M)} &= -ika [j_n(ka)[k_p a j_n(k_p a)]' - j_n(k_p a)[ka j_n(ka)]'] \\ S_n^{(N)} &= \frac{i}{k_p a} [(k_p a)^2 j_n(k_p a)[ka j_n(ka)]' \\ &\quad - (ka)^2 j_n(ka)[k_p a j_n(k_p a)]'] \end{aligned} \quad (6)$$

$$B_n^{(M)} = \frac{i}{ka} \frac{1}{j_n(k_p a)[ka h_n(ka)]' - h_n(ka)[k_p a j_n(k_p a)]'}$$

$$B_n^{(N)} = \frac{1}{(k_p a)^2 j_n(k_p a)[ka h_n(ka)]' - (ka)^2 h_n(ka)[k_p a j_n(k_p a)]'} \quad (7)$$

The unknowns in (1) are exciting field coefficients. We can rewrite the equation for $w_{mn}^{(M)}$ and $w_{mn}^{(N)}$ as

$$\begin{aligned} w_{mn}^{(M)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} a_{mn}^{(M)} + \sum_{p=1, p \neq q}^N \sum_{\mu\nu} [A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) \\ &\quad \times T_v^{(M)} w_{\mu\nu}^{(M)(p)} + B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) T_v^{(N)} w_{\mu\nu}^{(N)(p)}] \end{aligned} \quad (8)$$

$$\begin{aligned} w_{mn}^{(N)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} a_{mn}^{(N)} + \sum_{p=1, p \neq q}^N \sum_{\mu\nu} [B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) \\ &\quad \times T_v^{(M)} w_{\mu\nu}^{(M)(p)} + A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) T_v^{(N)} w_{\mu\nu}^{(N)(p)}] \end{aligned}$$

where $a_{mn}^{(M)}$ and $a_{mn}^{(N)}$ are the incident field coefficients and $A_{\mu\nu mn}$ and $B_{\mu\nu mn}$ are the spherical wave transformation between two particles [2,6,9]. Equation (8) is the exciting field formulation of multiple scattering equations.

We can also derive multiple scattering equations for the scattered and internal fields. Multiplying T -matrix coefficients $T_n^{(M)}$ or $T_n^{(N)}$ on both sides of (8) and applying the relationship between exciting field and scattered field, we then have the Foldy–Lax equations for scattered field

coefficients:

$$\begin{aligned} a_{mn}^{S(M)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} T_n^{(M)} a_{mn}^{(M)} + T_n^{(M)} \sum_{p=1, p \neq q}^N \sum_{\mu\nu} \\ &\quad [A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) a_{\mu\nu}^{S(M)(p)} + B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) a_{\mu\nu}^{S(N)(p)}] \end{aligned} \quad (9)$$

$$\begin{aligned} a_{mn}^{S(N)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} T_n^{(N)} a_{mn}^{(N)} + T_n^{(N)} \sum_{p=1, p \neq q}^N \sum_{\mu\nu} \\ &\quad [B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) a_{\mu\nu}^{S(M)(p)} + A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) a_{\mu\nu}^{S(N)(p)}] \end{aligned}$$

The unknowns of (9) are the scattered field coefficients. Thus, it is called the *scattered field formulation*. Replacing $T_n^{(M)} w_{mn}^{(M)}$ and $T_n^{(N)} w_{mn}^{(N)}$ with $S_n^{(M)} c_{mn}^{(M)}$ and $S_n^{(N)} c_{mn}^{(N)}$, respectively, in (9) and multiplying respective $B_n^{(M)}$ and $B_n^{(N)}$ on both sides, we then have the internal field formulation of Foldy–Lax equations:

$$\begin{aligned} c_{mn}^{(M)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} B_n^{(M)} a_{mn}^{(M)} + B_n^{(M)} \sum_{p=1, p \neq q}^N \sum_{\mu\nu} \\ &\quad [A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) S_\mu^{(M)} c_{\mu\nu}^{(M)(p)} + B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) S_\nu^{(N)} c_{\mu\nu}^{(N)(p)}] \\ c_{mn}^{(N)(q)} &= e^{i\vec{k}_i \cdot \vec{r}_q} B_n^{(N)} a_{mn}^{(N)} + B_n^{(N)} \sum_{p=1, p \neq q}^N \sum_{\mu\nu} \\ &\quad [B_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) S_\mu^{(M)} c_{\mu\nu}^{(M)(p)} + A_{\mu\nu mn}(k\vec{r}_q \vec{r}_p) S_\nu^{(N)} c_{\mu\nu}^{(N)(p)}] \end{aligned} \quad (10)$$

We have studied the condition numbers of the various types of Foldy–Lax formulations [8,9]. The scattered and exciting field formulations have similar condition numbers; however, the matrices based on scattered field formulations have much larger condition number than do those based on internal field formulations for the same set of parameters. Thus, the internal field formulation is applied in the three-dimensional scattering simulations.

After solving the multiple scattering equations, the scattered field coefficients $a_{mn}^{S(M)}$ and $a_{mn}^{S(N)}$ can be calculated, and the scattered far-field coefficients in the scattering direction $\hat{\mathbf{k}}_s = \hat{\mathbf{x}} \sin \theta_s \cos \phi_s + \hat{\mathbf{y}} \sin \theta_s \sin \phi_s + \hat{\mathbf{z}} \cos \theta_s$ are given by

$$\begin{aligned} \bar{\mathbf{E}}_s(\theta_s, \phi_s) &= \frac{e^{ikr}}{kr} \sum_{q=1}^N e^{-i\vec{k}_s \cdot \vec{r}_q} \sum_{mn} \gamma_{mn} [a_{mn}^{S(M)(q)} \bar{\mathbf{C}}_{mn}(\theta_s, \phi_s) i^{-n-1} \\ &\quad + a_{mn}^{S(N)(q)} \bar{\mathbf{B}}_{mn}(\theta_s, \phi_s) i^{-n}] \end{aligned} \quad (11)$$

where $\bar{\mathbf{B}}_{mn}(\theta, \phi)$ and $\bar{\mathbf{C}}_{mn}(\theta, \phi)$ are vector spherical wavefunctions and γ_{mn} is a coefficient [2,6].

The scattered field can be further decomposed into coherent and incoherent parts. The scattering coefficient arises from the incoherent fields because the coherent wave propagates in the forward transmitted direction and does not contribute to scattering or extinction. For Monte Carlo simulation with N_r realizations, the coherent

scattered field ($\bar{\mathbf{E}}_s$) is calculated by averaging over realizations

$$\langle \bar{\mathbf{E}}_s(\theta_s, \phi_s) \rangle = \frac{1}{N_r} \sum_{\sigma=1}^{N_r} \bar{\mathbf{E}}_s^\sigma(\theta_s, \phi_s) \quad (12)$$

where $\bar{\mathbf{E}}_s^\sigma$ is the scattered field for realization σ and angular brackets represent averaging over realizations. The incoherent scattered field is given by

$$\bar{\mathbf{E}}_s^\sigma(\theta_s, \phi_s) = \bar{\mathbf{E}}_s^\sigma(\theta_s, \phi_s) - \langle \bar{\mathbf{E}}_s(\theta_s, \phi_s) \rangle \quad (13)$$

The bistatic scattering cross section is proportional to the averaged incoherent intensity:

$$\sigma_b(\hat{\mathbf{k}}_s, \hat{\mathbf{k}}_i) = r^2 \frac{\langle |\bar{\mathbf{E}}_s^\sigma(\theta_s, \phi_s)|^2 \rangle}{|\bar{\mathbf{E}}_{\text{inc}}|^2} \quad (14)$$

The scattering cross section is the result of integrating the bistatic cross section over solid angles. The scattering coefficient is the scattering cross section per unit volume

$$\kappa_s = \frac{\sigma_s}{V} = \frac{1}{V} \int_0^\pi d\theta_s \sin\theta_s \int_0^{2\pi} d\phi_s \sigma_b(\hat{\mathbf{k}}_s, \hat{\mathbf{k}}_i) \quad (15)$$

where V is the sample volume in the simulation. The power absorbed by particle q can be written as [5]

$$W_a^{(q)} = -\frac{1}{2\eta k^2} \sum_{mn} [|w_{mn}^{(M)(q)}|^2 (\text{Re } T_n^{(M)} + |T_n^{(M)}|^2) + |w_{mn}^{(N)(q)}|^2 (\text{Re } T_n^{(N)} + |T_n^{(N)}|^2)] \quad (16)$$

The absorption coefficient is expressed as

$$\kappa_a = \frac{1}{V} \sum_{q=1}^N \frac{W_a^{(q)}}{W_{\text{inc}}} = -\frac{1}{Vk^2 |\bar{\mathbf{E}}_{\text{inc}}|^2} \sum_{q=1}^N \sum_{mn} [|w_{mn}^{(M)(q)}|^2 (\text{Re } T_n^{(M)} + |T_n^{(M)}|^2) + |w_{mn}^{(N)(q)}|^2 (\text{Re } T_n^{(N)} + |T_n^{(N)}|^2)] \quad (17)$$

2.3. Results of Using Different Number of Particles

In Monte Carlo simulations, it is important to demonstrate convergence of the results with respect to the numbers of particles used. Physically, this means that the simulated extinction coefficients are extinction per unit volume and should not be dependent on the number of particles used. The number of particles used in the simulations is chosen on the basis of frequencies, volume fractions, and particle diameters. The particle positions are first generated within a unit cube for selected fractional volume and number of particles. The positions are then scaled according to the actual particle size. It has the following relationship

$$f_v = \frac{N_{\text{part}}}{V} \frac{4}{3} \pi a^3 \quad (18)$$

Table 1. Scattering Coefficients and Box Sizes for Different Number of Particles

Number of Particles	L in λ Units	κ_e/k
10	0.189	6.754639×10^{-5}
100	0.407	1.605086×10^{-4}
1000	0.877	1.963294×10^{-4}
2000	1.105	1.998608×10^{-4}

where f_v is the fractional volume, N_{part} the number of particles within the simulated volume V , a the radius of particle, and $V=L^3$. In general, to ensure that a sufficient amount of incoherent fields is generated as a result of scattering in the sample volume, L has to be larger than (or at least close to) one wavelength λ . Table 1 lists the results of extinction coefficients for $ka=0.2$, $f_v=20\%$, and $\epsilon_p=(3.2+i0.01)\epsilon_0$ with different numbers of particles. The simulated box size L is also shown in the table in the unit of wavelength. As illustrated in the table, results show convergence with respect to the number of particles and with respect to box size.

Monte Carlo simulations are performed for different frequencies and physical parameters, including particle size, permittivity, and stickiness. Results based on independent scattering are also shown. The numerical parameters, such as N_{max} , number of particles, and number of realizations, are chosen such that results converge. The maximum number of particles used in simulations is 2000, and up to 50 realizations are used. The simulation results for permittivities ϵ_p with different loss tangents, $\epsilon_p = \epsilon'_p + i\epsilon''_p$, are shown in Fig. 1. Nonsticky particles (i.e., lacking interparticle forces) with diameter 1.2 mm occupying 20% of volume fraction are used in Fig. 1. Results of scattering coefficient κ_s for $\epsilon_p=(3.2+i0.01)\epsilon_0$ and $\epsilon_p=(3.2+i0.02)\epsilon_0$ are quite similar, as shown in Fig. 1a. The scattering coefficient based on independent scattering assumption is larger than that calculated based on QCA or Monte Carlo (MC) simulations. The absorption rate κ_a varies because of the difference in the imaginary part of ϵ_p , as indicated in Fig. 1b, where κ_a is larger for larger ϵ''_p . MC simulations predict higher absorption rate than do the other methods. Generally, independent scattering gives the largest extinction coefficient while QCA predicts the smallest.

2.4. Frequency Dependence of Sticky and Nonsticky Particles

Figure 2 shows the results for different stickiness parameter τ . Particles with diameter 1.2 mm occupying 20% of volume with permittivity $\epsilon_p=3.2\epsilon_0$ are used. The extinction coefficient and scattering coefficient are the same because there is no absorption in this case. The smaller the τ is, the larger the interparticle forces are. Three stickiness parameters are used in the simulations: $\tau=0.1$, $\tau=0.5$, and nonsticky, which corresponds to $\tau=\infty$. For $\tau=0.1$, however, the scattering coefficient is larger than independent scattering at 18, 35, and 60 GHz. It is smaller than independent scattering at 90 GHz. This is because for small τ , the particles strongly tend to adhere

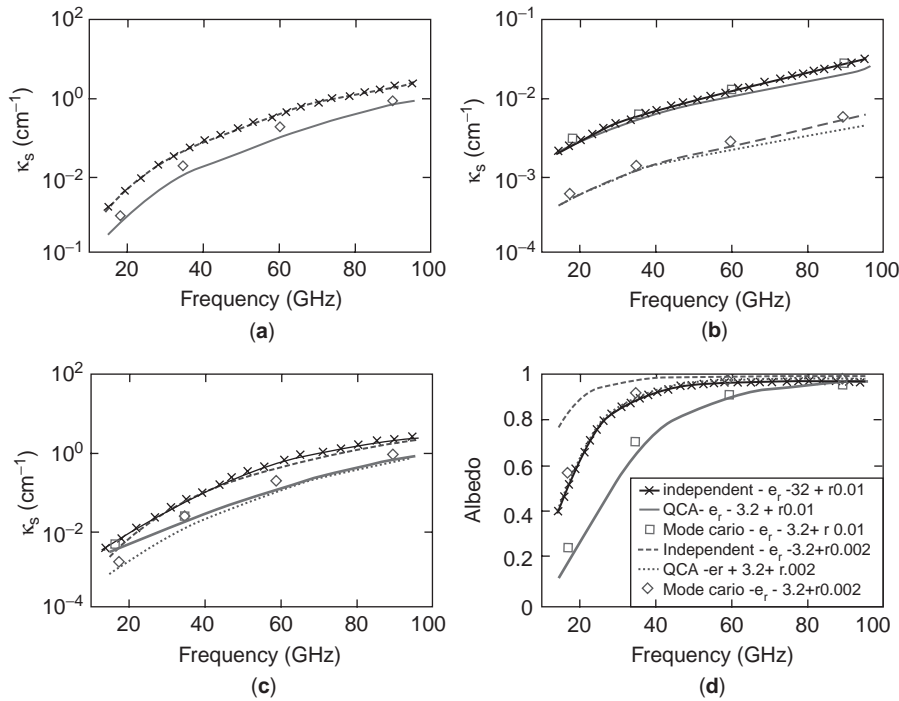

Figure 1. Results of different particle permittivities: $\epsilon_p = (3.2 + i0.01)\epsilon_0$ and $\epsilon_p = (3.2 + i0.02)\epsilon_0$ —particles occupy 20% of volume fraction with diameter 1.2mm: (a) scattering coefficient; (b) absorption rate; (c) extinction coefficient; (d) albedo ($\hat{\omega}$) as a function of frequency. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 2. Extinction coefficient in reciprocal centimeters (cm⁻¹) as a function of frequency in gigahertz (GHz) of different stickiness parameter $\tau = 0.1, \tau = 0.2,$ and ∞ . Particles occupy 20% of volume fraction with diameter 1.2mm and $\epsilon_p = 3.2\epsilon_0$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

and form clusters. The result is that the particles have larger effective sizes. The effect of the property is exhibited at low frequencies. At higher frequency, the clustering effect of scattering declines and the particles scatter more like the usual dense media. Therefore, the frequency dependence decreases as τ gets smaller. Results for $\tau = 0.5$ and non-sticky particles are about the same. This means that the stickiness represents little difference in scattering except for small stickiness parameter τ . Table 2 lists the scattering coefficients for various stickiness parameters at selected frequencies. The scattering coefficient at 18GHz is used as reference. To study the frequency dependence, we define n such that

$$\frac{\kappa_s(\text{at } f_2)}{\kappa_s(\text{at } f_1)} = \left(\frac{f_2}{f_1}\right)^n \tag{19}$$

where f_1 and f_2 are the two frequencies and κ_s is the scattering coefficient at a specific frequency and n is a power law to be determined. On the basis of the simulated

Table 2. Scattering Coefficients in (dB/m) for Various Stickiness Parameters at Selected Frequencies

Frequency (GHz)	Monte Carlo		QCA		Independent Scattering
	$\tau = 0.1$	$\tau = 0.5$	$\tau = 0.1$	$\tau = 0.5$	
18	12.051	0.738	9.450	0.571	1.376
35	82.761	13.203	63.856	8.172	20.359
60	326.643	116.167	297.824	72.251	185.546
90	707.985	443.461	957.044	354.834	862.510

Table 3. Frequency Dependence n Based on Scattering Coefficients from Table 2

Frequency (GHz)	Monte Carlo		QCA		Independent Scattering
	$\tau = 0.1$	$\tau = 0.5$	$\tau = 0.1$	$\tau = 0.5$	
18	—	—	—	—	—
35	2.898	4.338	2.873	4.001	4.038
60	2.741	4.202	2.866	4.020	4.063
90	2.531	3.976	2.869	3.996	4.051

results, the frequency dependence n is calculated by

$$n = \frac{\log \left[\frac{\kappa_s(atf_2)}{\kappa_s(atf_1)} \right]}{\log \left(\frac{f_2}{f_1} \right)} \tag{20}$$

The results for $f_1 = 18$ GHz are shown in Table 3. The frequency dependence n for stickiness $\tau = 0.1$ is less than that of nonsticky particles and $\tau = 0.5$. For nonsticky particles, dense media scattering is less than independent scattering. This reduction of scattering for dense media becomes a smaller effect at higher frequency. Thus results in Table 3 can exhibit index larger than 4. Note that a least-square fit with snow extinction measurements gives an index n between 2 and 3 [22]. The index is consistent with the simulated index n of sticky particles.

Figure 3 shows the results for nonsticky particle with different sizes. Particles occupying 20% of volume with permittivity $\epsilon_p = 3.2\epsilon_0$ are used. The extinction coefficients versus frequency are plotted. We note that scattering increases with particle size, and the scattering by Monte Carlo simulation is less than independent scattering. However, the difference gets smaller at high frequencies. Figure 4 shows results for a sticky particle with $\tau = 0.1$, and the diameters of particles are 1, 1.2, and 1.5 mm. These represent typical ice grain sizes in snow. Note that

scattering increases with particle size. For sticky particles, the simulation results are larger than independent scattering at low frequencies and are smaller than independent scattering at high frequencies. At 90 GHz, the extinction is large. Thus at such high frequency, passive remote sensing will not be useful to determine snow depth.

We next compare Monte Carlo simulation results with that of QCA. For nonsticky particles, the extinction coefficient calculated from QCA is smaller than that from MC at low frequencies while the extinction coefficients of MC and QCA are comparable at higher frequency. For sticky particles, larger particles generally have higher extinction coefficients. We note that the QCA results are generally much closer to simulations than independent scattering. The QCA formulation has been used in dense media formulation and applied to passive remote sensing of spaceborne sensors [7,26].

In the results described above, we have not taken into account the dependence of loss tangent on frequency because the computed results of extinction are dominated by scattering rather than absorption. However, in comparison with experimental data in Fig. 5, we include the dependence of loss tangent on frequency. The permittivity of ice as a function of frequency can be found in Ref. 5. In Fig. 5 we compare Monte Carlo simulation, independent scattering, and snow extinction measurement data at 18, 35, 60, and 90 GHz [22]. We use ground truth mean grain diameter of 1 mm and snow density of 0.315 g/cm^3 [22].

Figure 3. Extinction coefficient in cm^{-1} of different particle sizes as a function of frequency in GHz for nonsticky particles. Particles occupy 20% of volume with permittivity $\epsilon_p = 3.2\epsilon_0$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 4. Extinction coefficient in cm^{-1} of different particle sizes as a function of frequency in GHz for sticky particles ($\tau = 0.1$). Particles occupy 20% of volume with permittivity $\epsilon_p = 3.2\epsilon_0$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 5. Comparison of Monte Carlo simulation results with experimental data and independent scattering. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The simulation is based on a volume fraction of 0.4134. The permittivity of ice grains chosen is $\epsilon_p = 3.2\epsilon_0 + i\epsilon_s''$. The loss tangent depends on frequency and $\epsilon_s''/\epsilon_0 = 0.007, 0.009, 0.011, \text{ and } 0.014$, respectively, at 18, 35, 60, and 90 GHz, which correspond to a salinity of 0.12 parts per thousand [44]. The frequency dependence as exhibited by Monte Carlo simulation is in reasonable agreement with experiment and is much better than that of independent scattering.

In this section we present the Monte Carlo simulations performed for various frequencies, particle sizes, particle permittivities, and cases with different stickiness parameters τ . Monte Carlo simulation results compare well with QCA results. Scattering based on the sticky particle assumption has a much weaker frequency dependence than does that of independent scattering of frequency to the fourth power. This frequency dependence has been shown to better match the observed frequency dependence of snow terrain [7,26]. For problems of very complicated geometry, Monte Carlo simulations provide the correct solutions for Maxwell equations. The results of simulations can be tabulated and further combined with dense media radiative transfer theory. The dense media radiative transfer theory has been used extensively for mapping of snow depth using spaceborne radiometer.

3. POLARIMETRIC PASSIVE MICROWAVE REMOTE SENSING OF WIND VECTORS WITH FOAM-COVERED OCEAN SURFACE

Fully polarimetric microwave remote sensing means that all four Stokes parameters are measured [45]. There has been an increasing interest in the applications of polarimetric microwave radiometers for ocean wind remote sensing [46–49]. It is known that the presence of foam on the ocean surface has a profound effect on the brightness temperatures measured by microwave radiometers. Although foam typically covers only a few percent of sea

surfaces, increasing foam coverage on the sea surface can substantially increase the sea surface emissivity [50–52]. However, there is a great concern on the impact of foam on the retrieval of the ocean surface wind vector from satellite-mounted microwave instruments, which is due in large part to the difficulty in making measurements at high-wind conditions when significant foam coverage is present. In the past, empirical microwave emissivity models [48,50,51,53–55] were used to estimate the effect of the foam above the ocean surface on the passive microwave remote sensing measurements. These are empirical fitting procedures using experimental data and the empirical models do not take into account the physical microstructure of foam and the foam-layer thickness. The subject of foam dynamics has also attracted great attention. Huang and Jin discussed a composite model of foam scatterers and two-scale wind-driven rough sea surface [52]. Controlled field experiments were performed to measure foam dynamics and the microwave emissivity of calm seawater [56,57].

More recently, physically based approaches, based on the quasicrystalline approximation (QCA) dense media model or Monte Carlo simulations, have been developed to account for the microstructure of foam [10–12]. The model treats the foam as densely packed air bubbles coated with thin seawater coating. In order to model high-density packing, a face-centered-cubic (fcc) structure is used to place the air bubbles. It was shown that the polarization and frequency of the brightness temperatures depend on the physical microstructure properties of foam and the foam-layer thickness. In this section, we present the polarimetric microwave emission model for foam-covered ocean surfaces. The dense media model of foam is applied to calculate the values of the complex effective propagation constants, the extinction coefficients, and the albedo. These are used to describe the characteristics of the foam layer. In Section 3.1, we describe the physical and geometric model of foam. The Monte Carlo simulation by solving Maxwell's equations and DMRT theory are summarized in Sections 3.2 and 3.3, respectively. In the Monte Carlo simulations, the volume integral equation has been used. The absorption, scattering, and extinction coefficients are calculated, and the simulation results for emissivity with typical foam parameters at 10.8 and 36.5 GHz are presented in Section 3.4. Comparisons are also made with experimental data [57] for vertical and horizontal polarizations. The Monte Carlo simulation results with those based on QCA are compared in Section 3.5. The effects of boundary roughness of ocean surface can be included in the boundary conditions of dense media radiative transfer (DMRT) theory by using the second-order small perturbation method (SPM) [2,7,46]. A fully polarimetric passive model for wind-generated and foam-covered rough sea surfaces, using the empirical Durden–Vesecy spectrum [58], is presented in Ref. 12.

3.1. Description of Foam Model

Figure 6 shows a video micrograph of the bubble structure of artificially generated foam on the surface of Chesapeake Bay [57]. Analysis of this and similar images shows that

Figure 6. Videomicrograph of artificially generated bubbles in foam on the surface of Chesapeake Bay. The scale in the upper left corner shows a distance of 1 mm.

the void fraction of this foam is 80–90% in most cases. To simplify the foam model, the foam is assumed to be composed of densely packed spherical air bubbles with thin seawater coating [10–12]. The physical and geometric structure of a spherical dielectric-coated particle is illustrated in Fig. 7, where s_j denotes that the coated particle is of the j th species, $s_j = 1, 2, \dots, L$. The core of the coated particle is air, and the shell is seawater. It is assumed that all the particles have the same outer radius a_{s_j} , but need not be identical in coating thicknesses ($a_{s_j} - b_{s_j}$). $\epsilon_{a_{s_j}}$ and $\epsilon_{b_{s_j}}$ are permittivities within the shell and in the core of the coated particle, respectively.

Figure 7. Spherical dielectric-coated particle; a_{s_j} and b_{s_j} are the outer and inner radii of the spherical shells, respectively, and $\epsilon_{a_{s_j}}$ and $\epsilon_{b_{s_j}}$ are permittivities within the shell and in the core of the coated particle, respectively.

To achieve high-density packing, the coated particles are arranged in a FCC lattice structure that has a packing density of $\pi/\sqrt{18} \approx 74\%$ [11,12]. The air regions include the core regions of the coated particles and the interstitial space between the coated particles. For example, let V be the total volume of the foam and N be the number of coated particles. The j th coated particles has a inner radius b_j and outer radius a_j . The fractional volume of coated particles is about 74%; the fractional volume of seawater f_w is then

$$f_w = \frac{1}{V} \sum_{j=1}^N \frac{4\pi}{3} (a_j^3 - b_j^3) \quad (21)$$

By choosing values for the inner and outer radii, the foam void fraction ($1.0 - f_w$) can be on the order of 90%, which is in agreement with experimental measurements of artificially generated foam [57].

3.2. Absorption and Extinction Based on Monte Carlo Simulation by Solving Maxwell's Equations

Consider the thermal emission from a layered medium with coated particles embedded in a background medium of air, as indicated in Fig. 8. The layer consists of coated particles (region 1), and covers a half-space of ocean (region 2). The scattering coefficient and absorption coefficient of a collection of N coated particles are defined respectively as scattering cross section per unit volume and absorption cross section per unit volume. In the Monte Carlo simulation approach, we place N particles in volume V , and calculate the absorption and scattering of these N particles collectively by solving Maxwell's equations and then averaging over realizations and dividing them by the volume V . These are done for large N and the results of the scattering and absorption coefficients computed in this manner converge for large N .

A volume integral equation derived from Maxwell's equations is used to solve scattering and absorption for the N particles [6,11,12]. The volume integral equation has the internal electric field in the coated region as the unknown. The internal field $\vec{E}_i(\vec{r})$ in the seawater coating

Figure 8. Geometric configuration for thermal emission from foam-covered ocean. The foam layer is region 1 and is absorptive and scattering. Region 2 is the ocean.

region of particle i , $\bar{r} \in V_i$, is given by

$$\begin{aligned} \bar{\mathbf{E}}_i(\bar{r}) = & \bar{\mathbf{E}}^e(\bar{r}) + k^2 \sum_{j=1}^N \int_{V_j} d\bar{r}' g(\bar{r}, \bar{r}') (\epsilon_{vj} - 1) \bar{\mathbf{E}}_j(\bar{r}') \\ & - \sum_{j=1}^N \nabla \int_{V_j} d\bar{r}' \nabla' g(\bar{r}, \bar{r}') (\epsilon_{vj} - 1) \bar{\mathbf{E}}_j(\bar{r}') \end{aligned} \quad (22)$$

where $\bar{\mathbf{E}}^e(\bar{r})$ is the incident field, $g(\bar{r}, \bar{r}')$ the free space scalar Green's function, ϵ_{vj} the relative permittivity of particle within the coating, V_j the volume occupied by particle j , and $i = 1, 2, \dots, N$. We expand the internal field in the coating region of particle j , $\bar{\mathbf{E}}_j(\bar{r})$, into three basis functions. The basis functions are from the electrostatic solutions of the coating region of a coated sphere [11]. The subscript j is suppressed in Eqs. (23) and (24)

$$\bar{\mathbf{E}}_j(\bar{r}) = \sum_{\alpha=1}^3 c_{\alpha}(\bar{r}) \bar{f}_{\alpha}(\bar{r}) \quad (23)$$

$$\begin{aligned} \bar{f}_1(\bar{r}) = & \frac{1+2\epsilon_r}{3\epsilon_r} \hat{x} + \frac{1-\epsilon_r}{3\epsilon_r} b^3 \\ & \times \left[\hat{r} \frac{2}{r^3} \sin \theta \cos \phi - \frac{1}{r^3} (\hat{\theta} \cos \theta \cos \phi - \hat{\phi} \sin \phi) \right] \\ \bar{f}_2(\bar{r}) = & \frac{1+2\epsilon_r}{3\epsilon_r} \hat{y} + \frac{1-\epsilon_r}{3\epsilon_r} b^3 \\ & \times \left[\hat{r} \frac{2}{r^3} \sin \theta \sin \phi - \frac{1}{r^3} (\hat{\theta} \cos \theta \sin \phi + \hat{\phi} \cos \phi) \right] \\ \bar{f}_3(\bar{r}) = & \frac{1+2\epsilon_r}{3\epsilon_r} \hat{z} + \frac{1-\epsilon_r}{3\epsilon_r} b^3 \left[\hat{r} \frac{2}{r^3} \cos \phi + \hat{\theta} \frac{1}{r^3} \sin \theta \right] \end{aligned} \quad (24)$$

where $\bar{r} \in V_j$. Letting

$$\begin{aligned} \bar{q}_{j\alpha}(\bar{r}) = & k^2 \int_{V_j} d\bar{r}' g(\bar{r}, \bar{r}') (\epsilon_{vj} - 1) \bar{f}_{j\alpha}(\bar{r}') \\ & - \nabla \int_{V_j} d\bar{r}' \nabla' g(\bar{r}, \bar{r}') (\epsilon_{vj} - 1) \bar{f}_{j\alpha}(\bar{r}') \end{aligned} \quad (25)$$

we can express the integral equation (22) as

$$\begin{aligned} \sum_{\alpha=1}^3 c_{i\alpha} \bar{f}_{i\alpha}(\bar{r}) = & \bar{\mathbf{E}}^{\text{ex}}(\bar{r}) + \sum_{j=1, j \neq i}^N \sum_{\alpha=1}^3 c_{j\alpha} \bar{q}_{j\alpha}(\bar{r}) \\ & + \sum_{\alpha=1}^3 c_{i\alpha} \bar{q}_{i\alpha}(\bar{r}) \end{aligned} \quad (26)$$

We then apply the Galerkin method to rewrite (26) in a linear system of equations for the coefficients

$$\begin{aligned} & \sum_{\alpha=1}^3 c_{i\alpha} \int_{V_i} d\bar{r} \bar{f}_{i\alpha}(\bar{r}) \cdot [\bar{f}_{i\alpha}(\bar{r}) - \bar{q}_{i\alpha}(\bar{r})] \\ = & \int_{V_i} d\bar{r} \bar{f}_{i\beta}(\bar{r}) \cdot \bar{\mathbf{E}}^e(\bar{r}_i) \\ & + \sum_{j=1, j \neq i}^N \sum_{\alpha=1}^3 c_{j\alpha} \int_{V_j} d\bar{r} \bar{f}_{i\beta}(\bar{r}) \cdot \bar{q}_{j\alpha}(\bar{r}) \end{aligned} \quad (27)$$

with $i = 1, 2, \dots, N$ and $\beta = 1, 2, 3$. Taking the small particle assumption into account, we can make approximations of (27):

$$\begin{aligned} & \sum_{\alpha=1}^3 c_{i\alpha} \int_{V_i} d\bar{r} \bar{f}_{i\alpha}(\bar{r}) \cdot [\bar{f}_{i\alpha}(\bar{r}) - \bar{q}_{i\alpha}(\bar{r})] \\ = & \int_{V_i} d\bar{r} \bar{f}_{i\beta}(\bar{r}) \cdot \bar{\mathbf{E}}^e(\bar{r}_i) + \sum_{j=1, j \neq i}^N \sum_{\alpha=1}^3 k^2 (\epsilon_{rj} - 1) c_{j\alpha} \\ & \times \int_{V_i} d\bar{r} \bar{f}_{i\beta}(\bar{r}) \cdot \bar{\mathbf{G}}(\bar{r}_i, \bar{r}_j) \int_{V_j} d\bar{r}' \bar{f}_{j\alpha}(\bar{r}') \end{aligned} \quad (28)$$

After simplifications, (28) can be written as

$$\begin{aligned} c_{i\beta} \bar{K}_i = & \bar{s}_{i\beta} \cdot \bar{\mathbf{E}}^e(\bar{r}_i) + \sum_{j=1, j \neq i}^N \sum_{\alpha=1}^3 k^2 (\epsilon_{rj} - 1) \\ & \times c_{j\alpha} \bar{s}_{i\beta} \cdot \bar{\mathbf{G}}(\bar{r}_i, \bar{r}_j) \cdot \bar{s}_{j\alpha} \end{aligned} \quad (29)$$

where

$$\begin{aligned} \bar{K}_i = & \frac{2\epsilon_{ri} + 1}{3\epsilon_{ri}} \cdot \frac{1}{9\epsilon_{ri}} \cdot \frac{4\pi}{3} (a_i^3 - b_i^3) \\ & \times \frac{(2\epsilon_{ri} + 1)(2 + \epsilon_{ri}) - 2b_i^3(\epsilon_{ri} - 1)^2}{a_i^3} \end{aligned} \quad (30)$$

and

$$\begin{aligned} \bar{s}_{i1} = & \int_{V_i} d\bar{r} \bar{f}_{i1}(\bar{r}) = \frac{2\epsilon_{ri} + 1}{3\epsilon_{ri}} \cdot \frac{4\pi}{3} (a_i^3 - b_i^3) \hat{x} \\ \bar{s}_{i2} = & \int_{V_i} d\bar{r} \bar{f}_{i2}(\bar{r}) = \frac{2\epsilon_{ri} + 1}{3\epsilon_{ri}} \cdot \frac{4\pi}{3} (a_i^3 - b_i^3) \hat{y} \\ \bar{s}_{i3} = & \int_{V_i} d\bar{r} \bar{f}_{i3}(\bar{r}) = \frac{2\epsilon_{ri} + 1}{3\epsilon_{ri}} \cdot \frac{4\pi}{3} (a_i^3 - b_i^3) \hat{z} \end{aligned} \quad (31)$$

After solving the matrix equations, the power absorbed by N coated particles can be calculated by

$$P_{\text{abs}} = \frac{1}{2} \omega \sum_{j=1}^N \int_{V_j} d\bar{r} \epsilon_{vj}'(\bar{r}) |\bar{\mathbf{E}}_j(\bar{r})|^2 \quad (32)$$

and the absorption coefficient is the absorption per unit volume

$$\kappa_{\text{abs}} = \frac{P_{\text{abs}}}{\frac{1}{2\eta} |\bar{\mathbf{E}}^e|^2 V} \quad (33)$$

where η is the free-space wave impedance. The scattered far field can be calculated as following

$$\begin{aligned} \bar{\mathbf{E}}_s(\bar{\mathbf{r}}) = & \frac{k^2 e^{ikr}}{4\pi r} (\hat{v}_s \hat{v}_s + \hat{h}_s \hat{h}_s) \sum_{j=1}^N \int_{V_j} d\bar{\mathbf{r}} \\ & \times (\epsilon_{vj} - 1) \bar{\mathbf{E}}_j(\bar{\mathbf{r}}) e^{-ik\hat{s} \cdot \bar{\mathbf{r}}_j} \end{aligned} \quad (34)$$

Then the scattered power is

$$P_s = \frac{1}{2\eta} \int_0^{2\pi} d\phi_s \int_0^\pi d\theta_s \sin \theta_s (|E_{vs}|^2 + |E_{hs}|^2) \quad (35)$$

where E_{vs} and E_{hs} are vertical and horizontal polarized components of the scattering fields, respectively. The scattering coefficient is scattering cross section per unit volume

$$\kappa_s = \frac{P_s^{\text{inco}}}{\frac{1}{2\eta} |\bar{\mathbf{E}}^{\text{ex}}|^2 V} \quad (36)$$

where P_s^{inco} is the incoherent part of the scattered power.

The coherent wave is obtained by averaging the scattered field over the Monte Carlo realizations [6,11]. To obtain the incoherent power, we have to subtract the coherent intensity. Thus

$$\begin{aligned} P_s^{\text{inco}} = & \frac{1}{2\eta} \int_0^{2\pi} d\phi_s \int_0^\pi d\theta_s \sin \theta_s \{ \langle |E_{vs}|^2 \rangle \\ & - \langle E_{vs} \rangle \langle E_{vs} \rangle^* + \langle |E_{hs}|^2 \rangle \\ & - \langle E_{hs} \rangle \langle E_{hs} \rangle^* \} \end{aligned} \quad (37)$$

where the angular brackets represent averaging over realizations. The extinction coefficient is $\kappa_e = \kappa_s + \kappa_{\text{abs}}$, and the albedo is $\tilde{\omega} = \kappa_s / \kappa_e$. The effective permittivity can be calculated as follows. In the forward direction $\bar{k}_s = \bar{k}_i$, the scattered field in the incident polarization can be written as $E_s = F e^{ikr} / r$. Then the effective propagation constant K is given by

$$K = \text{Re} \left(\sqrt{k^2 + \frac{4\pi F}{V}} \right) + i \left(\frac{\kappa_e}{2} \right) \quad (38)$$

The effective permittivity is expressed as

$$\epsilon_{\text{eff}} = \frac{K^2}{k^2} \quad (39)$$

The effective permittivity of foam will be used in the Fresnel reflection coefficients for the air-foam flat interface and the foam-ocean flat interface in the dense media radiative transfer theory. The calculated scattering and

absorption coefficients are then substituted into dense media radiative transfer equations. A Rayleigh phase matrix is used in the dense media radiative transfer equations [2,7].

3.3. Dense Media Radiative Theory

Consider the thermal emission problem of a foam layer covered wind-roughened ocean surfaces, as indicated in Fig. 8. The foam layer consists of coated dielectric particles in region 1. The DMRT equations for passive remote sensing in region 1 can be written as follows

$$\begin{aligned} \frac{d}{dz} \bar{I}_u(z, \mu, \phi) = & -\kappa_{\text{es}} \bar{I}_u(z, \mu, \phi) \\ & + \kappa_{\text{as}} C \bar{T} + \bar{\mathbf{F}}_u(z, \mu, \phi) \end{aligned} \quad (40)$$

$$-\frac{d}{dz} \bar{I}_d(z, \mu, \phi) = -\kappa_{\text{es}} \bar{I}_d(z, \mu, \phi)$$

$$+ \kappa_{\text{as}} C \bar{T} + \bar{\mathbf{F}}_d(z, \mu, \phi)$$

$$\begin{aligned} \bar{\mathbf{F}}_u(z, \mu, \phi) = & \frac{\kappa_{\text{ss}}}{4\pi} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \\ & \times [\bar{\mathbf{P}}(\mu, \phi; \mu', \phi') \bar{I}_u(z, \mu', \phi') \\ & + \bar{\mathbf{P}}(\mu, \phi; -\mu', \phi') \bar{I}_d(z, \mu', \phi')] \end{aligned} \quad (41)$$

$$\begin{aligned} \bar{\mathbf{F}}_d(z, \mu, \phi) = & \frac{\kappa_{\text{ss}}}{4\pi} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \\ & \times [\bar{\mathbf{P}}(-\mu, \phi; \mu', \phi') \bar{I}_u(z, \mu', \phi') \\ & + \bar{\mathbf{P}}(-\mu, \phi; -\mu', \phi') \bar{I}_d(z, \mu', \phi')] \end{aligned}$$

where $\bar{I}_u(z, \mu, \phi)$ and $\bar{I}_d(z, \mu, \phi)$ represent, respectively, upward- and downward-going specific intensities and 4×4 matrices containing the four Stokes parameters; $\mu = \cos \theta$, $\mu' = \cos \theta'$, $\kappa_{\text{es}} = \kappa_e / \cos \theta$, $\kappa_{\text{ss}} = \kappa_s / \cos \theta$; κ_a and κ_s are the absorption and scattering coefficient matrices taken to be diagonal respectively; $C = K_b K'^2 / (\lambda^2 k^2)$, where K_b is the Boltzmann's constant [2,5]; $\bar{\mathbf{P}}(\mu, \phi; \mu', \phi')$ is the Rayleigh scattering phase matrix; and \bar{T} is the temperature profile in the layer. The boundary condition at $z = 0$ is

$$\bar{I}_d(z = 0, \theta, \phi) = \bar{\mathbf{R}}(\theta) \bar{I}_u(z = 0, \theta, \phi) \quad (42)$$

where $\bar{\mathbf{R}}(\theta)$ is a reflection matrix of the flat surface at the air-foam interface

$$\begin{aligned} & \bar{\mathbf{R}}(\theta) \\ = & \begin{bmatrix} |R_v(\theta)|^2 & 0 & 0 & 0 \\ 0 & |R_h(\theta)|^2 & 0 & 0 \\ 0 & 0 & \text{Re}(R_v(\theta) R_h^*(\theta)) & -\text{Im}(R_v(\theta) R_h^*(\theta)) \\ 0 & 0 & \text{Im}(R_v(\theta) R_h^*(\theta)) & \text{Re}(R_v(\theta) R_h^*(\theta)) \end{bmatrix} \end{aligned} \quad (43)$$

in which R_v and R_h are the Fresnel reflectivities with effective propagation constant K and effective relative permittivity ϵ_{eff} for dense media.

The rough surface boundary condition at $z = -d$ is bistatic and is determined by the second-order SPM

$$\begin{aligned} \bar{\mathbf{I}}_u(z = -d, \mu, \phi) &= \bar{\bar{\mathbf{G}}}_c(\theta, \phi) \bar{\mathbf{I}}_d(z = -d, \mu, \phi) \\ &+ \frac{K^2}{\mu} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \mu'^2 W(\bar{\mathbf{k}}_\perp - \bar{\mathbf{k}}'_\perp) \\ &\times \bar{\bar{\mathbf{G}}}_{\text{ic}}(\mu, \phi; -\mu', \phi') \bar{\mathbf{I}}_d(z = -d, \mu', \phi') + \bar{e}CT_g \end{aligned} \quad (44)$$

where $\bar{\bar{\mathbf{G}}}_c$ and $\bar{\bar{\mathbf{G}}}_{\text{ic}}$ respectively are the coherent and incoherent scattering phase matrixes of the rough surface at $z = -d$.

$$\bar{\bar{\mathbf{G}}}_{\text{c,ic}} = \begin{bmatrix} \langle |f_{vv}|^2 \rangle & \langle |f_{vh}|^2 \rangle & \text{Re}(f_{vv}f_{vh}^*) & -\text{Im}(f_{vv}f_{vh}^*) \\ \langle |f_{hv}|^2 \rangle & \langle |f_{hh}|^2 \rangle & \text{Re}(f_{hv}f_{hh}^*) & -\text{Im}(f_{hv}f_{hh}^*) \\ 2\text{Re}(f_{vv}f_{vh}^*) & 2\text{Re}(f_{vh}f_{hh}^*) & \text{Re}(f_{vv}f_{hh}^* + f_{vh}f_{hv}^*) & \text{Im}(f_{vh}f_{hh}^* - f_{vv}f_{hh}^*) \\ 2\text{Im}(f_{vv}f_{vh}^*) & 2\text{Im}(f_{vh}f_{hh}^*) & \text{Im}(f_{vv}f_{hh}^* + f_{vh}f_{hv}^*) & \text{Re}(f_{vv}f_{hh}^* - f_{vh}f_{hv}^*) \end{bmatrix} \quad (45)$$

For $\bar{\bar{\mathbf{G}}}_c$, $f_{\alpha\alpha} = f_{\alpha\alpha}^{(0)} + f_{\alpha\alpha}^{(2)}$, $f_{\alpha\beta} = f_{\alpha\beta}^{(2)}$, and for $\bar{\bar{\mathbf{G}}}_{\text{ic}}$, $f_{\alpha\beta} = f_{\alpha\beta}^{(1)}$. Here, symbols α and β represent vertical and horizontal. $f_{vv}^{(0)}$ and $f_{hh}^{(0)}$ are Fresnel reflection coefficients for vertical and horizontal polarizations with the zeroth-order fields considered. $f_{\alpha\beta}^{(1)}$ and $f_{\alpha\beta}^{(2)}$ are scattering coefficients of the α -polarized component of the first- and second-order scattered fields with β -polarized incident field, respectively, which are given in Ref. 7. The zeroth- and second-order fields give the coherent reflection coefficients of the surfaces. $f_{\alpha\beta}^{(1)}$ gives the incoherent polarimetric bistatic scattering coefficient due to the first-order scattered field. They are derived using the second-order small-perturbation method (SPM) [2, 7]. T_g is the temperature of the half-space below the foam and \bar{e} are the emissivities of the lower boundary. The differential equations in (40) have standard solutions of the form

$$\begin{aligned} \bar{\mathbf{I}}_u(z) &= \bar{\mathbf{I}}_u(-d)e^{-\kappa_{\text{es}}(z+d)} + \int_{-d}^z dz' [\bar{\mathbf{F}}_u(z') \\ &+ \kappa_{\text{as}}C\bar{\mathbf{T}}]e^{-\kappa_{\text{es}}(z-z')} \end{aligned} \quad (46)$$

$$\begin{aligned} \bar{\mathbf{I}}_d(z) &= \bar{\mathbf{I}}_d(0)e^{\kappa_{\text{es}}z} + \int_z^0 dz' [\bar{\mathbf{F}}_d(z') \\ &+ \kappa_{\text{as}}C\bar{\mathbf{T}}]e^{\kappa_{\text{es}}(z-z')} \end{aligned} \quad (47)$$

Next, we incorporate the rough surface boundary conditions into a form suitable for iterative solutions. Substituting the boundary conditions into (46) and (47), we

have

$$\begin{aligned} \bar{\mathbf{I}}_u(z) &= e^{-\kappa_{\text{es}}(z+d)} \bar{\bar{\mathbf{G}}}_c(\mu, \phi) \bar{\mathbf{I}}_d(z = -d, \mu, \phi) \\ &+ e^{-\kappa_{\text{es}}(z+d)} \frac{K^2}{\mu} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \mu'^2 W(\bar{\mathbf{k}}_\perp - \bar{\mathbf{k}}'_\perp) \\ &\times \bar{\bar{\mathbf{G}}}_{\text{ic}}(\mu, \phi; -\mu', \phi') \bar{\mathbf{I}}_d(z = -d, \mu', \phi') \\ &+ \bar{e}CT_g e^{-\kappa_{\text{es}}(z+d)} + \int_{-d}^z dz' [\bar{\mathbf{F}}_u(z') + \kappa_{\text{as}}C\bar{\mathbf{T}}] e^{-\kappa_{\text{es}}(z-z')} \end{aligned} \quad (48)$$

$$\begin{aligned} \bar{\mathbf{I}}_d(z) &= \bar{\bar{\mathbf{R}}}(\theta) \bar{\mathbf{I}}_u(z = 0, \theta, \phi) e^{\kappa_{\text{es}}z} + \int_z^0 dz' \\ &\times [\bar{\mathbf{F}}_d(z') + \kappa_{\text{as}}C\bar{\mathbf{T}}] e^{\kappa_{\text{es}}(z-z')} \end{aligned} \quad (49)$$

The source terms in (48) are the upward temperature originating from the layer temperature profile. We assume a temperature profile $T = T_g$

$$\int_{-d}^z dz' \kappa_{\text{as}}CTe^{-\kappa_{\text{es}}(z-z')} = C \frac{\kappa_a}{\kappa_e} T_g [1 - e^{-\kappa_{\text{es}}(z+d)}] \quad (50)$$

The contribution from the lower half-space is $\bar{e}CT_g \exp[-\kappa_{\text{es}}(z+d)]$. The source term in (49) is the downward temperature:

$$\int_z^0 dz' \kappa_{\text{as}}CTe^{\kappa_{\text{es}}(z-z')} = C \frac{\kappa_a}{\kappa_e} T_g [1 - e^{\kappa_{\text{es}}z}] \quad (51)$$

All other terms in (48) that depend on the upward and downward temperatures can be evaluated using these three source terms. Using (41), (50), and (51), and after taking integration over z , we have

$$\begin{aligned} \bar{\mathbf{V}}(z=0) &= \int_{-d}^0 dz' \bar{\mathbf{F}}_u(z') e^{\kappa_{\text{es}}z'} \\ &\approx \frac{1}{4\pi} \frac{\kappa_s \kappa_a}{\kappa_e \kappa_e} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \bar{\bar{\mathbf{P}}}(\mu, \phi; \mu', \phi') \\ &\times \left[c_0 \bar{\mathbf{T}} + \left(\bar{e}CT_g \frac{\kappa_e}{\kappa_a} - \bar{\mathbf{T}} \right) c_1 e^{-\kappa_e d / \mu'} \right] \\ &+ \frac{1}{4\pi} \frac{\kappa_s \kappa_a}{\kappa_e \kappa_e} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \bar{\bar{\mathbf{P}}}(\mu, \phi; \\ &- \mu', \phi') c_0 \bar{\mathbf{T}} + \bar{\mathbf{T}}(c_0 - c_2) \end{aligned} \quad (52)$$

where $c_0 = 1 - \exp(-\kappa_{\text{es}}d)$, $c_1 = \{1 - \exp[-\kappa_{\text{es}}d(1 - \mu/\mu')]\} / (1 - \mu/\mu')$, and $c_2 = \{1 - \exp[-\kappa_{\text{es}}d(1 + \mu/\mu')]\} / (1 + \mu/\mu')$. Another term in (48) accounting for upward scattering of

the downward temperature by the lower boundary at $z = -d$ can be evaluated using the source term given by (51) as

$$\begin{aligned}
 \overline{SG}(z=0) &= \overline{G}_c(\mu, \phi) \bar{I}_d(z = -d, \theta, \phi) e^{-\kappa_{es}d} \\
 &+ \frac{K'^2}{\mu} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \mu'^2 W(\bar{\mathbf{k}}_{\perp} - \bar{\mathbf{k}}'_{\perp}) \overline{G}_{ic}(\mu, \phi; \\
 &- \mu', \phi') \bar{I}_d(z = -d, \mu', \phi') e^{-\kappa_{es}d} \\
 &\approx C \frac{\kappa_a}{\kappa_e} \overline{G}_c(\mu, \phi) \bar{T}(1 - e^{-\kappa_{es}d}) e^{-\kappa_{es}d} \\
 &+ C \frac{\kappa_a}{\kappa_e} \frac{K'^2}{\mu} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \mu'^2 W(\bar{\mathbf{k}}_{\perp} - \bar{\mathbf{k}}'_{\perp}) \\
 &\times \overline{G}_{ic}(\mu, \phi; -\mu', \phi') \bar{T}(1 - e^{-\kappa_{es}d/\mu'}) e^{-\kappa_{es}d}
 \end{aligned} \tag{53}$$

Thus the complete expression for the upward temperature at $z=0$ within the layer is

$$\begin{aligned}
 \bar{I}_u^{(1)}(z=0) &= C \frac{\kappa_a}{\kappa_e} \bar{T}(1 - e^{-\kappa_{es}d}) + \bar{e}CT_g e^{-\kappa_{es}d} \\
 &+ \bar{V}(z=0) + \overline{SG}(z=0)
 \end{aligned} \tag{54}$$

This is the first-order solution of \bar{I}_u . The second order solution for the upward temperature at $z=0$ is

$$\begin{aligned}
 \bar{I}_u^{(2)}(z=0) &= C \frac{\kappa_a}{\kappa_e} \bar{T}(1 - e^{-\kappa_{es}d}) + \bar{e}CT_g e^{-\kappa_{es}d} \\
 &+ \bar{V}(z=0) + \overline{SG}^{(2)}(z=0)
 \end{aligned} \tag{55}$$

where

$$\begin{aligned}
 \overline{SG}^{(2)}(z=0) &= \overline{G}_c(\mu, \phi) \bar{I}_d(z = -d, \theta, \phi) e^{-\kappa_{es}d} \\
 &+ \frac{K'^2}{\mu} \int_0^1 d\mu' \int_0^{2\pi} d\phi' \mu'^2 W(\bar{\mathbf{k}}_{\perp} - \bar{\mathbf{k}}'_{\perp}) \\
 &\times \overline{G}_{ic}(\mu, \phi; -\mu', \phi') \bar{I}_d(z = -d, \mu', \phi') e^{-\kappa_{es}d}
 \end{aligned} \tag{56}$$

The brightness temperatures \bar{T}_B in the direction (θ_0, ϕ_0) , where $\theta_0 = \sin^{-1}(K' \sin \theta/k)$ as related to θ by Snell's law,

are given by

$$\bar{T}_B(\theta_0, \phi_0) = \overline{\bar{T}}(\theta) \bar{I}(z=0, \theta, \phi) \tag{57}$$

$\overline{\bar{T}}(\theta) =$

$$\begin{bmatrix}
 1 - |R_v(\theta)|^2 & 0 & 0 & 0 \\
 0 & 1 - |R_h(\theta)|^2 & 0 & 0 \\
 0 & 0 & \frac{\cos \theta_0}{\cos \theta} \text{Re}(T_v(\theta)T_h^*(\theta)) - \frac{\cos \theta_0}{\cos \theta} \text{Im}(T_v(\theta)T_h^*(\theta)) \\
 0 & 0 & \frac{\cos \theta_0}{\cos \theta} \text{Im}(T_v(\theta)T_h^*(\theta)) & \frac{\cos \theta_0}{\cos \theta} \text{Re}(T_v(\theta)T_h^*(\theta))
 \end{bmatrix} \tag{58}$$

where $T_v(\theta) = 1 + R_v(\theta)$, and $T_h(\theta) = 1 + R_h(\theta)$.

3.4. Numerical Simulations of Emissivities for Foam-Covered Flat Ocean Surfaces

In this section, we illustrate the numerical results of the emissivity, based on a model of coated particles in a FCC structure, for a foam-covered flat ocean surface and compare with these results some experimental measurements. The absorption rate, scattering rate, and effective permittivity are first calculated using the Monte Carlo simulation. Subsequently, these quantities are used to compute the emissivity. The foam parameters are summarized as follows: a_j and b_j , the respective outer and inner radii of air bubble j ; N , number of air bubbles; V , total sample volume in the Monte Carlo simulations; f_w , the volume fraction of seawater in foam; ϵ_w , the permittivity of seawater; and θ , the observation angle. Note that the permittivity of seawater ϵ_w is a function of frequency and other physical parameters, such as the temperature and salinity. In the following simulations, the permittivities of seawater at 10.8 and 36.5 GHz are $49.149 + i40.105$ and $13.448 + i24.784$, respectively [60]. The experimental measurements are conducted at the Chesapeake Bay Detachment at 10.8 and 36.5 GHz. The diameter of air bubble ranges from 500 to 5000 μm with median between 900 and 1000 μm [57].

In the Monte Carlo simulations, different realizations of the sample of spheres are obtained by rotations of the sample volume. From the results of the different realizations, the coherent fields and the incoherent fields are calculated. The parameters used for Monte Carlo simulations are summarized in Table 4. The total number of coated air bubbles, which are arranged in a face-centered-cubic structure, is $N = N' + N'' = 500$, where two species of coated air bubbles are used. They have the same outer radii but have different inner radii, b' and b'' . We choose N' bubbles randomly of inner radii b' , and the rest have inner radii of b'' . Seven realizations are generated by rotations of the sample. The respective absorption rate, scattering rate, extinction rate, albedo, and effective permittivity calculated from Monte Carlo simulations are given in Tables 5–7. Figures 9 and 10 plot the microwave emissivity dependence on the observation angle at 10.8 and

Table 4. Parameters for Monte Carlo Simulations Shown in Figs. 9–13

	a (mm)	b' (mm)	N'	b'' (mm)	N''	V (mm ³)	f_w (%)

Figure 12	0.5	0.2271	75	0.49885	425	353.6	10.5
Figure 13	0.25	0.1285	75	0.24945	425	44.19	10.5

36.5 GHz for vertical and horizontal polarizations, respectively. The foam parameters are listed in Table 4. As the size of the bubbles increases, the scattering coefficient increases, and the albedo also increases. The increase in albedo causes the corresponding brightness temperatures to decrease.

The microwave emissivities, at 10.8 and 36.5 GHz and for vertical and horizontal polarizations, as a function of the thickness of foam layer with different sizes of coated air bubbles are plotted in Figs. 11–13. In actual foam, the air bubbles have a size distribution with mean diameter about 1 mm. However, scattering increases with particle sizes and the effective scattering mean size can be substantially larger than the mean size. In our simulations, we use single size particles. Three radii of air bubbles, 1.0, 0.5, and 0.25 mm, are used and represent the effective scattering mean. In actual foam, the coating thicknesses vary and also vary as a function of depth. For convenience, we have used two coating thicknesses. The observation angle is $\theta = 53^\circ$. From these figures, we can see that as the foam layer thickness increases, the emissivity increases correspondingly and then saturates at a particular thickness of the foam layer, for both horizontal and vertical polarizations. The saturation point of horizontal polarization is slightly larger than that of vertical polarization. For layer thickness larger than the saturation thickness, the *difference* of emissivity between the two frequencies increases as the size of coated air bubbles increases.

In Figs. 14 and 15, the simulation results of microwave emissivities are compared with the experimental data as a function of observation angle. An average foam layer thickness 2.8 cm is used. The parameters used for Monte Carlo simulation are the same as those used in Figs. 9–11, with a coated air bubble radius of 1.0 mm. In the experiment, the emissivities of horizontal and vertical polarizations are measured, at 10.8 and 36.5 GHz, for a foam layer with a mean thickness of 2.8 cm. To facilitate the comparisons, we list in Table 8, the experimental data, the DMRT model results, and the air–ocean half-space results for the emissivities at 10.8 and 36.5 GHz. From Figs. 14 and 15, we see that Monte Carlo simulations produce results in

reasonably good agreement with experimental measurements. Both simulations and experiments indicate that absorption at 10.8 GHz is appreciable. In addition, the simulations show that emissivities at 10.8 and 36.5 GHz are comparable. The absorption coefficient at 36.5 GHz is larger than that at 10.8 GHz. However, scattering has a significant effect at 36.5 GHz. The results are in good agreement at small angles of incidence. At large incidence angles, the difference increases. We are presently studying the refinement of the model by investigating realistic foam generation algorithms that can improve the model.

3.5. Comparison with Quasicrystalline Approximation

In this section, we compare the Monte Carlo results with those based on QCA, in which wave scattering and emission in a medium consisting of densely packed coated particles are solved by using QCA in combination with the DMRT theory [10]. It is assumed that there are two species of air bubbles that have the same outer radius a , but have different coating thickness with inner radii of b_1 and b_2 . The parameters of the foam model are given in Table 9. Emissivities of horizontal and vertical polarizations are simulated at 10.8 and 36.5 GHz.

The quantities for foam layer calculated by QCA and by Monte Carlo simulations are shown in Tables 10 and 11, respectively. Figure 16 is based on Monte Carlo simulations. We can see that the emissivities at 10.8 and 36.5 GHz are comparable. This feature is consistent with experimental measurements [57]. On the other hand, as shown in Fig. 17, which is based on QCA, the emissivities at 36.5 GHz are higher than at 10.8 GHz. For dense media consisting of particles densely packed, there are two different cases. They are differentiated by a large loss tangent and small loss tangent where the loss tangent is $\sigma/(\omega\epsilon)$ and σ is the conductivity of the medium. A large loss tangent represents the case where the conductive current is much larger than the displacement current, while the reverse is true for the small loss tangent case. It has been shown by extensive simulations [27] that QCA is valid for the small loss tangent case. The QCA theory has been

successful in dry snow [7,26]. However, the QCA theory is less successful when conductive current dominates [59]. The conductive current can go through several connected particles. On the other hand, QCA is limited to pair distribution functions. Thus the applicability of QCA is also dependent on frequency through the dependence on $\sigma/(\omega\epsilon)$. We can see that the results of QCA are in better agreement with those of Monte Carlo simulations at high frequency of 36.5 GHz, and less successful at low frequency of 10.8 GHz. However, the experiment reported in Refs. 11 and 57 was at 19.0 GHz and QCA was reasonably successful. Since Monte Carlo simulations provide the exact solution of Maxwell equations, this model will be applied to calculate the four Stokes parameters in the next section.

Four Stokes parameters of brightness temperature for foam-covered rough ocean surface are theoretically analyzed. Important features are shown by the results at 10.8, 19.0, and 36.5 GHz for the four Stokes parameters. It is important to determine, with respect to these Stokes parameters, how the foam affects brightness temperatures and retrieval of the ocean surface wind vector. The first two Stokes parameters are increased with the presence of foam, and the third and fourth parameters are reduced. The azimuthal variations of polarimetric brightness temperature are also illustrated. The first two Stokes parameters are even functions of ϕ ; the last two parameters are odd functions. Emissions with various windspeeds and foam layer thickness are also studied. The four Stokes

parameters of brightness temperature are dependent on windspeeds and foam thickness.

4. TREE SCATTERING MODEL AT UHF/VHF USING SPARSE MATRIX ITERATIVE APPROACH

Electromagnetic wave interaction with plants plays an important role in microwave remote sensing applications. Various scattering models have been developed to study wave propagation and scattering in vegetation canopy [1–7]. In the past, vector radiative transfer theory was used extensively to compute the backscattering coefficients of forests for comparison with microwave backscatter measurements [1–4]. While the radiative transfer approach can handle complicated geophysical structures, it ignores coherent wave interactions within the tree structure. A coherent addition approximation (CAA) scattering model has been applied to take into account the effects of coherent scattering and branching structure

Figure 11. Emissivity as a function of the thickness of the foam layer at observation angle 53° . The radius of the coated air bubble is 1.0 mm. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

[6,61]. The volume and surface integral equation formulations with the method of moments computational models have also been employed to investigate tree scattering [6,62–64]. Monte Carlo simulations and tree geometric models based on Lindenmayer systems [65] have also been applied to take into account the random nature of trees [6,16,63]. Foliage attenuation has driven the application of radar frequency down to the VHF/UHF region. At these low frequencies, it is useful to have a clear understanding of the coherent interaction effects of tree branches and trunk of a single tree or a small group of trees. In this section we describe a computationally efficient model for computing tree scattering at VHF/UHF frequencies. At these low frequencies, the effects of scattering by tree leaves can be neglected. A structure model with dielectric cylinders is employed to simulate trees with bare branches. The method of moments is used to calculate tree scattering signatures by discretizing the volume integral equation and transforming it into a matrix equation [6]. An efficient numerical algorithm based on the

sparse matrix iterative approach (SMIA) [13–16] is used to solve the matrix equation. In the SMIA method, the impedance matrix of the resultant matrix equation is decomposed into a sparse matrix for the near interactions and a complementary matrix, for the far interactions among the cylindrical subcells of the tree structures. Using a direct sparse solver to estimate the strong interaction part, we iteratively included the weak interaction contribution to update the solution. The key feature of this approach is that very little iteration is required to obtain convergent solutions. The SMIA technique has been applied in combination with the canonical grid method to solve rough surface scattering [6,13] and analyze microstrip interconnects [14,15]. Section 4.1 gives the volume integral equation formulation and the MoM treatment for the tree scattering problem, and describes the SMIA method. In Section 4.2, some numerical results are illustrated for scattering from simulated trees and demonstrate that the SMIA method can significantly reduce the number of iterations when compared to the conventional conjugate gradient method (CGM).

4.1. Formulation and Sparse Matrix Iterative Approach

The discrete-dipole approximation (DDA) has been applied to calculate electromagnetic scattering and absorption by trees [6,16,63]. At VHF/UHF frequencies, the tree trunks and branches can be modeled as thin dielectric circular cylinders. In the discretization process, each tree branch is divided into cylindrically shaped subcells with the same radius. The volume integral equation for the electric field is given by

$$\bar{\mathbf{E}}(\bar{\mathbf{r}}) = \bar{\mathbf{E}}^{\text{inc}}(\bar{\mathbf{r}}) + \frac{k_0^2}{\varepsilon_0} \int_V \bar{\mathbf{G}}_0(\bar{\mathbf{r}}, \bar{\mathbf{r}}') \cdot [\varepsilon_p(\bar{\mathbf{r}}') - \varepsilon_0] \bar{\mathbf{E}}(\bar{\mathbf{r}}') d\bar{\mathbf{r}}' \quad (59)$$

where $\bar{\mathbf{E}}^{\text{inc}}(\bar{\mathbf{r}})$ is the incident field, $\varepsilon_p(\bar{\mathbf{r}})$ is the permittivity distribution within region V and k_0 , ε_0 , and $\bar{\mathbf{G}}_0(\bar{\mathbf{r}}, \bar{\mathbf{r}}')$ are the wavenumber, permittivity, and free-space dyadic Green function, respectively. If we subdivide the volume into small elemental volumes ΔV_i , each centered at $\bar{\mathbf{r}}_i$, $i = 1, 2, \dots, N$, the discretized version of (59) becomes

$$\bar{\mathbf{p}}_i = \bar{\alpha}_i \cdot \bar{\mathbf{E}}_i^{\text{inc}} - \bar{\alpha}_i \cdot \frac{k_0^2}{\varepsilon_0} \sum_{j=1, j \neq i}^N \frac{\int_{\Delta V_j} d\bar{\mathbf{r}}' \bar{\mathbf{G}}_0(\bar{\mathbf{r}}_i, \bar{\mathbf{r}}')}{\Delta V_j} \cdot \bar{\mathbf{p}}_j \quad (60)$$

where $\bar{\mathbf{E}}_i^{\text{inc}}$, $\bar{\mathbf{p}}_i = \Delta V_i (\varepsilon_{pi} - \varepsilon_0) \bar{\mathbf{E}}_i$, and $\bar{\mathbf{E}}_i$ are the respective vectors of the incident field, dipole moment, and electric field at the center $\bar{\mathbf{r}}_i$ of the i th elemental volume ΔV_i . The summation over j runs over all the subcells ($j \neq i$) that form the tree structure. ε_{pi} is the permittivity of the i th elemental volume, which is assumed to be constant within ΔV_i . In (60), the dyad $\bar{\alpha}_i = \hat{\mathbf{x}}\hat{\mathbf{x}}\alpha_{ix} + \hat{\mathbf{y}}\hat{\mathbf{y}}\alpha_{iy} + \hat{\mathbf{z}}\hat{\mathbf{z}}\alpha_{iz}$ is a diagonal matrix whose elements, for a vertical circular cylindrical cell of radius

a_i and length ℓ_i , are given by [6]

$$\begin{aligned} \alpha_{ix} &= \Delta V_i (\varepsilon_{pi} - \varepsilon_0) \frac{1}{1 + \left(\frac{\varepsilon_{pi}}{\varepsilon_0} - 1\right) (L_{ix} - k_0^2 D_{ix})} \\ \alpha_{iy} &= \Delta V_i (\varepsilon_{pi} - \varepsilon_0) \frac{1}{1 + \left(\frac{\varepsilon_{pi}}{\varepsilon_0} - 1\right) (L_{iy} - k_0^2 D_{iy})} \\ \alpha_{iz} &= \Delta V_i (\varepsilon_{pi} - \varepsilon_0) \frac{1}{1 + \left(\frac{\varepsilon_{pi}}{\varepsilon_0} - 1\right) (L_{iz} - k_0^2 D_{iz})} \end{aligned} \quad (61)$$

where

$$\begin{aligned} L_{ix} &= L_{iy} = \frac{\ell_i}{2\sqrt{\ell_i^2 + 4a_i^2}} \\ L_{iz} &= 1 - \frac{\ell_i}{2\sqrt{\ell_i^2 + 4a_i^2}} \end{aligned} \quad (62)$$

and

$$\begin{aligned} D_{ix} &= D_{iy} = \frac{a_i^2}{8} \ln \frac{\sqrt{\ell_i^2 + 4a_i^2} + \ell_i}{\sqrt{\ell_i^2 + 4a_i^2} - \ell_i} + \frac{\ell_i}{8} \\ &\quad \times \left(\sqrt{\ell_i^2 + 4a_i^2} - \ell_i \right) + i \frac{k_0 a_i^2 \ell_i}{6} \\ D_{iz} &= \frac{a_i^2}{4} \ln \frac{\sqrt{\ell_i^2 + 4a_i^2} + \ell_i}{\sqrt{\ell_i^2 + 4a_i^2} - \ell_i} + i \frac{k_0 a_i^2 \ell_i}{6} \end{aligned} \quad (63)$$

Table 9. Parameters of Foam Model for Simulation Results in Figs. 16 and 17

d	$2a$	$2b_1$	$2b_2$	f	f_w	f_1	f_2
3 cm	2000 μm	1220 μm	1995.9 μm	74%	10.3%	12.9%	61.1%

Table 10. Quantities of Foam Based on QCA from Fig. 18

Parameter	At 10.8 GHz	At 36.5 GHz
Absorption rate κ_{abs} (cm^{-1})	0.1763	0.9042
Scattering rate κ_{s} (cm^{-1})	0.0567	0.01553
Extinction rate κ_{e} (cm^{-1})	0.2330	0.9197
Albedo	0.2435	0.01689
Effective permittivity ϵ_{eff}	$1.4573 + i0.1245$	$1.356 + i0.140$

As can be seen from (59), we need to consider only those volumes that have $\epsilon_{\text{pi}} \neq \epsilon_0$. The matrix equation (60) is of dimension $3N \times 3N$, where N is the total number of small cylindrical cells. The factor 3 arises from the Cartesian components of the polarization vector.

Equation (60) is the DDA matrix equation, which can be expressed as

$$\bar{\bar{Z}} \cdot \bar{X} = \bar{C} \quad (64)$$

where the vector \bar{C} corresponds to the known incident field and \bar{X} is the unknown polarization vector to be solved numerically. In general, the impedance matrix $\bar{\bar{Z}}$ resulting from the discretization of the volume integral equation is large, dense, and complex. Its elements are proportional to the integrals of the Green dyad as shown in (60). Usually an iterative solver, such as conjugate gradient method (CGM), is coupled with some kind of preconditioning strategy to improve the spectral properties of the impedance matrix $\bar{\bar{Z}}$ such that the matrix equation (64) can be solved much more rapidly [66]. Several preconditioners, such as blockdiagonal [67], sparse approximate inverse (SPAI) [68], and incomplete LU (ILU) factorization [69], have been considered in the electromagnetic wave scattering problem.

The sparse matrix iterative approach (SMIA) technique [6,13–16] has been applied to solve the matrix equation (64). Equation (64) is solved iteratively by decomposing the impedance matrix $\bar{\bar{Z}}$ into two parts

$$\bar{\bar{Z}} = \bar{\bar{Z}}^{(s)} + \bar{\bar{Z}}^{(w)} \quad (65)$$

where $\bar{\bar{Z}}^{(s)}$, which is a sparse matrix, includes the near or strong interactions among the close-by cylindrical sub-cells, and $\bar{\bar{Z}}^{(w)}$, which is a complementary matrix accounting for the far or weak interactions, contains the remaining elements of the impedance matrix $\bar{\bar{Z}}$.

Table 11. Quantities of Foam Based on Monte Carlo Simulations from Fig. 16

Figure 16. Emissivities as a function of observation angle for vertical and horizontal polarizations at 10.8 and 36.5 GHz, using the model based on Monte Carlo simulations.

The numerical procedure uses a sparse solver to estimate the first-order solution $\bar{X}^{(1)}$

$$\bar{\bar{Z}}^{(s)} \cdot \bar{X}^{(1)} = \bar{C} \quad (66)$$

and iteratively includes the weak interaction contribution to update the higher-order solution $\bar{X}^{(n+1)}$:

$$\bar{\bar{Z}}^{(s)} \cdot \bar{X}^{(n+1)} = \bar{C} - \bar{\bar{Z}}^{(w)} \cdot \bar{X}^{(n)} \quad (67)$$

The iterations are carried out until the error norm criterion

$$\frac{\|\bar{\bar{Z}} \cdot \bar{X}^{(n)} - \bar{C}\|}{\|\bar{C}\|} \leq \delta \quad (68)$$

is satisfied. δ has been set equal to 1×10^{-4} for the numerical computations presented in Section 4.2.

Figure 17. Emissivities as a function of observation angle for vertical and horizontal polarizations at 10.8 and 36.5 GHz, using the model based on QCA.

4.2. Numerical Results

As shown in Fig. 18, six trees are generated on the basis of the Lindenmayer systems [6,65]. The tree characteristics are given in Table 12. We can see that the tree height varies from 2.67 to 5.65 m, and the total number of branches, including the trunk, can be as much as several hundreds. The total number of discretized cylindrical subcells N and the total number of unknown polarizations $3N$ are also given. The total number of unknowns ranges from several hundreds for a simpler tree to several thousands for a more complicated tree. We can see that the number of unknowns is much smaller when compared to using a surface integral equation approach for calculating the tree scattering [64]. In addition, Table 12 includes the expansions of the trees in the x and y directions, the variations of the radii and lengths of branches for each tree, and the woody volume of each tree.

A number of numerical examples for the polarimetric bistatic scattering from the simulated trees are presented in the following. The permittivities used are $\epsilon_p = 9.62 + i4.332$ and $\epsilon_p = 33.357 + i21.408$, which are calculated from the formula developed by Ulaby et al. [3]. The two permittivities are for gravimetric moisture contents of $M_g = 26\%$ and $M_g = 68\%$ at 300 MHz, respectively. The radiowavelength is $\lambda = 1$ m, and the incidence angle is $\theta_i = 45^\circ$. The bistatic scattering cross sections of trees 5 and 6 for $\epsilon_p = 9.62 + i4.332$ are shown in Figs. 19 and 20, respectively. We also use the solutions for an exact full matrix inversion (INV) and the conjugate gradient method (CGM) as baselines to illustrate the accuracy of the SMIA approach. We can see that solutions of the SMIA method agree very well with the solutions of exact matrix inversion and CGM.

Figure 21 shows the number of iterations required to achieve convergence, and compares the convergence rates for solving the scattering from trees 5 and 6 using the CGM and SMIA techniques. Note that CGM requires thousands of iterations for the percentage error to reduce to $10^{-2}\%$ while the SMIA requires only about 10 iterations. In Table 13 we present a comparison of the condition number of the impedance matrix \bar{Z} , the number of iterations for horizontal and vertical-polarization incidence, matrix filling, solving, and total computation time for the scattering solutions of six trees. The computational time is based on a Dell Latitude C800 with a 512 M RAM memory and 848 MHz microprocessor. It is noted that, because of their large condition numbers, trees 3 and 4 require a large number of iterations to converge by using the conventional CGM, while the SMIA method takes only a few iterations to reach a convergent solution. It is clear from Table 13 that, compared to the CGM, the SMIA technique reduces the number of iterations by a factor of >100 and provides a much faster numerical solution scheme for computing tree scattering while keeping the sufficient accuracy.

In Figs. 22 and 23 we plot the respective bistatic scattering cross sections of trees 5 and 6 for a larger tree permittivity $\epsilon_p = 33.357 + i21.408$. These plots show that solutions based on the SMIA method agree very well with the exact matrix inversion for this high-dielectric-constant case. As shown in Table 14, because of the large matrix condition numbers in this high-dielectric-contrast case, scattering results for the CGM are not computed. Compared to Table 13, the SMIA method requires more iteration to converge for scattering from trees with larger permittivities. However, SMIA is still more efficient than the full matrix inversion in matrix solving.

We have illustrated the use of SMIA numerical tree scattering model to calculate scattering from simulated trees with up to several hundred branches. We use the solutions of an exact full matrix inversion and the conjugate gradient method (CGM) as baselines to illustrate the accuracy and efficiency of the SMIA algorithm. Solutions based on the SMIA method agree very well with the exact matrix inversion and the CGM. Compared to the CGM, the SMIA approach can significantly reduce the number of iterations and provides a much faster numerical scheme for computing tree scattering.

5. WAVE SCATTERING BY DISCRETE SCATTERERS USING UV MULTILEVEL PARTITION METHOD

With the advent of modern computers and the development of fast numerical methods, Monte Carlo simulations

of volume scattering problems have become an attractive approach. A common method that has been used in numerical simulations is the volume integral equation method and its solution by the method of moments (MoM). Conventional implementation of the MoM requires $O(N^3)$ operations and $O(N^2)$ computer memory storage. Several fast numerical methods have been used, such as the sparse matrix canonical grid (SMCG) method [6,70–72] and the fast multipole method (FMM) [73,74], and a characteristic basis function has been used to solve volume scattering problems [75]. In all these approaches, subsectional basis functions and the lowest-order Green function or the lowest-order partial wave are used to construct the impedance matrix. In Ref. 71, small circular discrete scatterers were used for the SMCG method and the matrix multiply operation was extended to partial waves higher than the lowest order.

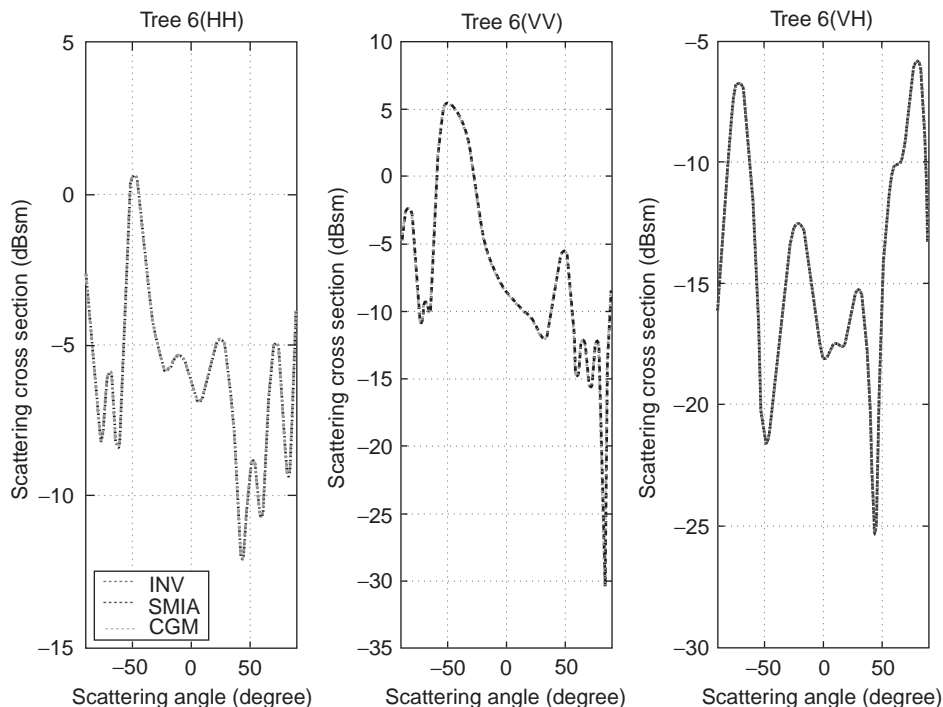

Figure 19. Comparison of the bistatic scattering cross sections of tree 5 calculated by the full matrix inversion (INV), conjugate gradient method (CGM), and sparse matrix iterative approach (SMIA). The wavelength is $\lambda = 1$ m, the incidence angle $\theta_i = 45^\circ$, and the permittivity $\epsilon_p = 9.62 + i4.332$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 20. Comparison of the bistatic scattering cross sections of tree 6 calculated by the full matrix inversion (INV), conjugate gradient method (CGM) and sparse matrix iterative approach (SMIA). The wavelength is $\lambda=1$ m, the incidence angle $\theta_i=45^\circ$, and the permittivity $\epsilon_p=9.62+i4.332$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

In this section, we present a UV method using multi-level partitioning (UV-MLP) to solve volume scattering problems [20]. The UV method has also been used to solve rough surface scattering problems [18,19]. The method consists of setting up a table of transmitting and receiving block sizes and their separations. For a specific scattering problem with given geometry, the scattering structure is partitioned into multilevel blocks. We will illustrate the

UV method for the case of scattering by a large number of circular cylinders. The cylinders are moderate in size with diameter comparable to wavelength. The problem has many physical applications, such as interesting resonant scattering and weak and strong localization occur when particles of wavelength sizes are densely packed together [7]. For this kind of problems, the Foldy-Lax multiple scattering equations can be used with higher-order partial waves as basis functions. The impedance matrices are thus in terms of Green functions of higher-order partial waves. It is shown that the UV decomposition can be applied directly to the impedance matrix of partial waves of higher order. We also apply the multilevel matrix partitioning (MLP) to partition the partial waves impedance matrix \bar{Z} . By looking up the rank in the predetermined table, the partial waves impedance matrix for a given transmitting and receiving block of discrete scatterers is expressed into a $U \times V$ matrix product. In Section 5.2, we describe the problem of independent rank determination. We give the Foldy-Lax equations of scattering by a conglomeration of circular cylinders in Section 5.3. In Section 5.4, we describe the multilevel partitioning process and the UV method, in Section 5.5. In Section 5.6, the computational complexity of the proposed algorithm is derived. In Section 5.7, we demonstrate the technique for a problem with up to 4096 cylinders, each with diameter equal to 1 wavelength. If a volumetric subsectional element is used with MoM for the problem of 1024 cylinders, using 100 points per square wavelength, the number of unknowns will be approximately 80,425. Using the present method of multilevel UV, the solution is completed in 14 min using a single PC processor of 2.6 GHz. The numerical results are illustrated and discussed.

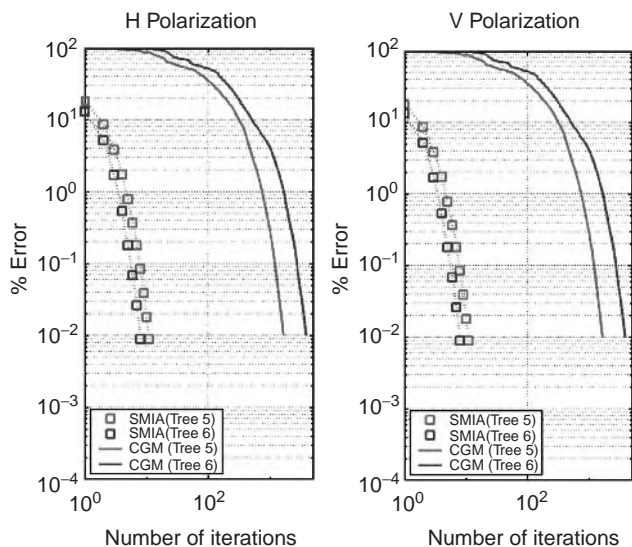

Figure 21. Comparison of the convergence rates for calculating scattering from trees 5 and 6 using the conjugate gradient method (CGM) and sparse matrix iterative approach (SMIA). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

5.1. Problem Independent Rank Table

We describe two methods of predetermination of rank used in volume scattering problems. Consider two square blocks each of side S . The center is separated by distance R as shown in Fig. 24. Because of multilevel partitioning, we have $2S \leq R \leq C_D S$, where C_D is a constant depending on the dimension of the problem.

5.1.1. Method of Volume Discretization or Boundary Discretization

5.1.1.1. Volume Discretization. We discretize the blocks by 100 points per square wavelength. Let there be N points in the transmitting block and N points in the receiving block. Let receiving points be denoted by $\bar{\rho}_p$, $p = 1, 2, \dots, N$, and the transmitting points denoted by $\bar{\rho}_q$, $q = 1, 2, \dots, N$. The Green function in a two-dimensional problem is given by

$$Z_{pq} = \frac{i}{4} H_0^{(1)}(k|\bar{\rho}_p - \bar{\rho}_q|) \quad (69)$$

Then the impedance matrix is of dimension $N \times N$. We can use the singular value decomposition (SVD) method to determine the rank. Let σ_1 be the largest singular value, and let the singular values be arranged in decreasing magnitude. Given a threshold ε , the rank r is such that $|\sigma_{r+1}/\sigma_1| \leq \varepsilon$.

5.1.1.2. Enclosing Boundary Radiation. By Huygen's principle, the equivalent sources are the boundary surfaces that are the four sides of the block. By choosing the boundary radiation, it will reduce the number of points and yet get similar rank for the impedance matrix.

5.1.1.3. Coarse Sampling. As block size increases, the method described becomes prohibitive. However, we know from previous experience that the rank is much smaller than the size of the matrix. Thus we can use much coarser sampling. We use the terminology in which *dense* sampling is the usual 10 points per wavelength for boundary or volume sampling and *coarse* sampling

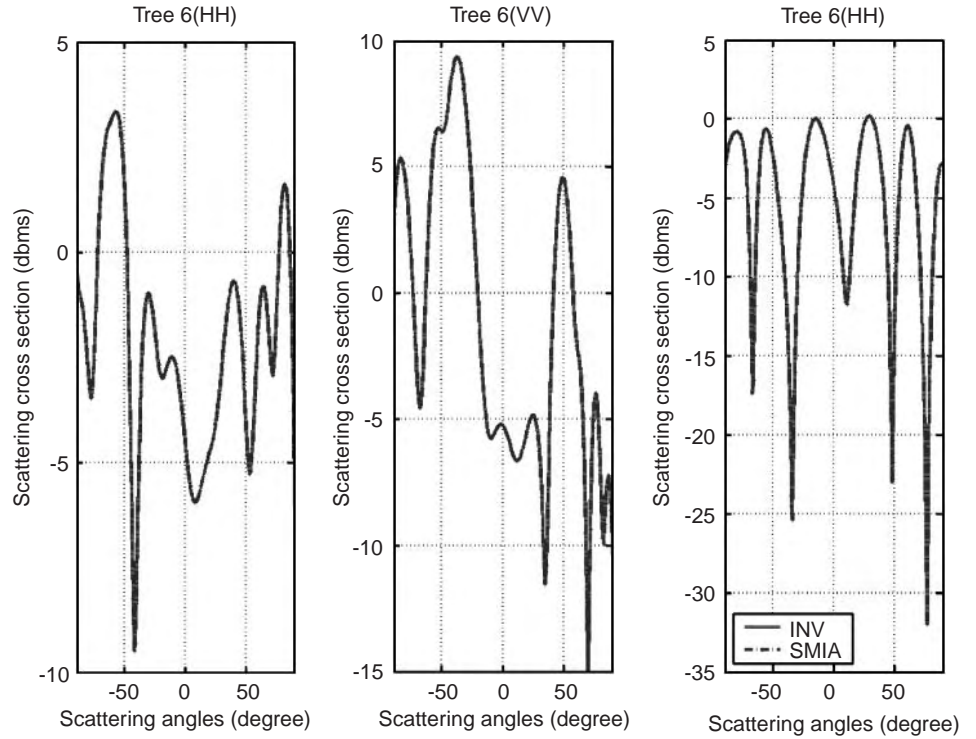

Figure 22. Comparison of the bistatic scattering cross sections of tree 5 calculated by the full matrix inversion (INV) and sparse matrix iterative approach (SMIA). The wavelength is $\lambda = 1$ m, the incidence angle $\theta_i = 45^\circ$, and the permittivity $\varepsilon_p = 33.357 + i21.408$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 23. Comparison of the bistatic scattering cross sections of tree 6 calculated by the full matrix inversion (INV) and sparse matrix iterative approach (SMIA). The wavelength is $\lambda = 1$ m, the incidence angle $\theta_i = 45^\circ$, and the permittivity $\epsilon_p = 33.357 + i21.408$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

means that we pick the number of points to be slightly greater than the rank. This means that we have a priori knowledge of roughly what the rank is on the basis of the numerical experiments carried out. *Coarse* sampling means that we pick the number of points several times larger than the rank. In forming a matrix, we need to select the number of points in the receiving region and a set of points in the transmitting region. Thus we have (receiving sampling)–(transmitting sampling). This means that we can have *dense-coarse sampling*, meaning dense in the receiving region and coarse in the transmitting region etc. To establish the rank of a matrix, we find that it is sufficient to have coarse-coarse sampling.

5.1.2. Method of Using Two Circular Cylinders. We can replace the transmitting and receiving blocks by two cylinders of diameter $D_b = 2S/\sqrt{\pi}$, as illustrated in Fig. 25, where both the cylinder and the square will have the same area. The centers of the receiving cylinder

and the transmitting cylinder are respectively $\bar{\rho}_r$ and $\bar{\rho}_t$. If partial waves are used to describe the waves from the transmitting cylinder to the receiving cylinder, we can truncate the partial waves at $N_c^b = 0.75kD_b$. We use the subscript “b” to denote *block*, reflecting the fact that the purpose of these two large equivalent cylinders is only to set up the rank table and not the physical size of the many cylinders in the multiple scattering problems. From Foldy–Lax equations [6], for two equivalent receiving and transmitting cylinders, the interaction matrix has the following form

$$w_m^{(r)} = \text{incidence wave} + \sum_{n=-N_c^b}^{N_c^b} H_{(m-n)}^{(1)} \times (k|\bar{\rho}_r - \bar{\rho}_t|) e^{i(m-n)\phi_{\bar{\rho}_r\bar{\rho}_t}} T_n w_n^{(t)} \quad (70)$$

where $m = -N_c^b, -N_c^b + 1, \dots, N_c^b$. Then the Foldy–Lax partial wave impedance matrix $\bar{\bar{Z}}_b$ is of dimension

Figure 24. Illustration of rank determination.

$(2N_c^b + 1) \times (2N_c^b + 1)$ and the elements are given by

$$(\bar{\bar{Z}}_b)_{mn} = H_{(m-n)}^{(1)}(k|\bar{\rho}_r - \bar{\rho}_t|) e^{i(m-n)\phi_{r\bar{\rho}_t}} \quad (71)$$

where $m, n = -N_c^b, -N_c^b + 1, \dots, N_c^b$. We can apply the SVD to determine the rank of $\bar{\bar{Z}}_b$. This is a fast method because $N_c^b \ll N$. This has a slightly larger rank because their smallest separation is slightly less.

On the basis of the two techniques described above, a rank table is given in Table 15, where the superscripts 1, 2, 3, and 4 are used to indicate the different cases of (1) area sampling (100 points per square wavelength), (2) boundary (line) dense sampling (10 points per wavelength), (3) boundary (line) coarse sampling (4 points per wavelength), and (4) cylindrical wave expansion, respectively. The threshold chosen for rank determination is 1×10^{-5} . It is seen that all of them gives essentially same rank for same physical problem.

5.2. Foldy-Lax Partial-Wave Equation

Consider N_p cylinders of permittivity ε_p and radius a distributed arbitrarily in a square, as illustrated in Fig. 26. Let a plane TM wave be incident on them. The Foldy-Lax multiple scattering equation in terms of partial wave expansions is expressed as [6,20]

$$\begin{aligned} c_n^{(N)(q)} = & \frac{-i^n e^{-in\phi_i}}{k} e^{i\bar{k}_i \cdot \bar{\rho}_q} E_{vi} B_n^{(N)} \\ & + B_n^{(N)} \sum_{n'=-N_c}^{N_c} \sum_{p=1, p \neq q}^{N_p} H_{(n-n')}^{(1)}(k|\bar{\rho}_p - \bar{\rho}_q|) \\ & \times e^{-i(n-n')\phi_{p\bar{\rho}_q}} S_{n'}^{(N)} c_{n'}^{(N)(p)} \end{aligned} \quad (72)$$

Figure 25. Illustration of rank determination with Foldy-Lax equation.

Table 15. Rank Table of Volume Scattering

$L_x = L_y$ (λ)	Points in Block	Distance (λ)	Rank
1.0	100	2.00	$9^1, 9^2, 9^3, 8^4$
1.0	100	4.24	6, 6, 6, NA
2.0	400	4.00	10, 11, 11, 11
2.0	400	8.48	7, 7, 7, NA
4.0	1,600	8.00	12, 13, 13, 15
4.0	1,600	17.0	8, 9, 9, NA
8.0	6,400	16.0	NA, 18, 18, 23
16.0	25,600	32.0	NA, 26, 26, 37
32.0	102,400	64.0	NA, 41, 41, 63

where $c_n^{(N)(q)}$ is internal field coefficient, $\bar{\rho}_q$ is the position of the q th cylinder and $B_n^{(N)}$ and $S_{n'}^{(N)}$ are given by [6,20]

$$\begin{aligned} B_n^{(N)} = B_{-n}^{(N)} = & -\frac{2ik}{\pi a k_p} \\ & \times \frac{1}{k_p H_n^{(1)}(ka) J_n'(k_p a) - k H_n^{(1)'}(ka) J_n(k_p a)} \end{aligned} \quad (73)$$

$$\begin{aligned} S_n^{(N)} = S_{-n}^{(N)} = & -\frac{i\pi a k_p}{2k} [k_p J_n(ka) J_n'(k_p a) \\ & - k J_n'(ka) J_n(k_p a)] \end{aligned} \quad (74)$$

Parameter k_p is wavenumber inside the particle. Each particle has N_c partial waves. Note that the number N_c is different from N_c^b , which denotes rank determination for block structure. For each particle, the partial wave is truncated at $N_c = 1.5ka$.

The Foldy-Lax equation is a matrix equation with the dimension of $N = N_p (2N_c + 1)$. Each particle has $(2N_c + 1)$ coefficients. The impedance matrix for the particle with itself is a $(2N_c + 1) \times (2N_c + 1)$ unit matrix. The impedance matrix for two different particles p and

Figure 26. Illustration of many random distributed cylinders.

q , $\bar{\bar{Z}}_{pq}$, is of dimension $(2N_c + 1) \times (2N_c + 1)$, and the matrix elements are given by $-B_n^{(N)} H_{(n-n')}^{(1)}(k|\bar{\rho}_p - \bar{\rho}_q|) \exp[-i(n - n')\phi_{\bar{\rho}_p \bar{\rho}_q}] S_n^{(N)}$.

5.3. Matrix Compression for Partial Waves

Suppose that the cylinders are of diameter 1 wavelength and are densely packed as in Fig. 26. Then $N_c = 0.75(2\pi) = 4$, so that there are nine partial waves for each particle. Consider two blocks of side S wavelengths, with the distance separated by distance R , as shown in Fig. 27, the number of cylinders in each block is approximately S^2 . The dimension of the impedance matrix using partial waves between the two blocks is $S^2(2N_c + 1) = 9S^2$.

For example, if $S = 32$ wavelengths, then the impedance matrix of the blocks is of dimension $(9)(32 \times 32) = 9216$. However, the rank is only 41 from Table 15. We observe the following:

1. If volume discretization is used, and assuming 100 volumetric elements per square wavelength over the areas of the cylinders, the dimension of the impedance matrix between the two blocks is 80,425.
2. Since the particles of the physical problem are of 1 wavelength diameter, using partial wave expansion, the dimension of the impedance matrix between these two blocks is only 9216, which is substantially less than that of volume discretization. This reduction is even more for three-dimensional problems.
3. Whether volume discretization or partial wave expansion for the 1λ cylinders, the rank is the same and is 41.
4. Since the use of partial waves reduces the dimension of the matrix, it is advantageous to use partial waves.
5. It is important to recognize that UV method can directly be applied to the compression of the partial wave impedance matrix of dimension 9216.
6. The impedance matrix is of the form of $-B_n^{(N)} H_{(n-n')}^{(1)}(k|\bar{\rho}_p - \bar{\rho}_q|) \exp[-i(n - n')\phi_{\bar{\rho}_p \bar{\rho}_q}] S_n^{(N)}$. Only the factor $H_{(n-n')}^{(1)}(k|\bar{\rho}_p - \bar{\rho}_q|) \exp[-i(n - n')\phi_{\bar{\rho}_p \bar{\rho}_q}]$ depends on both particles. Thus the compression needs be done only for this term. After the compression is done, we can postmultiply by $-B_n^{(N)}$ and premultiply by $S_n^{(N)}$.

Figure 27. Illustration of interactions of many cylinders within two blocks.

After the internal field coefficients are determined, the scattered field in direction ϕ_s is

$$E_s = \sqrt{\frac{2k}{\pi\rho}} e^{i(k\rho - \pi/4)} \sum_{q=1}^{N_p} \sum_{n=-N_c}^{N_c} S_n^{(N)} c_n^q e^{in(\phi_s - \pi/2)} e^{-i\bar{k}_s \cdot \bar{\rho}_q} \quad (75)$$

The bistatic scattering coefficient as defined in Ref. 2 can be calculated.

5.4. Multilevel Partition Process

For the physical problem of the cylinders distributed in Fig. 28, we use the same techniques to do multilevel partitioning as in the case of three-dimensional rough surface scattering [19]. However, the matrix equation is in terms of partial waves form and there are $(2N_c + 1)$ partial waves for each cylinder. If there are M_r cylinders in the receiving group and M_t cylinders in the transmitting groups, the size of the interaction matrix is $M_r(2N_c + 1) \times M_t(2N_c + 1)$.

Assuming that we have a square area as shown in Fig. 28a, we first split it into four blocks as shown in Fig. 28b. Each of the four blocks is a subgroup at the P th level, which has the largest group size. Then we split each subblock into another four small groups as shown in Fig. 28c. This splitting process is continued until we reach the smallest group size, which is at the first level. We decompose the full impedance matrix in Eq. (76) as the sum of P sparse matrices as follows:

$$\bar{\bar{Z}} = \bar{\bar{Z}}^{(0)} + \bar{\bar{Z}}^{(1)} + \bar{\bar{Z}}^{(2)} + \dots + \bar{\bar{Z}}^{(P-1)} \quad (76)$$

Matrix $\bar{\bar{Z}}^{(0)}$ includes all the interactions among neighboring groups (including the self group) at the first level. Matrix $\bar{\bar{Z}}^{(1)}$ includes all the interactions among neighboring groups at the second level and consists of blocks in the first level. Similarly, matrix $\bar{\bar{Z}}^{(i)}$ includes all the interactions among neighboring groups at the $(i + 1)$ th level, but these consist of blocks in the i th level.

To facilitate understanding of the multilevel partitioning process, we give an example that has 64 subgroups at the first level. Assume each group has M elements. For this example, the highest level is $P = 3$. Thus $\bar{\bar{Z}} = \bar{\bar{Z}}^{(0)} + \bar{\bar{Z}}^{(1)} + \bar{\bar{Z}}^{(2)}$ and the impedance matrix of $\bar{\bar{Z}}$ is $64M \times 64M$ and has $4096 M \times M$ blocks.

Figure 28. Illustration of multilevel partitioning process.

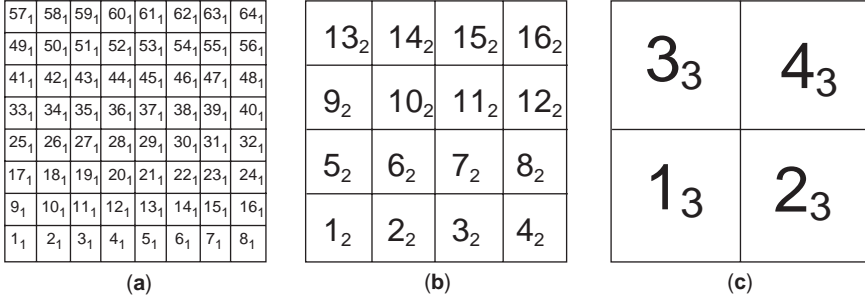

Figure 29. Illustration of multilevel partitioning process with 64 subgroups at the first level.

In Fig. 29a, the 64 subgroups of the first level are expressed as $1_1, 2_1, \dots, 64_1$. E. In Fig. 29b, the level 2 groups are shown and are represented as $1_2, 2_2, \dots, 16_2$. Each of the level 2 groups has four level 1 groups. For example, the group 3_2 has 4 groups of $5_1, 6_1, 13_1$, and 14_1 . In Fig. 29c, the level 3 groups are shown, denoted as $1_3, 2_3, 3_3$, and 4_3 . Each of the level 3 groups has four level 2 groups. For example, the group 2_3 has four groups of $3_2, 4_2, 7_2$, and 8_2 .

We use m_i to represent the group m of the level i . Then the matrix \bar{Z}_{m_i, n_i} represents the interactions between the receiving group m and the transmitting group n of the i th level. Since the four level 1 groups form a level 2 group and four level 2 groups form a level 3 group, the dimension of \bar{Z}_{m_1, n_1} is $M \times M$, and the dimension of \bar{Z}_{m_2, n_2} is $4M \times 4M$. Examples are as follows:

$$\bar{Z}_{3_2, 5_2} = \begin{bmatrix} \bar{Z}_{5_1, 17_1} & \bar{Z}_{5_1, 18_1} & \bar{Z}_{5_1, 25_1} & \bar{Z}_{5_1, 26_1} \\ \bar{Z}_{6_1, 17_1} & \bar{Z}_{6_1, 18_1} & \bar{Z}_{6_1, 25_1} & \bar{Z}_{6_1, 26_1} \\ \bar{Z}_{13_1, 17_1} & \bar{Z}_{13_1, 18_1} & \bar{Z}_{13_1, 25_1} & \bar{Z}_{13_1, 26_1} \\ \bar{Z}_{14_1, 17_1} & \bar{Z}_{14_1, 18_1} & \bar{Z}_{14_1, 25_1} & \bar{Z}_{14_1, 26_1} \end{bmatrix} \quad (77)$$

$$\bar{Z}_{6_2, 5_2} = \begin{bmatrix} \bar{Z}_{19_1, 17_1} & \bar{Z}_{19_1, 18_1} & \bar{Z}_{19_1, 25_1} & \bar{Z}_{19_1, 26_1} \\ \bar{Z}_{20_1, 17_1} & \bar{Z}_{20_1, 18_1} & \bar{Z}_{20_1, 25_1} & \bar{Z}_{20_1, 26_1} \\ \bar{Z}_{27_1, 17_1} & \bar{Z}_{27_1, 18_1} & \bar{Z}_{27_1, 25_1} & \bar{Z}_{27_1, 26_1} \\ \bar{Z}_{28_1, 17_1} & \bar{Z}_{28_1, 18_1} & \bar{Z}_{28_1, 25_1} & \bar{Z}_{28_1, 26_1} \end{bmatrix} \quad (78)$$

$$\bar{Z}_{1_3, 2_3} = \begin{bmatrix} \bar{Z}_{1_2, 3_2} & \bar{Z}_{1_2, 4_2} & \bar{Z}_{1_2, 7_2} & \bar{Z}_{1_2, 8_2} \\ \bar{Z}_{2_2, 3_2} & \bar{Z}_{2_2, 4_2} & \bar{Z}_{2_2, 7_2} & \bar{Z}_{2_2, 8_2} \\ \bar{Z}_{5_2, 3_2} & \bar{Z}_{5_2, 4_2} & \bar{Z}_{5_2, 7_2} & \bar{Z}_{5_2, 8_2} \\ \bar{Z}_{6_2, 3_2} & \bar{Z}_{6_2, 4_2} & \bar{Z}_{6_2, 7_2} & \bar{Z}_{6_2, 8_2} \end{bmatrix} \quad (79)$$

In $\bar{Z}^{(0)}$, we select interactions of the level 1 groups with their nearest neighbors. For example, 20_1 has eight neighbors of $11_1, 12_1, 13_1, 19_1, 21_1, 27_1, 28_1$, and 29_1 . Thus $\bar{Z}^{(0)}$ includes $\bar{Z}_{11_1, 20_1}, \bar{Z}_{12_1, 20_1}, \bar{Z}_{13_1, 20_1}, \bar{Z}_{19_1, 20_1}, \bar{Z}_{20_1, 20_1}, \bar{Z}_{21_1, 20_1}, \bar{Z}_{27_1, 20_1}, \bar{Z}_{28_1, 20_1}$, and $\bar{Z}_{29_1, 20_1}$, a total of nine matrices. Note that self-interaction is also included here. We note that (1) block size of \bar{Z}_{m_1, n_1} is $M \times M$, (2) there are 36 interior

first-level 1 groups of blocks $= 36 \times 9 = 324$ ($M \times M$) blocks, (3) 24 edge first-level groups of six blocks $= 24 \times 6 = 144$ ($M \times M$) blocks, and (4) four corner first-level groups of four blocks $= 4 \times 4 = 16$ ($M \times M$) blocks. Thus $\bar{Z}^{(0)}$ has total of $324 + 144 + 16 = 484$ ($M \times M$) blocks.

In $\bar{Z}^{(1)}$, we select the interactions between level 2 groups and their nearest neighbors. For example, we need to include $\bar{Z}_{6_2, 5_2}$. However, we need to exclude those that have been included $\bar{Z}^{(0)}$. We define the impedance matrix primes, for example

$$\bar{Z}'_{6_2, 5_2} = \begin{bmatrix} \bar{Z}_{19_1, 17_1} & \bar{0}_1 & \bar{Z}_{19_1, 25_1} & \bar{0}_1 \\ \bar{Z}_{20_1, 17_1} & \bar{Z}_{20_1, 18_1} & \bar{Z}_{20_1, 25_1} & \bar{Z}_{20_1, 26_1} \\ \bar{Z}_{27_1, 17_1} & \bar{0}_1 & \bar{Z}_{27_1, 25_1} & \bar{0}_1 \\ \bar{Z}_{28_1, 17_1} & \bar{Z}_{28_1, 18_1} & \bar{Z}_{28_1, 25_1} & \bar{Z}_{28_1, 26_1} \end{bmatrix} \quad (80)$$

where $\bar{0}_1$ is the zero matrix of dimension ($M \times M$). Thus $\bar{Z}^{(1)}$ includes the entire \bar{Z}'_{m_2, n_2} where m_2 and n_2 are neighbors. As shown in Eq. (80), the matrix \bar{Z}'_{m_2, n_2} consists of blocks with size of $M \times M$, and each block consists of a transmitting region and a receiving region that are not neighbors of each other. For example, in $\bar{Z}_{19_1, 17_1}$, the receiving region is 19_1 and the transmitting region is 17_1 , and the two are not neighbors of each other; also, the separation R between the transmitting and the receiving regions is at a minimum of $2S$ for $\bar{Z}_{19_1, 17_1}$, where S is the block size. It is at a maximum of $R = 3\sqrt{2}S$ for $\bar{Z}_{44_1, 17_1}$ that is in $\bar{Z}'_{10_2, 5_2}$. Thus $\bar{Z}^{(1)}$ includes (1) four interior level 2 groups that have eight neighbors, four of which have 12 blocks and four of which have 15 blocks [the total number of blocks is $4 \times (4 \times 12 + 4 \times 15) = 432$]; (2) eight edge level 2 groups that have five neighbors, three of which have 12 blocks, while two of them have 15 blocks [the total number of blocks is $8 \times (3 \times 12 + 2 \times 15) = 528$]; and (3) four corner level 2 groups that have three neighbors, two of which have 12 blocks and one that has 15 blocks [the total number of blocks is $4 \times (2 \times 12 + 1 \times 15) = 156$]. Thus matrix $\bar{Z}^{(1)}$ includes $432 + 528 + 156 = 1116$ ($M \times M$) blocks.

In $\bar{Z}^{(2)}$, we select the interactions between level 3 groups and their nearest neighbors. For example, we need to include $\bar{Z}_{1_3, 2_3}$. However, some of the interactions have already been included in $\bar{Z}^{(0)}$ and $\bar{Z}^{(1)}$ and therefore

need to be excluded. We define the prime impedance matrices, for example

$$\bar{\bar{Z}}'_{1_3 2_3} = \begin{bmatrix} \bar{\bar{Z}}_{1_2 3_2} & \bar{\bar{Z}}_{1_2 4_2} & \bar{\bar{Z}}_{1_2 7_2} & \bar{\bar{Z}}_{1_2 8_2} \\ \bar{\bar{0}}_2 & \bar{\bar{Z}}_{2_2 4_2} & \bar{\bar{0}}_2 & \bar{\bar{Z}}_{2_2 8_2} \\ \bar{\bar{Z}}_{5_2 3_2} & \bar{\bar{Z}}_{5_2 4_2} & \bar{\bar{Z}}_{5_2 7_2} & \bar{\bar{Z}}_{5_2 8_2} \\ \bar{\bar{0}}_2 & \bar{\bar{Z}}_{6_2 4_2} & \bar{\bar{0}}_2 & \bar{\bar{Z}}_{6_2 8_2} \end{bmatrix} \quad (81)$$

Note that the building blocks of $\bar{\bar{Z}}'_{1_3 2_3}$ are level 2 blocks and are of size $(4M \times 4M) = 16M \times M$. This is important, as it indicates that as the level increases, the block size will grow by 4 times as we go up each level. We have four level 3 groups, and each of them has two neighbors with 12 level 2 blocks and one neighbor with 15 level 2 blocks. Thus, we have $4 \times (2 \times 12 + 1 \times 15) = 156$ level 2 blocks. Since each level 2 block has 16 level 1 blocks, we then have a total of $16 \times 156 = 2496$ level 1 blocks in $\bar{\bar{Z}}^{(2)}$.

Thus the total count is $484 + 1116 + 2496 = 4096$, and all the level 1 blocks are counted exactly once. To summarize, the block size in $\bar{\bar{Z}}^{(0)}$ is of $M \times M$, in $\bar{\bar{Z}}^{(1)}$ is of $M \times M$, and in $\bar{\bar{Z}}^{(2)}$ is of $4M \times 4M$. In applying UV decomposition, the UV is applied to each block for that level. Each block consists of a transmitting region and a receiving region that are not neighbors of each other. However, their separations are within a restricted range as indicated before.

5.5. UV Method

The matrix $\bar{\bar{Z}}_{m_i n_i}$, which represents the interactions of two nonneighbor groups m_i and n_i , can be represented by UV decomposition. The matrix $\bar{\bar{Z}}_{m_i n_i}$ is of dimensions $4^{(i-1)}M(2N_c + 1) \times 4^{(i-1)}M(2N_c + 1)$. The rank of $\bar{\bar{Z}}_{m_i n_i}$, r , is much smaller than $4^{(i-1)}M(2N_c + 1)$. For simpler notation, we denote $\bar{\bar{Z}}_{m_i n_i}$ by $\bar{\bar{A}}$, which has dimension of $N \times N$ and rank of r with $r \ll N$. To decompose $\bar{\bar{A}}$ by the SVD and Gram-Schmidt processes will be CPU and memory-intensive because N is large. Note that in Section 5.6, the SVD is applied to find r . But because of coarse-coarse sampling, the selected matrices are roughly of dimension $r \times r$ only. To perform UV decomposition, we need only r independent columns of $\bar{\bar{A}}$ and r independent rows of $\bar{\bar{A}}$.

Let the column of $\bar{\bar{A}}$ be denoted by $\bar{\bar{a}}_l$, where $l = 1, 2, \dots, N$, where $N = 4^{(i-1)}M(2N_c + 1)$. The matrix element A_{mn} is the m th element of the column vector $\bar{\bar{a}}_n$, $A_{mn} = (\bar{\bar{a}}_n)_m$. Note that the N columns are the number of cylinders $4^{(i-1)}M$ times the number of partial waves $(2N_c + 1)$ in the transmitting region. However there are only r independent columns. In the transmitting region, we select r columns from the N columns. The r elements must be uniformly distributed in the transmitting region. If the rank r is less than the number of cylinders inside the transmitting area, we select the zeroth-order partial wave of r cylinders uniformly distributed. If the rank r is larger than the number of cylinders $4^{(i-1)}M$, we select the zeroth-order harmonics of all the cylinders first, and then select the first-order partial wave of $4^{(i-1)}M$ uniformly distributed cylinders.

We compute the r columns $\bar{\bar{u}}_l$, $l = 1, 2, \dots, r$. Each column is of dimension of N and coincides with a column of $\bar{\bar{A}}$

$$U_{ml} = (\bar{\bar{u}}_l)_m = A_{mp(l)} \quad (82)$$

where $m = 1, 2, \dots, N$ and $p(l)$ is a column index of $\bar{\bar{A}}$ that depends on l . Note that to get U_{ml} , one needs to go through all the N elements in the receiving region. Thus the matrix $\bar{\bar{U}}$ has rN elements.

Because of linear independence, any general column $\bar{\bar{a}}_m$ of $\bar{\bar{A}}$ is a linear combination of $\bar{\bar{u}}_l$, that is

$$\bar{\bar{a}}_m = \sum_{l=1}^r v_{lm} \bar{\bar{u}}_l \quad (83)$$

where $m = 1, 2, \dots, N$, and v_{lm} are the coefficients to be determined.

We pick r rows of $\bar{\bar{A}}$, which has total of rN elements. The r rows correspond to r elements in the receiving group. The criterion for picking up elements is the same as in the transmitting area. We first put these rows in a matrix of $\bar{\bar{R}}$, its matrix elements are given as $R_{m_a p} = A_{m(m_a)p}$, with $p = 1, 2, \dots, N$ and $m_a = 1, 2, \dots, r$. We next pick the m_a rows in $\bar{\bar{u}}_l$, $l = 1, 2, \dots, r$. That will give us an $r \times r$ matrix named $\bar{\bar{U}}$ with $\bar{\bar{U}}_{m_a n_a} = (\bar{\bar{u}}_{n_a})_{m(m_a)}$. Then we set

$$R_{m_a l} = \sum_{n_a=1}^r \bar{\bar{U}}_{m_a n_a} v_{n_a l} \quad (84)$$

with $l = 1, 2, \dots, N$. In matrix notation, $\bar{\bar{V}}$ is of dimension $r \times N$, $\bar{\bar{R}}$ is of dimension $r \times N$, $\bar{\bar{U}}$ is of dimension $r \times r$, $\bar{\bar{R}} = \bar{\bar{U}}\bar{\bar{V}}$, and $\bar{\bar{V}} = \bar{\bar{U}}^{-1}\bar{\bar{R}}$. This completes the UV decomposition of $\bar{\bar{A}}$, and

$$\bar{\bar{A}} = \bar{\bar{U}}\bar{\bar{V}} \quad (85)$$

To summarize, we take r columns of $\bar{\bar{A}}$ and then r rows of N , representing a total of $2rN$ elements. We need to take the inverse of an $r \times r$ matrix $\bar{\bar{U}}$, and a matrix multiplication of an $r \times r$ matrix with an $r \times N$ matrix. The computational and memory efficiency is achieved when $r \ll N$.

5.6. Computational Complexity Analysis

5.6.1. Multilevel Group Sizes and Number of Groups.

The centers of the cylinders are generated in a square area with $\sqrt{N_p}$ points in both x and y directions, such that the total number of cylinders is N_p . Note that each cylinder has a finite radius of a . We use various subgroup sizes at P level to partition the whole area as follows:

1. At the P th level, split the whole area as four groups. Each group has $N_p/4$ cylinders. Let L_P be the number of groups and M_P be the number of cylinders of each group at the P th level. Thus, $L_P = 4 = 2^{2(P-P+1)}$, and $M_P = N_p/4 = N_p/L_P$.
2. Split each group into four subgroups and continuing this partitioning, at the i th level, we have

$L_i = 2^{2(P-i+1)}$ subgroups and $M_i = N_p/L_i$ cylinders of each subgroup at the i th level, respectively.

- At the first level, we have respectively $L_1 = 2^{2P}$ level 1 subgroups and $M_1 = N_p/L_1$ cylinders of each subgroup.

5.6.2. Cost Function at i th Level. In $\bar{\bar{Z}}^{(i)}$, we select the interactions between level $(i+1)$ groups and their nearest neighbors. However, some of the interactions have already been included in the lower-level groups and must be excluded from them. There are five kinds of neighboring groups:

- Groups Sharing Only One Common Point.** As shown in Fig. 30a, for the neighboring groups of $m_{(i+1)}$ and $n_{(i+1)}$, only one common point is shared between them. The impedance matrix that will be calculated is

$$\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}} = \begin{bmatrix} \bar{\bar{Z}}_{m_i^{(1)}n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(1)}n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(1)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(1)}n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(2)}n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(2)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(2)}n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(3)}n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(3)}n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(3)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(3)}n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(4)}n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(4)}} \end{bmatrix} \quad (86)$$

The dimension of matrix $\bar{\bar{Z}}_{m_i n_i}$ is of $M_i(2N_c+1) \times M_i(2N_c+1)$. The computational steps for $\bar{\bar{Z}}_{m_i n_i} \cdot \bar{\mathbf{b}}_{M_i}$ through the UV is of $2(2N_c+1)M_i r_i$, where r_i is the rank of $\bar{\bar{Z}}_{m_i n_i}$. In here we assume that the rank r_i of $\bar{\bar{Z}}_{m_i n_i}$ is the same for all block interactions at the same level. There are 15 nonzero matrices of $\bar{\bar{Z}}_{m_i n_i}$ in the $\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}}$. The total computational steps for $\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}} \cdot \bar{\mathbf{b}}'_{M_{(i+1)}}$ are $30(2N_c+1)M_i r_i$.

- Groups Sharing One Common Edge.** As shown in Fig. 30b, for the neighboring groups of $m_{(i+1)}$ and

$n_{(i+1)}$, one common edge is shared between them. The impedance matrix that will be calculated is

$$\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}} = \begin{bmatrix} \bar{\bar{Z}}_{m_i^{(1)}n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(1)}n_i^{(3)}} & \bar{0}_i \\ \bar{\bar{Z}}_{m_i^{(2)}n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(2)}n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(2)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(2)}n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(3)}n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(3)}n_i^{(3)}} & \bar{0}_i \\ \bar{\bar{Z}}_{m_i^{(4)}n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(4)}n_i^{(4)}} \end{bmatrix} \quad (87)$$

There are 12 nonzero matrices of $\bar{\bar{Z}}_{m_i n_i}$ in $\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}}$. The total computational steps for $\bar{\bar{Z}}'_{m_{(i+1)}n_{(i+1)}} \cdot \bar{\mathbf{b}}'_{M_{(i+1)}}$ are $24(2N_c+1)M_i r_i$.

- Interior Groups.** Interior groups have eight neighbors, four of which share only one common point and four others that share one common edge. There are $(\sqrt{L_{(i+1)}}-2)^2$ interior groups at the $(i+1)$ th level. Thus computational steps for the interior groups at the i th level are $(\sqrt{L_{(i+1)}}-2)^2[4 \times 30(2N_c+1)M_i r_i + 4 \times 24(2N_c+1)M_i r_i] = 216(\sqrt{L_{(i+1)}}-2)^2(2N_c+1)M_i r_i$.
- Edge Groups.** Edge groups have five neighbors; two of them share only one common point and three of them share one common edge. There are $4(\sqrt{L_{(i+1)}}-2)$ edge groups at the $(i+1)$ th level. Thus computational steps for the edge groups at the i th level are $4(\sqrt{L_{(i+1)}}-2)(2 \times 30M_i r_i + 3 \times 24M_i r_i)(2N_c+1) = 528(\sqrt{L_{(i+1)}}-2)(2N_c+1)M_i r_i$.
- Corner Groups.** Corner groups have three neighbors. One of them shares only one common point and two of them share one common edge. There are four corner groups at the $(i+1)$ th level. Thus computational steps for the corner groups at the i th level are $4(1 \times 30M_i r_i + 2 \times 24M_i r_i)(2N_c+1) = 312(2N_c+1)M_i r_i$.

Thus the total computational step at the i th level is the sum of $216(\sqrt{L_{(i+1)}}-2)^2 M_i r_i (2N_c+1)$ for the interior groups, $528(\sqrt{L_{(i+1)}}-2) M_i r_i (2N_c+1)$ for the edge groups,

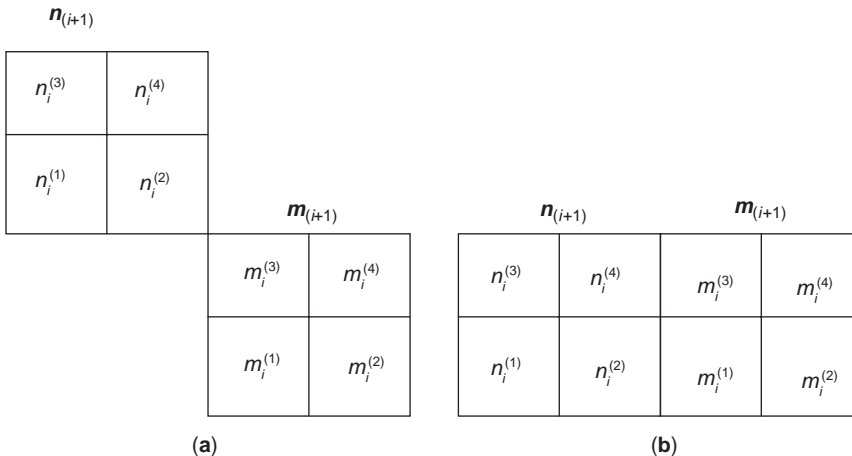

Figure 30. Illustration of interactions of multiple cylinders within two blocks.

and $312M_i r_i (2N_c + 1)$ for the corner groups, which is equal to

$$2M_i r_i \left(108L_{(i+1)} - 168\sqrt{L_{(i+1)}} + 60 \right) (2N_c + 1) \quad (88)$$

5.6.3. Cost Function for the Multilevel UV Method (Non-near). The total computational steps for nonneighbor block interactions through the multilevel UV decomposition are

$$\sum_{i=1}^{P-1} 2r_i M_i \left[108L_{(i+1)} - 168\sqrt{L_{(i+1)}} + 60 \right] (2N_c + 1) \quad (89)$$

Generally speaking, the rank of each level block will increase with increase in block size. For simplicity, we assume $r_i = r$ to be a constant here, and substituting this r in Eq. (89), we have

$$27rN(2N_c^b + 1) \log_2 \left(\frac{N}{M_1} \right) + 60rN(2N_c^b + 1) - 120rM_1(2N_c + 1) \quad (90)$$

5.6.4. Cost Function for Near-Field Interactions in $\bar{Z}^{(0)}$. All the near-field interactions are included in the matrix $\bar{Z}^{(0)}$, which is computed directly as the original impedance matrix. The block size in $\bar{Z}^{(0)}$ is of dimension of $(2N_c + 1)M_1 \times (2N_c + 1)M_1$. The computational steps for the block and block interaction are $(2N_c + 1)^2 M_1^2$.

1. *Interior Group.* The interior group has nine blocks (including self-interaction). There are $(\sqrt{L_1} - 2)^2$ interior groups at the first level. Thus the computational steps for the interior groups at the first level are $9(\sqrt{L_1} - 2)^2 M_1^2 (2N_c + 1)^2$.
2. *Edge Groups.* Each edge group has six blocks (including self-interaction). There are $4(\sqrt{L_1} - 2)$ edge groups at the first level. Thus the computational steps for the edge groups at the first level are $6(\sqrt{L_1} - 2)M_1^2 (2N_c + 1)^2$.
3. *Corner Groups.* Each corner group has four blocks (including self). There are four corner groups at the first level. Thus the computational steps for the corner groups at the first level are $4M_1^2 (2N_c + 1)^2$.

The total computational step for near-field interaction is then the sum of $9(\sqrt{L_1} - 2)^2 M_1^2 (2N_c + 1)^2$ for the interior groups, $6(\sqrt{L_1} - 2)M_1^2 (2N_c + 1)^2$ for the edge groups, and $4M_1^2 (2N_c + 1)^2$ for the corner groups, which is equal to

$$(9NM_1 - 12N^{1/2}M_1^{3/2} + 4M_1^2)(2N_c + 1)^2 \quad (91)$$

5.6.5. Cost Function. The total computational step for multilevel partitioning UV is sum of the near and nonnear

interactions and is given by

$$\left[27rN \log_2 \frac{N}{M_1} + 60rN - 120rM_1 \right] (2N_c + 1) + (9NM_1 - 12N^{1/2}M_1^{3/2} + 4M_1^2)(2N_c + 1)^2 \quad (92)$$

5.7. Numerical Results and Discussion

The numerical simulation results are presented and compared in terms of the matrix–vector product and solutions of the Foldy–Lax equation with an iterative solver. Simulations are based on the periodic distributions of many cylinders and the random distribution of many cylinders. We assume that all the cylinders have the same diameter of 1 wavelength. The horizontal and vertical separations between the centers of two neighboring cylinders are taken as 1.3 wavelengths for periodic distribution. For the case of random distribution, the center of each cylinder is moved randomly within the range from -0.15 to 0.15 wavelength in both horizontal and vertical directions. The relative dielectric constant of all the cylinders is 3.2 in Fig. 29 and is equal to 1.5 in Figs. 30 and 31. The computer used in the simulations is a Pentium single processor of 2.6 GHz with 2 GB (gigabyte) memory.

5.7.1. Rank Determination for Foldy–Lax Equation. First, we illustrate the rank determination for the problem. The cylinders are first grouped with the multilevel partitioning process, and then we know the size of each group. On the basis of the coarse–coarse boundary sampling, we can calculate the ranks of interaction groups with the SVD method. Since the UV is not as strict as the SVD method, we actually use a rank a little bit higher than that calculated when constructing the UV matrix.

5.7.2. CPU for the UV. In Table 16, we list the CPU time based on the UV method for different numbers of cylinders. The diameter of each cylinder is 1 wavelength, and the number of partial waves is 9. This means that there are nine partial waves unknowns to be determined for each cylinder. The numbers of cylinders are 64, 256, 1024, and 4096. The preprocessing time of the UV method is the time used to construct $U \times V$ matrix and also the time for rank determination. The CPU time for matrix–vector multiplication means the CPU time spent for one time matrix–vector multiplication. For the case of 4096 cylinders, which corresponds to 36,864 partial wave unknowns, it takes less than ~ 7.34 s for the matrix–vector multiplication. This case corresponds to 321,700 equivalent numbers of volumetric unknowns.

5.7.3. Comparisons of the Matrix–Vector Product. The results for 4096 cylinders are shown in Fig. 31. Because of the limited computer resource, the direct multiplication is not possible for this case. Thus we make comparison between the SVD-based QR method and the UV method. We use the product from the SVD method as the horizontal values and the product from the UV method as the vertical

Figure 31. Comparisons of the matrix–vector products calculated by the SVD-based QR method and the UV method. The number of cylinders is 4096 with a diameter of 1.0 wavelength. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

values. Figure 31a shows results for the real part and Fig. 31b, is for the imaginary part. We can see that all the points are along a 1–1 line, which means that the products from both methods are matched well for this case.

In Table 16, we also list the relative norm errors for the matrix–vector product compared with direct matrix–vector multiplication for all the cases cited above. The errors inside parentheses for 1024 cylinders indicate random

Table 16. CPU for the UV Method and Norm Error

Number of Cylinders	Preprocessing Time (s)	Matrix–Vector Product (s)	Norm Error
64	1	0.02	0.0033
256	14	0.13	0.0020
1024	115	1.03	0.0015 (0.0017)
4096	999	7.34	0.0127

distribution. It can be seen that the errors are pretty small. This means that an accurate matrix–vector product can be reached through the UV method.

5.7.4. Comparisons of the Solutions of Foldy–Lax Equation for Different Numbers of Cylinders. Using the proposed UV method, we have solved the Foldy–Lax equation with an iterative solver for randomly distributed cylinders. The relative dielectric constant of all the cylinders is 1.5 and the convergent condition for the iterative approach is set up at 1×10^{-3} . We have done this for 1024 cylinders. For this case, we have made comparisons with the solutions from the SVD-based QR method. Good agreement was obtained.

In Table 17, we list the CPU time and relative norm errors for each solution. We also show the number of CG iterations and CPU time for the rank determination. The CPU time for rank determination is included in the second column in brackets. The numbers of iterations are listed in column 3 and in parentheses. The total CPU for 64 cylinders is 3 s with a total of 36 s for 256 cylinders. For 1024 cylinders, preprocessing time is 121 s, taking only 32 s for rank determination based on the coarse–coarse sampling. The CPU for iteration method is 711 s, which needs 330 iterations to reach the convergence. The relative errors are 0.0014 for 64 cylinders, 0.0078 for 256 cylinders, and 0.0189 for 1024 cylinders. Thus, using the UV method, we can solve the partial wave equation very efficiently and accurately. However, the number of CG iterations grows with the number of cylinders. This property of the Foldy–Lax partial wave equation needs to be investigated further.

5.7.5. Bistatic Scattering Coefficients for Different Numbers of Cylinders. After the solutions of the Foldy–Lax equation, we can calculate the scattering coefficients. Figure 32 shows the bistatic scattering coefficients for cylinders totaling 1024. The incidence angle is 30° . The diameter of all cylinders is 1.0 wavelength and the

Table 17. CPU for the UV-CG Method and Norm Error

Number of Cylinders	Preprocessing Time (s)	CG Time (s)	Total CPU Time (s)	Norm Error
64	2 ($<1^a$)	1 (21^b)	3	0.0014
256	15 (4)	21 (75)	36	0.0078
1024	121 (32)	711 (330)	832	0.0189

^aCPU time for rank determination.

^bNumber of iterations for the conjugate gradient method.

Figure 32. Bistatic scattering coefficients based on the UV method. The number of cylinders is 1024, with radius of 1.0 wavelength. The incidence angle is 30° . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

relative permittivity is 1.5. The cylinders are randomly distributed.

The UV-MLP method is presented for the rapid solution of integral equation. Like SMCG and FMM methods, the UV-MLP method emphasizes on the reduction of both CPU and memory requirements for matrix–vector multiplication. On the other hand, the method of characteristic basis functions [75] emphasizes the drastic reduction in basis functions.

CONFORMAL ANTENNAS

DIPAK L. SENGUPTA
University of Detroit Mercy
Detroit, Michigan

A conformal antenna may be defined as an antenna whose radiating aperture conforms to the surface of the body on which it is mounted. Ideally, such antennas are flush mounted or low profile (i.e., they do not protrude appreciably out of the mounting surface). Basic slot and microstrip (patch) antennas are typical examples of conformal antenna elements. The term *conformal array* has no unique definition. Kummer [1] defines it as an array that is nonplanar. We shall assume here that a conformal

array consists of conformal (or low-profile) antenna elements placed on a nonplanar surface. The array surface is not generally at the disposal of the antenna designer and is often dictated by the specific application. For ground-based application, a conformal phased array requiring coverage over 360° in azimuth (omnidirectional coverage) or coverage over a hemisphere the array surface may be cylindrical or spherical, respectively. For conformal arrays on aircraft, missiles, satellites, and surface ships, the array shape may assume another form dictated by the contour of the vehicle. Basic slot and microstrip antennas are extensively discussed in the literature—for example, the textbook by Balanis [2] is a typical reference. These antennas provide ideal performance only when they are mounted on planar surfaces. During conformal application the curvature of the mounting surface can affect their impedance and radiation properties; such effects must be taken into account during the design of such antennas.

The need for conformal phased arrays for aircraft and missile applications, and for ground-based arrays with omnidirectional coverage in azimuth or complete hemispherical coverage in space, has grown continually with requirements that emphasize maximum utilization of available space and minimum cost. Many of the developments in conformal arrays have been extensions of the concepts for planar phased arrays, which are extensively discussed in the literature (for example, in Ref. 2). However, there are significant differences between planar and conformal arrays that must be taken into account during the design of the latter. The individual elements on curved bodies point in different directions that make it necessary to turn off those elements that radiate primarily away from the desired beam direction. For this reason also, one cannot factor out the element pattern out of the total radiation pattern—this makes the conformal array analysis and synthesis more difficult. The element orientation may also cause severe crosspolarization. In addition, the mutual coupling effects between the elements can be severe in some cases.

Within the limitations of space allowed, it is not possible to describe here every aspect of conformal antennas and antenna arrays. Instead, we shall at first describe briefly certain aspects of a few basic antennas that are commonly used either singly or as array elements for conformal applications. Then we give brief descriptions of a selected number of conformal antennas and antenna arrays. Specifically, this article describes the following:

1. The specific considerations that must be given to the performance of basic slot and microstrip or patch antenna elements when mounted on nonplanar conducting surfaces
2. A selected number of conformal antennas: for example, microstrip conformal antennas and dielectric-filled edge slot (DFES) antennas
3. A class of wraparound antennas and antenna arrays
4. Cylindrical and spherical phased arrays used for omnidirectional and hemispherical coverage, respectively.

All of these antennas have found practical applications. Detailed descriptions of their development, design procedures, and analysis of their performance are described in the references cited at appropriate places.

Literature on conformal antennas is vast and ranges from technical journal articles to numerous textbooks and specialized books, of which Refs. 2–8 are typical.

1. BASIC ANTENNA ELEMENTS

Elementary slot and microstrip patch antennas are commonly used singly or as array elements for conformal application. However, these radiators provide ideal performance only when they use plane conducting surfaces. Ideal theory can be used when the radii of curvature of the surfaces are large compared to the operating wavelength. In other cases both the impedance and radiation characteristics may be affected significantly.

1.1. Slots on Curved Surfaces

The radiation patterns of slot antennas can be significantly altered by the curved mounting surface. Pathak and Kouyoumjian [9] give a convenient extension of the geometric theory of diffraction (GTD) for apertures in curved surfaces. Figure 1, taken from Ref. 9, shows the patterns of an axial slot element on perfectly conducting circular cylinders of various radii; the results indicate the accuracy of the approximate theory. The effects of the cylinder radius on the patterns shown in Fig. 1 should be noticed. A similar slot on a flat ground plane would have a constant pattern from $\phi = 0$ to 180° . Radiation patterns of slots on a variety of other generalized surfaces are discussed in Refs. 10–12. Mailloux [13] summarizes some of the results of Pathak and Kouyoumjian [9] shown in Fig. 2, which gives the radiated power pattern in the upper half-plane ($\theta \leq 90^\circ$) for an infinitesimal slot in a cylinder of radius a . The angular extent of the transition zone is on the order of $(k_0 a)^{-1/3}$ on each side of the shadow boundary, where

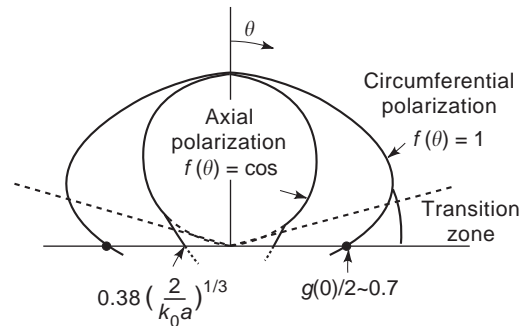

Figure 2. Approximate pattern of a thin slot on a conducting cylinder of radius a ; k_0 is the free-space propagation constant. (After Ref. 6.)

$k_0 = 2\pi/\lambda_0$ is the propagation constant in free space. The results indicate that above the transition zone (i.e., the illuminated zone) the circumferentially polarized radiation is nearly constant but the axially polarized radiation has a $\cos \theta$ pattern. Compared with the field strength in the $\theta = 0^\circ$ direction, the field strengths in the $\theta = 90^\circ$ area are found to be about 0.7 and $0.4(2/k_0 a)^{1/3}$ for circumferential and axial polarizations, respectively. It should be noted that in the case of flat surface the field reduces to zero in the $\theta = 90^\circ$ area.

1.2. Slots on Metallic Cones

Slots and slot arrays on metallic cones are found advantageous to use for missile or missilelike bodies. For efficient design of such arrays, the self- and mutual admittances must be taken into account. Theoretical and experimental investigation of slot antennas on metallic cones are discussed in Ref. 14, where the effects of scattering from a sharp tip on the mutual admittances have been investigated for pairs of circumferential and radial slots on a semi-infinite metallic cone. The base of the conical model used in the experimental study was terminated in a spherical cap to minimize scattering from the finite length of the apparatus. The two slot antennas configurations considered are shown in Fig. 3. Self- and mutual admittance expressions for pairs of slots shown in Fig. 3 have been derived by Golden et al. [14], and the results have been confirmed by measurements. These admittance results can be immediately applied to determine the aperture voltages required for the analysis of N -element slots on cones.

In Ref. 14 the circumferential slot results illustrate interference effects between the direct coupling from slot to slot via the geodesic path over the conical surface and the tip backscattering. For the radial slot configuration, the results indicate negligible tip scattering effects. Golden and Stewart [15] have found that the current distribution near a slot for a sharp cone can be approximated by the distribution on an equivalent cylinder if scattering from the apex (on tip) is small. Thus, the mutual admittance between two slots can be approximately calculated by using a cylindrical model with the same local radii of curvature as the cone, provided the wave scattering from either

Figure 1. Patterns of a thin axial slot on a perfectly conducting cylinder. (After Ref. 9.)

Figure 3. Slotted-cone geometry.

the tip or the base region of the vehicle is negligible. The slotted cone and equivalent cylinder are shown in Fig. 4, which reveals that the cylinder has a radius equal to the radius of the circular cross section of the cone midway between the two slots antennas. For small-angle cones ($\theta_0 \sim 180^\circ$), the radial separation of the slots on the cone can be equated to the axial separation of the slots on the equivalent cylinder.

Mutual coupling ($|S_{12}|$ parameter) results versus azimuthal separation for two circumferential and axial slots on a cylinder are shown in Figs. 5 and 6, respectively. The mutual coupling between two radial slots on a 12.2° half-angle cone is shown in Fig. 7 as a function of frequencies. Figure 8 shows the mutual coupling versus frequencies for circumferential slots on a 12.2° (half-angle) cone. The

Figure 4. Slotted cone and equivalent cylinder.

Figure 5. Mutual coupling for circumferential slots on cylinder, $\rho_0 = 5.057$ cm. (After Ref. 14.)

results illustrate the interference effects between the direct and tip-scattered components. The mutual coupling between circumferential slots on an 11° (half-angle) cone is shown in Fig. 9. Using the results given in Ref. 14, it may be concluded that for the case of circumferential slots (radial electric fields) the tip-scattered portion of the azimuthal magnetic field at the slot aperture can be expressed in terms of an appropriate diffraction coefficient; in the case of radial slots (azimuthal electric fields) there is no radial component of the magnetic field in the far field of tip and therefore no contribution to the mutual admittance. More detailed results and discussions are given in Refs. 14 and 15.

1.3. Microstrips on Curved Surfaces

Microstrip or patch is a popular low-profile, flush-mounted antenna developed in the 1970s. Detailed descriptions of

Figure 6. Mutual coupling for axial slots on cylinder, $\rho_0 = 5.057$ cm. (After Ref. 14.)

Figure 7. Mutual coupling for radial slots versus frequency, $\rho_0 = 9.622$ cm. (After Ref. 14.)

the research and development of microstrip antennas can be found in Refs. 16 and 17. Such antennas generally use a metallic patch on a dielectric substrate backed by a planar ground plane, and they are excited either by a stripline or a coaxial line. The shape of the patch can be rectangular, circular, or some other shape, in general, of which the first two are the most popular. We shall mostly describe the basic rectangular patch antenna whose one dimension is $\lambda/2$ at the operating wavelength in the substance and the other dimension is slightly less than the former. Ideally, such antennas produce similar E - and H -plane patterns that have maxima in the broadside direction; generally, the polarization is linear and parallel to the patch plane but they can be designed to produce circular polarization also. For conformal applications, it is necessary to take into account the effects of nonplanar surfaces on the performance of such antennas.

1.4. Cylindrical–Rectangular Patch Antenna

The geometry of a rectangular microstrip patch antenna mounted on a conducting cylinder is shown in Fig. 10. Resonant frequencies and radiation characteristics of this antenna are discussed in Refs. 18 and 19. For thin substrate satisfying $h \ll a$, Luk et al. [19] give the following expression for the (transverse magnetic mode with respect

Figure 8. Mutual coupling for circumferential slots versus frequency, $\rho_0 = 9.622$ cm. (After Ref. 14.)

Figure 9. Mutual coupling for circumferential slots versus frequency; $\rho_0 = 5.041$ cm. (After Ref. 14.)

to ρ) TM_ρ resonant frequencies for the antenna

$$f_{mn} = \frac{c}{2\sqrt{\epsilon_r}} \left[\left(\frac{m}{2(a+h)\theta_1} \right)^2 + \left(\frac{n}{2b} \right)^2 \right]^{1/2} \quad (1)$$

where c is the velocity of light in free space, ϵ_r is the dielectric constant of the substrate, and $m, n = 0, 1, 2, \dots$, but $m = n \neq 0$. Equation (1) indicates that if the dimensions of the patch—that is, $2(a+h)\theta$ and $2b$ —are fixed, the resonant frequencies of the TM_ρ modes are not affected by the curvature of the thin substrate. However, to account for fringing fields, effective values of the dimensions are to be used in Eq. (1), as mentioned by Carver and Mink [20]. Luk et al. [19] discuss the E - and H -plane radiation patterns produced by the antenna using $\epsilon_r = 1.06$, $\epsilon_r = 2.32$, and different values a . It is found that the patterns are not sensitive to the thickness. For a curved patch, there is significant radiation in the lower hemisphere for the TM_{01} mode; the deviation from the flat patch results increases for larger value of ϵ_r . Compared to the TM_{10} mode, there is less radiation in the lower hemisphere for the TM_{01} mode. Wong and Ke [21] describe the design of this antenna for

Figure 10. Geometry of a cylindrical–rectangular microstrip patch antenna.

circular polarization by using the TM_{01} and TM_{10} modes excited by a single coaxial feed located on a diagonal line and the operating frequency chosen between the two lowest frequencies f_{01} and f_{10} given by Eq. (1).

Kashiwa et al. [22] describe the application of a strip-line-fed cylindrically curved rectangular patch antenna as a small, portable antenna for mobile communication. It has been found that near the resonant frequency the real part of the input impedance approaches $50\ \Omega$. The radiation patterns near the broadside direction are found to be similar to those of the equivalent planar antenna; however, significant differences have been found in large off-broadside directions.

Radiation patterns of a cavity-backed microstrip patch antenna on a cylindrical body of arbitrary cross section have been investigated theoretically and experimentally by Jin et al. [23]. The finite-element method is used to characterize the microstrip patch antennas, and then the reciprocity theorem is applied in conjunction with a two-dimensional method of moments to calculate the radiated field. The method can be extended to characterize the radiation patterns of conformal microstrip patch antennas on general three-dimensional bodies.

1.5. Microstrip Patch Antennas on Conical Surfaces

The use of microstrip antennas on conical surfaces is of interest for aerospace vehicles with portions of their bodies conically shaped. Performance of a basic rectangular patch antenna on a metallic cone has been investigated theoretically by Descardecì and Giarola [24]. In the analysis the substrate thickness is assumed to be very small compared with the distance of the patch to the cone apex, and the curvature radius of the cone surface large compared with the operating wavelength. The capacitive effects and losses associated with surface waves have been neglected. Except for these assumptions, the cavity model analysis used is general and applies to any conical surface. Within the approximations made, the resonant frequency is not significantly affected by the conical surface. However, the radiation pattern is affected, with a consequent influence on the input impedance and the total quality factor. Details can be found in Ref. 24.

2. CONFORMAL ANTENNAS

2.1. The Omnidirectional Microstrip Antenna

The omnidirectional (also known as *nondirectional* or “omni”) microstrip or spiral slot antenna discussed in Refs. 25–27 is essentially a short-circuited quarter-wavelength microstrip patch wrapped around a cylindrical surface to form a spiral, as shown in Fig. 11. The cylinder is an epoxy fiberglass dielectric, and the copper conduction is added using an electroless plating–masking–electroplating technique. The lower end and the insider of the patch are similarly plated to form a short circuit and ground plane. The spiral slot antenna has a height and diameter of $0.06\lambda_0$ but, unlike conventional small antennas, has well-matched input voltage standing-wave ratio (VSWR) of less than 2:1 over a 2% bandwidth at 238 MHz. The

Figure 11. (a) Linear short-circuited $\lambda_g/4$ microstrip resonator; (b) omnidirectional microstrip antenna: a cylindrical $\lambda/4$ microstrip resonator. (After Ref. 27.)

radiation patterns are similar to those of a dipole oriented parallel to the cylinder axis, and the +1 dB gain indicates an efficiency of better than 50%. The spiral slot has also been developed for 42-MHz application in which the antenna has to be contained in a $0.04\lambda_0 \times 0.15\lambda_0$ cylindrical volume.

2.2. Dielectric-Filled Edge Slot Antenna

A class of circumferential slot antennas, called the DFES antennas, that are ideally suited for conformal mounting on conducting bodies of revolution has been described by Schaubert et al. [28]. As shown in Fig. 12, the simplest form of the antenna consists of a disk of dielectric substrate that is copper-coated on both sides and mounted between the two halves of a conducting body so that the radiating aperture coincides with the surface. The antenna is excited at the center by a coaxial line whose outer conductor is connected to the lower conducting surface, and the inner conductor is extended through the dielectric and finally connected to the conducting surface at the upper end of the substrate. The input reflection coefficients of the antenna are found to assume minimum values at some discrete frequencies, called the *operating frequencies*,

Figure 12. Two-element edge slot antenna.

where the antenna also radiates most efficiently. The DFES antenna can be tuned for a desired operating frequency by using a number of axially oriented passive metallic posts. The antenna without the tuning posts is referred to as the “basic” DFES antenna, which generally provides the highest operating frequency. By varying the number and location of the inductive posts, the operating frequency of the antenna can be tuned over a 6:1 range; instantaneous bandwidths of 3% are typical. The theory and design of basic and tuned DFES antennas mounted on a conducting cylinder have been developed and discussed by Sengupta and Martins-Camelo [29]. The radiation patterns of edge slot excited conducting bodies of revolution display a high degree of azimuthal symmetry. The radiation pattern of DFES antennas is strongly influenced by the body on which it is mounted. The patterns in Fig. 13 are typical of the performance of the antenna when mounted on a conducting cylinder.

Sometimes it is not possible to place a flat disk across the body, and at times the antenna must be mounted near the top of a conical body where the diameter is not sufficient to build an antenna operating at the desired frequency. In such cases the planar disk can be deformed (symmetrically) to fit in the available space and to operate at the required frequency. A conical edge slot antenna is described in Ref. 28, and its radiation patterns are shown

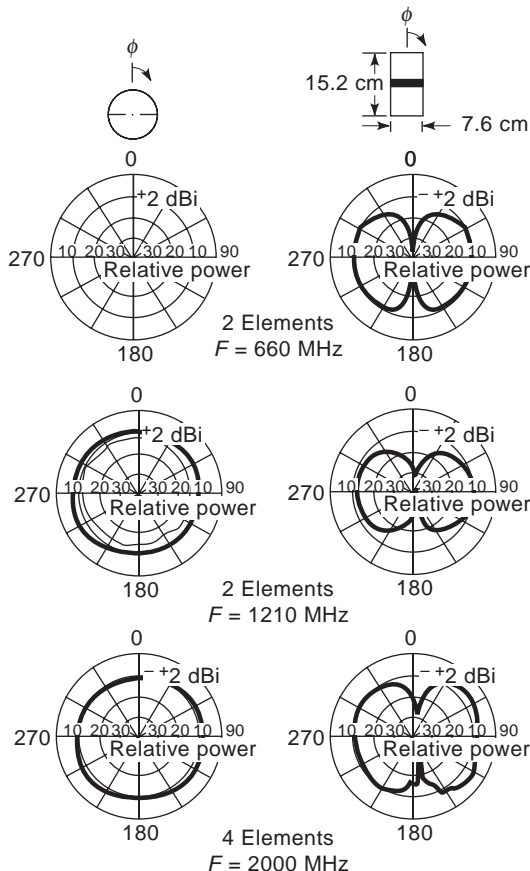

Figure 13. Radiation patterns of a 7.6-cm DFES antenna mounted on a cylinder. (After Ref. 28.)

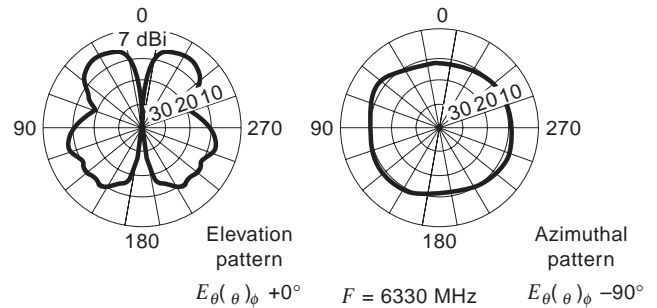

Figure 14. Radiation patterns of four-element edge slot antenna mounted on conical base. (After Ref. 28.)

in Fig. 14. The DFES antenna is a versatile and useful radiator. Because the azimuthal symmetric radiation pattern can be obtained at any desired frequency within a very wide range, system designers are not restricted in their choice of operating frequency. Also, DFES antennas can be integrated into a variety of structures because their shape can be varied to conform to the body and the available space.

2.3. Microstrip Wraparound Antennas

Microstrip wraparound antennas consisting of continuous metal strips that wrap around missiles, rockets, and satellites can provide omnidirectional coverage. Various forms of such antennas are described in Refs. 30–34. Munson [30] proposes a continuous radiator for linear polarization, as shown in Fig. 15, which shows that the microstrip feed network is a parallel (or corporate) feed network where two-way power splits are equal phase to all of the feedpoints. The number of power divisions can be 2, 4, 8, 16, and so on. The specific number of feeds and power divisions required is dictated by the microstrip radiator. The number of feedpoints N_F must exceed the number of wavelengths in the dielectric in the L direction (i.e., N_F). The following design relations can be used for the antenna shown in Fig. 15:

$$\lambda = \frac{\lambda_0}{\sqrt{\epsilon_r}} \quad (2)$$

$$w = \frac{\lambda_0}{2\sqrt{\epsilon_r}} = \frac{\lambda}{2} \quad (3)$$

$$L = \pi D \quad (4)$$

$$L_D = \frac{L(\epsilon_r)^{1/2}}{\lambda_0} \quad (5)$$

$$N_F > L_D \quad (6)$$

$$\text{With } \lambda_0 = \text{wavelength in free space} \quad (7)$$

The pattern coverage of the omnidirectional antenna shown in Fig. 15 depends on the diameter of the missile. A

Figure 15. Microstrip wraparound antenna. (After Ref. 30.)

typical measured E -plane pattern of a wraparound antenna mounted on an 8-in. (203-mm) cylinder given in Ref. 31 is reproduced in Fig. 16. The limiting factor in the omnidirectional coverage is a hole at the tip and tail of the missile that gets narrower as the diameter of the missile increases.

Reference 33 studies radiation patterns of wraparound microstrip antenna on a spherical body for different radii of the conducting sphere, frequencies, dielectric constant, and thickness of the dielectric. Specifically, the antenna studied consists of a metal strip of width d wrapped around a conducting sphere of radius a covered with a dielectric substrate of chosen thickness d . A φ -symmetric transverse electromagnetic mode of excitation is used. The parameter d is kept equal to half a wavelength (λ) inside the dielectric for constructive interference to occur in the

Figure 16. Measured E -plane pattern of the 8-in. (203-mm) wraparound microstrip antenna. The antenna pattern is a figure of revolution about the missile axis. (After Ref. 31.)

broadside direction. The following comments summarize the findings of the investigation reported in Ref. 33:

1. Radiation patterns are almost independent of the pressure of the patch when the radius of the sphere is much larger than the strip width.
2. The larger the radius of the sphere ($a \gg \lambda_0$), the better the omnidirectional pattern.
3. The dielectric constant ϵ_r does not have significant influence on the pattern shape. The radiation intensity tends to increase with increase of the dielectric constant.
4. The shape of the radiation patterns remains almost unchanged for different substrate thickness (h) for $h \ll \lambda_0$. However, sidelobe levels increase with increase of ϵ_r .

Radiation patterns of rectangular microstrip patches arrayed circumferentially on a circular cylinder (wrap-around array) have been computed in Ref. 34. Both axial and circumferential patches, using axial and circumferential modes of excitation, respectively, have been used. In general, it has been found that the number of circumferential patches required for a given ripple in the gain pattern is considerably less than that required in the axial case, thus simplifying the feed network for the former case. Results given in Ref. 34 compared favorably with reported measurements.

2.4. A Patch Array for Aircraft

A patch array designed for an aircraft to satellite communication link is described by Sanford [35] and is shown in Fig. 17. Eight patches are mounted together with the phase shifting and feeding circuitry to scan the beam in the elevation direction. Designed for operation at 1.5 GHz, the array, including the radome, is 3.6 mm thick. Element phasing was optimized for maximum multipath rejection at low scan angles and to account for the curvature of the mounting surface. Each element was pointed in a different direction and has an inherent phase error relative to the center elements. A digital computer was used to determine how the design parameters actually affect the performance of the array. The spacing of the array elements must be greater than 0.32λ (in free space) because the physical size of the radiating element on Teflon fiberglass requires thin space. The spacing required to prevent the

Figure 17. Conformal array for aircraft application. (After Ref. 35.)

formation of grating lobes is given by

$$D \leq \frac{\lambda}{1 + \sin \theta} \quad (8)$$

where D is the separation distance between the patch element, λ is the wavelength in free space, and θ is the maximum beamsteering angle. For a 50° maximum steering angle, D must be less than 0.57λ .

2.5. Concentric Microstrip Ring Arrays

Bhattacharyya and Garg [36] describe the design of a concentric annular ring microstrip antenna array that can be excited by means of a single feed by interconnecting two consecutive rings with an impedance transformer. The feasibility of such an antenna is based on the observation that annular rings with different mean radii can be designed to resonate at the same frequency for the TM_{12} mode. An impedance bandwidth of about 5% for $VSWR \leq 2$ has been reported in Ref. 36. It has been found possible to control the principal plane patterns for concentric arrays independently of each other by appropriately designing the feed system.

Saha-Misra and Chowdhury [37] describe electromagnetically fed concentric microstrip ring arrays using the log-periodic principle that have been reported to have increased impedance and radiation pattern bandwidths. Specifically, circular, square, and triangular concentric rings have been investigated. Generally, these antennas work at multiple bands of frequencies with some bands having larger bandwidths than standard microstrip antennas. With a nonuniformly spaced concentric annular ring array, almost 20% bandwidth for $VSWR \leq 2$ has been reported. A planar, wideband feed for a slot spiral antenna has been described by Nurnberger and Volakis [38]. The antenna has been developed for operation at very high frequency (VHF) frequencies. In contrast to most traditional printed spiral antenna designs, the one reported in Ref. 38 incorporates a completely planar spiral microstrip balun feed, thereby making it attractive for a variety of conformal applications.

3. CONFORMAL ARRAYS

Antenna arrays conforming to a nonplanar surface are suitable and may even be a requirement for a number of applications. For example, phased arrays of flush-mounted elements conformally mounted on the surface of an aircraft or missile reduce the aerodynamic drag and hence are preferable. Also, in some cases a nonplanar array surface may provide some natural advantage for broad-beam coverage in space. Spherical, cylindrical, and conical arrays have been developed for ground, airborne, and missile applications. We shall consider here the class of conformal arrays where the radiating surface is nonplanar with a radius of curvature large compared to the operating wavelength. Conformal arrays that are highly curved are generally difficult to design because of the following reason [1,3,4,8]:

1. Array elements point in different directions, and so it is often necessary to switch off those elements that radiate primarily away from the desired direction of radiation. This, in turn, requires more sophisticated switching mechanisms for activation of elements.
2. The fact that element patterns cannot be factored out of the total radiation pattern makes the analysis and synthesis of such antennas more complicated.
3. Mutual coupling effects can be very severe and difficult to ascertain.
4. Nonplanar arrangement of elements may give rise to severe cross-polarization effects.

3.1. Spherical Arrays

Certain applications require phased arrays capable of steering the beam over a complete hemisphere. For this requirement a spherical array surface seems to provide some natural advantage for beam steering. Schrank [39] discusses the manner in which an array of radiating elements placed on a sphere provides a natural configuration for obtaining hemispherical coverage with nearly identical highly directive beams. A spherical phased array consisting of circularly polarized flat spiral antenna elements has been developed by Sengupta et al. [40,41]. Theoretical design and other considerations are given in Ref. 42, and experimental fabrication and results are given in Ref. 41. As described in Ref. 40, a special element distribution was obtained from the consideration of icosahedron geometry resulting in a best possible uniformity of element spacing. It was found that the array could operate with widely spaced elements. The special element distribution developed for this purpose considerably suppressed the grating lobes in the pattern and thereby made the array significantly broadband. Figure 18 shows the icosahedron geometry of element locations on a spherical surface. The choice of circularly polarized elements made the antenna beam retain its circular polarization fairly well over the entire range of beam steering directions [39,40]. Experimental results given in Ref. 41 demonstrate the capability of a spherical array of 16 flat spiral antennas over a frequency range of 0.6–3 GHz. The work reported in Ref. 41 used manual control of phase and illuminated aperture area; consequently, the results obtained were limited in scope. However, with the availability of modern sophisticated

Figure 18. Icosahedron geometry of element locations. (After Ref. 39.)

computer control mechanisms, it seems that such spherical arrays could provide almost complete hemispherical phased coverage over a broad band.

3.2. Cylindrical Arrays

Conformal elements such as microstrips and slots arrayed around the circumference of large metal cylinders have been used to obtain omnidirectional pattern coverage. Such coverage may also be obtained with the help of wrap-around antenna, as discussed earlier. References 42–46 show that an array of slots equally spaced around the circumference of a cylinder can produce a pattern with very low ripple. Crosswell and Knop [43] have obtained extensive numerical data using realistic patterns for slots on perfectly conducting planes. In such arrays the design parameters are the numbers of elements, radiating elements, and feed network. The number of elements is chosen to provide a nearly omnidirectional pattern; the minimum number of elements is determined by the allowed amplitude ripple. The evaluation of the amplitude ripple can be given in terms of the fluctuation, which is defined as the ratio of maximum $|F|$ to minimum $|F|$, where F is the total far-field pattern of an S -element circular array and is given by [42]

$$F = S \sum_{n=0}^N A_n (-j)^n \frac{d^n}{dz^n} [J_0(z) + 2(j)S J_S(z) \cos S\phi] \quad (9)$$

where $J_S(z)$ is the Bessel function of the first kind of order S , $z = k_0 a \sin \theta$; k_0 is the free-space wavenumber; a is the radius of the circular array; θ, ϕ are the usual coordinates; the z axis is the axis of the cylinder; and $N \leq S$.

The preceding expression assumes that the single element pattern $f(\phi^1)$ can be expressed by a Fourier cosine series

$$f(\phi') = \sum_{n=0}^{\infty} A_n \cos^n \phi' \quad (10)$$

A practical single-element pattern can be approximated by

$$f(\phi') = \begin{cases} \frac{1 + \cos \phi'/2}{2} \\ \frac{2 + 3 \cos \phi' + \cos 2\phi'}{6} \end{cases} \quad (11)$$

Pattern fluctuations as a function of size of cylinder and number of elements for the preceding two single-element patterns are given in Ref. 43. Cylindrical phased arrays, where selected sections are illuminated to provide a beam in a certain direction, are sometimes found advantageous to use for some requirements. Sophisticated types of electronic switches for such circular arrays are based on a concept originally proposed by Shelton [45] and developed by Sheleg [46]. The antenna uses a Butler matrix-fed circular array with fixed phase shifters to execute current modes around the array and variable phase shifters to provide continuous scanning of the radiated beam over

Figure 19. Coordinates for continuous cylindrical sheet of vertical current elements.

360°. The operation was experimentally demonstrated with a 32-dipole circular array.

The principles involved in scanning a multimode array are readily seen by considering a continuous distribution of current, as described by Sheleg [46]. Figure 19 shows the configuration of a continuous cylindrical sheet of vertical current elements around a vertical conducting cylinder of radius a . Referring to Fig. 19, consider a current distribution $I(x)$ to be the sum of a finite number of continuous current modes $I_n e^{jn\alpha}$ with $-N \leq n \leq N$. The radiation pattern for $I(x) = I_n e^{jn\alpha}$ is then given by

$$E(\phi) = \sum_{n=-N}^N C_n e^{jn\phi} \quad (12)$$

where C_n are complex constants given by

$$C_n = 2\pi K j^n I_n J_n \left(\frac{2\pi a}{\lambda} \right) \quad (13)$$

where K is a constant, λ is the wavelength of operation, and J_n is the Bessel function defined earlier. If, in the antenna being considered, it is desired that the pattern mode be equal in magnitude and be in phase at $\phi = 0$, the excitation of the current modes must be

$$I_n = \frac{1}{2\pi K j^n J_n \left(\frac{2\pi a}{\lambda} \right)} \quad (14)$$

Under this condition, the radiation pattern is given by

$$E(\phi) = \sum_{n=-N}^N e^{jn\phi} = \sin \left(\frac{2N+1}{2} \phi \right) / \sin \frac{\phi}{2} \quad (15)$$

If the phase difference between the adjacent modes is ϕ_0 (i.e., multiply I_n by $e^{-jn\phi_0}$), the resultant radiation

Figure 20. Schematic diagram of scanning multimode array. (After Ref. 46.)

pattern is

$$E(\varphi) = \frac{\sin[(2N+1)(\varphi - \varphi_0)/2]}{\sin[(\varphi - \varphi_0)/2]} \quad (16)$$

which indicates a beam in the φ_0 direction. As described by Sheleg [46], it was possible to excite simultaneously and independently all the modes both positive and negative n , from 0 to $N/2$, by connecting a single ring on N elements to the outputs of a Butler matrix. A schematic diagram of a scanning multimode array is shown in Fig. 20. The desired phase and amplitude distribution is established over the inputs of the Butler matrix by fixed phase shifts and a corporate structure. Once the pencil-beam pattern is formed at some azimuth angle, it is scanned just as in a linear array; the mode amplitudes are held fixed and a linear phase progression is set up on the mode inputs by operating the variable phase shifters.

3.3. Conical Array

Kummer [1] discusses a number of difficulties associated with antenna pattern synthesis utilizing conical surfaces. An array on a conical surface generally looks different at different aspect angles; also, the geometry is such that all elements do not contribute equally to the main beam direction, thereby causing cross-polarization problems. In spite of this, for their obvious applications to missile and other similar vehicles, conical arrays have been considered for conformal array development. Theoretical and experimental investigations of various aspects of conical arrays are discussed in Refs. 15, 47, and 48. The experimental studies of Munger et al. [48] provide some data on the characteristics of several conical arrays. Balzano and Dowling [47] developed an effective method to evaluate the pattern of elements in a conical array. The method takes into account the mutual coupling between array

elements and aperture matching conditions. By properly matching the array aperture, the radiation in a certain direction can be substantially increased, thus allowing the designer to meet specific design goals in the application of conical arrays to airborne or missileborne systems. Moreover, it has been shown that in some cases, the element pattern can be approximated by much simpler planar and cylindrical models.

CONFORMAL MAPPING TECHNIQUES

ERDEM YAZGAN

VOLKAN AKAN

Hacettepe University

Beytepe, Ankara, Turkey

1. INTRODUCTION

Conformal mapping (MP) is the transformation of a region defined in a complex plane to a distinct region in the reference plane of another complex variable by using a proper transformation function. Since 1867, conformal mapping techniques (CMTs) have been used by many mathematicians and engineers. Many engineering applications such as boundary value problems and electromagnetic field problems in which the components of the fields are confined in a defined plane can be tackled by using CMTs. Here the crucial point is that a complex and cumbersome structure can be transformed into a simpler and well-known one. When the transformation is done, an important characteristic is retained: the angle between lines of flux and equipotential lines or transversity of fields (e.g., electric and magnetic fields). Also, there is a wide area for CMT applications such as heat, fluid flow problems, and electromagnetic problems. According to the known general literature as reviewed in detail by Schinzinger [1]. Routh [2] has transformed vibrating membrane structure into simpler configurations, and in 1900. Carter [3] published a note on airgap and interpolar induction as the first application of conformal mapping to a real engineering problem. After then, usage of CMTs began to spread in

very large areas such as wave propagation between irregular boundaries [4–7], acoustic channels [8], radio propagation around Earth [9,10], reflection from waveguide corners [11], calculation of quasistatic parameters of coplanar striplines, coplanar waveguides, and microstrip lines, electrooptical applications, and also resonance frequency calculations of microstrip patch antennas and resonators [12–34].

Potential and flux functions are defined below with related mathematical equations, followed by a detailed definition and discussion of the basic properties of conformal mapping.

In Section 4, the Schwarz–Christoffel transformation, which is used widely for quasistatic models, is defined. Finally, examples of CM applications in electromagnetic problems are illustrated and explained.

2. POTENTIAL FUNCTION AND FLUX FUNCTION AS CONJUGATE FUNCTIONS

The basic mathematical definitions are presented below in order to introduce the potential function and the flux function as conjugate functions.

If two complex numbers are considered

$$\begin{aligned} z &= x + jy \\ r &= x - jy \end{aligned} \tag{1}$$

where

$$j = \sqrt{-1}$$

it is very simple to show that z and r satisfy Laplace equation. The real parts and the imaginary parts of these numbers satisfy the Laplace equation.

If $F = u + jv$ is a function of $z = x + jy$ as

$$\begin{aligned} F &= G(x + jy) \\ F &= G(z) \end{aligned} \tag{2}$$

This can be rewritten as

$$\begin{aligned} \frac{\partial F}{\partial x} &= \frac{\partial G(z)}{\partial z} \frac{\partial z}{\partial x} \\ \frac{\partial F}{\partial x} &= G'(z) \end{aligned} \tag{3}$$

Then

$$\frac{\partial^2 F}{\partial x^2} = G''(z) \tag{4}$$

and for the imaginary part

$$\begin{aligned} \frac{\partial F}{\partial y} &= \frac{\partial G(z)}{\partial z} \frac{\partial z}{\partial y} \\ \frac{\partial F}{\partial y} &= jG'(z) \end{aligned} \tag{5}$$

and

$$\begin{aligned} \frac{\partial^2 F}{\partial y^2} &= j \frac{\partial G'(z)}{\partial z} \frac{\partial z}{\partial y} \\ \frac{\partial^2 F}{\partial y^2} &= j^2 \frac{\partial G'(z)}{\partial z} \\ \frac{\partial^2 F}{\partial y^2} &= -G''(z) \end{aligned} \tag{6}$$

From Eqs. (4) and (6) one can obtain

$$\frac{\partial^2 F}{\partial x^2} + \frac{\partial^2 F}{\partial y^2} = 0 \tag{7}$$

Examination of these in terms of u and v yields

$$\frac{\partial^2 F}{\partial x^2} = \frac{\partial^2 u}{\partial x^2} + j \frac{\partial^2 v}{\partial x^2} \tag{8}$$

and

$$\frac{\partial^2 F}{\partial y^2} = \frac{\partial^2 u}{\partial y^2} + j \frac{\partial^2 v}{\partial y^2} \tag{9}$$

If Eqs. (8) and (9) are summed, and using Eq. (7), the following equation is obtained:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + j \left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) = 0 \tag{10}$$

Equation (10) shows that

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0 \tag{11}$$

and

$$\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = 0 \tag{12}$$

From these equations it can be seen that real and imaginary parts of any function of a complex variable $x + jy$ satisfy Laplace's equation.

Briefly, if F is a function of z where $F = u + jv$ and $z = x + jy$, this leads to

$$\nabla^2 u = 0, \quad \nabla^2 v = 0 \tag{13}$$

where \mathbf{u} is the *potential function* and the conjugate function \mathbf{v} is the *flux function*.

The relations between potential and flux functions, known as the *Cauchy–Riemann* equations, are very important.

Again

$$F = u + jv \quad (F = G(z))$$

$$z = x + jy$$

and

$$\frac{\partial F}{\partial x} = \frac{\partial u}{\partial x} + j \frac{\partial v}{\partial x} \tag{14}$$

Also, one can write

$$\frac{\partial F}{\partial x} = \frac{\partial G(z)}{\partial z} \frac{\partial z}{\partial x}$$

$$\frac{\partial F}{\partial x} = \frac{\partial G(z)}{\partial z} \tag{15}$$

from which

$$\frac{\partial u}{\partial x} + j \frac{\partial v}{\partial x} = \frac{\partial G(z)}{\partial z} \tag{16}$$

and

$$\frac{\partial F}{\partial y} = \frac{\partial u}{\partial y} + j \frac{\partial v}{\partial y}$$

$$\frac{\partial F}{\partial y} = \frac{\partial G(z)}{\partial z} \frac{\partial z}{\partial y}$$

$$\frac{\partial F}{\partial y} = j \frac{\partial G(z)}{\partial z}$$

so

$$\frac{\partial u}{\partial y} + j \frac{\partial v}{\partial y} = j \frac{\partial G(z)}{\partial z} \tag{17}$$

If Eq. (17) is multiplied by j and then summed with Eq. (16), the following equation is obtained:

$$\left(\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y}\right) + j\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) = 0 \tag{18}$$

Then

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \tag{19}$$

$$\frac{\partial v}{\partial x} = -\frac{\partial u}{\partial y} \tag{20}$$

Equations (19) and (20) are Cauchy–Riemann equations. It must be emphasized that these equations are crucial points of conjugate functions.

3. CONFORMAL MAPPING

After explaining the conjugate functions for CM, we can now define conformal mapping. Kreyszig [35] defined CM as “The mapping defined by an analytic function $f(z)$ is conformal, except at critical points, that is, points at which the derivative $f'(z)$ is zero.” In other words, if the function is analytic at point z and $f'(z) = df/dz \neq 0$, then the transformation is said to be conformal. The most important property of CM is illustrated in Fig. 1.

As seen in Fig. 1, following CM, curves 1 and 2 form the same angle ψ , the angle between their oriented tangents at the intersection point. Note that this is the same angle in both magnitude and direction. One also determine whether a mapping function is analytic using the Cauchy–Riemann equations. If these equations [(19) and (20)] are satisfied by a complex function, this complex function is analytic.

As mentioned in Ref. 1 for CM, scaled factors must be taken into account. For this case, examination of infinitesimal displacements between p and w planes, where $p = x + jy$ and $w = \phi + j\theta$, will be beneficial:

$$d\phi \leftrightarrow dl_\phi \text{ or } dl_\phi = h_\phi(\phi, \theta)d\phi \tag{21}$$

$$d\theta \leftrightarrow dl_\theta \text{ or } dl_\theta = h_\theta(\phi, \theta)d\theta \tag{22}$$

For the static case we can use constant lines F and V (see Fig. 2) as flux lines and equipotentials, and for wave propagation E and H fields can be parallel to these constant lines. As shown in Ref. 1 for relating curl and divergence between planes p and w , regardless of time, the curvilinear squares are helpful. So in p plane dl_ϕ, dl_θ is written as $d\phi, d\theta$, where $dl_\phi = dl_\theta = dp/\sqrt{2}$ and $d_\phi = d_\theta = dw/\sqrt{2}$:

$$h_\phi = \left|\frac{dl_\phi}{d\phi}\right| = h_\theta = \left|\frac{dl_\theta}{d\theta}\right| = h = \left|\frac{dp}{dw}\right| \tag{23}$$

Here h is a function of p or w and h can be written as

$$h = \left|\frac{dp}{dw}\right| = \left|g'_{w-p}(w)\right| \tag{24}$$

$$\frac{1}{h} = \left|\frac{dw}{dp}\right| = \left|g'_{p-w}(p)\right| \tag{25}$$

It must be noted that CM requires that scaling factors be equal in all directions because of the Cauchy–Riemann

Figure 1. Conformal mapping for curves 1 and 2 and their images after transformation.

Figure 2. Transformation between p and w planes.

equations. In order to obtain equal scaling factors in all directions, m is introduced instead of h as in Ref. 1. For instance, transformation from the Cartesian coordinates to the cylindrical coordinates r, ϕ, z (not the same as ϕ with $w = \phi + j\theta$ plane) is $x = r \cos \phi$ $y = r \sin \phi$ $z = z$ $h_r, h_\phi,$ and h_z are expressed as $h_r = 1, h_\phi = r$ and $h_z = 1$. Now, let's write $m_r, m_\phi,$ and m_z such that m directly assigns for $d\phi$ a factor $1/r$:

$$m_r = h_r, \quad m_\phi = \frac{h_\phi}{r} \quad (26)$$

$$m_z = h_z$$

If axially uniform configuration is taken into account, then

$$m_z = 1 \quad (27)$$

and

$$m_r = m_\phi = m \quad (28)$$

This is also the general case for any coordinate transformations in CM. This generalization is shown in Table 1.

Table 1. Field Equations

Equation	p Plane, with x, y, z as Coordinates	w Plane, with ξ, η, ζ as coordinates
Metric coefficient	$m_x = 1$ $m_y = 1$ $m_z = 1$	$m_\xi = m$ $m_\eta = m$ $m_\zeta = 1$

Source: Ref. 1.

If Table 1 is examined carefully, an important point is seen, namely, that the field components can be rearranged as follows after transformation:

$$\begin{aligned} E_\phi &= mE_\xi, & H_\phi &= mH_\xi \\ E_\theta &= mE_\eta, & H_\theta &= mH_\eta \end{aligned} \quad (29)$$

where $\phi = \xi, \theta = \eta,$ and $q = \zeta$. It is understood (see Fig. 3) that the effect of transformation has been reflected to fields and a new set of coordinates have been formed as ϕ, θ, q . As demonstrated in Ref. 1, the new medium obtained has characteristics $\sigma, \mu,$ and ϵ that remain unchanged in the w plane, but along the z direction they are seen as (see also Table 1)

$$\sigma_z = m^2 \sigma, \quad \mu_z = m^2 \mu, \quad \epsilon_z = m^2 \epsilon_z \quad (30)$$

On the basis of this equation, the new medium introduced is anisotropic. Moreover, it can be inhomogeneous if m is a function of coordinates [$m_{(x,y)}$ or $m_{(\phi,\theta)}$]. Some complexities occur because for this reason. These complexities can be resolved by simplification of the boundary. In addition,

Figure 3. Demonstration of changing fields and coordinates after transformation.

depending on the features of m , some approximations can be used in many applications.

If wave propagation is considered, one can write again the equations in phasor form as shown in Table 1. They can also be written for TE, TM, and TEM cases. Table 2 shows these equations and also includes wave equations.

If Table 2 is examined carefully, the vanishing anisotropy (note that there is no change along the z direction) can be seen, and this leads to a simplification.

In many problems the main purpose is to find the characteristic impedance of a transmission line or propagation constant. For these cases, application of local boundary conditions will be adequate. There is no need to obtain the entire solution for the wave propagation. As is known, m is generally variable but an effective m can be used in such problems.

4. SCHWARZ-CHRISTOFFEL TRANSFORMATION

The Schwarz-Christoffel transformation opens out the interior of a polygon in a defined plane into half of another plane, obtaining a simpler structure with a known solution. It's a powerful method and is often used in transmission-line problems (coplanar stripline and waveguide). This method involves a procedure between two structures

(the original structure and a transformed simpler one) in order to obtain the transformation equation. As shown in Fig. 4, the polygon has been opened between points A and B . One must note that the opening point is not one of the corners. If opening is required at a corner, then this corner is not taken into account for transformation. Here, the conformal transformation equation is

$$w = f(z) \tag{31}$$

The transformation equation is obtained by using the well-known relation [36]

$$\frac{dw}{dz} = M(z - x_1)^{(\alpha_1/\pi)-1} (z - x_2)^{(\alpha_2/\pi)-1} (z - x_3)^{(\alpha_3/\pi)-1} \dots \tag{32a}$$

where M is a complex constant, x_n are real number representing points on the x axis of the z plane in Fig. 4b and satisfying $x_1 < x_2 < \dots < x_{N-1} < x_N$, and α_N are interior angles of the polygon in Fig. 4a. Note that the number of factors must be equal to the number of sides of the polygon plus constant M (as a factor). Integrating Eq. (32a) with

Figure 4. The Schwarz–Christoffel transformation, (a) polygon in w plane; (b) transformed structure in z plane.

respect to z gives

$$w = f(z) = M \int \prod_{n=1}^N (z - x_n)^{\alpha_n/\pi - 1} dz + Q \quad (32b)$$

where Q is an arbitrary constant. It determines the position of the polygon in the w plane. This mapping is known as the *Schwarz–Christoffel transformation*. Briefly, as seen from Fig. 4, the interior region of the polygon in the z plane is transformed into the upper half-plane in the p plane. Afterward, using another transformation, the simpler structure can be obtained.

5. APPLICATIONS OF CM

Some CM applications in electromagnetic problems are given below, such as effective resistance calculation, calculation of quasistatic parameters of asymmetric coplanar waveguide, elliptical and cylindrical striplines, calculation of resonant frequency of rectangular patch antennas, Earth-flattening procedures for radiowave propagation, and, finally, bent rectangular waveguides.

5.1. Effective Resistance Calculation of a Current Path between Two Planar Electrodes

In the example given by Gibbs [36], two electrodes are semiinfinite (longitudinally). Also, between these electrodes there exists a known voltage value. Here the problem is to find the effective resistance of the current path per unit length. This problem is illustrated in Fig. 5.

Figure 5. Cross-sectional view of semiinfinite conductors in z plane.

After transformation the region shown in Fig. 6 is obtained. The points a' , b' , c' , and d' are obtained via the Schwarz–Christoffel transformation relation

$$\begin{aligned} \frac{dw}{dz} &= M(z - a)^{\alpha_{a'}/\pi - 1} \\ &\times (z - 1)^{\alpha_{b'}/\pi - 1} \\ &\times (z + 1)^{\alpha_{c'}/\pi - 1} \\ &\times (z - d)^{\alpha_{d'}/\pi - 1} \end{aligned} \quad (33)$$

where

$$\begin{aligned} d &= -a \text{ and } a = \frac{1}{k} \\ \alpha_{a'} &= \alpha_{b'} = \alpha_{c'} = \alpha_{d'} = \frac{\pi}{2} \end{aligned} \quad (34)$$

so

$$\begin{aligned} \frac{dw}{dz} &= M(z - a)^{-(1/2)} \\ &\times (z - 1)^{-(1/2)} \\ &\times (z + 1)^{-(1/2)} \\ &\times (z + a)^{-(1/2)} \end{aligned} \quad (35)$$

and

$$w = M \int \frac{dz}{(z^2 - 1)^{1/2}(z^2 - a^2)^{1/2}} \quad (36)$$

Figure 6. Mapping of electrodes using the Schwarz–Christoffel transformation.

Then, letting $k = 1/a$, the integral can be formed as follows

$$w = C \int \frac{dz}{(1 - z^2)^{1/2}(1 - k^2z^2)^{1/2}} \quad (37)$$

where $C = -kM$. Equation (37) is the elliptic integral. From definition of the complete elliptic integral and its complementary value, the following equations can formulated:

At

$$b' \quad w = \int_0^1 \frac{dz}{(1 - z^2)^{1/2}(1 - k^2z^2)^{1/2}} = K$$

At

$$\begin{aligned} a' \quad w &= \int_0^{1/k} \frac{dz}{(1 - z^2)^{1/2}(1 - k^2z^2)^{1/2}} \\ w &= \int_0^1 \frac{dz}{(1 - z^2)^{1/2}(1 - k^2z^2)^{1/2}} \\ &+ j \int_1^{1/k} \frac{dz}{j(1 - z^2)^{1/2}(1 - k^2z^2)^{1/2}} \\ w &= K + jK' \end{aligned} \quad (38)$$

Also, points c' and d' can be expressed as

$$\begin{aligned} w &= -K \quad \text{for } c' \\ w &= -K + jK' \quad \text{for } d' \end{aligned} \quad (39)$$

If points a , b , c , and d are chosen as $a = 2$, $b = 1$, $c = -1$, and $d = -2$, then, from $1/k = 2$, we see that k is equal to 0.5.

In the w plane the resistance between $|b'a'|$ and $|c'd'|$ per unit length is

$$R = \rho \frac{|c'b'|}{|b'a'|} \quad (\Omega) \quad (40)$$

The effective resistance between electrodes is invariant under CM, so

$$\begin{aligned} R &= \rho \frac{|c'b'|}{|b'a'|} \\ R &= \rho \frac{2K}{K'} \quad (\Omega) \end{aligned} \quad (41)$$

where K is the complete elliptic integral of first kind and K' is complementary to K . For $k = 0.5$, we obtain

$$R = 1.56 \times \rho(\Omega) \quad (42)$$

The application of CM has been shown above for the calculation of effective resistance.

Figure 7. The original ACPW.

5.2. Calculations of quasistatic parameters of asymmetric coplanar waveguide

In this section we consider another example, which has been studied via the quasi-TEM approximation [24]. In this study, the characteristic impedance and the effective permittivity relations of ACPW (asymmetric coplanar waveguide) have been derived by the authors. The cross section of ACPW is shown in Figs. 7 and 8.

In Fig. 7 dielectric–air interfaces are assumed to be magnetic walls. Figure 8 shows a detailed version of Fig. 7 (coordinates have been defined).

Using the method of superposition of partial capacitances, analytical expressions for the total line capacitance C , the characteristic impedance Z_0 , and the effective dielectric constant ϵ_{eff} of quasi-TEM lines can be obtained. We can begin with calculation of total capacitance per unit length:

$$\begin{aligned} C &= C_a + C_d \\ &= C_a + \epsilon_r C_{0\epsilon_r} \\ &= (C_a + C_{0\epsilon_r}) + \epsilon_r C_{0\epsilon_r} - C_{0\epsilon_r} \\ &= C_0 + C_{0\epsilon_r}(\epsilon_r - 1) \end{aligned} \quad (43)$$

Here, C_a is the air capacitance, C_d refers to capacitance of the dielectric part, $C_{0\epsilon_r}$ refers to capacitance of the dielectric part without substrate, and C_0 refers to summation of capacitances C_a and $C_{0\epsilon_r}$. Now we can calculate C_0 by first transforming the upper half-plane of Fig. 8 into the rectangular region as shown in Fig. 9. This mapping was done by the Schwarz–Christoffel transformation, the integral equation of which is

$$W = \int_{t_0}^t \frac{dt}{\sqrt{(t - t_1)(t - t_2)(t - t_3)(t - t_4)}} \quad (44)$$

Figure 8. Cross section of the original ACPW in t plane.

Figure 9. Transformation into a parallel-plate capacitor.

Then C_0 is given by

$$C_0 = 2\epsilon_0 \frac{K(k_0)}{K(k'_0)} \quad (45)$$

and

$$k_0 = \sqrt{\frac{1 + [(g_1 + g_2)/w]}{[1 + (g_1/w)][1 + (g_2/w)]}} \quad (46)$$

As a second step, the calculation of the dielectric capacitance is given.

Since the dielectric part of the structure is finite, we first transform the dielectric region (shaded area) in Fig. 8 is transformed into the lower-half region of Fig. 10 using the mapping function

$$z = \sinh\left(\frac{\pi t}{2h}\right) \quad (47)$$

We can then transform the lower half-plane shown in Fig. 10 into the parallel-plate capacitor using the Schwarz-Christoffel transformation in the same way

Figure 10. Intermediate mapping for the dielectric region (into z plane).

as we did earlier. The integral equation for this transformation is

$$w = \int_{z_0}^z \frac{dz}{\sqrt{(z - z_1)(z - z_2)(z - z_3)(z - z_4)}} \quad (48)$$

Then

$$C_{0\epsilon_r} = \epsilon_0 \frac{K(k_d)}{K(k'_d)} \quad (49)$$

where

$$k_d = \sqrt{\frac{2(G_1 + G_2)/W}{(1 + G_1/W)(1 + G_2/W)}} \quad (50)$$

and

$$\begin{aligned} W &= \sinh\left(\frac{\pi w}{4h}\right) \\ G_1 &= \sinh\left(\frac{\pi(w + 2g_1)}{4h}\right) \\ G_2 &= \sinh\left(\frac{\pi(w + 2g_2)}{4h}\right) \end{aligned} \quad (51)$$

Now, the total line capacitance relation per unit length can be written

$$\begin{aligned} C &= C_0 + C_{0\epsilon_r}(\epsilon_r - 1) \\ C &= 2\epsilon_0 \frac{K(k_0)}{K(k'_0)} + \epsilon_0(\epsilon_r - 1) \frac{K(k_d)}{K(k'_d)} \end{aligned} \quad (52)$$

and the effective permittivity is given by

$$\epsilon_{\text{eff}} = \frac{C}{C_0} = 1 + \frac{\epsilon_r - 1}{2} \frac{K(k_d)}{K(k'_d)} \frac{K(k'_0)}{K(k_0)} \quad (53)$$

and as seen from Eq. (53), the filling factor is

$$q = \frac{K(k_d)}{K(k'_d)} \frac{K(k'_0)}{K(k_0)} \quad (54)$$

Also, the characteristic impedance can be calculated easily by using the quasistatic approximation as follows:

$$Z_0 = \frac{60\pi}{\sqrt{\epsilon_{\text{eff}}}} \frac{K(k'_0)}{K(k_0)} \quad (55)$$

One must note that the quasi-TEM approximation is valid only at low frequencies. But, because of their dispersion characteristics, CPWs and CPSSs with cross-sectional dimensions that do not exceed the substrate thickness are slightly sensitive to changes in frequency for almost the entire microwave region.

Thus, the accuracy of this method shows good agreement with other methods and experimental results that

^aObtained in Refs. 15 and 24, where $\epsilon_r = 9.9$ and $h = 635$ mm.

are available in the literature. The results can be seen in Table 3.

Having completed these basic planar problems, we now study more complicated geometries such as elliptical and cylindrical transmission lines.

5.3. Calculations of Quasistatic Parameters of Elliptical, Cylindrical, and Asymmetrical Coplanar Striplines

In Fig. 11, a cross section of an elliptical coplanar stripline (ECPS) with infinitely small arc strips on the outer surface of a dielectric substrate (having relative dielectric ϵ_r) is shown. As seen, the two ellipses are given as confocal. Semi-major and semi-minor axes of the elliptical cylinders are $a_1, a_2, b_1,$ and $b_2,$ respectively.

The focal distance of the two confocal elliptical cylinders is given as follows:

$$c = [a_1^2 - b_1^2]^{1/2} = [a_2^2 - b_2^2]^{1/2} \tag{56}$$

In order to transform the ECPS in the ξ plane in Fig. 11 into a cylindrical coplanar stripline (CCPS) in the z plane as shown in Fig. 12, the following formula is used:

$$z = \frac{1}{c}(\xi \mp \sqrt{\xi^2 - c^2}) \tag{57}$$

Figure 11. Cross-sectional illustration of ECPS.

The radii of the cylindrical structure in Fig. 12 are

$$r_1 = \left[\frac{a_1 + b_1}{a_1 - b_1} \right]^{1/2}, \quad r_2 = \left[\frac{a_2 + b_2}{a_2 - b_2} \right]^{1/2} \tag{58}$$

By using the mapping function

$$u = j \ln \frac{z}{r_2} + \frac{\pi}{2} \tag{59}$$

the CCPS is transformed into the asymmetric coplanar striplines (ACPS) with a finite-boundary dielectric substrate on the u plane as seen in Fig. 13.

After the finite boundary substrate ACPS is obtained as shown in Fig. 13, the total capacitance per unit length of this structure is equal to the sum of the free-space capacitance C_0 after replacing the dielectric substrate by air and the capacitance C_d of the substrate having dielectric constant $(\epsilon_r - 1)$ as done in the previous example. Thus, the structure without the substrate in Fig. 13 is transformed into the rectangular region in Fig. 14 using the

Figure 12. Cross-sectional illustration of CCPS.

Figure 13. Cross-sectional illustration of ACPS.

Schwarz–Christoffel transformation as given in Ref. 26. Here

$$W = \int_{u_0}^u \frac{du}{\sqrt{(u - u_3)(u - u_4)(u - u_5)(u - u_6)}} \quad (60)$$

$$C_0 = 2\varepsilon_0 \frac{K(k'_0)}{K(k_0)} \quad (61)$$

and modular k_0 can be written as

$$k_0 = \left[\frac{2s(2s + w_1 + w_2)}{(2s + w_1)(2s + w_2)} \right]^{\frac{1}{2}} \quad (62)$$

Figure 14. Transformation into a parallel-plate capacitor.

$K(k_0)$ is the complete elliptic integral of the first kind with modulus k_0 and $k'_0 = (1 - k_0^2)^{1/2}$.

In order to compute the dielectric capacitance C_d , the dielectric region in Fig. 13 is first transformed into the lower-half region in Fig. 15 by using the mapping function as seen in Ref. 26:

$$t = sn \left(\frac{K(k)}{\pi} \mu, k \right) \quad (63)$$

Then, the structure obtained in Fig. 15 is again mapped into the rectangular region in Fig. 14 using the Schwarz–Christoffel transformation

$$W = \int_{t_0}^t \frac{dt}{\sqrt{(t - t_3)(t - t_4)(t - t_5)(t - t_6)}} \quad (64a)$$

where

$$t_3 = s_t + w_{t2}, \quad t_4 = s_t \quad (64b)$$

$$t_5 = -s_t, \quad t_6 = -s_t - w_{t1}$$

So

$$C_d = \varepsilon_0(\varepsilon_r - 1) \frac{K(k'_d)}{K(k_d)} \quad (65)$$

where

$$k_d = \left[\frac{2t_4(t_3 - t_6)}{(t_3 + t_4)(t_4 - t_6)} \right]^{\frac{1}{2}} \quad (66a)$$

and

$$t_3 = s_t + w_{t2}, \quad t_4 = s_t \quad (66b)$$

$$t_5 = -s_t - w_{t1}$$

After this, the total line capacitance C and the characteristic impedance Z_0 per unit length can be

Figure 15. The intermediate transformation for the dielectric region.

obtained as

$$C = 2\epsilon_0\epsilon_{\text{eff}} \frac{K(k'_0)}{K(k_0)} \quad (67)$$

$$Z_0 = \frac{60\pi}{\sqrt{\epsilon_{\text{eff}}}} \frac{K(k_0)}{K(k'_0)} \quad (68)$$

(a)

(b)

Figure 16. Z_0 and ϵ_{eff} for ECPS and CCPS versus $\theta_1/(\theta_1 + \theta_2)$ [$\epsilon_r = 3.78$, $\theta_2 = 30^\circ$, $(a_2 + b_2)/(a_1 + b_1) = 3$]: (a) characteristic impedance; (b) effective dielectric constant (from Ref. 26).

where the effective permittivity ϵ_{eff} is given by

$$\epsilon_{\text{eff}} = 1 + \frac{\epsilon_r - 1}{2} \frac{K(k_0)}{K(k'_0)} \frac{K(k'_d)}{K(k_d)} \quad (69)$$

The formulation derived is used to see the effect of w , s , h in the variation of ϵ_{eff} and Z_0 of ECPS, CCPS, and ACPS.

Some results for the characteristic impedance and the effective dielectric constants can be seen in Figs. 16a and 16b, where finally, the variation of the characteristic impedance and the effective dielectric constant with respect to $\theta_1/(\theta_1 + \theta_2)$ is seen for ECPS and CCPS, respectively.

5.4. Resonant Frequency Calculation of Rectangular Patch Antennas with Multidielectric Layers

Zhong et al. [31] have reported that the longlasting problem of analyzing rectangular patch antennas with multidielectric layers has been solved (for calculation of resonant frequency) by CMT and the transmission-line model. According to this approach, the microstrip patch antenna is taken up as a microstrip line. In addition, when the quasi-TEM wave propagates in this line, a quasistatic value of ϵ_e or ϵ_{eff} (effective dielectric constant) can be obtained by using CMT [31]. The rectangular patch is shown in Fig. 17. Using the Wheeler transformation [32] the z plane in Fig. 17 is mapped into Fig. 18.

After one transformation and approximation (shown in Figs. 18 and 19, respectively), the quasistatic effective permittivity is obtained as follows

$$\epsilon_e = \epsilon_{r1}\epsilon_{r2} \frac{(q_1 + q_2)^2}{\epsilon_{r1}q_2 + \epsilon_{r2}q_1} + \epsilon_{r3} \frac{(1 - q_1 - q_2)^2}{\epsilon_{r3}(1 - q_1 - q_2 - q_3) + q_3} \quad (70)$$

where q_1 , q_2 , and q_3 are the filling factors, which are defined by the ratio of partial areas S_1 , S_2 , and S_3 to the total area S_c , respectively, as shown in Figs. 18 and 19.

These can be written for $\frac{w}{h} \geq 1$ (wide microstrip line) as

$$q_1 = \frac{S_1}{S_c} = \frac{h_1}{2h_{12}} \left\{ 1 + \frac{\pi}{4} - \frac{h_{12}}{w_e} \times \ln \left[\frac{2w_e}{h_1} \sin \left(\frac{\pi h_1}{2h_{12}} \right) + \cos \left(\frac{\pi h_1}{2h_{12}} \right) \right] \right\} \quad (71)$$

$$q_2 = \frac{S_2}{S_c} = 1 - q_1 - \frac{h_{12}}{2w_e} \ln \left(\frac{\pi w_e}{h_{12}} - 1 \right) \quad (72)$$

$$q_3 = \frac{S_3}{S_c} = 1 - q_1 - q_2 - \frac{h_{12} - v_e}{2w_e} \times \ln \left(\frac{2w_e}{2h_{13} - h_{12} + v_e} \cdot \cos \left(\frac{\pi v_e}{2h_{12}} \right) + \sin \left(\frac{\pi v_e}{2h_{12}} \right) \right) \quad (73)$$

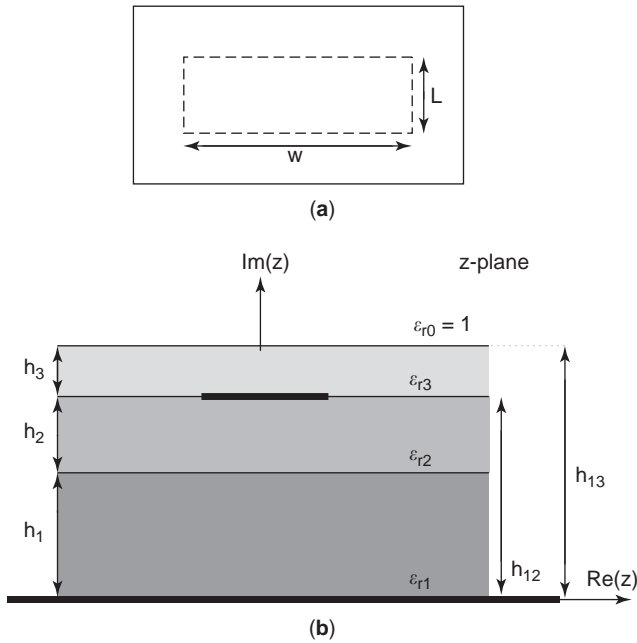

Figure 17. The original structure: (a) top view; (b) cross-sectional view (from Ref. 31).

where the w_e (effective linewidth) and the quantity V_e are given [32] by

$$w_e = w + \frac{2h_{12}}{\pi} \ln \left[17.08 \left(\frac{w}{2h_{12}} + 0.92 \right) \right] \quad (74)$$

$$v_e = \frac{2h_{12}}{\pi} \tan^{-1} \left[\frac{2\pi}{\pi w_e - 4h_{12}} (h_{13} - h_{12}) \right] \quad (75)$$

and ϵ_{eff} can be determined as mentioned by Zhong et al. [31] by

$$\epsilon_{\text{eff}} = \epsilon'_r - \frac{\epsilon'_r - \epsilon_e}{1 + P(f)} \quad (76)$$

This last equation (76) has been developed for a microstrip line on one substrate, but here the multilayer line is

Figure 18. The boundary curves after transformation (from Ref. 31).

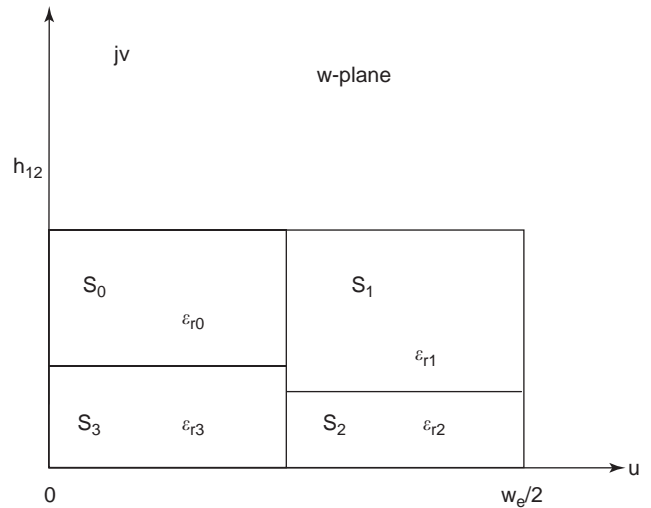

Figure 19. Approximation of the individual dielectric areas in Fig. 18 (from Ref. 31).

taken as a normal line having substrate with ϵ_e and equivalent relative dielectric constant ϵ'_r . The relation between ϵ_e and ϵ'_r is as below

$$\epsilon_e = \frac{1}{2} [\epsilon'_r + 1 + (\epsilon'_r - 1) A] \quad (77)$$

$$A = \left(1 + \frac{12h_{12}}{w} \right)^{-1/2} \quad (78)$$

and

$$\epsilon'_r = \frac{2\epsilon_e - 1 + A}{1 + A} \quad (79)$$

and $P(f)$, which depends on frequency, is given [33] as

$$P(f) = P_1 P_2 [(0.1844 + P_3 P_4) 10 f h_{12}]^{1.5763} \quad (80)$$

in which

$$\begin{aligned} P_1 &= 0.27488 \\ &+ \left[0.6315 + \frac{0.525}{(1 + 0.157 f h_{12})^{20}} \right] \\ &\times u' - 0.065683 \exp(-8.7513 u') \\ P_2 &= 0.33622 [1 - \exp(-0.03442 \epsilon'_r)] \\ P_3 &= 0.0363 \exp(-4.6 u') \\ &\times \left\{ 1 - \exp \left[- \left(\frac{f h_{12}}{3.87} \right)^{4.97} \right] \right\} \\ P_4 &= 1 + 2.751 \\ &\times \left\{ 1 - \exp \left[- \left(\frac{\epsilon_r}{15.916} \right)^8 \right] \right\} \end{aligned} \quad (81)$$

Table 4. Comparison between Experimental Results and Results of Present Method Where $L = 33.25$, $h_1 = 0$, $h_2 = 3.18$, $w = 32.25$, $\epsilon_{r2} = \epsilon_{r3} = 2.32$

Cover Thickness h_3 (mm)	Experiment f_r (GHz)	Calculated f_{r0} (GHz)
3.18	2.749	2.718
6.36	2.704	2.701
9.54	2.682	2.688
12.72	2.670	2.678

Source: Ref. 31.

Eventually, the resonant frequency f_r can be written as

$$f_r = \frac{c}{2(L + 2\Delta L)\sqrt{\epsilon_{\text{eff}}}} \quad (82)$$

Experimental and reported methods [31] are compared in Table 4.

The comparison of results between calculation and experiments indicates the evaluation accuracy of CMT application in calculation of the resonance frequency.

5.5. The Earth-Flattening Procedures in Radiowave Propagation via CMT

Another application of CM that has been used for Earth-flattening procedures in radio propagation problems by Richter [9] is discussed here. In this example wave propagation along the spherical Earth is the main subject, but Earth is assumed to be a cylinder; that is, Earth's curvature transverse to the direction of propagation can be neglected. Also, it is mentioned in this article that this is a frequently valid assumption in practice. The mapping function for the cylinder can be applied to the spherical geometry, thus significantly simplifying the differential equations. Figures 20 and 21 illustrate this transformation.

Figure 20. Polar coordinate system (original structure) (from Ref. 9).

Figure 21. Cartesian coordinate system after transformation (from Ref. 9).

Specifically, this mapping is the transformation from the polar into the Cartesian coordinate system by

$$q = jb_2 \ln\left(\frac{p}{b_1}\right) \quad \text{or} \quad p = b_1 \exp\left(-\frac{jq}{b_2}\right) \quad (83)$$

where

$$j = [-1]^{1/2}, \quad p = \zeta e^{-j\varphi}, \quad \xi = \zeta\varphi \quad (84)$$

and

$$q = x + jz \quad (85)$$

Then

$$z = b_2 \ln \frac{\zeta}{b_1} \quad \text{and} \quad x = b_2\varphi \quad (86)$$

For $\zeta = a$, $z = 0$, so $b_1 = a$, and if $\zeta = h + a$ for $z = h$, then

$$b_2 = \frac{h}{\ln\left(1 + \frac{h}{a}\right)} \quad (87)$$

In Fig. 20 the p plane is considered as a Riemann surface and its range is $0 \leq \varphi \leq 2\pi$; in the q plane the range is $0 \leq x < 2\pi b_2$. The CM relation between p and q is

$$F(x, z) = \frac{d\zeta}{dz} = \frac{d\xi}{dx} \quad (88)$$

and

$$F(z) = \frac{a}{h} \left[\ln\left(1 + \frac{h}{a}\right) \right] \left(1 + \frac{h}{a}\right)^{z/h} \quad (89)$$

Here, it must be noted that F is only a function of z and is independent of x . Therefore this case simplifies the solution for wave propagation.

In Eq. (89) $F(z)$ has been expanded for $(\frac{h}{a}) \ll 1$ in Ref. 9 as follows:

$$F(z) = 1 + \frac{z}{a} - \frac{h}{2a} \quad (90)$$

Now, TE and TM waves, which are guided by Earth, can be examined by using CM. Here, Earth is assumed to be a perfectly conducting cylinder surrounded by an isotropic, nonconducting medium, and its permittivity $\varepsilon(\zeta)$ is a function of only ζ .

5.5.1. TM Case. In p plane the (Fig. 20) one can express the components of the TM wave as E_ζ, E_ξ and H_η and in the q plane (Fig. 21) after transformation these components can be written as E_z, E_x , and H_y , respectively. It must be noted that the coordinates η and y are perpendicular to these planes (p plane and q planes, respectively). The following partial-differential equation can be reached using Maxwell equations for E_ζ, E_ξ, H_η :

$$\begin{aligned} F^2(z) &= \mu(z), \quad \varepsilon(\zeta) = \varepsilon'(z) \\ H_\eta &= H_y, \quad F(z)E_\xi = E_x, \quad F(z)E_\zeta = E_z \end{aligned} \quad (91)$$

Then

$$\begin{aligned} \frac{d^2 H_y(z)}{dz^2} - \frac{1}{\varepsilon'(z)} \frac{d\varepsilon'(z)}{dz} \frac{dH_y(z)}{dz} \\ + [\beta_0^2 \varepsilon'(z) F^2(z) - \beta^2] H_y(z) = 0 \end{aligned} \quad (92)$$

where

$$\beta = \frac{2\pi}{\lambda}, \quad \beta_0^2 = \omega^2 \mu_0 \varepsilon_0, \quad \text{and } \lambda = \text{wavelength} \quad (93)$$

5.5.2. TE Case. The TE wave components are H_ζ, H_ξ , and E_η in p plane and H_z, H_x , and E_y in the q plane. Using the following relations for the TE wave

$$\begin{aligned} \varepsilon(\zeta) &= \varepsilon'(z), \quad F^2(z) = \varepsilon''(z) \\ E_y &= E_\eta, \quad H_x = F(z)H_\xi, \quad H_z = F(z)H_\zeta \end{aligned} \quad (94)$$

then similarly

$$\frac{d^2 E_y(z)}{dz^2} + [\beta_0^2 \varepsilon'(z) F^2(z) - \beta^2] E_y(z) = 0 \quad (95)$$

Equation (92) indicates that following transformation in Fig. 21, the permeability $\mu(z) = K^2(z)$ and permittivity $\varepsilon'(z)$ are space-dependent.

Richter [9] has explained the meaning of $K^2(z)$, in which the elements of volume of both systems are different; however, the magnetic field strengths are equal. Thus, there exists a fictitious permeability so that the total magnetic energy would be equal in both coordinate systems. In addition, in Eq. (95) there is space-dependent permittivity [i.e., $\varepsilon'(z) \cdot \varepsilon''(z)$]. Here again, the reason is the

same as the previous one for introducing a fictitious permittivity.

If Eqs. (92) and (95) are written in another form where

$$\beta = \beta_0 F(h) \cos \theta_h \quad (96)$$

then θ_h is the angle of the wave normal to the x axis at height h . Therefore, Eqs. (92) and (95) can be written as follows:

$$\frac{d^2 f}{dz^2} + B_0^2 t^2 f = 0 \quad (97)$$

It must be noted that $\varepsilon^l(z)$ is assumed to be a constant. Here t is

$$\begin{aligned} t^2 &= F^2(z) - \left(\frac{\beta}{\beta_0}\right)^2 \\ &= F^2(z) - F^2(h) \cos^2 \theta_h \end{aligned} \quad (98)$$

Finally, the differential equations can be solved by using different methods as mentioned in Ref. 9.

5.6. Bent Rectangular Waveguide

The procedure of analyzing bent rectangular waveguide has been summarized [9] by using CM. The analyzed waveguide geometry in $z = x + jy$ plane is seen in Fig. 22. As mentioned in this article, in one case the wave travels in the plane of irregularity. The transformed structure in the $w = u + jv$ plane is shown in Fig. 23.

The wave equation in the transformed plane is

$$\frac{\partial^2 Q}{\partial u^2} + \frac{\partial^2 Q}{\partial v^2} + m^2 k^2 Q = 0 \quad (99)$$

where Q represents the electrical or magnetic components of the wave and the metric coefficient m (see Section 3) is

$$\begin{aligned} m &= 1 + g(u, v) = |f'(u + jv)|^2 \pi^2 / b^2 \\ 1 + g(u, v) &= [\cosh u + \cos v]^{2\alpha} [\cosh(u - t)]^{-\alpha} \\ &\quad \times [\cosh(u + t) - \cos \theta]^{-\alpha} \end{aligned} \quad (100)$$

Figure 22. The original bent waveguide in z plane (from Ref. 9).

Figure 23. The waveguide after transformation [$z = x + jy = f(u + jv) = f(w)$] in w plane (from Ref. 9).

Here $f'(u + jv)$ denotes the first derivative of the transformation function $f(w)$ (obtained using the Schwarz–Christoffel transformation in Ref. 9), $2\pi\alpha$ is the total angle of the bend, and t is a parameter that depends on α and the ratio $|N_4 - N_0|/|N_4 - N_6|$. Also, k can be written as

$$k = \frac{2b}{\lambda} \left\{ 1 - \left(\frac{\lambda_0}{2a} \right)^2 \right\}^{1/2} = -j\Gamma \frac{b}{\pi} \quad (101)$$

$$\Gamma = j2\pi \lambda_0^{-1} (1 - \lambda_0^2 a^{-2} / 4)^{1/2}$$

$$\gamma_i^2 = i^2 - k^2, \quad i = 0, 1, 2, 3, \dots, \gamma_0 = jk$$

where λ_0 is the free-space wavelength and a is the largest of the rectangular cross section of the waveguide. This application method can be used in other irregularities such as inserts in the channel as argued in Ref. 34.

6. SUMMARY

A limited number of examples of conformal mapping techniques (CMTs) have been presented in this article. However, as seen from each example, analytical closed-form expressions have been obtained easily via these CMTs. These equations can be implemented in CAD tools accurately. Other methods such as the finite-difference method, integral equation method, and full-wave analysis are unwieldy, since they require excessive amounts of computer memory and calculation time.

As shown from a comparison of the results of conformal mapping with other methods and measured values from experiments reported in the general literature, accuracy of the CM techniques is very good. Also, it has been mentioned many articles that since this method is analytical, the relation between parameters to be calculated and physical parameters can be interpreted easily.

CONICAL ANTENNAS

SABURO ADACHI
Tohoku Institute of Technology
Sendai, Japan

This article describes characteristics such as input impedance, radiation pattern, and directivity gain of conical antennas consisting of solid conducting cones, conducting conical plates, or their modifications. Conical conducting

structures on which simple antenna elements such as dipole and a slot are mounted are also described. An important general feature of conical antennas is their lack of sensitivity to frequency variation, that is, their broadband characteristics. Note that a conical horn antenna is described in HORN ANTENNAS.

The history of the practical use of conical antennas is long. Sir Oliver Lodge constructed a biconical antenna in 1897 and made a wireless communication experiment, while a single cone antenna on the ground and a fan (flat triangular) antenna were used by Marconi and others. The history of the theory of conical antennas is also long. The spherical coordinate is one of the few coordinates for which the method of variable separation in electromagnetic field problems can be applied. The conical surface is defined by a constant polar angle $\theta = \psi$ in the spherical coordinate system. For this reason conical antennas and biconical antennas, in particular, have been extensively investigated by Schelkunoff [1,2], Smith [3], Tai [4,5], Papas and King [6], and many others.

In the limit as $\psi \rightarrow 0$ and π , the biconical antenna is reduced to a vanishingly thin linear antenna that is very sensitive to frequency (that is, of narrow bandwidth). As the cone angle increases, the antenna shows broadband characteristics that make it useful for practical applications.

Figure 1 shows an infinitely long, symmetric biconical conductor with a half-cone angle ψ and an infinitesimally small feeding gap (δ gap). The antenna is assumed to be located in free space. This structure can support the transverse electromagnetic (TEM) transmission line mode, that is, the outward-propagating principal spherical-wave mode expressed by

$$H_\phi = \frac{1}{r \sin \theta} H_0 e^{-j\beta r} \quad (1)$$

$$E_\phi = \eta H_\phi \quad (2)$$

where $\beta = 2\pi/\lambda$ (λ : wavelength) is the free-space wavenumber and $\eta = \sqrt{\mu_0/\epsilon_0}$ is the free-space wave impedance. The

Figure 1. Infinite biconical conductor fed by a δ -gap generator.

Figure 2. Characteristic impedance of a biconical transmission line.

characteristic impedance K of the biconical transmission line is given by the ratio of the transmission voltage (i.e., the integral of E_θ along the cone meridian) to the conduction current along the cone as follows:

$$K = \frac{\eta}{\pi} \ln \left[\cot \frac{\psi}{2} \right] \tag{3}$$

Figure 2 shows the characteristic impedance K versus the half-cone angle ψ .

1. BICONICAL ANTENNAS

Figure 3 shows the geometry of the biconical antenna. The conducting antenna surfaces are defined by the conical surfaces $\theta = \psi$ and $\theta = \pi - \psi$, and the two spherical end surfaces at $r = a$. The analytical procedure of the biconical antenna will be outlined below. In region I, the electric and magnetic fields are represented as a sum of the outward- and inward-traveling TEM principal modes and an infi-

Figure 3. Symmetric biconical antenna.

Figure 4. Equivalent circuit of a symmetric biconical antenna.

nite number of complementary (higher) transverse magnetic (TM) modes. In region II, the fields are represented by an infinite series of complementary radiating modes. Boundary conditions on the aperture indicated by the dashed lines in Fig. 3 and the end surfaces of the cone at $r = a$ are used to obtain an infinite set of linear algebraic equations from which the amplitudes of the complementary modes and the principal mode reflected back at the aperture are determined.

The input admittance of the biconical antenna is represented by the equivalent transmission line circuit as shown in Fig. 4, where K is the characteristic impedance given by Eq. (3). The terminal admittance Y_t represents the effect of the truncation of the biconical transmission line at $r = a$, that is, the transformation of the outward-traveling TEM mode into the complementary modes in both regions and the reflected TEM mode, which eventually determines the input admittance of the biconical antenna Y_i .

Schelkunoff [2] has formulated the abovementioned boundary value problem rigorously and has discussed in detail special cases of a vanishingly thin antenna and a very wide-angle cone, or a spherical antenna with a very narrow equatorial gap. Tai [4] has obtained the exact analytical solution of the terminal admittance of the vanishingly thin antenna, which has been found to be identical to the expression obtained ingeniously by Schelkunoff. Tai [5] has also made an important contribution to the development of the theory for biconical antennas by applying Schwinger’s variational method. He has given the first-order variational numerical solution for the specific wide cone angles $\psi = 39.23^\circ, 57.43^\circ,$ and 66.06° .

The more recent development of computers has made feasible the numerical solution of Schelkunoff’s formulation. However, it is still not easy to solve the infinite set of linear determining equations with reasonable accuracy because of slow convergence of the infinite series when the cone-angle decreases. For example, 15 or more modes for $\psi = 5^\circ$ [7], and 13 modes for $\psi = 5^\circ$ [8] are necessary for computation of the input impedance. A conical monopole above an image plane driven by a coaxial line has been numerically analyzed by using the finite difference time domain method [9].

When the upper half-cone of the biconical antenna is mounted on an infinite conducting plane (ground plane), the antenna forms a conical unipole having one half of the input impedance of the biconical antenna. Figures 5 and 6 (from Brown and Woodward, Jr. [10]) show respectively the measured input resistance and reactance of a conical unipole having flat caps instead of spherical caps. It is clear that the antenna tends to have a constant input

Figure 5. Measured input resistance of a conical unipole versus length in electrical degrees showing broadband characteristics with increasing cone angle (from Ref. 10).

Figure 6. Measured input reactance of a conical unipole versus length in electrical degrees showing broadband characteristics with increasing cone angle (from Ref. 10).

resistance and a small reactance around zero versus frequency, showing broadband characteristics as the cone angle is increased.

The radiation pattern of the biconical antenna has been computed by Papas and King [6] and by Bevensee [11]. Figure 7 shows the far-zone electric field pattern [6] for

the cone angle of $\psi = 30^\circ$. It is found that the patterns are not much different from those of a straight wire antenna.

Theoretical analysis of biconical antennas loaded with and/or immersed in dielectric, lossy, and ferromagnetic materials has been provided by Schelkunoff [2], Tai [4],

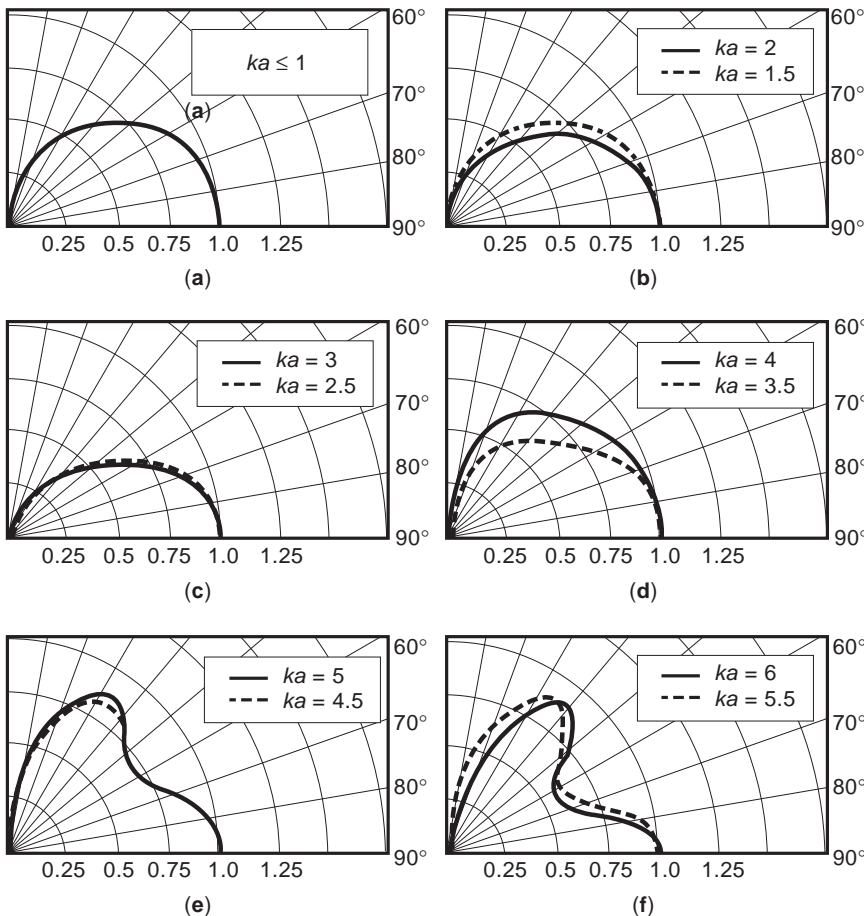

Figure 7. Far-zone electric field patterns of a biconical antenna, $\psi = 30^\circ$. Patterns do not change very much from $ka = 0$ to $ka \approx \pi$.

Polk [12], and others. These topics are reviewed by Wait [13]. The theory of an asymmetric biconical antenna was also discussed by Schelkunoff [2]. The variational approach by Tai was extended to a semiinfinite asymmetric conical antenna consisting of an infinite cone and a finite cone [14].

To reduce wind resistance and/or weight, a solid biconical antenna can be replaced by a skeletal conducting wire structure using several radial rods [15,16]. It has been found, however, by analysis using the moment method that a considerable number of wires (e.g., 16) is required to approximate the solid biconical antenna.

2. ANTENNAS ON CONICAL STRUCTURE
