According to the constitutive equations above, a *general symmetric condensed node* (GSCN) may be derived where material properties may be shared between linklines and stubs. The advantage of this option is that an optimization is possible to achieve, for example, particular dispersion characteristics. This in general results in a node with six different characteristic impedances, six stubs, and six lossy elements. The general theory of the GSCN and its scattering properties may be found in Ref. 17.

4.2. Field-Theoretic Derivation of TLM

An elegant derivation of TLM SCN method is by applying the method of moments (MoM) to Maxwell's equations [19, 20]. The field components are expanded in a set of subdomain basis functions, as shown below for the x components,

$$\begin{aligned} E_x(\vec{x}, t) &= \sum \lim its_{k,l,m,n} k + (1/2) E_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ &\quad + \sum \lim its_{k,l,m,n} k + (1/2) E_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ H_x(\vec{x}, t) &= \sum \lim its_{k,l,m,n} k + (1/2) H_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ &\quad + \sum \lim its_{k,l,m,n} k + (1/2) H_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \end{aligned} \quad (22)$$

where

$$k + (1/2) E_{l,m,n}^\mu, \quad k + (1/2) H_{l,m,n}^\mu, \quad \mu = x, y, z$$

are the expansion coefficients. The other components are obtained by permutation of x, y, z and the corresponding

discrete coordinates l, m, n . The basis functions in time are defined as

$$T_{k\pm(1/2)}(t) = g\left(\frac{t}{\Delta t} - k \mp \frac{1}{2}\right)$$

where

$$g(x) = \begin{cases} \text{trix}1 - |x|, & |x| < 10, \\ |x|, & |x| \geq 1 \end{cases}$$

The spatial basis functions are defined as

$$F_{l,m,n}^{\mu}(\vec{x}) = H_l(x)F_{m\pm(1/2),n}(pa, \mu, v)$$

where H is a rectangular pulse function and F is a two-dimensional triangular basis function. This spatial basis functions provides a step approximation in the μ direction and a piecewise linear approximation in the diagonal directions of the plane perpendicular to the μ direction. Substituting these expansions into Maxwell's equations, sampling with delta functions and the derivatives of delta functions, and combining the 12 resulting equations gives the following form:

$$(M_1 + TM_2)\mathbf{b} = (M_3 + TM_4)\mathbf{a} \quad (23)$$

In this expression \mathbf{a} and \mathbf{b} are the incident and reflected wave amplitudes, respectively. Introducing the normal TLM choices for the timestep, one obtains, after some manipulation [19]

$$\mathbf{b} = TS\mathbf{a} \quad (24)$$

where S is the normal scattering matrix for the TLM SCN node, thus demonstrating that the TLM scattering scheme may be derived directly from MoM procedures. An interesting development, which stems from the theoretical foundation of TLM described above, is the derivation of the alternating TLM (ATLM) scheme, which reduces computational effort and removes spurious solutions at the expense of more complicated boundary conditions [20].

4.3. Dispersion Properties of TLM

A mesh consisting of a lattice of SCN TLM nodes is essentially a lowpass network, and therefore propagation properties are dependent on both frequency and propagation angle. At the interface between areas of the mesh with different spatial resolutions, waves encounter, effectively, a numerical discontinuity. These features are generally described as "dispersion" and are common to all numerical schemes such as FDTD. However, each particular scheme has its own unique dispersion characteristics, and a basic understanding is useful in applications where control of errors is important. A simple analysis of the 3D SCN based on circuit concepts may be done in certain cases [21], and results may be obtained using numerical means [22]. For propagation along the diagonal, the regular SCN exhibits no dispersion, but in other directions there is dispersion that increases with frequency. The best advice, which is common to all similar

numerical schemes, is to use a resolution of at least 10 segments per wavelength at the highest frequency of interest. If this is done, dispersion errors of a few percent under the worst circumstances should be expected. Studying dispersion properties by deriving dispersion relations in a closed analytical form is a much more demanding task, but some significant progress has been reported [23,24].

The problem of propagation behavior at the interface between different meshes is a difficult one, and no general analytical expressions are available that allow a rapid assessment of prevailing errors. Most studies are based on numerical work and the general advice is that abrupt changes in resolution should be avoided. A study that compares the behavior of TLM and FDTD for the same grading ratios across interfaces may be found in Ref. 25.

4.4. A Modal View of TLM

Another interesting insight into TLM is to examine its structure in terms of modal components.

At the surface of each mode there are 12 electric and 12 magnetic field components, which are related by an admittance operator Y :

$$\mathbf{H} = Y\mathbf{E} \quad (25)$$

Expressing field components in terms of incident and reflected voltages at the node gives

$$\mathbf{E} = \mathbf{V}^i + \mathbf{V}^r, \quad \mathbf{H} = y_0(\mathbf{V}^i - \mathbf{V}^r) \quad (26)$$

where y_0 is a scalar quantity. Combining these expressions, one obtains the scattering equation for the TLM node

$$\{y_0 I + Y\}\mathbf{V}^r = \{y_0 I - Y\}\mathbf{V}^i \quad (27)$$

where I is the identity matrix. The best way to solve Eq. (27) is to solve an eigenvalue problem

$$Y\mathbf{U}_n = \gamma_n \mathbf{U}_n \quad (28)$$

where \mathbf{U}_n and γ_n are the eigenvectors and eigenvalues of Y , respectively. Defining a matrix U with columns that are the eigenvector of Y , the voltage components incident and reflected at each node may be expressed in terms of modal components:

$$\mathbf{V}^i = U\mathbf{X}^i, \quad \mathbf{V}^r = U\mathbf{X}^r \quad (29)$$

Combining these expressions with (27) gives the following equation, after some manipulation:

$$X_n^r = \frac{y_0 - \gamma_n}{y_0 + \gamma_n} X_n^i \quad (30)$$

This expression shows that, effectively, the admittance seen into the node by each mode is the eigenvalue, as shown schematically in Fig. 8.

Figure 8. Admittance seen by each mode incident on a TLM node.

The structure of Y and its eigenvalues can be formally derived or obtained from physical intuition in terms of 12 cylindrical harmonics (two TE and two TM modes per coordinate direction). As an example for TM modes the field components are

$$\begin{aligned} E_{z,n} &= \frac{J_n(k_0 r)}{J_n(k_0 \Delta)} \cos(n\varphi) \\ H_{\varphi,n} &= \frac{1}{j\omega\mu} \frac{dJ_n(k_0 r)/dr}{J_n(k_0 \Delta)} \cos(n\varphi) \end{aligned} \quad (31)$$

where k_0 is the wavenumber and the fields were normalized at the edge of the node $r = \Delta$. The eigenvalues for this mode are

$$\gamma_n = \frac{H_{\varphi,n}}{E_{z,n}} = \frac{1}{j\omega\mu} \left. \frac{dJ_n(k_0 r)/dr}{J_n(k_0 r)} \right|_{r=\Delta} \quad (32)$$

Using a small argument expansion for the Bessel functions, the eigenvalue for the $n = 0$ TM_{z0} mode is obtained:

$$\gamma_0 = j \frac{\omega\epsilon\Delta}{2} \quad (33)$$

Hence the reflection coefficient for the TM_{z0} mode is

$$\Gamma = \frac{y_0 - \gamma_0}{y_0 + \gamma_0} \simeq e^{-jk\Delta} \quad (34)$$

This represents a simple phase shift on a lossless line segment. Similar expressions are obtained for the other modes. TLM therefore may be interpreted as a procedure for implementing in the time domain the process of analysis of total voltages into modes, the proper reflection of each mode at the node, and the recombination of modes to obtain total voltages for transmission to adjacent nodes. These ideas are useful in implementing schemes for embedding thin wires into TLM nodes. More details may be found in Ref. 26.

5. FURTHER DEVELOPMENTS AND SELECTED APPLICATIONS

5.1. Absorbing Boundary Conditions

All differential equation numerical techniques that are based on a volumetric discretization require special boundary conditions to deal with open-boundary problems.

Typically, at the extremities of the numerical mesh, where an open boundary exists, a termination must be

placed that mimics, as far as possible, the open boundary of the real physical problem. The simplest approach in TLM has been to use the “matched boundary condition,” which effectively terminates the line segments at the open boundary with the medium’s characteristic impedance. This is an inexpensive absorbing boundary condition to use and should be employed whenever possible. The resulting small reflections are acceptable in all except the most demanding problems.

In cases where a better absorbing boundary condition is required, two approaches have emerged for use in a TLM mesh. The first approach is based on the Johns matrix concept and is particularly suitable for terminating waveguide problems [27]. In time-domain diakoptics the impulse response of the TLM mesh at selected input points is in effect a discrete Green function, which is referred to as the “Johns matrix”. If this response is known, then the response to any excitation is obtained by convolving the excitation with its Johns matrix. At an interface marking an open boundary, the Johns matrix is in effect a reflection coefficient matrix such as impulses reflected at the interface are dependent on the impulses not only at a given time but also at previous times. This approach works well and efficiently on simple open boundaries such as those found in waveguide problems.

For terminating open boundaries in more general configurations, the computational cost of the Johns matrix approach is unacceptable and schemes based on the “perfectly absorbing layer” [also known as “perfectly matched layer” (PML)] are generally preferred. This effectively introduces a fictitious material as an absorber and is used extensively in FDTD schemes. An implementation of the PML boundary condition in TLM is described in Ref. 28. It should be noted that the PML schemes exhibit instabilities under certain conditions, notably when terminating waveguides contain irises, and hence in such cases the Johns matrix approach should be preferred.

5.2. Multigrid Schemes

Mesh refinement is necessary whenever fine features such as wires, wire looms, edges, and thin walls with perforations need to be described in the mesh. It would appear that the simplest way and the one resulting in the best accuracy is to use a finer mesh so that the finest feature can be accommodated by the resolution of the mesh. This would imply typically four sampling points per fine feature. The resulting size of the computation, however, would be excessively large. An alternative is to use a finer mesh only where it is required, thus resulting in a multigrid mesh.

Substantial effort has been expended in this area over many years as reviewed in Ref. 29. There are many difficulties to overcome, and it appears that an entirely satisfactory scheme is not available. Two schemes, that allow for a multigrid mesh in TLM are described in Refs. 30,31. Multigrid schemes are available mainly as research tools and should be used with caution and only for small resolution ratios between fine and coarse meshes.

5.3. The ADI TLM

Another development in TLM, which results in an implicit algorithm, is the alternate-direction-implicit TLM (ADI-TLM) or split-step TLM (SS-TLM) [32–34] scheme. These algorithms split sampling in time into two steps. As an example, for the x component of the electric field, two sub-equations are obtained:

$$\begin{aligned} \frac{1}{2} \left[\epsilon \frac{\partial E_x}{\partial t} + \sigma E_x \right] &= \frac{\partial H_z}{\partial y} \\ \frac{1}{2} \left[\epsilon \frac{\partial E_x}{\partial t} + \sigma E_x \right] &= -\frac{\partial H_y}{\partial z} \end{aligned} \tag{35}$$

The first step is implemented by approximating the first equation in (35) between times $(n - \frac{1}{2})\Delta t$ and $n \Delta t$ and the second equation between $n \Delta t$ and $(n + \frac{1}{2})\Delta t$. The second step is similarly obtained by approximating the second equation between $(n + \frac{1}{2})\Delta t$ and $(n + 1)\Delta t$, and the first between $(n + 1)\Delta t$ and $(n + \frac{3}{2})\Delta t$. This results in an implicit algorithm, but a larger timestep can be employed compared to nonsplit explicit TLM algorithms. The overall result is that in some circumstances a computational saving is achieved. It is not clear at present whether these benefits persist when dealing with general EM problems with inhomogeneous materials, embedded wires, or similar.

5.4. Modeling of General Materials with Frequency-Dependent Properties in the Time Domain

Simple materials with frequency independent properties are easily modeled in TLM by adjusting node parameters (dielectrics, losses) or reflection coefficients (perfect conductors). For more general materials, which may involve dependence on frequency, anisotropy, chirality, nonlinearity, and other properties, special techniques need to be developed for time-domain models. The simplest way to visualize the procedures to be followed in the development of such models, is to consider that in the frequency-domain material properties represent in effect the transfer function of an analog filter. By deriving an equivalent digital filter, which has the same frequency response as the analog filter, a time-domain procedure is readily obtained that can be directly embedded into the time-domain TLM model.

A simple yet important example is of propagation in a Debye material where

$$\epsilon(\omega) = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + j\omega\tau} \tag{36}$$

where $\epsilon_s, \epsilon_\infty, \tau$, are the static permittivity, permittivity at infinite frequencies, and relaxation time, respectively. Limiting, for simplicity, the discussion to 1D propagation in a Debye medium the calculation proceeds as follows.

The basic circuit equivalent for the problem is shown in Fig. 9. The TLM equivalent of this circuit is shown in

Figure 9. A segment of a model to describe 1D propagation in a Debye medium.

Fig. 10, where all impedances are normalized to

$$Z_0 = \frac{1}{Y_0} = \sqrt{\frac{\mu_0}{\epsilon_0}} \tag{37}$$

The timestep and the following parameters are calculated from

$$\begin{aligned} \Delta t &= \frac{\Delta x}{c} \\ \beta &= \exp\left(\frac{-\Delta t}{\tau}\right) \\ \alpha &= (\epsilon_s - \epsilon_\infty)(1 - \beta) \\ g &= \sigma \Delta x Z_0 \\ t &= \frac{2}{2\epsilon_\infty + g + 2\alpha} \\ t_s &= 2t(\epsilon_\infty + \alpha - 1) \\ t_f &= t\beta \end{aligned} \tag{38}$$

Figure 10. The normalized equivalent circuit of the circuit in Fig. 9, where lumped components were replaced by link and stub lines.

The total voltage is obtained from

$${}_k V = t({}_k V_0^i + {}_k V_1^i) + t_s {}_k V_s^i + t_f {}_{k-1} u \quad (39)$$

The quantity u is obtained by the procedure shown in Fig. 11. The reflected voltages are then calculated as follows:

$$\begin{aligned} {}_k V_0^r &= {}_k V - {}_k V_0^i \\ {}_k V_1^r &= {}_k V - {}_k V_1^i \\ {}_k V_s^r &= {}_k V - {}_k V_s^i \end{aligned} \quad (40)$$

The algorithm requires one backstore variable. Similar procedures are available to deal with material modeling in three dimensions and with a range of material parameters [35–39].

5.5. Multiscale Schemes

The problem of fine features in large computations and the need to deal effectively and efficiently with multiscale problems were already discussed [29]. Two examples are given here for two important practical problems: the simulation of coupling to wires and the simulation of the shielding effectiveness of cabinets.

For describing thin wires, the approach first described by Holland and Simpson [40] has been used for some time. It is based on the principle of calculating an in-cell capacitance to represent the wire and thus building an interface between the wire and the rest of the TLM mesh. Calculation of the parameters of this interface is based on the quasistatic assumption regarding the field around the wire. Several papers discuss in detail the nature of this interface for a wire placed between nodes [41], a wire placed at the node center [42], and multiconductor looms [43]. All these developments suffer from a number of assumptions and limitations.

An alternative technique is based on taking into account more than one modes for the field around the wire [modal expansion technique (MET)]. Because MET takes more modes into account (some of which are asymmetric), it is suited to placing the wire arbitrarily anywhere in the node. It is also accurate and removes several other restrictions inherent in the conventional approach. MET is based on the approach described in Section 4.4 for a node without a wire, with the important modification that more modes need now be taken into account, and, the imped-

ance seen by incoming pulses takes account of the presence of the wire. The complete field solution for a long wire is

$$\begin{aligned} E_z(r, \varphi) &= \sum_{n=-\infty}^{\infty} B_n e^{jn\varphi} \left[J_n(k_0 r) - \frac{J(k_0 a)}{N_n(k_0 a)} N_n(k_0 r) \right] \\ H_\varphi(r, \varphi) &= \frac{1}{j\omega\mu_0} \frac{\partial E_z}{\partial r} \end{aligned} \quad (41)$$

From this it can be seen that the static solution used in the conventional approach based on Holland and Simpson is only the first term in this expansion. Depending on the degrees of freedom available, several modes may be used. In two dimensions, where TLM nodes have four ports, four modes are employed. In three dimensions, for a z -directed wire, four modes (TE, TM, TEM odd, TEM even) and four angular instances are selected, making a total of 16 modes. Wires that are offset from the center of the node may also be described by exploiting as an example the addition theorems for Bessel functions. The approach of working out the eigenvalues, the impedance seen by each mode and for constructing suitable algorithms, may be found in Ref. 26.

Another problem of importance in many applications is the description of a thin wall with numerous perforations that is part of a resonant box (e.g., equipment cabinet). It is simply computationally far too expensive to generate a mesh with the necessary resolution to describe all relevant features. The simplest approach to this type of problem is to place the thin wall with perforations between nodes and to account for its properties by a frequency-dependent scattering matrix $S(\omega)$ implemented during the connection process in TLM. This technique is referred to as a *digital filter interface* (DFI) since it reduces to a time-domain algorithm as part of the connection process. Each coefficient of the scattering matrix is put into standard Padé form and then the frequency-domain Prony method is used to find its poles and zeros. The resulting expression is converted into the discrete time domain by application of the bilinear transformation. The resulting equations in state form relating incident and reflected voltages are of the form

$$\begin{aligned} V^i &= B_0 V^r + \mathbf{B}' X \\ X &= z^{-1} A' X + z^{-1} \mathbf{1}' V^r \end{aligned} \quad (42)$$

Figure 11. Signal flow diagram representing the algorithm for implementing the model for Debye materials.

In (42) the first equation is the output equation and the second is the state equation, and the computational procedure is shown in Fig. 12. Details may be found in Ref. 44. Using this approach, very substantial computational savings can be made. Moreover, the frequency-dependent scattering matrix may be obtained by numerical simulation, analytically or experimentally. The calculation of the poles and zeros is a preprocessing task and therefore is not an overhead on the main timestepping simulation.

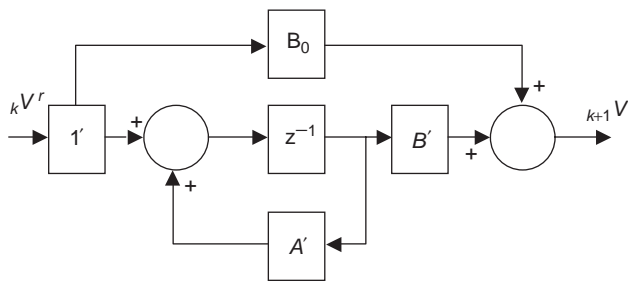

Figure 12. Signal flow diagram of the “connection” process to account for fine features using the DFI algorithm.

5.6. Frequency-Domain TLM (FD-TLM)

TLM is mainly used as a time-domain method but can also be implemented in the frequency domain. In FD-TLM time-harmonic variations are used and therefore discretization in space only is required. This considerably simplifies the modeling of materials and other features. However, the algorithm requires the inversion of a large matrix.

Several schemes are available in which either the characteristic impedance of each line is kept the same or phase constants are kept the same. Details may be found in the literature [45–48].

TRANSMISSION LINE THEORY

RAGHU K. SETTALURI
Oregon State University
Corvallis, OR

A transmission line is a network that connects a generator circuit to a load for the purpose of transmitting electric energy or information from one point to another. Examples of transmission lines include cable connection between a service provider and your television set, telephone wires, interconnection between a transmitter and an antenna, and optic nerves and neural networks in human brain. The list can go on and on with the same essential purpose of transporting energy or information between

two points. In these examples, we can notice one important difference for each scenario. The choice of transmission line is different and depends on the purpose and application. For example, high-power transmission lines that are used to transport megawatts of electric energy need to be thicker and bulkier to accommodate the large power-handling capability and minimize power losses. On the other hand, a microminiaturized interconnect in the 4 GHz central processor of your desktop or laptop needs to be precisely designed to transfer the information in a densely packed circuit environment! In electrical engineering applications, the choice of a suitable transmission medium depends on a variety of factors including the frequency of operation, power handling, and the topology.

Many readers might be familiar with basic circuit analysis techniques for low-frequency electric circuits, which have been well developed over decades. At low frequencies, the physical size of the circuit is much smaller compared with the wavelength. This condition implies that when a load is connected to a voltage source via a length of transmission line, the voltage appears instantaneously at the load end without any time delay, which also implies that lumped elements such as inductors, capacitors, and resistors will have much smaller sizes compared with wavelength, and we can conveniently assume that the voltage across an element on one side of the circuit was exactly in phase with the voltage on the other side. Thus size or separation between elements was never an issue in the low-frequency circuit design!

When the size of an element is a considerable fraction of a wavelength or many wavelengths, the network becomes *distributed* in nature. In this case, aside from time variation, voltages and currents can vary in magnitude and phase as a function of distance. A transmission line may no longer be considered as a simple interconnecting mechanism between two points. It behaves like a distributed-parameter network, for which the transmission properties need to be considered as a part of the design process, which leads to electromagnetic wave propagation on transmission lines with possible standing wave formations.

1. PROPAGATION MODES

The orientation of electric and magnetic fields and their interaction along a transmission line is essentially decided by the geometry of the transmission line structure, which is generally characterized by the *mode* supported by the transmission line structure for the electromagnetic wave propagation. Figure 1 shows several commonly used transmission lines, which are broadly classified into three main categories. The two-wire line, coaxial line, and strip-line, shown Figs. 1a–1c, support transverse electromagnetic (TEM) mode, where the electric and magnetic fields are entirely transverse to the direction of propagation. Many of the characteristics of wave propagation in TEM supporting structures are the same as those for a uniform plane wave propagating in an unbounded dielectric medium.

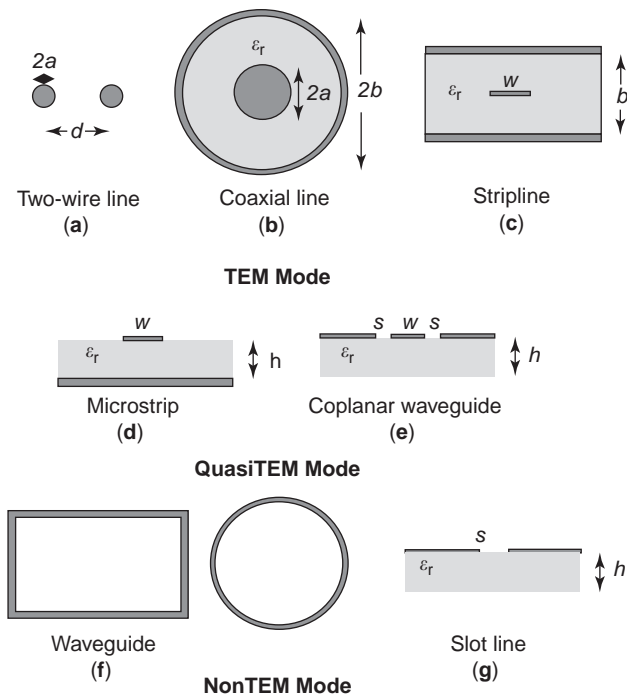

Figure 1. Commonly used transmission lines supporting different propagation modes.

A microstrip line and a coplanar waveguide (Figs. 1d and 1e) are two commonly used planar transmission lines at microwave frequencies. As a result of the presence of the air-dielectric interface, these structures are considered as inhomogeneous transmission lines. Here, the field lines between the conducting strip and the ground lines are not contained entirely in the substrate, and these structures support quasiTEM mode of propagation. However, because the nontransverse field components are considerably smaller compared with the transverse field components, for most practical applications, they can be included in the TEM class of transmission lines. A common feature among TEM and quasiTEM transmission line structures is that they require at least two conductors to support TEM mode and frequencies as low as DC can propagate along these lines.

Several other transmission lines exist that do not support TEM or quasiTEM mode of propagation. These include the rectangular and circular waveguides (Fig. 1f) and slotlines (Fig. 1g). Depending on the configuration, these structures support several higher order modes, such as transverse electric (TE) and transverse magnetic (TM), where the presence of a longitudinal field component cannot be ignored. The minimum frequency (also called the *cutoff* frequency) of the electromagnetic wave that can be supported in these structures depends on factors such as mode number and physical dimensions. Further, the transmission properties will have a strong frequency dependence. As transmission lines supporting TEM/quasiTEM wave propagation are more commonly used in practice, this article focuses on understanding

the wave propagation in the case of TEM supporting structures.

2. TRANSMISSION LINE EQUATIONS

As we have noticed in our earlier discussion, incorporating the spatial dependence of fields is important while addressing the characteristics of the transmission lines at high frequencies. For a given structural geometry, the transmission line characteristics can be determined by solving the Maxwell's equations [1] in various regions. This approach can provide a complete description of electric and magnetic fields at every point in the region. However, many times we are interested in terminal quantities such as voltage, current, impedance, and power, for which a discretized circuit representation of a distributed transmission line may offer simpler, yet adequately accurate solution.

Let us consider a transmission line connected to a source at one end and a load at the other end, as shown in Fig. 2a. If we choose a small section of the line with differential length Δz , it can be modeled as a discrete circuit, as shown in Fig. 2b and described by the following four basic parameters:

- R , resistance per unit length for both conductors, in Ω/m
- L , inductance per unit length for both conductors, in H/m
- G , conductance per unit length in S/m
- C , capacitance per unit length in F/m

The inductance L , represents the total series self inductance in both the conductors and the capacitance C , represents the capacitive coupling between the two conductors, which depends on the proximity between the conductors. R and G develop because of the conductor losses of both conductors and dielectric losses that exist in the medium between the conductors respectively. Thus R and G are essentially the *attenuation* or *loss* parameters of the transmission line. A finite length of transmission line can be considered as a cascade of several sections of infinitesimal length Δz , representing the distributed nature of the line.

The quantities $v(z, t)$ and $i(z, t)$ represent the instantaneous voltage and current at the input of the differential length section at node N . Similarly, $v(z + \Delta z, t)$ and $i(z + \Delta z, t)$ represent the same quantities on the output side at node $N + 1$. Applying Kirchhoff's voltage law, we obtain

$$v(z, t) - R\Delta z i(z, t) - L\Delta z \frac{\partial i(z, t)}{\partial t} - v(z + \Delta z, t) = 0 \quad (1a)$$

Rearranging the terms in Eq. (1a) leads to

$$-\frac{v(z + \Delta z, t) - v(z, t)}{\Delta z} = Ri(z, t) + L \frac{\partial i(z, t)}{\partial t} \quad (1b)$$

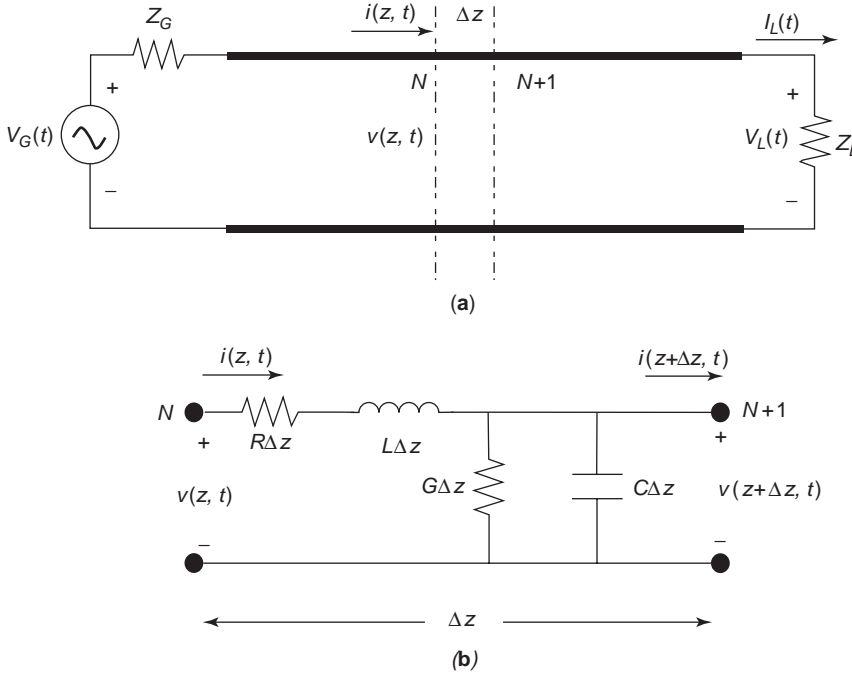

Figure 2. Transmission line and lumped-element representation for the purpose of deriving the Telegrapher's equations. (a) Definition of voltages and currents on a transmission line connected between a source and a load. (b) Lumped-element equivalent circuit for an elemental length of transmission line.

Similarly, applying Kirchhoff's current law to node $N+1$ in Fig. 2b leads to

$$i(z, t) - G\Delta z v(z + \Delta z, t) - C\Delta z \frac{\partial v(z + \Delta z, t)}{\partial t} - i(z + \Delta z, t) = 0 \quad (2a)$$

Again, rearranging the terms in Eq. (2a), we have

$$-\frac{i(z + \Delta z, t) - i(z, t)}{\Delta z} = Gv(z, t) + C \frac{\partial v(z, t)}{\partial t} \quad (2b)$$

In the limit, $\Delta z \rightarrow 0$, Eqs. (1b) and (2b) become

$$-\frac{\partial v(z, t)}{\partial z} = Ri(z, t) + L \frac{\partial i(z, t)}{\partial t} \quad (3a)$$

$$-\frac{\partial i(z, t)}{\partial z} = Gv(z, t) + C \frac{\partial v(z, t)}{\partial t} \quad (3b)$$

The first-order partial differential equations given in Eqs. (3) are the time-domain form of the transmission line equations, which are also called the *Telegrapher's* equations.

As we are primarily interested in sinusoidal steady-state conditions, we can apply the phasor notation with cosine reference to represent the time-domain equations given in Eqs. (3) in frequency-domain. For this, we define

$$v(z, t) = \text{Re}[V(z)e^{j\omega t}] \quad (4a)$$

$$i(z, t) = \text{Re}[I(z)e^{j\omega t}] \quad (4b)$$

where, $V(z)$ and $I(z)$ are phasor quantities dependent on space coordinate z only, and each of them could be real or

complex, and Re represents the real part of a complex quantity. Substituting Eqs. (4a) and (4b) in Eqs. (3) yields the following first-order ordinary differential equations in frequency-domain:

$$-\frac{dV(z)}{dz} = (R + j\omega L)I(z) \quad (5a)$$

$$-\frac{dI(z)}{dz} = (G + j\omega C)V(z) \quad (5b)$$

Eqs. (5) are called the *time-harmonic transmission line equations*.

3. WAVE PROPAGATION ON AN INFINITE TRANSMISSION LINE

The two coupled first-order time-harmonic transmission line equations given in Eqs. (5) can be combined to give two second-order uncoupled differential equations in $V(z)$ and $I(z)$ as

$$\frac{d^2V(z)}{dz^2} - \gamma^2 V(z) = 0 \quad (6a)$$

$$\frac{d^2I(z)}{dz^2} - \gamma^2 I(z) = 0 \quad (6b)$$

where

$$\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)} \quad (m^{-1}) \quad (7)$$

is the *complex propagation constant* of the transmission line, whose real and imaginary parts, α and β , represent

the *attenuation constant* (Np/m) and *phase constant* (rad/m) of the line, respectively. For all passive transmission lines, α will be either zero or a positive quantity.

The wave equations given in Eqs. (6) have solutions of the form

$$V(z) = V_0^+ e^{-\gamma z} + V_0^- e^{\gamma z} \tag{8a}$$

$$I(z) = I_0^+ e^{-\gamma z} + I_0^- e^{\gamma z} \tag{8b}$$

The terms $e^{-\gamma z}$ and $e^{\gamma z}$ represent the wave propagation in $+z$ and $-z$ directions, respectively. V_0^+ and I_0^+ are the wave amplitudes in the $+z$ direction, and V_0^- and I_0^- are the wave amplitudes in the $-z$ direction. These amplitudes are related via the expression

$$\frac{V_0^+}{I_0^+} = -\frac{V_0^-}{I_0^-} = \frac{R + j\omega L}{\gamma} \tag{9}$$

The ratio of the forward wave amplitudes or the negative of the backward wave amplitudes is also defined as *characteristic impedance*, Z_o , of the transmission line, where

$$Z_o = \frac{R + j\omega L}{\gamma} = \frac{\gamma}{G + j\omega C} = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \tag{10}$$

Note that the parameters γ and Z_o can be complex and are independent of the length of the transmission line. As seen in Eqs. (7) and (10), these characteristic properties of the line are directly related to the line parameters R , L , G , and C , which are real in nature. These parameters are dependent on the geometry of the transmission line and material properties of the conductors and the dielectric medium. For example, the line parameters for coaxial line and a two-wire transmission line are given in Table 1.

3.1. Special Cases

3.1.1. Lossless transmission line. The transmission line equations derived in Section 3 are for a general transmission line taking the effect of finite conductivity of the conductors and dielectric losses into account. However, in many practical situations, transmission lines at radiofrequencies are designed to have conductors with high

conductivities and dielectric materials with small values of loss tangent, $\tan\delta$, which would result in values of $R \ll \omega L$ and $G \ll \omega C$. Therefore, if we approximate $R = 0 = G$ in Eqs. (7) and (10), we get

$$\gamma = \alpha + j\beta = j\omega\sqrt{LC} \tag{11a}$$

$$\alpha = 0 \tag{11b}$$

$$\beta = \omega\sqrt{LC} \tag{11c}$$

$$Z_o = \sqrt{\frac{L}{C}} \tag{11d}$$

Thus, the propagation constant, γ , for a lossless transmission line becomes purely imaginary, reasserting the fact that attenuation will be zero for ideal lines with no dielectric and conductor losses. From Eq. (11d), it can be seen that the characteristic impedance, Z_o , becomes real for a lossless line. Phase velocity v_p , which is defined as the velocity of propagation of an equiphase front on the transmission line, is given as

$$v_p = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \tag{12}$$

From Eq. (12), it can be seen that the phase velocity is independent of the frequency of the propagating wave. As any arbitrary signal can be composed of a combination of sinusoidal waves of different frequencies and amplitudes, a constant phase velocity for all frequencies will ensure that all these waves will travel with the same velocity along a lossless line without suffering any attenuation, thus preserving the shape of the signal. On the other hand, for a general lossy transmission line, from Eq. (7), it can be seen that the phase velocity, β , and attenuation, α , are functions of frequency. As different frequency components propagate with different velocities and attenuation factors, the signal suffers *dispersion* and gets *distorted* as it propagates along the line.

3.1.2. Distortionless line. The theory for distortionless line was first proposed by Oliver Heaviside, whose contributions to the electromagnetism were well described in [2]. Consider a general lossy transmission line, which

Table 1.

Structure	Transmission line parameters			
	R (Ω/m)	L (H/m)	G (S/m)	C (F/m)
Two-wire Line (Fig. 1a)	$\frac{R_s}{\pi a}$	$\frac{\mu}{\pi} \ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)$	$\frac{\pi\sigma}{\ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)}$	$\frac{\pi\epsilon}{\ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)}$
Coaxial Line (Fig. 1b)	$\frac{R_s}{2\pi} \left[\frac{1}{a} + \frac{1}{b}\right]$	$\frac{\mu}{2\pi} \ln\left(\frac{b}{a}\right)$	$\frac{2\pi\sigma}{\ln\left(\frac{b}{a}\right)}$	$\frac{2\pi\epsilon}{\ln\left(\frac{b}{a}\right)}$

Notes:

a. μ , ϵ , and σ are the material properties of the dielectric medium.

b. R_s is the surface resistance of the conductors, which is related to the frequency and material properties of the conductor.

satisfies the condition

$$\frac{R}{L} = \frac{G}{C} \quad (13)$$

Substituting Eq. (13) in Eqs. (7) and (10), we get

$$\gamma = \alpha + j\beta = R\sqrt{\frac{C}{L}} + j\omega\sqrt{LC} \quad (14)$$

$$Z_o = \sqrt{\frac{L}{C}} \quad (15)$$

Phase velocity, v_p , is given by,

$$v_p = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \quad (16)$$

Comparing Eqs. (14)–(16) with Eqs. (11) and (12), it can be seen that, except for a nonzero value of attenuation constant, the distortionless line has same characteristics as that of a lossless line. Although the signal suffers attenuation as it propagates along the line, because of the constant phase velocity, waves of different frequency components will travel with the same velocity, thus preserving the shape of the signal, which is why it is called the *distortionless line*.

4. WAVE CHARACTERISTICS ON TERMINATED TRANSMISSION LINE

As you may recall, the general solution for transmission line wave equations given in Eqs. (8) consists of two types of wave propagation—the wave traveling in forward (+z) direction and the wave traveling in the backward (−z) direction. When a wave is incident at one end on an infinitely long transmission line, it continues to propagate in +z or −z direction depending on the direction of the incident wave. Thus, only one of the two terms consisting of either $e^{-\gamma z}$ or $e^{+\gamma z}$ exists. Let us now consider a transmission line of finite length l , terminated by an arbitrary load impedance Z_L , as shown in Fig. 3. It is assumed that the load is at $z=0$ and the source is connected at $z=-l$.

Using Eqs. (9) and (10), Eqs. (8a) and (8b) can be modified to contain only two unknown voltage amplitudes V_o^+ and V_o^- as

$$V(z) = V_o^+ e^{-\gamma z} + V_o^- e^{\gamma z} \quad (17a)$$

$$I(z) = \frac{V_o^+}{Z_o} e^{-\gamma z} - \frac{V_o^-}{Z_o} e^{\gamma z} \quad (17b)$$

At $z=0$, Eqs. (17a) and (17b) become

$$V_L = V(z=0) = V_o^+ + V_o^- \quad (18a)$$

$$I_L = I(z=0) = \frac{V_o^+}{Z_o} - \frac{V_o^-}{Z_o} \quad (18b)$$

Also, V_L and I_L are related via the load impedance, Z_L , as

$$Z_L = \frac{V_L}{I_L} \quad (19)$$

Using Eqs. (18a) and (18b) in Eq. (19) and rearranging terms, we get

$$V_o^- = \Gamma V_o^+ \quad (20a)$$

where

$$\Gamma = |\Gamma| e^{j\theta_r} = \left(\frac{Z_L - Z_o}{Z_L + Z_o} \right) \quad (20b)$$

Γ , which is the ratio of the reflected wave amplitude and the incident wave amplitude, is called the *voltage reflection coefficient*. As both Z_o and Z_L could be complex quantities, Γ can also be complex in general. It may be seen that, for all transmission lines, $|\Gamma| \leq 1$.

Using Eq. (20a) in Eqs. (17a) and (17b), we get

$$V(z) = V_o^+ (e^{-\gamma z} + \Gamma e^{\gamma z}) \quad (21a)$$

$$I(z) = \frac{V_o^+}{Z_o} (e^{-\gamma z} - \Gamma e^{\gamma z}) \quad (21b)$$

The ratio of $V(z)$ and $I(z)$ is called the *input impedance*, Z_{in} , and is given by

$$Z_{in}(z) = \frac{V(z)}{I(z)} = Z_o \left[\frac{1 + \Gamma e^{2\gamma z}}{1 - \Gamma e^{2\gamma z}} \right] \quad (\Omega) \quad (22)$$

At the input of the transmission line, the input impedance can be written as

$$Z_{in}(-l) = Z_o \left[\frac{1 + \Gamma e^{-2\gamma l}}{1 - \Gamma e^{-2\gamma l}} \right] \quad (\Omega) \quad (23)$$

Substituting Eq. (20b) in Eq. (23) and rearranging the terms, we get

$$Z_{in}(-l) = Z_o \left[\frac{Z_L + Z_o \tanh \gamma l}{Z_o + Z_L \tanh \gamma l} \right] \quad (\Omega) \quad (24)$$

Thus, Z_{in} is the impedance seen at the input of the transmission line, when the line is terminated with a load impedance Z_L . From the generator standpoint, the transmission line-load impedance combination can be replaced by a simple impedance Z_{in} , without disturbing the input voltage and current amplitudes, as shown in Fig. 3b. If the line is lossless, we can substitute for $\gamma = j\beta$ in Eq. (24) and get a modified expression for Z_{in} , as

$$Z_{in}(-l) = Z_o \left[\frac{Z_L + jZ_o \tan \beta l}{Z_o + jZ_L \tan \beta l} \right] \quad (\Omega) \quad (25)$$

4.1. Standing Wave Ratio

Consider a lossless transmission line of characteristic impedance Z_o , which is terminated by an arbitrary load impedance Z_L . From Eqs. (21a) and (21b), the expressions for

Figure 3. (a) A finite length transmission line terminated with a load impedance, Z_L . (b) Equivalent representation in terms of the input impedance, Z_{in} .

$V(z)$ and $I(z)$ for the lossy transmission line can be written as

$$V(z) = V_0^+ (e^{-j\beta z} + \Gamma e^{j\beta z}) \tag{26a}$$

$$I(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} - \Gamma e^{j\beta z}) \tag{26b}$$

The magnitude of the voltage, $|V(z)|$, will be

$$|V(z)| = |V_0^+| \cdot |1 + |\Gamma| e^{j(\theta_r + 2\beta z)}| \tag{27}$$

where, $\Gamma = |\Gamma|e^{j\theta_r}$ has been substituted.

Equation (27) shows that the voltage magnitude oscillates as a function of z , as shown in Fig. 4, indicating the standing wave formation. We can see that the voltage will be maximum when $e^{j(\theta_r + 2\beta z)} = 1$, and is given by

$$V_{\max} = |V_0^+| (1 + |\Gamma|) \tag{28a}$$

Similarly, voltage will be minimum when $e^{j(\theta_r + 2\beta z)} = -1$, and is given by

$$V_{\min} = |V_0^+| (1 - |\Gamma|) \tag{28b}$$

It may be noticed that when the load impedance is the same as the characteristic impedance of the line, the reflection coefficient $\Gamma = 0$, from Eq. (27), and we can see that $|V(z)| = |V_0^+|$, a constant value independent of z . As $|\Gamma|$ increases, the ratio of V_{\max} to V_{\min} increases, which leads us to define *voltage standing wave ratio (VSWR)*, or simply *standing wave ratio (SWR)*, as

$$SWR = \frac{V_{\max}}{V_{\min}} = \frac{1 + |\Gamma|}{1 - |\Gamma|} \tag{29}$$

SWR is always a real number such that $1 \leq SWR \leq \infty$. For a matched transmission line (when $Z_0 = Z_L$), $SWR = 1$. It may also be noted that the distance between two successive voltage maxima (or minima) is $\lambda/2$, where λ is the wavelength on the transmission line.

4.2. Special Cases of Terminated Lossless Transmission Lines

Often, we use lossless transmission lines with special terminations to give interesting characteristics. For example, in impedance tuning networks and microwave filter design we commonly use *stubs* (open- or short-circuited transmission lines) in series or shunt configuration as part of the design. Also, at microwave frequencies, the

Figure 4. Standing wave formation on a lossless transmission line.

open- and short-circuited stubs can be used to replace lumped capacitors and inductors, which are otherwise impractical to realize. Similarly, we use lines with quarter wavelength for impedance transformation. Section 4.2.1 briefly describes the special properties of some of the lossless lines.

4.2.1. Open-Circuited Line. When a transmission line is open-circuited at one end, as shown in Fig. 5a, it sees an infinite load impedance ($Z_L = \infty$). From Eq. (20b), we can see that the voltage reflection coefficient $\Gamma = 1$, which means that the SWR becomes ∞ . From Eqs. (26a) and (26b), the voltage and current on an open-circuited loss-

Figure 5. A lossless transmission line terminated with an (a) open circuit, (b) voltage distribution, (c) current distribution, and (d) input reactance as a function of the distance from the termination.

less transmission line are given by

$$V_{oc}(z) = V_0^+ (e^{-j\beta z} + e^{j\beta z}) = 2V_0^+ \cos \beta z \quad (30a)$$

$$I_{oc}(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} - e^{j\beta z}) = \frac{-2jV_0^+}{Z_0} \sin \beta z \quad (30b)$$

Both voltage and current are plotted as a function of the distance from the load location in Figs. 5b and 5c, respectively. As a result of the sinusoidal nature, both the quantities are periodic and repeat for multiples of λ .

Substituting $Z_L = \infty$ in Eq. (25) for the expression for input impedance, we get

$$Z_{oc} = Z_{in} = -jZ_0 \cot \beta z \quad (\Omega) \quad (31)$$

We can see from Eq. (30) that the input impedance Z_{oc} for the open-circuited line is always purely imaginary irrespective of length z . The variation of open-circuit reactance (imaginary part of Z_{oc}) is plotted as a function of z in Fig. 5d. The plot is again periodic and repeats for multiples of $\lambda/2$. The behavior varies between being inductive and capacitive as the length z is varied.

4.2.2. Short-circuited line. A lossless transmission line short circuited at the load end ($Z_L = 0$) is shown in Fig. 6a. Here, $\Gamma = -1$ and $SWR = \infty$. The voltage and current along the line can be given by

$$V_{sc}(z) = V_0^+ (e^{-j\beta z} - e^{j\beta z}) = -2jV_0^+ \sin \beta z \quad (32a)$$

$$I_{sc}(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} + e^{j\beta z}) = \frac{2V_0^+}{Z_0} \cos \beta z \quad (32b)$$

From Eq. (25), the input impedance for a short-circuited line can be given as

$$Z_{sc} = jZ_0 \tan \beta z \quad (\Omega) \quad (33)$$

The voltage, current, and the input reactance are plotted in Figs. 6b–6d as a function of the distance, z . As it can be seen, the input reactance for a shorted transmission line is also purely imaginary irrespective of the value of z . Comparing Figs. 5 and 6, we can see that in the range where X_{oc} is inductive, X_{sc} is capacitive, and vice versa. The input reactances of the short-circuited and open-circuited lossless transmission lines are essentially the same if their lengths differ by an odd multiple of $\lambda/4$.

Consider an open-circuited transmission line of length much smaller compared with a wavelength. As the electrical length of the line $\beta l \ll 1$, we can make the approximation that $\tan \beta l \cong \beta l$. From Eq. (31), at the input of the line, we have

$$Z_{oc} \cong \frac{Z_0}{j\beta l} = \frac{\sqrt{L/C}}{\omega \sqrt{LC}l} = \frac{1}{j\omega Cl} \quad (34)$$

This equation implies that an open-circuited lossless transmission line with a very short length will behave as a capacitance of Cl farads as shown in Fig. 7a. Similarly,

Figure 6. A lossless transmission line terminated with a (a) short circuit, (b) voltage distribution, (c) current distribution, and (d) input reactance as a function of the distance from the termination.

consider a short-circuited transmission line of small length. From Eq. (33), we get

$$Z_{sc} \approx Z_0 \cdot j\beta l = \sqrt{L/C} \cdot j\omega \sqrt{LC}l = j\omega Ll \quad (35)$$

Thus a short-circuited lossless transmission line with a short length can behave as an inductance of Ll henries, as shown in Fig. 7b.

This property of open- or short-circuited transmission lines behaving as lumped inductors or capacitors will be a useful feature at microwave frequencies, where discrete capacitor or inductor realization will be very difficult because of the parasitics associated with the structure. By proper choice, an open-circuited or short-circuited

Figure 7. Transmission lines as circuit elements.

line can replace the lumped elements during circuit design.

4.2.3. Quarter-wave line. When the length of a transmission line is an odd multiple of $\lambda/4$, ($l = (2n - 1)\lambda/4$, n is a nonzero positive integer),

$$\beta l = \frac{2\pi}{\lambda} (2n - 1) \frac{\lambda}{4} = (2n - 1) \frac{\pi}{2} \Rightarrow \tan \beta l \rightarrow \pm\infty$$

and Eq. (25) becomes

$$Z_{in} = \frac{Z_0^2}{Z_L} \quad (36)$$

Hence, the load impedance connected at one end of a quarter-wave transmission line appears to be inverted at the other end. Thus, an open-circuited quarter-wave line appears to be short circuited at the input terminals and vice versa. This *impedance inverting* feature is used in many circuit design applications such as filters and impedance transformers.

4.2.4. Half-wave line. When the length of a lossless line is an integral multiple of $\lambda/2$ ($l = n\lambda/2$, n is a nonzero positive integer),

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{n\lambda}{2} = n\pi, \Rightarrow \tan \beta l \rightarrow 0$$

and Eq. (25) reduces to

$$Z_{in} = Z_L \quad (37)$$

which implies that a load impedance connected to a half-wave lossless transmission line appears to be the same without any change at the input terminals.

4.3. Transmission Line Characterization from Open- and Short-Circuit Measurements

A microwave network analyzer is an instrument, which can be used to measure the input impedance of any device connected to its input terminal. We can determine the characteristics of an unknown lossy transmission line of length less than or equal to $\lambda/2$, by measuring the input impedance under open-circuit and short-circuit conditions.

From Eq. (24), when $Z_L = \infty$,

$$Z_{oc} = Z_o \coth \gamma l \quad (\text{open-circuited line}) \quad (38)$$

when $Z_L = 0$,

$$Z_{sc} = Z_o \tanh \gamma l \quad (\text{short-circuited line}) \quad (39)$$

From Eqs. (38) and (39), we have

$$Z_o = \sqrt{Z_{oc} Z_{sc}} \quad (\Omega) \quad (40)$$

and

$$\gamma = \frac{1}{l} \tanh^{-1} \sqrt{\frac{Z_{sc}}{Z_{oc}}} \quad (\text{m}^{-1}) \quad (41)$$

where Z_o and γ are the characteristic impedance and propagation constant of the lossy line, respectively.

Example 1. A lossless transmission line of characteristic impedance of 50 ohms is connected to a load impedance of $60 \angle 60^\circ \Omega$. What is the load reflection coefficient? Find the input impedance and voltage reflection coefficient at $l = \lambda/8$ and $3\lambda/8$. Also, calculate the standing wave ratio of the line.

Solution: A simple schematic indicating input impedances at different locations is shown in Fig. 8a.

Load reflection coefficient,

$$\begin{aligned} \Gamma_L &= \frac{(Z_L - Z_o)}{(Z_L + Z_o)} = \frac{(30 + j51.96 - 50)}{(30 + j51.96 + 50)} \\ &= 0.1279 + j0.571 = 0.5837 \angle 78^\circ \end{aligned}$$

From Eq. (25), we have,

$$Z_{in} = Z_o \left[\frac{Z_L + jZ_o \tan \beta l}{Z_o + jZ_L \tan \beta l} \right]$$

Case (i) $l = \lambda/8$

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{\lambda}{8} = \frac{\pi}{4} \Rightarrow \tan \beta l = 1$$

$$(Z_{in})_{\lambda/8} = 50 \left[\frac{30 + j51.96 + j50}{50 + j(30 + j51.96)} \right]$$

$$= 165.96 - j60.85 \quad \Omega$$

$$\Gamma_{\lambda/8} = \left(\frac{165.96 - j60.85 - 50}{165.96 + j60.85 + 50} \right)$$

$$= 0.571 - j0.121 = 0.5837 \angle -12^\circ$$

Case (ii) $l = 3\lambda/8$

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{3\lambda}{8} = \frac{3\pi}{4} \Rightarrow \tan \beta l = -1$$

$$(Z_{in})_{3\lambda/8} = 50 \left[\frac{30 + j51.96 - j50}{50 - j(30 + j51.96)} \right]$$

$$= 13.28 + j4.87 \quad \Omega$$

The input impedance Z_{in} at $3\lambda/8$ can also be determined using a different procedure. Once we have calculated the input impedance at $\lambda/8$, that length of line terminated with the load can be replaced by the calculated input impedance at $\lambda/8$, as shown in Fig. 8b, which leaves with a line with length $3\lambda/8 - \lambda/8 = \lambda/4$. Thus, we have a quarter-

Figure 8. Transmission line problem in Example 1.

wave line of characteristic impedance 50Ω , terminated with a new load $(Z_{in})_{\lambda/8} = 165.96 - j60.85 \Omega$. From Eq. (36), we can calculate $(Z_{in})_{3\lambda/8}$ as

$$\begin{aligned} (Z_{in})_{3\lambda/8} &= \frac{Z_o^2}{(Z_{in})_{\lambda/8}} = \frac{50^2}{165.96 - j60.85} \\ &= 13.28 + j4.87 \Omega \end{aligned}$$

The reflection coefficient at $3\lambda/8$ can be calculated as

$$\begin{aligned} \Gamma_{3\lambda/8} &= \left(\frac{13.28 + j4.87 - 50}{13.28 + j4.87 + 50} \right) = -0.571 + j0.121 \\ &= 0.5837 \angle 168^\circ \end{aligned}$$

We can see that the magnitude of reflection coefficient at different locations is the same, and only the angle changes depending on the distance from the load.

The SWR for the line is

$$SWR = \frac{1 + |\Gamma|}{1 - |\Gamma|} = \frac{1 + 0.5837}{1 - 0.5837} = 3.804$$

5. SMITH CHART

Transmission line calculations, such as determination of input impedance and reflection coefficient, often involve manipulations with complex quantities making it tedious compared with dealing with real numbers. The *Smith chart*, which was developed by P.H. Smith [3,4], is considered to be the most widely used graphical technique for the analysis and design of transmission line circuits. Some readers may feel that in today’s world of powerful computers and modern scientific calculators, graphical ways of solving engineering problems may seem out of the ordinary. More than just being a graphical tool, the Smith chart provides a powerful way of visualizing the transmission line phenomenon, which is why many commercially available popular CAD software used for RF and microwave circuit design have integrated Smith chart calculations into the design stream.

The most common form of the Smith chart is shown in Fig. 9. First, it is important to understand that a Smith chart is essentially a polar plot of the voltage reflection coefficient, Γ . Therefore, we begin with expressing Γ as a complex quantity

$$\Gamma = |\Gamma|e^{j\theta_\Gamma} = \Gamma_r + j\Gamma_i \tag{42}$$

The right-hand side of the horizontal diameter in the chart represents the Γ_r axis, and the top side of the vertical diameter represents the Γ_i axis. $|\Gamma|$ is plotted as a radius ($|\Gamma| \leq 1$) from the center of the chart. The angle, θ_Γ ($-180^\circ \leq \theta_\Gamma \leq 180^\circ$) is measured from the Γ_r axis. We can also relate Γ to the load impedance as

$$\Gamma = \left(\frac{Z_L - Z_o}{Z_L + Z_o} \right) = \left(\frac{Z_L/Z_o - 1}{Z_L/Z_o + 1} \right) = \left(\frac{z_L - 1}{z_L + 1} \right) \tag{43}$$

where

$$z_L = r + jx = \frac{Z_L}{Z_o}$$

z_L is the *normalized* load impedance. In fact, all impedances we plot on the chart are normalized with respect to the characteristic impedance, Z_o .

From Eq. (43), we can write z_L in terms of Γ as

$$z_L = \left(\frac{1 + \Gamma}{1 - \Gamma} \right) \tag{44}$$

Thus, we can write

$$z_L = r + jx = \left(\frac{1 + \Gamma_r + j\Gamma_i}{1 - \Gamma_r - j\Gamma_i} \right) \tag{45}$$

The real and imaginary parts of this equation are

$$r = \frac{1 - \Gamma_r^2 - \Gamma_i^2}{(1 - \Gamma_r)^2 + \Gamma_i^2} \tag{46a}$$

$$x = \frac{2\Gamma_i}{(1 - \Gamma_r)^2 + \Gamma_i^2} \tag{46b}$$

Eqs. (46a) and (46b) can be rearranged as

$$\left(\Gamma_r - \frac{r}{1+r} \right)^2 + \Gamma_i^2 = \left(\frac{1}{1+r} \right)^2 \tag{47}$$

$$(\Gamma_r - 1)^2 + \left(\Gamma_i - \frac{1}{x} \right)^2 = \left(\frac{1}{x} \right)^2 \tag{48}$$

Equation (47) describes a family of circles called the *resistance circles*, where each circle is associated with a specific value of resistance, r . The resistance circles for different values of r are shown on the chart. We can notice that the centers of all r -circles lie on the horizontal axis. All circles pass through the $(\Gamma_r = 1, \Gamma_i = 0)$ point. The largest r -circle is the $r = 0$ circle with a unity radius.

Equation (48) represents the other family of circles called the *reactance circles*, which are also shown on the chart. Different values of x lead to circles of different radii with centers at different positions on the $\Gamma_r = 1$ line. These circles are always orthogonal to the resistance circles. Reactance circles with positive reactance ($x > 0$) lie in the upper half of the chart and those with $x < 0$ lie in the lower half. Intersection of a resistance and reactance circle represents the normalized load impedance, z_L .

One of the main advantages of the Smith chart is that it can be used directly to read the reflection coefficient for a given normalized load impedance and vice versa without having to calculate them. Another useful feature is that the value of the resistance passing through the intersection of the $|\Gamma|$ circle and the Γ_r axis (positive real axis) directly equals the standing wave ratio, SWR. Perhaps the most important feature of the Smith chart is that the angular motion on a constant $|\Gamma|$ circle in a clockwise or counterclockwise direction represents a corresponding movement on a terminated transmission line toward the generator or the load, respectively. Thus, a movement of half a wavelength in the line length on the transmission line corresponds to a complete 360° revolution on the $|\Gamma|$

Figure 9. The Smith chart.

circle reaching the same normalized impedance (or reflection coefficient) point, which reasserts the fact we have seen earlier in the case of a half-wave line, where the input impedance is same as the load impedance. Thus the Smith chart takes into account the periodic behavior of the transmission line.

Example 2. Calculate the input impedance and reflection coefficient for the problem given in Example 1 at $\lambda/8$ and $3\lambda/8$ using the Smith chart. Also, find the SWR of the line.

Solution: The procedure for calculating the above parameters using the Smith chart is described in steps as shown below:

1. Calculate normalized $z_L = Z_L/Z_0 = 0.6 + j1.039$ and mark the same on the Smith chart as point A in Fig. 10.
2. With OA as the radius, draw a circle. Measure the radius and normalize it with respect to the radius of the largest r circle ($r = 0$ circle). Read $|\Gamma| = 0.58$.
3. Extend OA to intersect the angular scale given on the Smith chart for reflection coefficient. Mark the reading. This gives the angle of Γ in degrees. $\theta_r = 78^\circ$.
4. Mark the reading where the $|\Gamma|$ circle intersects the positive real axis. This gives $SWR = 3.8$.
5. From point A, move 0.125λ toward the generator to reach point B. Mark the reading on the angular scale of reflection coefficient. This gives angle of Γ at

Figure 10. The Smith chart solution for Example 2.

$l = \lambda/8$. The magnitude of Γ remains the same. Measure $(\theta_\Gamma)_{\lambda/8}$ as -12° .

6. Mark the normalized impedance value by observing r and x values at B, where $\Gamma = 0.58 \angle -12^\circ$. We get

$$r = 3.3 \text{ and } x = -1.21$$

$$\begin{aligned} \therefore (Z_{in})_{\lambda/8} &= 50.(z_{in})_{\lambda/8} = 50.(3.3 - j1.21) \\ &= 165 - j60.5 \Omega \end{aligned}$$

7. From B, move $\lambda/4$ toward the generator to reach point C. Join OC and extend it to intersect the

angular scale for Γ at 168° . This gives $(\Gamma)_{3\lambda/8} = 0.58 \angle 168^\circ$.

$$(z_{in})_{3\lambda/8} = r + jx = 0.265 + j0.1$$

$$\begin{aligned} (Z_{in})_{3\lambda/8} &= 50.(z_{in})_{\lambda/8} = 50.(0.265 + j0.1) \\ &= 13.25 + j5 \Omega \end{aligned}$$

6. NETWORK PARAMETERS OF A GENERAL LOSSY TRANSMISSION LINE

Transmission lines are used in every microwave network system design. When we look at various blocks of a

Table 2.

Type	Two-port Parameters	
ABCD	$A = \cosh(\gamma l)$ $C = Y_C \sinh(\gamma l)$	$B = Z_C \sinh(\gamma l)$ $D = \cosh(\gamma l)$
Z	$Z_{11} = Z_C \coth(\gamma l)$ $Z_{12} = Z_{21}$	$Z_{21} = Z_C \operatorname{cosech}(\gamma l)$ $Z_{22} = Z_{11}$
Y	$Y_{11} = Y_C \coth(\gamma l)$ $Y_{12} = Y_{21}$	$Y_{21} = -Y_C \operatorname{cosech}(\gamma l)$ $Y_{22} = Y_{11}$
S	$S_{11} = \frac{Z_C^2 - Z_o^2}{2Z_C Z_o \coth \gamma l + Z_C^2 + Z_o^2}$ $S_{12} = S_{21}$	$S_{21} = \frac{2Z_C Z_o}{2Z_C Z_o \cosh \gamma l + (Z_C^2 + Z_o^2) \sinh \gamma l}$ $S_{22} = S_{11}$

microwave system, such as a transceiver, we see components such as amplifiers, mixers, oscillators, and filters interconnected using transmission lines of different characteristic impedances, propagation constants, and lengths. Depending on the overall system requirement, these transmission lines could be realized in different configurations such as a microstrip line, coplanar waveguide, stripline, or waveguide among several variations. For a given physical geometry, the electrical characteristics, Z_o and γ for these transmission lines, can be obtained based on the available analytical/numerical approaches from the literature. Interested readers are encouraged to refer to [5–7].

A common approach in microwave network analysis is to represent each component as a two-port or multiport network and use the network analysis principles to calculate the overall characteristics of the larger network formed by interconnecting various components. In this procedure, each component is associated with a set of network parameters, such as impedance (Z), admittance (Y), transmission (ABCD) or scattering (S) parameters, and the voltage/current or wave amplitudes are interrelated at various junctions/interconnections to obtain the overall characteristics of the system. As with other components, transmission lines can also be treated as microwave networks, and the knowledge of network parameters will often be useful when they are used in a system.

Table 2 presents various commonly used network parameters of a general lossy transmission line. The line is assumed to have a characteristic impedance of Z_C , propagation constant, γ , and length l . The expressions for the scattering (S) parameters assume that the reference port impedance is considered to be Z_o , which is different from the characteristic impedance Z_C . The expressions for a lossless transmission line can be directly obtained from Table 2 by replacing γ with $j\beta$. In the case of scattering

parameters, when $Z_C = Z_o$, the line becomes a matched lossy transmission line of length l and the scattering matrix reduces to

$$S = \begin{bmatrix} 0 & e^{-\gamma l} \\ e^{-\gamma l} & 0 \end{bmatrix} \quad (49)$$

TRANSMISSION LINES AND PARAMETERS

JI CHEN
 RICHARD L. CHEN
 University of Houston
 Houston, Texas

1. INTRODUCTION

In electromagnetic theory, the term *transmission line* usually refers to a structure that can guide TEM waves, such as parallel-plate waveguides or coaxial cables [1–3]. To support TEM waves, at least two conductors and a homogeneous medium in the propagation region are required [4]. Transmission lines are a special class of general electromagnetic waveguides, such as rectangular waveguides and dielectric waveguides. One of the most important properties of a TEM mode on transmission lines is that its voltage, current, and characteristic impedance can be uniquely defined by using the electromagnetic fields. In addition, transmission-line parameters, such as inductance per unit length and capacitance per unit length, can also be uniquely determined using electromagnetic field analyses. Hence transmission line theory bridges the specialized lumped-element electric circuits principles with the general and fundamental approach of electromagnetic theory [2,3,5].

For a TEM mode, only transverse electromagnetic components exist, and therefore electric and magnetic components can be obtained by solving two-dimensional Laplace’s equations in the cross section [2]. This approach is very similar to solving an electrostatic problem. For the simplest transmission line, which is a parallel-plate waveguide, solving Laplace’s equations is very straightforward. However, it is rather difficult to solve Laplace’s equations for transmission lines with more complex cross sections. Conformal transformation methods [6] are usually adopted to transform the complicated cross sections to simpler cases, such as a cross section of parallel-plate waveguides [1,7–14] whose analytical solutions are available. However, for some transmission-line structures, such as striplines, the procedure and results of the conformal transformation approach could be cumbersome [15]. In addition, for transmission lines with inhomogeneous media, such as microstrip lines, analytical solutions are impossible without approximations [16]. To obtain such a solution, quasi-TEM approximations [17–21] are often used. However, as the operating frequency increases due to the dispersive nature as well as the fringe effects, rigorous full-wave analyses, such as the spectral-domain approach [22,23], the integral equation method [24], and the method of lines [25], have to be considered.

This article starts with the derivation of the “telegrapher’s equations” by using the lumped-element circuit model. The transmission-line parameters will be defined and introduced during the derivation. Field analysis is then used to determine those parameters when a particular transmission line is introduced. Five typical transmission-line structures—parallel-plate waveguides,

coaxial cables, two-wire transmission lines, striplines, and microstrip lines—are studied, and their transmission-line parameters are derived on the basis of the results of field analysis. Finally, the transmission-line structures for the IC-level interconnects are introduced, and the challenges for future micro- and nanoscale transmission-line parameter extraction are discussed.

2. TELEGRAPHER’S EQUATIONS

Circuit analysis is the preferred technique when the physical dimensions of a network are much smaller than the wavelength of an electrical signal. However, at radiofrequency (RF) or microwave frequencies, the transmission-line dimension is usually comparable to or even greater than the electrical signal wavelength. The lumped-element circuit model is no longer valid for these types of applications. Under these circumstances, rigorous electromagnetic field analyses are required. To bridge the gap between the rigorous electromagnetic analysis and the circuit theory, a transmission line is modeled as a distributed-parameter network and the transmission-line theory is developed.

The theory starts with dividing the electrically long transmission line into many electrically small pieces, with a segment length Δz , within which region the lumped-circuit model can be applied. A segment of such a division is shown in Fig. 1, where L represents the inductance per unit length, C stands for the capacitance per unit length, R corresponds to the resistance per unit length due to the finite conductivity of the conductors, and G is the conductance per unit length due to the dielectric loss in the material between the two conductors. Both current and voltage are functions of position z and time t , as shown in the figure.

Applying Kirchhoff’s voltage law within each segment, we obtain

$$v(z, t) = v(z + \Delta z, t) + i(z, t)R \Delta z + L \Delta z \frac{\partial i(z + \Delta z, t)}{\partial t} \quad (1)$$

Similarly, applying Kirchhoff’s current law within each segment, we have

$$i(z, t) = i(z + \Delta z, t) + v(z + \Delta z, t)G \Delta z + C \Delta z \frac{\partial v(z + \Delta z, t)}{\partial t} \quad (2)$$

Figure 1. A segment of the divided transmission line.

Rewriting Eqs. (1) and (2) and letting $\Delta z \rightarrow 0$ yield the telegrapher's equations, we obtain

$$\frac{\partial v}{\partial z} = -Ri - L \frac{\partial i}{\partial t} \quad (3)$$

and

$$\frac{\partial i}{\partial z} = -Gv - C \frac{\partial v}{\partial t} \quad (4)$$

Then, combining (3) and (4) yields

$$\frac{\partial^2 v}{\partial z^2} - RGv - (RC + LG) \frac{\partial v}{\partial t} - LC \frac{\partial^2 v}{\partial t^2} = 0 \quad (5)$$

A similar differential equation can also be derived for the current. For time-harmonic cases, $v(z, t) = V(z)e^{j\omega t}$, (5) can be simplified as

$$\frac{d^2 V}{dz^2} - \gamma^2 V = 0 \quad (6)$$

where

$$\gamma = \alpha + j\beta = \sqrt{ZY} \quad (7)$$

In (7), γ is the complex propagation constant. Z and Y are series impedance and shunt admittance per unit length, written as

$$Z = R + j\omega L \quad (8)$$

and

$$Y = G + j\omega C \quad (9)$$

The general solution of (6) is

$$V(z) = V_0^+ e^{-\gamma z} + V_0^- e^{\gamma z} \quad (10)$$

Similarly, the general solution for the current distribution along the transmission can be written as

$$I(z) = I_0^+ e^{-\gamma z} + I_0^- e^{\gamma z} \quad (11)$$

In (10) and (11), the superscript + denotes the voltage/current that propagates along the +z direction and the superscript - denotes the voltage/current that propagates along the -z direction. The characteristic impedance of such transmission line is then defined as

$$Z_0 = \frac{V_0^+}{I_0^+} = -\frac{V_0^-}{I_0^-} = \sqrt{\frac{Z}{Y}} \quad (12)$$

For lossless cases, the transmission-line characteristic impedance can be simplified as follows:

$$Z_0 = \sqrt{\frac{L}{C}} \quad (13)$$

Another important parameter of the wave propagation along transmission lines is the phase velocity:

$$v_p = \frac{\omega}{\beta} \quad (14)$$

A lossless transmission line, can be expressed as follows:

$$v_p = \frac{1}{\sqrt{LC}} \quad (15)$$

The *phase velocity* is the quantity that describes the propagation speed of the constant wave front along the transmission line.

3. TRANSMISSION-LINE PARAMETERS

As shown in the previous section, an electrically long transmission line can be divided into many electrically small sections. Those small sections can be represented by lumped-circuit elements that are related to the per unit length transmission-line resistance, inductance, capacitance, and conductance. To accurately evaluate those parameters, rigorous electromagnetic analysis has to be used. Fortunately, the transmission-line theory discussed here is limited only to the TEM wave. Hence, the inductance, capacitance, and conductance per unit length can be determined from a static solution to a 2D Laplace equation in the cross section of transmission-line structures. The resistance per unit length can be obtained from electromagnetic field distribution inside the conductors.

The inductance per unit length is associated with the time-average stored magnetic energy for a 1-m section of the transmission line. If the transmission line structure is embedded in a homogeneous medium characterized by a permittivity of ϵ , a permeability of μ , and a loss tangent of $\tan \delta$, the inductance per unit length can be evaluated by [2]

$$L = \frac{4W_m}{|I_0|^2} = \frac{\mu}{|I_0|^2} \int_S \vec{H} \cdot \vec{H}^* ds \quad (16)$$

where the integration is carried out on the surface of a cross section S of the transmission line, W_m is the time-average stored magnetic energy, and I_0 is the total current on one of the conductors. The capacitance per unit length is related to the time-average stored electric energy for a 1-m section of the transmission line, which can be expressed as [2]

$$C = \frac{4W_e}{|V_0|^2} = \frac{\epsilon}{|V_0|^2} \int_S \vec{E} \cdot \vec{E}^* ds \quad (17)$$

where W_e is the time-average stored electric energy and V_0 is the potential difference between the two conductors. The conductance per unit length is related to the time-average power dissipated per unit length in the lossy dielectric medium. The per unit length conductance is given by [2]

$$G = \frac{2P_d}{|V_0|^2} = \frac{\omega\epsilon \tan \delta}{|V_0|^2} \int_S \vec{E} \cdot \vec{E}^* ds \quad (18)$$

where P_d is time-average power dissipated per unit length. Similarly, the resistance per unit length is related to the power loss per unit length due to the finite metal conductivity. For a good conductor with a conductivity of σ , the resistance per unit length is given by [2]

$$R = \frac{2P_c}{|I_0|^2} = \frac{R_s}{|I_0|^2} \int_{C_1+C_2} \vec{H} \cdot \vec{H}^* dl \quad (19)$$

where P_c is power loss per unit length due to the finite metal conductivity, $R_s = \sqrt{\omega\mu}/2\sigma$ is the surface resistance of the conductors, and C_1 and C_2 represent integral paths over the conductor boundaries.

With the parameters defined above, in the remainder of this section we discuss five typical transmission-line structures and derive their corresponding parameters.

3.1. Parallel-Plate Waveguide

A parallel-plate waveguide, shown in Fig. 2, is probably the simplest type of transmission-line structure that supports a TEM wave. It has two parallel metal plates with a width W and a separation h . A homogeneous medium characterized by a dielectric constant ϵ and a loss tangent $\tan \delta$ is filled in between. The strip width W is usually much greater than the separation h , so that fringing fields and field variations in the x direction can be ignored.

Assuming that the potential difference between the two plates is V_0 , the electric field can be obtained by solving Laplace's equations; hence

$$\vec{E} = -\hat{y} \frac{V_0}{h} e^{-jkz} \quad (20)$$

where k is the propagation constant along the z direction. The magnetic field is given by

$$\vec{H} = \frac{1}{\eta} \hat{z} \times \vec{E} = \hat{x} \frac{V_0}{\eta h} e^{-jkz} \quad (21)$$

where $\eta = \sqrt{\mu/\epsilon}$ is the intrinsic impedance in the medium.

Figure 2. Geometry of a parallel-plate waveguide.

The total current on either the top or bottom plate can be found from the surface current density:

$$I_0 = \int_{x=0}^W \vec{J}_s \cdot \hat{z} dx = \int_{x=0}^W (-\hat{y} \times \vec{H}) \cdot \hat{z} dx = \frac{WV_0}{\eta h} \quad (22)$$

Substituting (21) and (22) into (16), we can obtain the inductance per unit length of a parallel-plate waveguide as follows:

$$L = \frac{\mu}{|I_0|^2} \int_0^h \int_0^W \frac{|V_0|^2}{\eta^2 h^2} dx dy = \frac{\mu h}{W} \quad (23)$$

Similarly, substituting (20) into (17), (20) into (18), and (21) and (22) into (19), we can obtain the capacitance, conductance, and resistance per unit length as

$$C = \frac{\epsilon}{|V_0|^2} \int_0^h \int_0^W \frac{|V_0|^2}{h^2} dx dy = \frac{W\epsilon}{h} \quad (24)$$

$$G = \frac{\omega\epsilon \tan \delta}{|V_0|^2} \int_0^h \int_0^W \frac{|V_0|^2}{h^2} dx dy = \frac{\omega\epsilon \tan \delta W}{h} \quad (25)$$

and

$$R = \frac{2R_s}{|I_0|^2} \int_0^h \int_0^W \frac{|V_0|^2}{\eta^2 h^2} dx dy = \frac{2R_s}{W} \quad (26)$$

Usually the conducting loss or the dielectric loss is negligible when we evaluate the characteristic impedance [2]. Hence, the characteristic impedance of a parallel-plate waveguide is given by [2]

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{\eta h}{W} \quad (27)$$

3.2. Coaxial Cable

When the upper and lower conductors of a parallel-plate waveguide are folded into two concentric circles, a coaxial cable waveguide is formed. Coaxial cable transmission lines are widely used in many applications ranging from high-precision radiofrequency (RF) signal measurement to low-cost TV signal delivery. A typical cross section of a coaxial cable is shown in Fig. 3. It has an inner conductor with a radius a and an outer conductor with a radius b . A homogeneous medium, with a dielectric constant ϵ and a loss tangent $\tan \delta$, is filled between these two conductors.

The magnetic field between the inner and outer conductors can be derived by using Ampere's law:

$$\vec{H}(\rho) = \frac{I_0}{2\pi\rho} \hat{\phi} \quad (28)$$

Substituting (28) into (16), we can obtain the inductance per unit length as follows:

$$L = \frac{\mu}{|I_0|^2} \int_a^b \int_0^{2\pi} \frac{|I_0|^2}{(2\pi\rho)^2} d\phi \rho d\rho = \frac{\mu}{2\pi} \ln \frac{b}{a} \quad (29)$$

Figure 3. A cross section of a coaxial cable.

Also, applying Gauss' law in the region $a \leq \rho \leq b$ results in

$$E_\rho = \frac{\rho_l}{2\pi\epsilon\rho} \quad (30)$$

where ρ_l is the charge density per unit length. Integrating the electric field from the inner conductor to the outer conductor gives the voltage potential difference as

$$V_0 = - \int_b^a E_\rho d\rho = \frac{\rho_l}{2\pi\epsilon} \ln\left(\frac{b}{a}\right) \quad (31)$$

Substituting (30) and (31) into (17), we can obtain the capacitance per unit length:

$$C = \frac{2\pi\epsilon}{\ln(b/a)} \quad (32)$$

The conductance and resistance per unit length can be derived by substituting corresponding electric and magnetic fields into (18) and (19):

$$G = \frac{2\pi\omega\epsilon \tan \delta}{\ln(b/a)} \quad (33)$$

$$R = \frac{R_s}{2\pi} \left(\frac{1}{a} + \frac{1}{b} \right) \quad (34)$$

Neglecting the dielectric and conducting loss, we can obtain the characteristic impedance of a coaxial cable as

$$Z_0 = \eta \frac{1}{2\pi} \ln\left(\frac{b}{a}\right) \quad (35)$$

Figure 4. Conformal mapping from a cross section of coaxial cable to a cross section of a parallel-plate waveguide.

Alternatively, the parameters L , C , and G can also be obtained by using a conformal transformation, $w = \ln z$. After the transformation, the coaxial cable structure in the original complex plane z can be transformed to a parallel-plate waveguide in plane w , with a width 2π and a thickness $\ln(b/a)$, as shown in Fig. 4. Substituting the corresponding width and thickness into (23), (24), and (25), we can find that the parameters of L , C , and G are identical to those obtained from the direct electromagnetic analysis. However, the resistance per unit length cannot be derived from conformal transformation since this parameter depends on the electromagnetic field distribution inside the conductors rather than the electromagnetic fields between the conductors.

3.3. Two-Wire Transmission Line

Another kind of frequently used transmission-line structure is the two-wire transmission line. It is also referred to as a *twin-line structure*. This type of line is mostly used for powerlines, rural telephone lines, and telegraph lines. A cross section of a two-wire transmission-line structure is shown in Fig. 5. Both wires have a radius a , and the separation between these two wires is D . In general terms, we assume that the two-wire transmission line is embedded in a medium with a dielectric constant ϵ and a loss tangent $\tan \delta$. The effect of the wire conductivity can be represented by surface resistance R_s .

Since the electric and magnetic field solutions in the two-wire system have a more complex distribution than does either the parallel-plate waveguide or the coaxial cable structure, it is rather difficult to evaluate the transmission line parameters by simply integrating the electric or magnetic fields. However, by choosing an appropriate conformal mapping, we can transform the two-wire transmission line to a parallel-plate waveguide and hence the

Figure 5. A cross section of a two-wire transmission line.

capacitance, inductance and conductance per unit length can be easily derived.

Using the conformal transformation, $w = \frac{1}{2} \ln[(1+z)/(1-z)]$, we can map the cross section of a two-wire transmission line in the complex z plane to the cross section of a parallel-plate waveguide in the complex w plane, as shown in Fig. 6. The parallel-plate waveguide has a width of π and a separation distance of $\cosh^{-1}(D/2a)$. Hence substituting $W = \pi$ and $h = \cosh^{-1}(D/2a)$ into (23), (24) and (25), we have

$$L = \frac{\mu}{\pi} \cosh^{-1}\left(\frac{D}{2a}\right) \tag{36}$$

$$C = \frac{\pi\epsilon}{\cosh^{-1}(D/2a)} \tag{37}$$

and

$$G = \frac{\pi\omega\epsilon \tan \delta}{\cosh^{-1}(D/2a)} \tag{38}$$

Typically, the spacing between wires D is much larger than the wire radius a , so that proximity effects can be neglected [10]. For the same reason, the induced magnetic field on one wire due to the current on the other wire can be ignored. As a result, the resistance per unit length can be obtained from (19)

$$R = \frac{2R_s}{|I_0|^2} \int_0^{2\pi} \frac{|I_0|^2}{4\pi^2 a^2} a d\varphi = \frac{R_s}{\pi a} \tag{39}$$

Neglecting the dielectric and conductor loss, the characteristic impedance of a two-wire transmission line is given by

$$Z_0 = \eta \frac{\cosh^{-1}(D/2a)}{\pi} \tag{40}$$

3.4. Striplines

Striplines are often used in wideband networks and devices because of their low radiation, dispersion and loss. The cross section of a stripline is shown in Fig. 7. It has two parallel outer conductors with a separation b and also

Figure 6. Conformal mapping of the cross section of a two-wire transmission line to the cross section of a parallel-plate waveguide.

Figure 7. The cross section of a stripline transmission line.

a thin conducting strip with a width W , which is centered in between two conductors. The inner conductor is embedded in a homogeneous and isotropic dielectric with a relative dielectric constant ϵ_r and a loss tangent $\tan \delta$. Since a stripline structure has more than two conductors and a homogeneous dielectric, a TEM wave can be supported.

As in similar previous cases, we can apply the conformal transformation to map this complex structure into a parallel-plate waveguide [1]. Here, the Schwarz–Christoffel transformation needs to be applied twice. First, the cross section of a stripline in w plane is mapped to the real axis in z plane. Then another Schwarz–Christoffel transformation is used to map the real axis in the z plane to a cross section of the parallel-plate waveguide in the w' plane.

Due to the symmetry, we only need to consider a quarter of the structure, as shown in Fig. 8. Using a mapping function

$$w = -\frac{b}{\pi} \ln \left[z^{\frac{1}{2}} + (z+1)^{\frac{1}{2}} \right] + j \frac{b}{2}, \tag{41}$$

the structure in the w plane can be transformed to two flat strips in the z plane, as shown in Fig. 8. Note that five points, $w_0 = -W/2$, $w_1 \rightarrow -\infty$, $w_2 = 0$, $w_3 = jb/2$ and $w_4 \rightarrow -\infty + jb/2$ in the w plane are mapped to the points, $-x_0$, $x_1 \rightarrow -\infty$, $x_2 = -1$, $x_3 = 0$ and $x_4 \rightarrow \infty$ in the z plane correspondingly. As a result, the center strip and the ground plane in the w plane correspond to the short strip in the left half space and the half infinite strip in the z plane. The value of x_0 is

$$x_0 = \cosh^2 \left(\frac{\pi W}{2b} \right) \tag{42}$$

The new structure is still difficult to analyze. Therefore, a second Schwarz–Christoffel transformation is used to

Figure 8. Conformal mapping for a symmetric stripline.

map the structure in the complex z plane to a parallel-plate waveguide in the w' plane, as shown in Fig. 9. Through the second transformation, the points $-x_0$, x_2 , x_3 , and x_4 in the z plane are mapped to the points $w'_0=0$, $w'_2=1$, $w'_3=1+jv_0$, and $w'_4=jv_0$ in the w' plane, respectively. Therefore the center strip and the ground plane in the w plane correspond to the bottom and top plates in the w' plane.

The transformation function of this second mapping is given by

$$w' = A_0 \text{Sn}^{-1}[(-z)^{1/2}, x_0^{(1/2)}] + B_0 \quad (43)$$

where $A_0 = -jv_0/\{\text{Sn}^{-1}[1, x_0^{(1/2)}]\}$, $B_0 = 1 + jv_0$, and

$$\text{Sn}^{-1}(x, k) = \int_0^x \frac{d\lambda}{[(1-\lambda^2)(1-k^2\lambda^2)]^{1/2}}$$

Also $\text{Sn}^{-1}(x, k)$ is called an *inverse elliptic function*, and the separation between the parallel plates is given by

$$v_0 = \frac{j\text{Sn}^{-1}(1, x_0^{(1/2)})}{\text{Sn}^{-1}(1, x_0^{(1/2)}) - \text{Sn}^{-1}(x_0^{(1/2)}, x_0^{(1/2)})} \quad (44)$$

Obviously, the capacitance per unit length of the stripline is 4 times that of the mapping of one-quarter section in the w' plane; therefore it is given by

$$C = \frac{4\epsilon}{v_0} \quad (45)$$

Furthermore, the characteristic impedance can be obtained as

$$Z_0 = \frac{\sqrt{\epsilon\mu}}{C} \quad (46)$$

Simpler forms have been developed based on the curve fitting of the exact solutions developed above [15,23]. For example, for the characteristics impedance, it can be

Figure 9. Conformal mapping from z plane to w' plane.

approximated by [2]

$$Z_0 = \frac{30\pi}{\sqrt{\epsilon_r}} \frac{b}{W_e + 0.441b} \quad (47)$$

where W_e is the effective width of the center conductor given by

$$\frac{W_e}{b} = \frac{W}{b} - \begin{cases} 0 & \text{for } W/b > 0.35 \\ (0.35 - W/b)^2 & \text{for } W/b < 0.35 \end{cases} \quad (48)$$

The inductance per unit length can be obtained by

$$L = Z_0^2 C \quad (49)$$

For this particular structure, the attenuation constant is often used to characterize the dielectric loss. The attenuation constant due to the dielectric loss is given by [2]

$$\alpha_d = \frac{k \tan \delta}{2} \quad (50)$$

and the attenuation constant due to the conductor loss can be found by the perturbation method or Wheeler's incremental inductance rule. An approximate result is [2]

$$\alpha_c = \begin{cases} \frac{2.7 \times 10^{-3} R_s \epsilon_r Z_0}{30\pi(b-t)} A & \text{for } \sqrt{\epsilon_r} Z_0 < 120 \\ \frac{0.16 R_s}{Z_0 b} B & \text{for } \sqrt{\epsilon_r} Z_0 > 120 \end{cases} \quad (51)$$

with

$$A = 1 + \frac{2W}{b-t} + \frac{1}{\pi} \frac{b+t}{b-t} \ln \left(\frac{2b-t}{t} \right) \quad (52)$$

$$B = 1 + \frac{b}{(0.5W + 0.7t)} \left(0.5 + \frac{0.414t}{W} + \frac{1}{2\pi} \ln \frac{4\pi W}{t} \right) \quad (53)$$

where t is the thickness of the strip.

3.5. Microstrip Lines

The microstrip line is the most popular planar transmission line in microwave integrated circuits (MIC). Figure 10 shows a typical microstrip-line configuration. It has a conducting strip, with a width W , residing on the top of a dielectric slab that has a thickness of h and a dielectric constant of ϵ_r . The microstrip configuration is not capable of supporting a pure TEM wave [2]. The propagation modes on microstrip lines need to be accurately characterized by hybrid transverse magnetic (TM)–transverse electric (TE) modes. However, the hybrid modes cannot be fully described in terms of static capacitances and inductances, like the previous transmission lines. Fortunately, the substrate thickness is usually electrically thin, and hence a quasi-TEM-mode assumption can be made.

In the quasi-TEM approximation, an artificial homogeneous dielectric, which has an effective dielectric constant ϵ_e , is assumed to fill the entire upper half-space above the

Figure 10. Configuration of a microstrip line.

ground plane. The effective dielectric constant and characteristic impedance can be obtained using curve-fitting approximations from rigorous quasistatic solutions as described in Refs. 2 and 16. The effective dielectric constant of a microstrip line is given by

$$\epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \frac{1}{\sqrt{1 + 12h/W}} \quad (54)$$

The characteristic impedance is given by

$$Z_0 = \begin{cases} \frac{60}{\sqrt{\epsilon_e}} \ln\left(\frac{8h}{W} + \frac{W}{4d}\right) & \text{for } \frac{h}{d} \leq 1 \\ \frac{120\pi}{\sqrt{\epsilon_e}[W/h + 1.393 + 0.667 \ln(W/h + 1.444)]} & \text{for } \frac{h}{d} \geq 1 \end{cases} \quad (55)$$

The capacitance per unit length is given by

$$C = \frac{\sqrt{\epsilon_e}}{cZ_0} \quad (56)$$

where c is the speed of light in free space. The inductance per unit length is given by

$$L = Z_0^2 C \quad (57)$$

The attenuation constant due to the dielectric loss is

$$\alpha_d = \frac{k_0 \epsilon_r (\epsilon_e - 1) \tan \delta}{2\sqrt{\epsilon_e} (\epsilon_r - 1)} \quad (58)$$

The attenuation constant due to the conductor loss is

$$\alpha_c = \frac{R_s}{Z_0 W} \quad (59)$$

where $R_s = \sqrt{\omega\mu_0/2\sigma}$ is the surface resistivity of the conductor.

In this section, we have derived the parameters of five commonly used transmission-line structures for RF and microwave applications. Driven by future system-on-chip (SoC) and system-on-packaging (SoP) applications,

transmission-line structures have been extended to the IC level [26].

4. TRANSMISSION LINE AT IC LEVEL

For SoC/SoP applications, RF circuits and GHz digital circuits often reside on the same substrate at very close spacing. The undesired interaction between transmission-line pairs plays a significant role in determining circuit performance [27–30]. To reduce the crosstalk between different transmission-line pairs, a dedicated return ground is often required. As a result of the manufacturing process, it is difficult to fabricate a dedicated global ground for all transmission-line structures. To guarantee the quality of signal transmission at the IC level, the often used transmission-line structure is the coplanar waveguide (CPW). Similar to microstrip-line structures, the CPW structure also cannot support a pure TEM mode. A quasistatic approximation must be made in order to apply the transmission-line theory to analyze this structure.

A CPW structure at the IC level is shown in Fig. 11 [26]. The center conductor is the signal trace while two neighboring traces are considered as the ground. In general, due to the conductor skin effect, the width-to-height ratio of the conductor, the high conductive loss in the substrate, and the strong dispersive effects, it is very difficult to extract the transmission-line parameters using analytical approaches [26,29]. Numerical techniques, such as the method of moments (MoM), the partial-element equivalent circuit (PEEC), the finite-difference time-domain (FDTD) method, or the finite-element method (FEM) are often required to extract these transmission-line parameters. Each numerical method has its advantages and disadvantages for different IC applications. For example, the PEEC method is very efficient when it is applied to model the transmission-line conductors, while the FDTD and FEM methods have their advantages if the effects of the IC substrate profile must be included. How to efficiently extract the parameters for multi-layered transmission line at the IC level is still an ongoing research topic [31,32].

5. CONCLUSIONS

The transmission line is one of the key devices in RF circuits, microwave circuits, and high-speed digital circuits.

Figure 11. A common ground-signal-ground (GSG) transmission-line structure at IC level.

It is used to deliver signal or power from one device to other devices. Signal propagation behaviors on the transmission lines can be modeled using the telegrapher's equations. The electrical characteristics of different types of transmission lines can be described by using transmission-line parameters, such as the capacitance and the inductance per unit length for a lossless transmission line. If the conductor loss and the dielectric loss are considered, two more parameters, the resistance and the conductance per unit length, also need to be considered. This article starts with the derivation of the telegrapher's equations. Five commonly used transmission lines—parallel-plate waveguides, coaxial cables, two-wire transmission lines, striplines, and microstrip lines—are introduced and their transmission line parameters are derived. For the first three kinds of transmission line structures, four parameters, R , L , C , and G , as well as the characteristic impedance Z_0 , are derived from direct field analysis or conformal transformations. For stripline structures, a simple curve-fitting formula was developed for the capacitance per unit length. Then the inductance per unit length and the characteristic impedance were derived. The loss terms were described by the conductor loss constant and the dielectric loss constant, as shown earlier in the article. For microstrip lines, a quasi-TEM wave assumption was made to extract the transmission-line parameters Z_0 , C , and L . Similar to the striplines, the conductor loss constant and the dielectric loss constant were introduced.

As current technology allows us to develop transmission-line structures on ICs at high density, how to efficiently extract these transmission line parameters is still an ongoing research. As an example, an IC level CPW was discussed. With the development of new transmission-line structures at micrometer and nanometer scales, both the design of novel transmission-line structures and the techniques for their parameter extraction are topics currently being researched.

TRANSMITTERS FOR ANALOG TELEVISION

GERALD W. COLLINS
GW Collins Consulting,
Quincy, Illinois

Significant advances continue to be made in television (TV) transmitter technology. New technology has been introduced to provide high-quality TV signal transmission while improving reliability, reducing maintenance, and lowering overall cost of ownership. These new technologies include solid-state, high-power amplifiers and improvements in UHF tube transmitters. The FCC continues its policy of technical deregulation, which allows more flexibility in transmitter design and system operation. This article discusses the relevant technology and provides the information needed to understand the operation, design criteria, and some of the future developments of TV transmitters. Although this information is presented from the viewpoint of equipment used in the United States, the principles apply to analog TV broadcasting worldwide. Specific details and numerical constants may differ in other systems, but the fundamental principles are the same.

TV transmitters are composed of two essential components: the exciter and the RF power amplifier (PA). The exciter provides the signal processing functions to convert a baseband TV signal into a modulated RF signal on the assigned channel. These functions include baseband signal processing, modulation, precorrection, equalization, upconversion, bandlimiting, and amplification to a relatively low-power RF signal. Although different methods are used for different types of signals, all functions must be performed regardless of whether the baseband signal is video or audio. Because the output of the exciter is a modulated RF signal, most commercially available exciters are considered low-power transmitters.

The basic block diagram of a television transmitter that provides separate amplification of visual and aural signals is shown in Fig. 1. The visual portion of the exciter receives a video baseband signal, processes it, and converts it to a fully modulated vestigial sideband signal. Because intermediate-frequency (IF) modulation is used in all modern TV transmitters, most of the signal processing occurs in the video and IF stages. Similarly, the aural por-

tion of the exciter receives the audio baseband signal, processes it, and converts it to a frequency-modulated signal. The exciter includes all blocks through the upconverter.

For transparent transmission of video, it is important to optimize the incoming signal, which is done in the video processing section of the exciter. The following are the main functions of the exciter video processing circuitry:

- Assurance of proper sync:video ratio
- Removal of common mode signals
- Provision for overall video-level control
- DC restoration
- Prevention of overmodulation
- Frequency response correction

In nearly all IF-modulated transmitters, the visual modulator is a broadband, balanced, diode mixer. It is configured for maximum rejection of the local-oscillator signal and biased to provide excellent linearity, low noise, and capability to achieve carrier cutoff. The video signal is DC-offset to provide the proper modulation level. Peak of sync corresponds to maximum IF envelope output, and white corresponds to minimum IF output. The output signal of the modulator is a double-sideband AM signal that has a modulation depth of 12.5%. A surface acoustic wave (SAW) filter removes the lower sideband and produces vestigial sideband (VSB) modulation. This filter also bandlimits the upper sideband to within 4.75 MHz of the visual carrier.

In its most basic form, the aural exciter consists of an audio processor, a frequency-modulated IF oscillator, and an upconverter. To ensure that the transmitter is not the limiting factor in monaural and stereo audio reproduction, the transmitter must add as little distortion as possible to the incoming signal. Baseband audio of the BTSC multi-channel television sound (MTS) system may include monophonic or stereo, a second audio program (SAP), and professional channels. These signals may include frequency components out to 105 kHz. To achieve good stereo separation and minimum crosstalk between the stereo and the SAP channels, it is necessary to achieve good phase linearity, low distortion, and reduced amplitude ripples and rolloff over the stereo passband. Errors in phase linearity and amplitude response within the audio

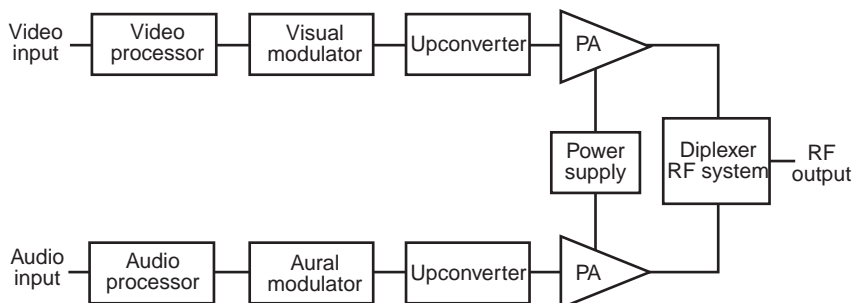

Figure 1. Block diagram of a basic television transmitter.

circuitry contribute to stereo separation degradation. As a general rule, amplitude rolloff should be less than 0.1 dB, and departure from phase linearity should be less than 1° for quality stereo.

Transmitters employing IF modulation generate visual IF, aural IF, and master oscillator signals for translating visual and aural IF to the final carrier frequencies. These signals are implemented with either digital synthesizers or crystal oscillators. An advantage of the synthesizer is that only one crystal is needed at a single standard frequency for all TV channels. Synthesized sources should be tested for spurious frequencies that may appear as FM noise. The crystal oscillator usually involves simpler circuitry.

The PA provides the “muscle” to amplify the modulated RF signal to the desired level for transmission. The type of power amplifier technology used to perform this function is key. Both solid-state and tube devices are available in commercial equipment. For VHF channels, solid-state devices predominate. For UHF, both solid-state and tube devices are used. TV transmitters are unique in that no other application requires such high levels of linear RF power generation while operating virtually uninterruptedly. This has led to the development of specialized techniques to assure highly efficient and reliable operation. The need for high efficiency has led to the near-universal use of partially saturated class AB final power amplifiers. This, in turn, has resulted in the development of precorrection and equalization techniques to compensate for residual nonlinearity inherent in this class of operation. To achieve the levels of reliability required, redundant system architectures that minimize single points of failure are used.

Traditionally, TV transmitters have used separate RF amplifier chains for the visual and aural signal paths. This is generally the most cost-effective approach for high-power, solid-state transmitters for both VHF and UHF. Many broadcast engineers believe that separate amplification provides the highest-quality transmitted video. With the introduction of inductive output tubes (IOTs) as final high-power UHF amplifiers, it has become popular to combine the visual and aural signals in the exciter and amplify them together in the stages that follow.

For visual signals in separate amplification and combined aural and visual signals in common amplification, it is important that the power amplifier have a linear transfer characteristic in amplitude and phase and flat, symmetric frequency response and minimum group delay variation across the modulation passband. For visual-only signals, the required bandwidth is 4.5 MHz. For common amplification and digital signals, 6 MHz is required.

Even though linear class AB amplifiers are used, some residual nonlinearity remains. With combined amplification, the visual, color subcarrier, and aural signals are mixed to produce in-band as well as the out-of-band intermodulation (IMD) and cross-modulation products. The out-of-band products sufficiently removed from the channel of operation may be eliminated by a high-level filter. However, in-band products can be reduced to acceptable

levels only by making the transmitter sufficiently linear. This requires highly effective precorrection circuits in the IF and/or RF signal paths. For example, the IMD within ± 920 kHz of the visual carrier can be precorrected by low-level IF circuitry.

For optimum stereo performance a nonlinear class C amplifier with flat response and group delay across the modulation passband may be used. Because frequency modulation and demodulation constitute a nonlinear process, there is no one-to-one correspondence between RF amplitude and phase response and baseband stereo separation and crosstalk. Generally, a 3 dB bandwidth of 1.5 MHz provides excellent stereo and SAP performance.

Other key functions in the PA, common to all amplifier technologies, include cooling and AC-to-DC power conversion. Proper cooling of the power amplifier, whether solid-state or tube is important for safe operation and high reliability. For example, it is generally acknowledged that the service life of a transistor doubles approximately for every 10°C reduction in junction temperature. Power amplifier cooling may employ either liquids or air. Distributed air-cooling systems using more than one fan offer good redundancy for solid-state amplifiers. Motor and fan technology has matured to the point where a single, large, direct drive fan is as reliable as many smaller fans. Because many RF power amplifiers modules may be employed in a solid-state transmitter, a large volume of air is needed to cool the heatsinks adequately. Low-pressure fans or blowers may be used if heatsink fin density is not high. This aids in reducing audible noise. The heat is distributed over a large volume of air, and the temperature rise is relatively low.

Cooling of most tube amplifiers requires large volumes of liquid. For example, cooling a 60-kW IOT, typically used for high-power UHF applications, requires about 25 gallons per minute of liquid for the collector under maximum ambient temperature conditions. The body of the tube is also liquid-cooled. A 50:50 water/glycol solution is typically used in cold climates without any special water purification. Input and output cavities are air-cooled. Lower-power IOTs may be air-cooled. Air cooling is also used to cool other transmitter components, such as the intermediate power amplifier (IPA).

Power supply design is critical to the performance and reliability of television transmitter power amplifiers, whether solid-state or tube. Because FET and bipolar devices are low-voltage devices, the power supplies that serve solid-state transmitters must provide low voltage and high current. High-reliability connections must be guaranteed in the DC distribution. Because the available power output from any amplifier varies with the square of the DC voltage applied, it is desirable that the supply remain very tightly controlled over incoming AC line variation. The amplifier current also changes with modulation, thus requiring videofrequency currents from the power supply. The supply must provide excellent regulation from no load (white picture) to full load (peak sync output) and a low source impedance for all videofrequencies. The efficiency of the power supply is important because dissipated power results in heat and unnecessarily high utility costs. Any voltage or current transients or

voltage sags at the AC input should be suppressed before reaching any solid-state device.

Television transmitters that employ separate amplification and use a common antenna and transmission line for visual and aural require a high level diplexer to combine the visual and aural signals before transmission. Other components required in the output RF system include harmonic filters and a color notch filter. If multiple transmitters or PA cabinets are combined, power combiners and RF switching devices are also required.

1. KEY PERFORMANCE FACTORS AND OPERATIONAL CONSIDERATIONS

The key performance factors for the visual portion of a television transmitter include power output, linearity, efficiency, and reliability. These factors are also important for the aural section except that linearity in separate amplification aural amplifiers is not needed.

The geographic separation and effective radiated power (ERP) of television stations are carefully specified by the FCC to assure reliable service within the coverage area and to avoid interference between stations operating on the same frequency, that is, cochannel interference. The visual transmitter power output (TPO) is determined from the ERP by using the antenna gain [1] *g* and the transmission-line efficiency η . Stated mathematically

$$TPO = \frac{ERP}{g\eta}$$

ERP is given in kilowatts (kW) of power at the peak of the synchronizing (sync) pulse so that the TPO is also in kW at the peak of sync. Table 1 relates TPO and ERP for typical lowband VHF, highband VHF, and UHF stations using the maximum allowable ERP for each band.

The transmission line efficiency varies depending on tower height and the type and size of line selected. The minimum line size is determined by the TPO and desired line efficiency.

Aural power may range from 5 to 20% of the visual peak sync value. Most stations transmit aural at 10%, although some UHF stations using common amplification reduce the aural power to as low as 5% to reduce IMD products.

Calibration of transmitter power is vitally important. ERP is specified by the FCC. Thus, maintaining TPO within tolerance assures that the ERP is in accordance with the allocation. If the power output is not accurately known, the amplifier dissipation and efficiency are equally

Table 1. Typical Transmitter Power Output (TPO) for VHS and UHF

Band	ERP (kW)	Antenna Gain	Line Efficiency (%)	TPO (kW)
Low VHF	100	6	85	19.6
High VHF	316	12	80	32.9
UHF	5000	30	76	219.3

unknown, and power amplifier device life may be shortened. In addition, linearity precorrection circuits must be set up at a known, stable power level to assure that system linearity is maintained. Calibration of power level is best done by using a calorimeter, especially for higher-power transmitters. In a calorimeter, the temperature rise of a known volume of water caused by the heat generated in a water-cooled load is used to determine the average power output. For the visual transmitter, this measurement is done with modulation at blanking level, or 75% of peak sync. The measured average power is converted to peak sync power by multiplying by the peak:average ratio (1.68). The formula for the power calculation is

$$P_o = (1.68)(0.264)(T_o - T_i)R_f$$

where T_o the temperature of the water exiting the load in degrees Celsius, T_i is the temperature of the water entering the load, and R_f is the flow rate in gallons per minute. The numeric factor 0.264 is the specific heat of water.

For aural output, the measurement technique may be similar. However, because the peak and average power for a frequency-modulated signal are the same, the peak:average factor is unity. Alternatively, the aural power may be set by observing the relative levels of the visual and aural signals on a spectrum analyzer. This is especially useful for measurements made after the signals are combined, as in common amplification.

Accurately calibrated couplers and low-level power meters located at the output of the transmitter RF system are also widely used for power measurement. Because the coupling factor is known, the reading of the power meter may be calibrated to the actual power output.

1.1. Efficiency

Because of environmental concerns and the high cost of electricity, TV transmitters must operate efficiently. Although efficient power conversion is important at VHF, it is unusually important for UHF transmitters because the transmitted power is almost always much higher and consequently much more expensive to generate. When considering the efficiency of TV transmitters, several factors must be understood. To determine total power consumed, the AC-to-RF conversion efficiency is the parameter of interest. For systems with unity power factor, determining the AC input power is relatively straightforward. For power factors less than unity, the relative phase of the AC fundamental voltage and current must be determined. In addition, in systems generating significant line harmonics, the relative level of these harmonics must be known [2]. Power factor is expressed either as displacement power factor or total power factor. The displacement power factor (DPF) is the cosine of the phase between the voltage and current at the fundamental frequency:

$$DPF = \cos(\phi_v - \phi_i)$$

The displacement power factor is equal to the total power factor only for undistorted sinusoidal voltage and current waveforms.

Total power factor is the ratio of total AC power input P_i to the apparent power VI :

$$PF = \frac{P_i}{VI}$$

Determining input power is simplified by considering only the DC-to-RF conversion process. In this case it is necessary to determine only the voltage and current provided by the power supply to the final amplifying devices. Although this is a useful tool for evaluating power amplifier performance, it has the disadvantage of ignoring the power consumed elsewhere in the transmitter, such as power supplies for drive stages, cooling systems, filament power, magnet power, and control system power. If these items are to be included in the efficiency calculation, they must be determined separately.

Determining output power for efficiency calculation is equally complex. As we have seen, transmitters are rated in terms of peak sync visual power. Exclusive use of this number neglects the aural output. Some amplifier technologies exhibit apparent efficiencies greater than 100% if visual peak power is used as the measure of output power. This has given rise to the use of a figure of merit (FoM) defined as

$$FoM = \frac{P_o}{P_{DC}}$$

where P_o is the visual peak sync output power and P_{DC} is the DC input power at 50% average picture level (APL). This definition is valid for transmitters using separate amplification. For common amplification, the aural input and output power must be added to the denominator and numerator, respectively. Typical values of the figure of merit for several tube amplifiers operating in separate amplification are shown in Table 2 [3].

The DC input power for a typical visual-only power amplifier is given by

$$P_i = V_b(I_s DF_s + I_v DF_v)$$

where V_b is the beam voltage, I_s is the beam current at peak sync, DF_s is the duty factor of the sync pulse (0.08), I_v is the beam current during video, and DF_v is the duty factor of the video (0.92). For a 60-kW-pulsed klystron, typical values are $V_b = 24$ kV, $I_s = 5.5$ A, and $I_v = 3.7$ A, so that

$$P_i = 24[(5.5 \times 0.08) + (3.7 \times 0.92)] = 92.2 \text{ kW}$$

Table 2. Figures of Merit for Commonly Used Tube Amplifiers

Amplifier Device	Figure of Merit
Tetrode	0.9–1.0
Integral cavity klystron	0.65–0.75
External cavity klystron	0.65–0.75
Klystrode or IOT	1.1–1.3
Depressed collector klystron	1.2–1.3

and

$$FoM = \frac{60}{92.2} = 0.65$$

Other important efficiency factors to consider include the power lost in the RF system and antenna transmission line. These losses can be considerable and represent added cost of operation after the full cost of generating the transmitter output power has been spent. Thus it is extremely important to minimize these losses. If losses are to be minimized, the largest coaxial transmission line or waveguide should be used consistent with avoiding higher-order modes and within the wind load capability of the transmission tower. At UHF, the choice is usually between $6\frac{1}{8}$ or $8\frac{3}{16}$ in. coaxial line or rectangular or circular waveguide. The larger the coaxial line, the lower the loss. However, at the higher UHF channels, $8\frac{3}{16}$ -inch line supports an evanescent waveguide mode. Rectangular and circular waveguides provide lower loss but are larger in cross section than coaxial lines. The larger the physical size of the line, the higher the wind load. Because of its cross-section, circular waveguide offers lower wind load than rectangular. Thus many factors must be considered when selecting transmission line type and size. The larger size coaxial lines and waveguides are more expensive to purchase and install. However, this is a one-time cost that should be carefully weighed against the long-term reduction in transmitter plant efficiency resulting from the use of a line with excessive loss.

1.2. Reliability

Many stations operate continuously unattended, making reliability a key requirement. There are many factors that affect the reliability of a TV transmitter. Overall design philosophy, device technology, module design, control architecture, power supplies, cooling, and cabinet design are critical areas, all of which must be considered. Consider a transmitter design that uses subsystems in series with no system redundancy. If one device fails, the entire transmitter fails; that is, each subsystem represents a critical point in the event of failure. This is illustrated in Fig. 2, which shows a system of three subsystems in series with no redundancy. This might represent a tube-type transmitter with a single exciter and IPA. If each device (a, b, c) has a reliability or probability of functioning until time t , the reliability of the system $R_s(t)$ is given by the product of each subsystem reliability:

$$R_s(t) = R_a R_b R_c$$

If three identical subsystems are operated in parallel, as in Fig. 3, and only one is required for on-air operation, there are no single points that may cause system failure. This represents a parallel arrangement of identical PAs,

Figure 2. Subsystems in series.

Figure 3. Subsystems in parallel.

each with their own IPA. In this case, the overall system reliability is given by

$$R_s(t) = R_a + R_b + R_c - R_a R_b - R_a R_c - R_b R_c + R_a R_b R_c$$

To illustrate, assume that each subsystem has a reliability of 0.5. In the series case, the system reliability is only 0.125. In the parallel case, the reliability is 0.875, an improvement by 8 times.

The reliability is related to failure rate λ as follows:

$$R(t) = e^{-\lambda t}$$

The mean time between failures (MTBF) is the reciprocal of the failure rate:

$$\text{MTBF} = \frac{1}{\lambda}$$

On-air availability is related to reliability but perhaps even more important. On-air availability is the percentage of time the transmitter is available for service, defined by the following equation

$$\text{Availability} = \frac{\text{MTBF}}{(\text{MTBF} + \text{MTTR} + \text{MPMT})} \times 100\%$$

where MTTR is the mean time to repair and MPMT is the mean preventive-maintenance time. All quantities are stated in hours (or other consistent time units).

There is little point in designing a transmitter that has a high MTBF figure if, because of poor design and mechanical packaging, it takes an inordinate length of time to make repairs, or if the transmitter has to be shut down frequently for routine preventive maintenance.

Many stations have very short signoff windows or operate 24 h a day. This often results in a less than optimum maintenance schedule, which can lead to premature failure or out-of-tolerance operation. One way to reduce the amount of off-air maintenance time is by making provisions for on-air maintenance or to have redundant transmitters. This significantly reduces the MPMT.

Several design factors should be considered for optimum on-air availability. These include high reliability of the fundamental circuits and provision for fast, easy access to all subassemblies. A subassembly, which can be readily removed, can be repaired by station personnel or returned to the manufacturer for exchange. Another

factor contributing to availability is the maximum use of common parts and subassemblies. If fewer items are needed, it is more economical for the station to maintain a full inventory of spares. If spares are on hand, the repair time may be much shorter.

1.3. Linearity

This parameter refers to the degree with which the transmitter output signal is directly proportional to the input. Common terms used to quantify the degree of transmitter nonlinearity include low frequency or luminance nonlinearity, differential gain, and AM-to-AM conversion. Output phase may also be a function of input level. The deviation from linear phase is often quantified as incidental-carrier phase modulation (ICPM), differential phase, and AM-to-PM conversion. These deviations from linearity are called *nonlinear distortions*, that is, distortions to the transmitted signal introduced by nonlinear components in the transmission path. A nonlinear component is any device whose complex output voltage is not directly proportional to input voltage. Power amplifiers operating near compression and intermediate power amplifiers (IPAs) are major contributors to nonlinear amplitude distortion. This process creates the frequency spectra of the lower sideband, usually called *lower-sideband reinsertion*. Filters are commonly used to reduce sideband spectral components, but these introduce phase distortions.

Differential gain is nonlinear chroma gain as a function of luminance level. A change in the picture color saturation results from differential gain. Differential phase is nonlinear chroma phase as a function of luminance level. A change in picture hue results from differential phase. Low-frequency or luminance nonlinearity is the change in luminance gain as a function of picture brightness level.

Precorrection is a technique to compensate for nonlinear distortion. The objective of precorrection is to provide a complementary transfer function that when operating on the nonlinear transfer function of the power amplifier, minimizes total system nonlinear distortion. Precorrection may be introduced in the baseband, IF or RF sections of the system and may be manually or adaptively adjusted.

IF linearity precorrection provides the correction for nonlinear distortions in the intermediate-frequency (IF) sections of the exciter. There are important advantages to correcting at IF. Because most distortions are caused in the high-power RF amplifiers after vestigial sideband (VSB) filter, a precorrector placed after the VSB filter can most accurately precorrect the modulated signal. Intermodulation products are caused by the nonlinear transfer function of the IPA and PA. As the power output increases toward saturation, amplitude compression and phase lag occur. The nonlinear transfer function gives rise to mixing products that occur at sum and difference frequencies around the visual carrier. Precorrection spectra generated at IF after the VSB filter produce energy components that can cancel intermodulation products generated in the amplifier stages. This is particularly important for pulsed klystron or common amplification transmitters.

An example of a basic gain expansion circuit used for precorrection is shown in Fig. 4. The signal is normally attenuated a fixed amount by using a resistive L-pad, R_1 and R_2 . The diodes, D_1 and D_2 , are normally reverse biased by equal but opposite DC voltages. Reducing the DC voltage permits the diodes to conduct on the signal peaks, inserting additional resistance in parallel with the series arm of the L-pad attenuator, thereby decreasing the attenuation. Varying the resistance in series with the diodes provides variable-gain expansion.

1.4. Incidental-Carrier Phase Modulation

Nonlinear phase distortions in high power amplifiers produce incidental-carrier phase modulation (ICPM) or spectral components in quadrature with the modulated signal. Fast video amplitude changes, such as a step or pulse, cause larger incidental-phase spectral components than slow changes. Receivers make this condition worse by attenuating the lower sidebands below 0.75 MHz. The receiver responds to the extra sidebands created by the phase modulation as if they were amplitude-modulated single sidebands, producing spikes. The faster the rise time of the signal, the more high-frequency energy is present, resulting in edge distortions in the picture.

The picture impairment due to ICPM is similar to simultaneous group delay and differential-phase errors in that edges are less sharp and the color hue changes with brightness. On a waveform monitor, overshoots are visible on trailing edges and as rounding of leading edges. These overshoots vary in severity depending on how far into saturation the power amplifier is driven.

Audio impairment is produced by ICPM in receivers employing intercarrier conversion. Intercarrier receivers use an AM or synchronous detector to produce a 4.5-HMz aural IF from the composite video IF. Any phase

modulation on the visual carrier is transferred to the aural carrier. For monoaural baseband audio, the effect of increasing amplitude versus frequency of ICPM is nullified to some degree by receiver deemphasis. With multi-channel sound, however, there is no deemphasis applied to the baseband stereo signal, and the distortion is more pronounced at the stereo subchannel and pilot frequencies. Audio companding is employed to counteract the effects of ICPM and other noise sources on the stereo subchannel. Although the audio companding process reduces some of the effects of ICPM, precorrection is essential for delivering clear, low-noise audio to intercarrier receivers.

There is no defined level of ICPM for a given stereo performance level because the signal-to-buzz ratio is highly dependent on the picture spectral components. Refer to the EIA recommended practices [4] for recommendations on ICPM limits.

ICPM precorrectors are grouped into two types: those using a phase modulator and those inserting a fixed phase directly on the signal. The phase modulator uses video to modulate the IF or a master oscillator with a phase characteristic opposite that of the nonlinear amplifier. A phase modulator can also operate directly on the IF signal using a video signal to set the amount of modulation. A block diagram of a master oscillator phase modulator is shown in Fig. 5.

ICPM precorrectors operating directly on the IF signal are implemented in several ways. Direct precorrection at IF is similar in concept to baseband differential phase precorrection. In both cases, the visual signal is split into two-phase quadrature paths, as shown in Fig. 6. In the IF corrector, the full video bandwidth is processed, whereas in the video precorrector only the chroma signal is affected. One method of implementation is to modify the quadrature signal gain function with level-dependent diode

Figure 4. Basic gain expansion circuit.

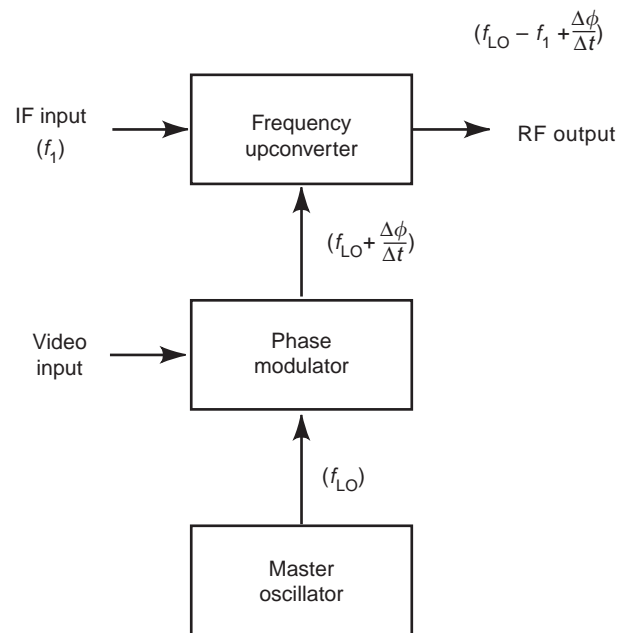

Figure 5. Block diagram of master oscillator phase modulator.

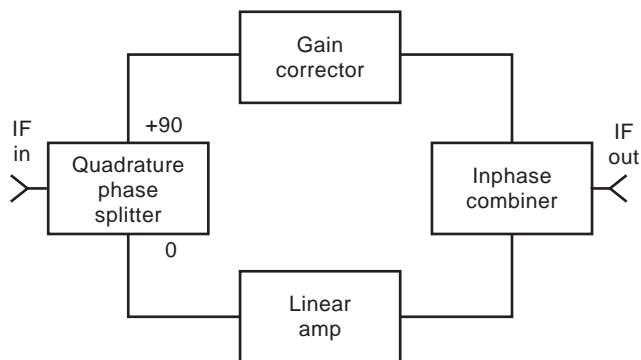

Figure 6. Direct ICPM corrector.

expansion or compression circuits. This can be done by the same techniques as in the linearity corrector.

The vector diagram shown in Fig. 7 illustrates the operating principles of the ICPM and linearity correctors. The input signal is represented by the vector on the left. Because of nonlinear distortions in the transmitter, the output signal is shifted in phase and compressed, producing the resultant distorted signal. To produce the correct output signal, it is necessary first to expand the in-phase signal and introduce an equal and opposite quadrature signal. When the resultant signal is amplified, the output signal is restored to the undistorted TV signal.

1.5. Linear Distortions

These are distortions to the transmitted signal that are not level-dependent. Unlike nonlinear distortions, linear distortions can be introduced by linear (as well as nonlinear) components in the transmission path. These components include any device with a nonconstant frequency response, such as matching networks, cavities, filters, diplexers, and other tuned circuits. Variations in both amplitude and phase are produced, that is, variations in both in-band amplitude response and group delay (GD) produce linear distortions.

Group or envelope delay is the nonuniform delay of different frequencies over the signal bandwidth, that is,

Figure 7. Vector representation of precorrection.

the first derivative of phase with respect to frequency:

$$GD = \frac{d\phi}{d\omega}$$

Group delay is caused by nonlinear phase as a function of frequency inherent in RF amplifiers, filters, combiners, and other devices. In general, the closer the amplitude rolloff is to the passband of a tuned circuit, the higher the group delay distortion.

Equalization is the technique used to compensate for linear distortions. The objective is to provide a complementary transfer function that when operating on the frequency response function, minimizes linear distortion. Equalization may be introduced in the baseband, IF, or RF sections of the system and may be manually or adaptively adjusted.

Group delay equalization of the aural transmitter introduces group delay equalization in the IF section of the aural modulator, effectively correcting the group delay in the diplexer. The result is improved TV stereo separation. The notch diplexer is a passive device, but it can introduce significant linear distortions that degrade stereo separation because the FM stereo signal is most sensitive to the notch diplexer group delay and amplitude response over the occupied bandwidth of the FM signal. The group delay and amplitude response of a single-cavity diplexer optimized for minimum aural reject power is shown in Fig. 8. The bandpass is somewhat narrow, and the group delay is steep. Fortunately, the response curves have a high degree of symmetry, which makes equalization possible. Equalization of the FM bandpass allows using a lower cost, single-cavity notch diplexer. A stagger-tuned, dual-cavity, notch diplexer might be used to provide more bandwidth. However, a dual-cavity, notch diplexer introduces more group delay in the visual path and is more expensive than a single-cavity diplexer.

Figure 8. Single-cavity notch diplexer amplitude response and group delay.

1.6. Transmitter Control Systems

The transmitter control system provides the interface to the user. It provides control, monitoring, and protection for the transmitter. Essential control features include transmitter ON and OFF states, output power raising and lowering, remote or local control selection, and automatic gain or level control. Other automatic control features, such as VSWR foldback, are desirable. VSWR foldback reduces forward power when reflected power is high, such as in antenna icing, and restores RF power to normal when the reflected power returns to normal.

Easy-to-read status indicators are essential for quick fault diagnosis. Typical status conditions displayed include exciter fault, VSWR fault, VSWR foldback status, power supply fault, controller fault, loss of cooling air, door open, failsafe interlock open, AC phase loss, RF power module fault, visual drive fault, aural drive fault, and external interlock open.

If individual RF amplifier modules and power supplies are self-protecting, the system control and monitoring functions are relatively simple and straightforward. A most effective approach is to distribute the control system throughout the transmitter, as shown in Fig. 9. In the distributed control system, the failure of any individual controller component does not affect the operation of the others. For example, failure of any single cabinet controller would not affect the operation of the other cabinet controllers or the main controller. Failure of the main controller would not cause an off-air condition if the cabinet controllers operate independently of the main controller. Failure of monitoring and metering should not cause an off-air condition. It is also important that the controller have backup memory to restore the transmitter operating condition after AC power failure.

2. TRENDS IN TV TRANSMITTER DESIGN

Television broadcasting is a mature technology. In the half-century or so since the adoption of the color standard, there has been steady progress in transmission technology. The prospect is for improvements to continue. Many of

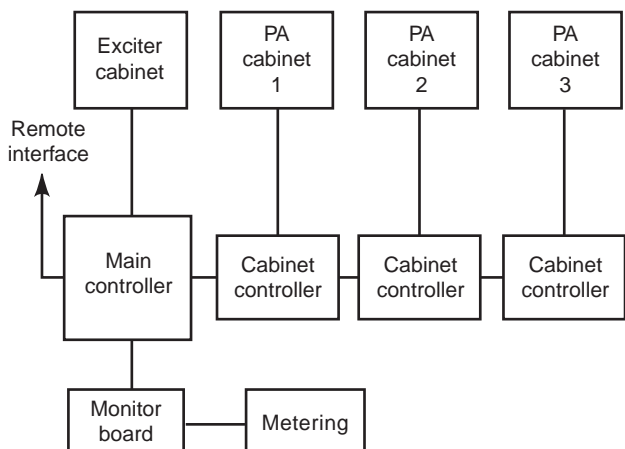

Figure 9. Distributed control and monitoring.

these will occur simply because TV transmitters involve such a wide range of electronics technology. Others will be driven by the implementation of digital television [8]. It may be expected that the analog transmission will benefit from many of the improvements created by the digital revolution. Improvements that reduce the cost of ownership, improve the human to transmitter interface, and simplify operation and maintenance are the areas in which the most progress can be expected. These will include steady improvements in high-power, solid-state devices and high-power UHF tubes, advances in digital signal processing and in microprocessor-based controls, and improved displays for monitoring functions. The pervasive use of digital technology will allow more and more functions that have traditionally been defined by the hardware design to be part of software.

3. SOLID-STATE DEVELOPMENTS

Technological advances in bipolar and field-effect transistors (FETs) have made the development of solid-state, high-power, linear amplifier modules for TV applications both practical and cost-effective. By combining RF modules, it is practical to create transmitters at any power range up to 75 kW. This is especially true for the VHF bands and is becoming increasingly true for UHF. The trend in solid-state technology is toward devices that produce higher power at higher frequencies and lower cost. As costs are reduced, the feasibility of higher power transmitters at UHF is enhanced. Solid-state power amplifiers are operated in class AB for the best tradeoff of efficiency, linearity, reliability, and cost. Driver stages usually contain class A amplifiers.

There are several advantages to high-power, solid-state technology. Solid-state transmitters maintain their performance over extended periods of time because of the absence of tuning controls and degradation of filament emissions. No warmup time is required. Solid-state transmitters produce full-rated power within seconds of activation. Solid-state transmitters most often are air-cooled. This has the advantage of eliminating any chance of coolant spills and concern for cooling system freeze up in cold climates. There have been some attempts to develop liquid-cooled solid-state transmitters. The advantages of liquid cooling include somewhat quieter operation and improved cooling efficiency. Safety is also enhanced in solid-state systems. Operating voltages are usually 65 V or lower compared to tens of kilovolts for tube amplifiers. There is no need for crowbars to protect solid-state devices in the event of a short circuit. However, protection against lightning and static-induced transients is required. Maintenance is also eased. Solid-state transmitters employ modular architectures in which a large number of RF and power supplies modules operate in parallel. Failure of any one of these units has only a minor effect on TPO. Thus immediate corrective action is not as critical as in tube transmitters in which there may be only a single output tube. Simple diagnostic displays make the identification of the failed unit easy. Hot pluggable designs and a minimum of spare modules make it possible to remove and

replace the failed unit while the transmitter remains on air. Repair of the failed unit may be done offline.

Both bipolar and field effect transistors (FETs) are used today as RF amplification devices. Vertical metal oxide silicon field-effect transistors (MOSFETs) are the devices of choice for VHF transmitters. Both bipolar transistors and MOSFETs have been available for UHF. However, UHF vertical MOSFETs are not as linear and therefore not as cost-effective as bipolar devices. Recently, laterally diffused metal oxide silicon field effect transistors (LDMOSFETs) have developed cost-effective linear power for UHF. This has enabled producing cost-effective, solid-state transmitters for UHF. Although both bipolar transistors and FETs have merit, FETs have some advantages over bipolar devices. FETs have an amplification factor higher than that in bipolar transistors, reducing the number of driver stages required. The fewer the drive stages, the lower the manufacturing cost, and the better the linearity because there are fewer parts contributing to cost and nonlinearity. The higher power supply voltage required by FETs reduces the current rating required for the power supply. Power supply cost is driven by current rating. Simple bias circuitry for FETs minimizes parts count and amplifier production cost.

New developments in high-power, solid-state devices are ahead. Silicon carbide (SiC) materials make it possible to produce a variety of devices. In addition to blue light-emitting diodes (LEDs) and switching transistors, linear high-power UHF transistors are under development [6]. These transistors promise to operate at voltages and temperatures higher than ordinary silicon devices, thereby increasing available power output, system efficiency, and cooling effectiveness while lowering transmitter system cost.

4. TRANSMITTER TUBES

Because higher transmitter power is needed, power consumption and efficiency are of utmost importance for UHF transmitters. Although solid-state transmitters offer many advantages to the broadcaster, many UHF stations find that the most cost-effective transmitter design is based on tube technology. Many of the advantages of solid-state transmitters may be adapted to tube-based designs. For the highest power multiple output tubes, each with its own drive chain, provide a minimum level of redundancy and the benefits of a soft-fail architecture. The high beam voltage required by tubes minimizes power supply cost. Liquid cooling for high-power tubes results in low acoustic noise within the transmitter plant. Some of the lower power and more efficient tubes are air-cooled. High-power tube designers have shown great ingenuity in improving operating efficiency and bandwidth, so that tubes remain a viable alternative for UHF transmitters [7].

A variety of tube technologies are available to address UHF requirements. These technologies include tetrodes, klystrons, multiple-stage depressed collector (MSDC) klystrons, and inductive output tubes (IOTs). Some are most suited for lower-power transmitter designs, and

others are more appropriate for the highest power requirements. Work has been reported on a constant-efficiency amplifier (CEA) that promises dramatic improvements in UHF transmitter efficiency. This tube combines the design of the IOT and the MSDC to achieve near-constant and high efficiency independent of drive level.

5. TETRODES

Tetrodes are a generic category of four-element tubes suitable for the linear amplification of RF signals [5]. The anode and screen grid are cooled with distilled water. Typical peak sync power ratings are up to 30 kW, although a "dual tetrode" design boasts a 60 kW rating. Tetrodes are biased for class AB operation and therefore, are more efficient than the class A klystron. The tetrode beam voltage is much lower than that of the klystron or inductive output tube. Tetrodes exhibit excellent linearity. The tradeoff for performance in these areas is power gain lower than most other amplifiers. The gain of a tetrode is only about 15 dB. Tetrode filament currents are high to minimize cathode current modulation of the cathode temperature. "Black heat" is used to reduce the time to on-air. This feature provides a lower than normal filament voltage and current to keep the filament warm when the transmitter is off-air. This reduces the thermal stress on the filament when going quickly to full power.

UHF power tetrodes combine visual and aural amplification. Ten percent aural power is the norm, and tubes are rated according to peak sync power with the aural carrier. For example, a typical UHF tetrode may be rated at 30 kW peak sync. With 10% aural power, the peak envelope power (PEP) is 52 kW.

6. KLYSTRONS

For a discussion of klystrons, refer to the article on this subject. See also Ref. 3.

7. INDUCTIVE OUTPUT TUBES (IOTS)

The IOT combines features of a tetrode and a klystron. The electron beam is constrained similarly to that of a klystron by using electromagnets. The mode of operation of the IOT is similar to that of a tetrode. However, there are significant differences because of differing geometry. An IOT, shown schematically in Fig. 10, is composed of an electron gun very similar to a klystron, a control grid, an input cavity, accelerating anode, drift tube, output cavity, and collector. The electrodes are arranged linearly unlike the concentric configuration of a tetrode. An IOT is physically smaller than a klystron. The electron beam is formed at the cathode. It is density-modulated by the input signal applied to the control grid via a resonant cavity and then accelerated through the anode aperture. The grid is biased negatively near cutoff. The first part of the tube may be thought of as a triode with a perforated anode through which the electron beam is guided by electric and magnetic fields. The beam is bunched at the radiofrequency and is accelerated

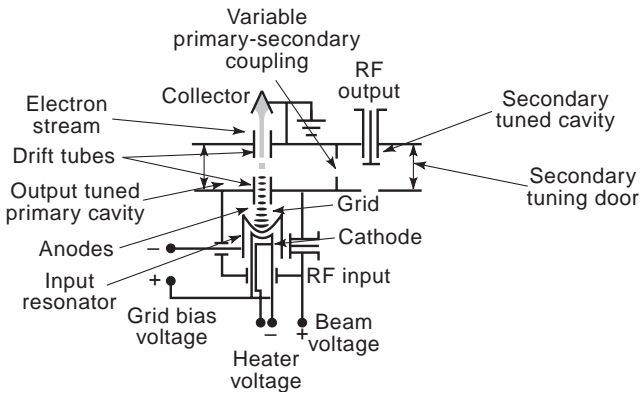

Figure 10. Inductive output tube schematic.

by the high anode potential. In its bunched form, the beam drifts through a field-free region (the anode extension cylinder, which is an electrostatic shield). Then the beam interacts with the RF field at the drift-tube gap in the output cavity. Power is extracted from the beam in the output cavity in the same manner as a klystron. The spent beam is dissipated in the collector, which is separate from the output RF interaction circuit. The grid may intercept some electrons, causing a small amount of grid current. This increases markedly if the tube is overdriven.

The fundamental benefit of the IOT is that it operates as a class AB amplifier, resulting in high efficiency. Thus the beam current I_b is proportional to the RF drive signal V_g and follows the modulation envelope according to the three-halves law

$$I_b = K(\mu V_g + V_a)^{3/2}$$

where μ is the amplification factor. The perveance K is proportional to the cathode area and inversely proportional to the square of the grid-to-cathode spacing. The drive voltage is not normally high enough to make the instantaneous grid voltage-positive.

In aural service, the IOT is tuned the same as for visual service. A single tube covers the entire UHF operating band, although two slightly different input cavities are required. Power gain in either visual or aural service is about 21 dB. Thus, drive power is about 500 W for the visual and 50 W for the aural, assuming 10% nominal aural power.

TRANSMITTERS FOR DIGITAL TELEVISION

ROBERT WEIRATHER
 Harris Corporation
 Quincy, Illinois

The television industry in the United States began the search to improve the quality of television images and sound as early as the 1970s, and the Federal Communication Commission (FCC) sought more spectrum in the 1990s. These two paths ultimately led to digital television (DTV). The desire was to put improved television (TV) in the same frequency bands allocated for existing TV channels. These frequencies are low VHF (55-88 MHz) channels 2-6, high VHF (176-225 MHz) channels 7-13, and UHF (476-860 MHz) channels 14-69. The DTV Standard (1998) allocated another complete set of digital TV stations that are frequency-compatible with the existing analog NTSC (National Television Systems Committee) TV channels. This requires that the new DTV channels be allocated between current channels and that neither service interfere with each other. As we shall see, this in-between (including adjacent) channel operation tightly restricts digital TV transmitters.

Paralleling the early development of DTV in the United States, other digital TV systems were being implemented worldwide. Nation after nation has adopted digital TV as a way of delivering more programming content with less spectrum. Better use of the spectrum is one driving force being development of digital RF technology. Digital has proved effective in cellular telephones, microwave telecommunication, and digital TV. Spectrum efficiency is not the only motivation for the use of digital RF means. Use of digital implies a possibility for multiple uses of the transmitted bit stream and thus the potential of serving more demands.

The design for practical digital television transmission systems began in the 1980s. These digital systems required a new approach to high-power over-the-air (OTA) TV broadcast. The television industry began to consider the use of OTA transmission of TV of such quality and function that new modulation and RF power schemes

evolved. The goal for producing significant digital TV signal power is to

- Create a digitally modulated RF signal (called the *modulator or exciter*)
- Reproduce the idealized signal suitable for demodulation (controllable linearity)
- Provide the highest efficiency (power out vs. power used)
- Deliver an RF signal that is reliable, practical, and thus useful

Over-the-air terrestrial digital TV requires high RF power, typically a few kilowatts to 100 kW. Compared with cable, wireless cable, or satellites, this is substantially different and deserves special attention. Whether the digital TV transmitter is used for the system in the United States or another digital system, as will be explained, the requirements are similar.

1. DIGITAL TV MODULATION

Currently analog systems use two separate signals to carry the TV signals. The visual information is carried by AM means, while the aural information is carried by FM means. When using two separate transmitters, class AB linear amplifiers amplify the visual RF carrier and class C nonlinear amplifiers typically provide the aural RF carrier. These two different carriers are combined and transmitted to form the RF TV signal.

Two digital modulation systems have been approved for use in terrestrial broadcast:

- Eight-level Vestigial Sideband (8VSB), often referred to as the Advanced Television System Committee (ATSC) standard. This system has been also termed *digital television (DTV)*.
- Coded orthogonal frequency division multiplex (COFDM), which is also referred to as *digital videobroadcasting—terrestrial (DVB-T)*.

8VSB uses a single modulated RF carrier to transport the digital information. 8VSB is 64 QAM with most of the lower sideband removed (vestigial). COFDM uses many RF carriers (thousands), each modulated with a portion of the digital information. These thousands of carriers are combined to create the transmitted digital RF signal. Both of these schemes (8VSB and OFDM) are required to reside compatibly within the RF channel allocated for analog.

Surprisingly, both 8VSB and COFDM exhibit similar spectra and time-varying waveforms. Both spectra are noiselike, while the time plots appear random in amplitude and duration (see Figs. 1 and 2).

The digital RF signals used for over-the-air (OTA) TV broadcast are a vector-modulated signal, thus containing amplitude modulation (AM) and phase modulation (PM). The RF digital signal is modulated with a bitstream of typically 30 Mbps (megabits per second). This results in a

Figure 1. Time-domain capture of 8VSB. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

high bit/per hertz efficient scheme (~30 Mbps within 6 MHz bandwidth or 5 bits/Hz).

Many other digital modulation techniques are used in television services, and other types of digital modulation are in use. Television delivery such as cable TV (CATV), satellite direct to home, wireless cable, or the PC (personal computer) telephone modem may use a scheme different to optimize delivery versus transmission path characteristics and digital payload. But transmitters for terrestrial broadcast are the subjects of this article.

It is significant to note that digital terrestrial TV modulation is generally thought of in terms of AM. This is a result of the fact that the signal does go to zero at some time. However, it is similar to PM/FM in that the signal has no low-rate time-varying component. Comparisons of terrestrial analog TV and digital TV at RF are enlightening:

Analog TV at RF	Digital TV at RF
Peak to average varies	Peak to average constant
RF never goes to zero	RF goes to zero
Power changes with picture content	Power constant for any picture content
In-channel noise corrupts picture	Noise below threshold does not corrupt
Two RF carriers	One RF carrier

These differences require approaches to digital power amplifiers that may be compared to conventional analog

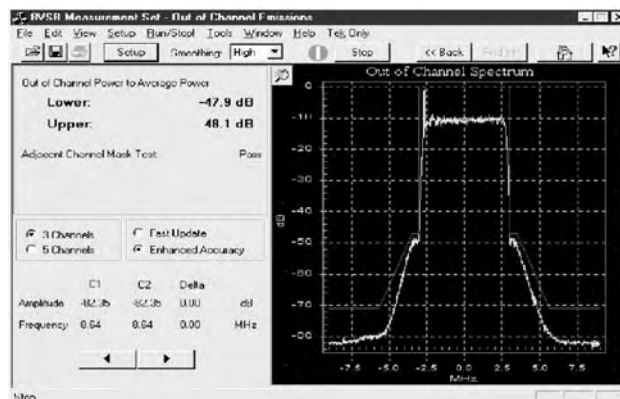

Figure 2. Spectrum capture of 8VSB. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

(NTSC/PAL/SECAM) RF amplifiers. As we shall see, the requirements for digital transmitters are sufficiently different enough to warrant specific considerations.

2. DIGITAL TV MODULATOR OR EXCITER

Generation of an 8VSB or COFDM RF signal can be best understood with the aid of block diagrams. A typical implementation for 8VSB is shown in Fig. 3.

3. DIGITAL RF MODULATION

Terrestrial digital TV such as 8VSB and COFDM signals are not symmetric and have both AM and PM components. Both system designs results in a signal that occupies the bandwidth with a noiselike signal. This noiselike characteristic requires the use of linear amplifiers for practical transmitter implementations.

3.1. Amplification of Digitally Modulated Signals

The most common way to increase the power of an RF signal is simple amplification. This is generally straightforward for signals of a few watts but becomes increasingly complicated as the power extends above several kilowatts. Cost is excessive to execute a linear amplifier at even a kilowatt. At high power the amplitude and phase linearity plus IMD (intermodulation distortion) of the amplifying chain dominate the details. Nonlinearity gives rise to bit error rates (BERs) that excessively degrade the digital signal.

3.2. Modulated Single-Carrier Systems: QAM, and 8VSB

The ATSC system is a modified quadrature amplitude-modulated (QAM) system generated by amplitude-modulating an RF carrier ($\sin \omega t$) and summing it with the same RF carrier 90° phase shifted [$\sin (\omega t + 90^\circ)$] that is modulated differently. By modulating these two carriers with multilevel digital signals, multilevel QAM is generated.

To create 8VSB, a 64-QAM signal can be generated and then filtered with a surface acoustic wave (SAW) to eliminate the lower sideband. In practice, 8VSB may be generated by all digital means using a combination of software and hardware.

3.3. Modulated Multicarrier Systems: DVB-T

To meet the needs of the European market, another digital modulation method was developed. European needs are different from those in the United States: multiple languages, more mountainous terrain, denser population, and single program coverage nationally, to name only a few. Today’s European analog systems, PAL (Phase Alternation Line) and SECAM (Sequential Couleur Avec Memoire), use lower-powered transmitters than in the United States. The system chosen for Europe, DVB-T or COFDM, uses many carriers (thousands), each digitally modulated and contained in a single TV channel (8-MHz in Europe vs 6 MHz in the United States). The carriers are each modulated with a portion of the digital information and thus spread the digital data across the 8 MHz spectrum. Spreading data across the spectrum improves the likelihood of lessened interference resulting from multipath propagation.

COFDM development has its roots in Europe but has spread worldwide. Many nations around the world have adopted the DVB standards for digital TV.

4. POWER AMPLIFIERS FOR TV

Power amplifiers are the last active element in the RF path before the antenna system. The power amplifier final amplifying stage is the most critical. This final stage determines several critical characteristics of the broadcast signal:

- Average power
- Peak power
- Distortion (intermodulation and harmonic)
- AC power (efficiency)
- Frequency response (bandlimiting and/or tilting)
- Signal quality (SNR, BER)
- Spectrum mask (compliance with standards, e.g., FCC)

The power of a digital transmitter is rated by its average power output. But digital TV signals have high peak-to-average time-varying envelopes. 8VSB exhibits a typical 7 dB peak-to-average values while DVB-T is closer to

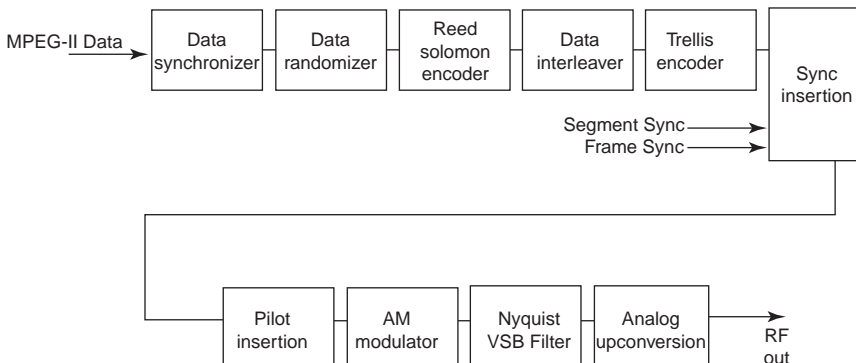

Figure 3. Block diagram of 8VSB exciter.

9 dB. Thus the peak power handling power and average power output are important factors for final PAs.

Power amplifiers are generally nonlinear and band-limiting, thus creating distortions of the input RF signal at the output. Power amplifier nonlinearity creates both in-band and out-of-band intermodulation distortion products within the amplifier. In-band products are important because the received bit error rate (BER) is affected and decoding errors will be produced if the intermodulation products (IPs) are too high.

Out-of-band nonlinearity (spectrum shoulders) must also be minimized to prevent interference with adjacent analog or digital services. In most transmitters, correction signals for amplitude and phase nonlinearities are applied to the input signal of the digital amplifier (feedforward), correcting both the in-band and out-of-band intermodulation distortions at the same time. Therefore, reductions in both the in-band and out-of-band IPs coincide. The only exception to this is when frequency response or group delay errors are present in the amplifier.

5. VACUUM-TUBE POWER DEVICES

Tubes have a unique place in high-frequency amplification; with a single device, they can amplify a signal to tens of kilowatts over a band from a few hundred megahertz to several gigahertz. Gridded tubes such as triodes, tetrodes, or pentodes modulate the electron beam with a small applied RF voltage to the grid. Other tubes such as klystrons use an applied RF voltage to bunch electrons generated from a gun, and these bunched electrons drift through additional cavities, creating additional bunching until reaching a final cavity that extracts energy from the formed beam.

Tube amplifiers usually are limited to 1–5% bandwidth. This is determined by the number of resonant circuits (usually cavities) and their loading (Q). This limited bandwidth is helpful to reduce IPs in adjacent channels but also causes group delay distortions at the channel band edges.

Other varieties of vacuum devices use a grid, a drift region, and an output cavity to form a tube called the *klystrode* or *inductive output tube* (IOT). The IOT (Fig. 4), which found favor with digital TV by providing peak powers in excess of 100 kW at a gain of over 20 dB with good linearity. Efficiencies of IOTs reach 30%.

The IOT has been integrated with a new collector: the depressed-voltage collector. This depressed collector IOT has many of the same characteristics of the IOT, except its efficiency can exceed 50%.

6. SOLID-STATE POWER DEVICES

The use of solid-state devices for amplifiers has an obvious attraction but comes with some limitations. Growth of solid-state devices has led to improvements and reduction in vacuum device usage. However, concentrated power (volts and amperes) and power density of RF transistors have

Figure 4. Inductive output tube.

limited the usage of transistors to combined configurations (Fig. 5). The RF transistors are frequently multicelled and multichip devices in a single package to reach a typical of 150 W peak power.

Figure 5. RF amplifier module.

6.1. Bipolar Transistors

Bipolar transistors are minority-carrier devices and as such exhibit several distinguishing characteristics. Bipolar transistors have moderate gain and reasonable linearity but suffer from thermal runaway.

6.2. Field-Effect Transistors

Generally, field-effect transistors (FETs) are majority carrier devices and can be characterized by properties inherent with this class of devices. FETs have higher gain and improved linearity and are tolerant of poor load VSWR without catastrophe.

6.3. Other Devices

Clearly, the FET and bipolar transistors are the most widely used semiconductor devices for power amplification. Other semiconductor technologies used for power generation include MOSFETs, lateral diffused MOSFETs (LDMOSFETs), HEMPT, and GaAs.

6.4. The Solid-State Amplifier

Transistors have one fundamental limit—they don't come with kilowatt power ratings at terrestrially delivered TV frequencies. Kilowatts (sometimes tens of kilowatts) of RF power are necessary for digital TV transmitters. To cover a substantial area with an antenna at a reasonable height, several tens of kilowatts of RF power may be required. A typical analog (NTSC) station has a coverage circle with radius of typically 55 mi. To duplicate this coverage with digital transmissions may take tens of kilowatts or even 100 kW of RF power radiated from an antenna placed 1000 ft or more in the air. Transistors cannot do this with one transistor in the final PA as can be done with a vacuum device.

A single large transistor can typically produce 150 W of peak power. This means that many transistors must be combined to generate a multikilowatt RF signal. The solid-state amplifier does exhibit a wider bandwidth than a tube version, thus reducing some degradation created by band limiting.

A single IOT can produce 25 kW average digital RF power (125 kW peak). To amplify equivalently to 25 kW with transistors would require almost 2000 transistors.

6.5. Amplifier Class of Operation

To amplify a signal with least distortion, current conduction over the 360° RF cycle (class A) is used. Class A operation is lowest in efficiency (same power supply draw regardless of amplifier power output) and thus preferred in lower-power stages where efficiency and dissipation are not of great concern. Class A may be either a small or large signal amplifier, depending on the scale of the design. Efficiency is limited to a theoretical maximum of 50% using class A. Generally this is optimistic, and efficiencies of 10–25% are far more typical.

Class B operation (180° Conduction) is ideally a linear mode of operation, but practically it is not used at high

Table 1. Efficiency for Various Classes of Operation

Class of Operation	Ideal Maximum Efficiency (%)
A	12.5
B	78
A/B	12–78
C	100
D	100

frequencies because of saturation and crossover distortions. Even with its more efficient operation, class B finds little use because of these limitations. Of more interest and practical use is class AB. Class AB biases the device (transistor or vacuum tube) with some idle current without RF drive and thus minimizes crossover distortions, but it retains the efficiency of class B at higher output power. Efficiency is limited to 78% for the class B amplifier. The class AB mode efficiency depends on bias conditions and thus can be bracketed somewhere between the class A and class B efficiencies.

Class C (less than 180° Conduction) and class D (switching or saturation mode) operation exhibit higher efficiencies but exhibit no linear amplification properties. Useful for FM or power supply modulated applications, class C amplifiers are rarely considered. Efficiency can theoretically approach 100% with class C or D. This efficiency is shown in Table 1.

6.6. Push-Pull Pairs

RF power amplification frequently employs the use of transistors in a push-pull configuration (Fig. 6). In a push-pull configuration, two parallel-driven transistors conduct on alternate halves of the RF cycle and then are summed. This approach simplifies the transistor combining, bias, and required circuit area.

7. THE FINAL POWER AMPLIFIER

Digital television transmitters for either DTV or DVB-T have only been in use since the mid-1990s. Digital TV

Figure 6. Simplified push-pull RF power amplifier.

transmitter characteristics aren't known as completely as those of other mature power amplifiers. Although the 8VSB and OFDM modulation schemes are very different, they have high peak-to-average ratios. The probability of peaks occurring varies as the difference between the average level and peak observed level increases. As may be expected, as the difference between the two increases, the probability of a peak reaching that amplitude decreases. With an 8000-carrier OFDM signal, the maximum theoretical peak level can be as high as 38 dB, but the probability of this occurring is very small. With both systems, the method of signal generation normally limits the peak-to-average ratio to 8 dB for 8VSB and 12 dB for OFDM without degrading performance (Fig. 7).

To amplify these signals transparently would require a perfectly linear amplifier with a power capability of 8–12 dB higher than the average power output. For example, to produce an average 1 kW output would require an amplifier of 6–16 kW peak.

7.1. Combiners

Power amplifiers, even those using vacuum devices of 100 kW or more, must sometimes be combined (external to the basic circuit power amplifier design). Various combiners of the following types are widely used:

- In-phase or star (impedance transformed to a single common point)
- Quadrature two-way [90°, hybrid, magic tee (also known as “magic T”)]
- Multiple input (bandwidth-limited)
- Isolated or nonisolated input ports (reject loads used or not)
- Constant impedance (independent of sources)
- Nonreciprocal (circulator/isolator used)

The choice of combiner is usually determined by minimum insertion loss and the need for isolation from other circuits or surroundings. At high power, it is wise to not waste precious RF watts generated in power amplifiers as

losses in combiners. Conductor losses prevail at higher powers, and thus air dielectric coax (coaxial cable)/stripline and waveguide are widely used to minimize losses.

By alternating both in-phase and quadrature combiners, arrangements that cancel certain intermodulation products can be made. This technique can be also used to divert RF that is intercepted by the antenna.

7.2. Control and Monitoring: Protection of the PA

High-power amplifiers need various controls and subsequent monitoring. Typically the monitor and control are focused on three broad areas:

1. RF path
 - Drive power
 - Output power
 - Load VSWR
 - RF signal phase
2. Power supply(ies)
 - Voltage
 - Current
 - Sequencing of supply turn on/off
3. Auxiliary
 - Dissipation
 - Temperature
 - Air/coolant flow
 - Arcing

The speed for the protection circuits in the power amplifier will depend on the robustness of the device. Very-high-power amplifiers will be operated near limits of performance, thus requiring fast and tight limit-setting circuits. Headroom in the PA is costly, and thus less costly protection circuits are preferred.

7.3. Peak and Average Power

RF power amplifiers are limited by several factors, but dynamic range of the RF signal governs much of the limitation. Generally, peak power determines the highest voltage/currents, whereas average power determines dissipation limit. The idealized digital signal has a higher peak-to-average ratio than is generally provided by many high-power PAs. If the highest peak were preserved, then the penalty would be an inefficient PA. By permitting some saturation and attendant nonlinearities, a nonideal but practical signal can be transmitted with reasonable cost and efficiency.

The 8VSB DTV signal has a peak-to-average ratio in excess of 8 dB. To observe the high state, peak cannot be captured and measured easily. To reach this peak may take a long time. Instrumentation used to measure ordinary highly repetitive signals will mislead the uninformed. This unusual phenomenon is caused by the number of combinations of digital states and the sequences that are possible. Finding that combination may take hours. As a result, the data lost by distorting these occa-

Figure 7. The DTV RF waveform.

Figure 8. Distribution of peak power.

sional symbols can be corrected by the forward error correction (FEC) codes. Tests indicate that a transmitted signal limited to 6–7 dB peak-to-average power ratio (Fig. 8) does not generate excessively uncorrectable IPs, and the receiver FEC can correct these errors. Similarly, OFDM has an even higher peak-to-average ratio. Two varieties of OFDM systems employ either 2000 or 8000 carriers. On average, half of the carriers would be turned on, whereas the peak would be all carriers turned on. The dynamic range extends from all carriers on to all carriers turned off. This very wide dynamic RF range and high peak-to-average ratio can be improved by not allowing certain states to exist to give high peaks and to let the FEC handle those occasional peaks that get clipped.

7.4. Efficiency and Dissipation

Knowing the average power output and efficiency of a PA, one can compute the dissipation. This dissipation may be limited by the power output, the cooling mechanism, the device, or the peak-to-average ratio. Efficiency has been measured for both class AB vacuum and solid-state amplifiers (Table 2). Efficiency is typically 25–35% of average output power. (Note: Higher efficiencies have been measured but at intolerable distortions.) This means that as much as 3 times as much power may be dissipated in the power amplifier as is delivered

to the load. Misleading is the high peak-to-average power ratio, perhaps leading one to quickly predict a low dissipation. One view is to consider that the class AB amplifier signal dwells in the low-efficiency class A most of the time, thus creating the lowered efficiency; where the signal dwells briefly at the higher-efficiency, class B peaks.

8. PRECORRECTION CIRCUITS

Powerful amplifiers characteristically modify the input signal in undesirable ways. High-power stages with little effect on the RF signal can be built, but they are not practical in terms of cost or efficiency. By choosing the design of a PA with limited but known distortion characteristics, one can use a number of ways to precorrect or correct these problems.

8.1. Frequency

The PA may exhibit ripple, passband tilt, or band edge problems. This is most notable in tube amplifiers using tuned cavities to extract the RF beam energy. This is often corrected by complementary tuning in the low-power drive. As the power amplifier reaches saturation, the frequency response often changes, thus complicating the correction process.

Table 2. DTV Transmitter Comparisons

	IOT (UHF)	FET (UHF)	FET (VHF)
Average DTV power	25 kW	5.5 kW	5.0 kW
Main supply (V)	37 kW	32 VDC	50 VDC
Main supply (I)	1.9 A	560 A	490 A
Signal-to-noise ratio (SNR)	25 dB	25 dB	26 dB
Error vector magnitude (EVM)	5%	5%	4%
Power consumption	70.3 kW at 25 kW	25 kW at 5.5 kW	32 kW at 5.0 kW
Power amplifier efficiency	35%	31%	22%
Transmitter efficiency	27%	22%	15%
Cooling	Air and liquid	Air	Air

8.2. Amplitude

A PA can have multiple sources of deviations from linear (power in versus power out). These nonlinearities can include saturation/compression, class B crossover distortion, or feedback/neutralization. These problems may be corrected with complementary circuits using diodes with multiple amplitude breakpoints. These circuits are implemented at lower powers ahead of the PA.

8.3. Phase or Group Delay

Power amplifier characterizations that focus only on amplitude come up short. Digital TV is both amplitude- and phase-modulated, and thus PA phase distortions limit performance, too. Phase problems are corrected by using all pass networks that exhibit tunable delay variations without amplitude variations. Usually, several of these networks are inserted at IF and have tunable characteristics over the RF band.

8.4. Analog Feedback

One of the oldest forms of distortion reduction is feedback. By sampling the amplified output, inverting it, and applying it to the input, linearity can be improved. The most common feedback in solid-state amplifiers is to leave some unbypassed resistance in the emitter (or drain). This may be done inside the transistor package. Similar feedback may be done with vacuum tubes, but some reduction in gain is required with each analog feedback scheme. It is also possible to neutralize the reactive feedback mechanism to improve the linearity characteristics. These techniques call for identifying the feedback path element and determining the best way to compensate this element reactively.

8.5. Feedforward

Feedforward has become highly developed. This technique is widely used in smaller amplifiers where very high linearity is required. Widely used is a method of distortion reduction using feedforward. There are many novel ways to accomplish feedforward, depending on the performance required. The simple form of feedforward takes a sample of the output signal from the PA, subtracts a sample of the input signal, linearly amplifies the result, and reinserts this correction into the delayed output (Fig. 9). The result is a highly corrected, linear RF output but with a lower power than the original capability of the PA.

8.6. Digital Feedback

Digital feedback can be used if the output signal can be compared to the internally generated modulator signal and an error signal can be derived. This error signal is digitized and is then used to distort or precorrect the digital signal in a manner that linearizes the transmitter. Two general classes of errors are linear and nonlinear. Linear errors are those that do not vary with signal strength. The linear errors are frequency response and group delay. Nonlinear errors are those caused by

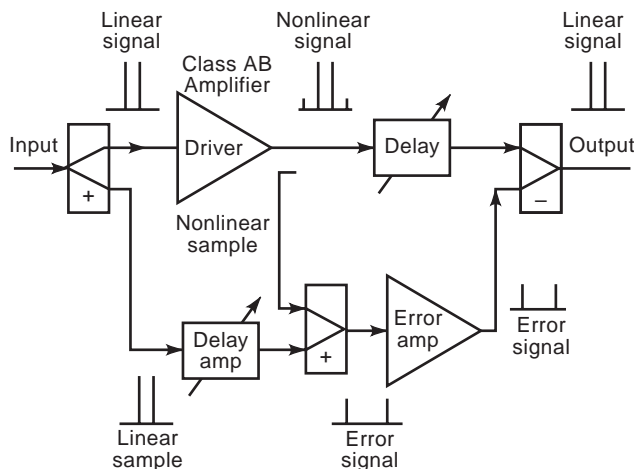

Figure 9. Feedforward block diagram.

the internal mixing action of nonlinear V_i/V_o response amplifiers.

Linear errors cause the digital constellation to be less defined, and hence demodulation uncertainties give rise to bit errors. This is shown in Fig. 10 for 8VSB.

- Phase shift (group delay) across the channel bandwidth and amplitude compression are common characteristics of power amplifiers. Similarly, filters with in-channel ripple responses and sharp cutoffs affect group delay, giving rise to linear errors.

Figure 10. Constellation errors.

Figure 11. P_{in} versus P_{out} for a power amplifier.

- Nonlinear errors are typically caused by amplifiers with gain compression and crossover distortion. Response such as that shown in Fig. 11 are what may be present in a typical efficient power amplifier.
- These nonlinear errors generate IPs that may either degrade the desired signal or create interference with an adjacent service.

9. OUTPUT FILTER

The high-power amplifiers all generate significant IP levels that are both in and out of band. The in-band IPs act as noise to degrade the SNR of the system. The IPs that are adjacent to the occupied band interfere with other services such as other TV channels. To minimize out-of-band IPs and other interference problems, using an output bandpass filter can improve the IPs. These filters degrade the digital TV signal by adding amplitude and group delay distortions. These filters are generally sharp-skirted filters to effect the IPs within 1 MHz of the channel edge. These sharp skirts have more of an impact on group delay than amplitude, and thus additional pre-correction must be added for this high-power bandpass filter.

To achieve the needed response, a many-pole filter must be used. A demanding filter may have a response as shown in Fig. 12.

The need and use of these types of filters are shown in Fig. 13. Here the amplifier is solid-state and has little bandwidth narrowing at the output. Placing a filter (not that of Fig. 12) can limit adjacent channel IPs significantly.

10. PUTTING IT ALL TOGETHER

Digital television transmitters are generally linear amplifiers using frequencies that terrestrial analog TV uses today. Thus the transmission layer is used to deliver the

Figure 12. Bandpass filter response.

transport layer digital payload, MPEG2. After generating the RF signal (8VSB or OFDM) at some low power, it is necessary to provide linear amplification. Examples of this are the IOT PA and the solid-state PA. Results of 8VSB

Figure 13. Filtered and unfiltered transmitter.

Figure 14. IOT power amplifier output without filtering.

Figure 15. Solid-state power amplifier output without filtering.

generation, precorrection, and filtering are shown in Figs. 14 and 15.

11. SUMMARY

Digital television has revolutionized our thinking about TV services to the home. Terrestrial digital TV delivery will be by means similar to analog TV, that is, by linearly amplifying a digital RF signal and then directing this power by antenna systems typically located 1000 ft above the served community. The purpose of the digital transmitter (power amplifiers and excitors) is to produce a digital signal faithfully and within the limits of broadcasters' financial means.

TRANSMITTERS FOR FM BROADCASTING

GEOFFREY N. MENDENHALL
 P. E. Richard J. FRY
 Harris Corporation

1. THE FM BROADCAST TRANSMITTER

The purpose of the FM transmitter is to convert one or more audiofrequency (composite baseband) input signal or an AES3 serial digital audio data bit stream into a frequency-modulated, radiofrequency (RF) signal at the desired power output level to feed into the radiating antenna system. In its simplest form, the FM broadcast transmitter can be considered an FM modulator and an RF power amplifier packaged in one unit.

Actually the FM transmitter consists of a series of individual subsystems each having a specific function:

1. The FM exciter converts the analog audio baseband or serial digital audio data into frequency-modulated RF and determines the key qualities of the signal.
2. The intermediate power amplifier (IPA) is required in some transmitters to boost the RF power level up to a level sufficient to drive the final stage.
3. The final power amplifier further increases the signal level to the final value required to drive the antenna system.
4. The power supplies convert the input power from the ac line into the various dc or ac voltages and currents needed by each of these subsystems.
5. The transmitter control system monitors, protects, and provides commands to each of these subsystems so that they work together to provide the desired result.
6. The RF low-pass filter removes undesired harmonic frequencies from the transmitter's output, leaving only the fundamental output frequency.

7. The directional coupler provides an indication of the power being delivered to and reflected from the antenna system.

Figure 1 shows a simplified block diagram of a typical FM transmitter.

2. FM BROADCAST TRANSMITTER POWER OUTPUT REQUIREMENTS

The FCC regulates the power of FM broadcast stations in terms of effective radiated power (ERP), which is determined by the class of station and the antenna height above the average terrain. The authorized ERP applies only to the horizontally polarized component of radiation. Elliptical or circular polarization is also permitted where the ERP of the vertically polarized component may be as great as the authorized horizontal component. This means that twice as much total power is radiated and twice as much transmitter power is required.

The transmitter power requirement is reduced by increasing the gain of the antenna. There is, of course, an economic tradeoff between the cost of a higher gain antenna versus the cost of a larger transmitter and the added primary power costs. For a high ERP, it is common to use antennas with up to 12 elements that provide a power gain of about 12.6 (or 6.3 in each polarization).

The long transmission lines associated with the tall towers commonly used are a source of considerable power loss. For example, the efficiency of 2000 ft of 3 1/8 in. rigid coax at 100 MHz is only about 62%.

The required ERP is first determined. Then the transmitter power output (TPO) can be calculated taking into account the transmission line losses and the antenna array gain. Depending on the particular situation, the TPO could vary from as little as 50 W to as much as 70 kW.

FM transmitters are designed to operate over a wide range of power outputs so that any required power output can be furnished with a few basic sizes. Popular maximum ratings range from 250 W to 70 kW. Most installations use a maximum TPO of 30 kW or less because it is more

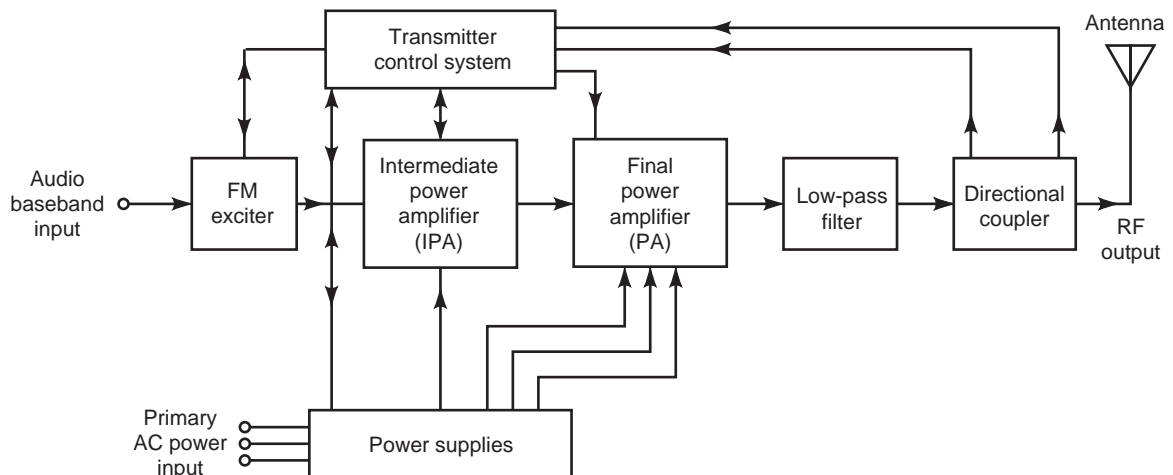

Figure 1. Simplified block diagram of an FM broadcast transmitter.

Figure 2. Stereo composite baseband with SCA subcarrier.

L or R only modulated 100% @ 5 kHz. Unmodulated SCA @ 10% injection

economical to achieve the maximum 100 kW of ERP with circular polarization by sufficient antenna gain.

2.1. FM exciters

The heart of an FM broadcast transmitter is its exciter. The function of the exciter is to generate and modulate the carrier wave with one or more inputs (mono, stereo, SCA) in accordance with the FCC standards. Then the FM carrier is amplified by a wideband amplifier to the level required by the transmitter’s following stage.

Stereo transmission places the most stringent performance requirements on the exciter. Because the exciter is the origin of the transmitter’s signal, it determines most of the signal’s technical characteristics, including signal-to-noise-ratio (SNR), distortion, amplitude response, phase response, and frequency stability. Waveform linearity, amplitude bandwidth, and phase linearity must be maintained within acceptable limits throughout the analog baseband chain from the stereo and subcarrier generators to the analog FM exciter’s modulated oscillator [1]. Figure 2 shows the frequency spectrum of the modulating baseband signal, including monaural, stereo pilot, stereo subchannel, and one SCA subcarrier. The recent introduction of AES3 (Audio Engineering Society Digital Audio Transport Standard) digital audio transport and all-digital

FM modulation techniques like direct digital synthesis (DDS) eliminate the distortions introduced by analog circuits. In a digital FM exciter, the left and right audio data are converted into a digital representation of stereo baseband by digital signal processing (DSP). Then these data are further converted into a frequency-modulated carrier by a DDS numerically controlled oscillator (NCO). From here, the FM carrier is usually amplified in a series of class C nonlinear power amplifiers, where any amplitude variation is removed. The amplitude and phase responses of all RF networks that follow the exciter must also be controlled to minimize degradation of the signal quality.

2.2. Direct FM

Direct FM is a modulation technique where the frequency of an oscillator can be made to change in proportion to an applied voltage. Such an oscillator, called a voltage tuned oscillator (VTO), was made possible by the development of varactor tuning diodes that change capacitance as their reverse bias voltage is varied (also known as a voltage-controlled oscillator or VCO).

If the composite baseband signal is applied to the tuning terminal of a VTO, the result is a *direct* FM modulated oscillator. Figure 3 is a block diagram that describes most of the modern direct FM exciters on the market.

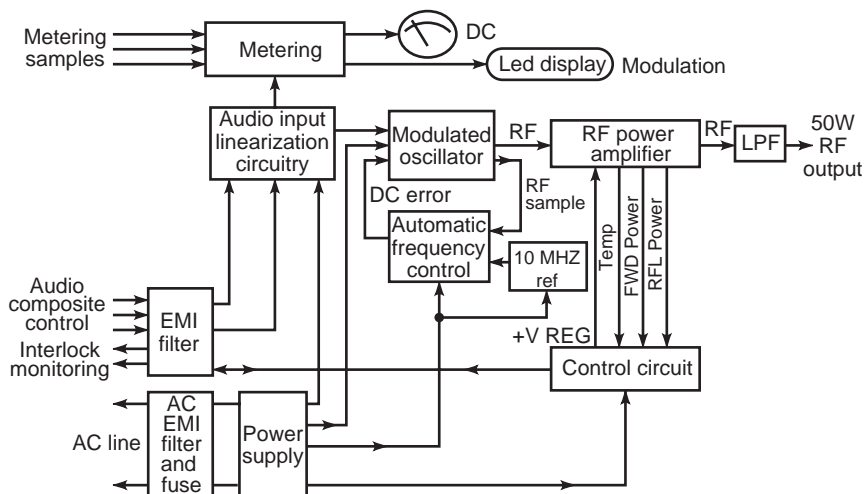

Figure 3. Analog FM exciter block diagram.

2.3. Automatic Frequency Control

The frequency stability of direct FM oscillators is not good enough to meet the FCC frequency tolerance of ± 2000 Hz. This requires an automatic frequency control system (AFC) that uses a stable crystal oscillator as the reference frequency.

The modulated oscillator need not have good long-term stability because the AFC feedback loop will correct for long-term drift to keep the average carrier frequency within limits. The modulated oscillator does need excellent short-term stability (less than 1 s) because the control-loop time constant must be long enough so that the AFC circuit does not try to remove desired low-frequency audio modulation. This means that the oscillator is essentially running open-loop at frequencies above a few hertz so that the noise performance of the modulator will also be determined by the short-term stability characteristics of the oscillator.

2.4. Phase-Locked-Loop Automatic Frequency Control

Phase-locked-loop (PLL) technology has provided a means of precisely controlling the carrier's average frequency while permitting wide deviation of the carrier frequency at baseband modulating frequencies. This implies that a PLL system behaves like an audio high-pass filter where higher modulating frequencies are ignored by the control loop, whereas lower frequencies are considered errors in the average frequency and are tracked out by the loop. An added advantage of the PLL is the ability to synthesize the desired frequency from a single reference oscillator, thereby eliminating the need to change crystals when changing the frequency of the exciter.

The block diagram shown in Fig. 4 includes the key elements in the PLL. The output of the modulated oscillator operating at the carrier frequency is digitally divided down to a frequency of a few kilohertz or even less, called the comparison frequency. Likewise, the reference crystal

oscillator is also digitally divided down to the reference frequency. The two frequencies are compared in a digital phase/frequency detector to develop an error voltage that corrects the carrier frequency of the modulated oscillator. The reason for dividing the modulated oscillator frequency so many times is to reduce the modulation index enough to limit the peak phase deviation at the reference frequency to a value that will not exceed the linear range of the phase/frequency detector. If the linear range is exceeded, the loop will lose lock. This is why some exciters may lose AFC lock in the presence of low-frequency modulation components [2].

The phase detector output is integrated and lowpass filtered to remove the comparison frequency and all other frequency components above a few hertz so that the AFC circuit does not try to track out low-frequency modulation. Some FM exciters use a dual-speed PLL to keep the loop-turnover frequency low enough to maintain good amplitude and phase response at 30 Hz, while also providing quick lock-up time. The PLL error correction circuitry must respond quickly during the initial frequency scan of the FM band to achieve lock-up to the precision reference oscillator in a few seconds. The loop bandwidth is wide during acquisition and lock-up. After lock is achieved, the bandwidth is reduced to provide the optimum modulation characteristic.

The reference oscillator is usually temperature compensated and requires no warm-up to maintain ± 3 PPM or better accuracy over the operating temperature range. A reference frequency of 10 MHz is often selected for convenient comparison with international frequency standards.

2.5. Digital FM Exciter using Direct Digital Synthesis

A new technology called direct digital synthesis (DDS) eliminates the need for a PLL in the FM modulation process by directly synthesizing the carrier frequency,

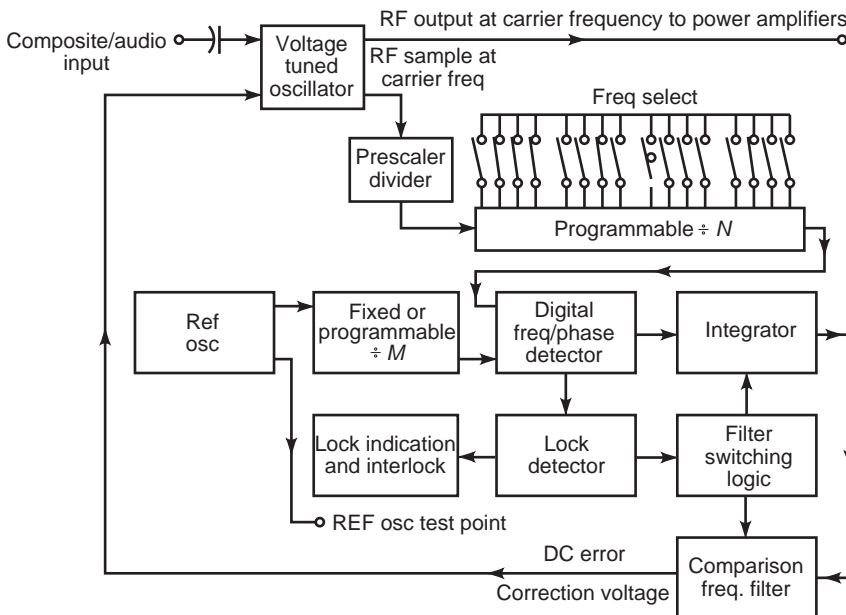

Figure 4. Phase-locked-loop frequency synthesizer.

including FM modulation, from a sine wave look-up table in a programmable read-only memory device (PROM) operating in conjunction with a digital phase accumulator and a fast digital-to-analog converter (DAC). When this technique is combined with digital signal processing (DSP) technology, the entire process of generating stereo baseband with SCAs (Subsidiary Communications Authorization) and FM modulating this baseband information onto the RF carrier can be done entirely in the digital domain. The cost-to-performance ratio of DDS/DSP technology has made it competitive with the analog technology in present excitors [3]. The full benefit of DDS/DSP technology requires digital transmission of audio information as an uncompressed, digital, bit stream all the way from the digital audio source through a digital console, digital audio processing, and an uncompressed, digital, studio-to-transmitter link (STL) to the AES3 digital input port of the DSP/DDS exciter [4]. This same technology is used in the fully digital audio broadcast (DAB) services with the European Eureka 147 (EU-147) transmission standard and other technical standards presently implemented worldwide [5].

2.6. Direct Digital Synthesis of the FM Waveform

Direct digital synthesis (DDS) is a technique in which the completely modulated FM waveform is generated totally in the digital domain. As digital modulation is an inherently linear process, no predistortion is required. The FM signal generated by a DDS device has extremely low noise and distortion, for true 16-bit digital audio quality (-96 dB FM signal-to-noise ratio and 0.0016% harmonic distortion for ± 75 kHz deviation and $75 \mu\text{s}$ preemphasis/deemphasis).

The current generation of DDS excitors use a 32-bit numerically controlled oscillator (NCO). The basic resting frequency of the NCO is set by a 32-bit tuning word. Frequency modulation occurs when modulation data varies the structure of the tuning word data within the phase accumulator section of the NCO. The modulated output of the NCO is converted to analog FM, upconverted, filtered, and amplified to become the RF excitation for a conven-

tional FM broadcast transmitter RF amplifier chain. A block diagram of a DDS digital FM exciter is shown in Fig. 5.

DDS FM excitors also eliminate several basic limitations found in analog excitors using direct FM via the modulation of a voltage-controlled oscillator (VCO). Very low audiofrequencies must be filtered from program signals to avoid affecting the automatic frequency control (AFC) circuits of the analog exciter, which see very low modulating frequencies as an off-frequency condition that needs correction. A DDS-based FM exciter has no such limitation, and modulation response extends virtually to dc (zero hertz). These lower octaves of program material are important for sonic realism and to preserve the phase correlation existing in the original program.

2.7. Digital Modulator

The digital modulator, which is the heart of a digital exciter, utilizes a 32-bit NCO to digitally generate the completely modulated FM waveform. Other supporting circuitry including a digital peak detector drives the front panel modulation display. The block diagram in Fig. 6 shows the functional subsystems of a digital modulator.

The input to the digital modulator is fed modulation data in the format and at the clock rate required. These data represent the stereo baseband created in the digital input module, which contains the DSP digital stereo generator and subcarrier input circuitry.

The digital modulator module includes a precise, digital peak detector to provide the drive for a peak modulation display. This circuit is driven by the same data as the NCO modulator. Therefore, the modulation indication on the front panel of the digital exciter has very high accuracy to within 0.25% of the true FM deviation value at any modulation index or frequency.

The output of the NCO is D/A converted to a precise, conventional FM signal at an intermediate frequency and bandpass filtered to remove the images produced in the DDS process [6].

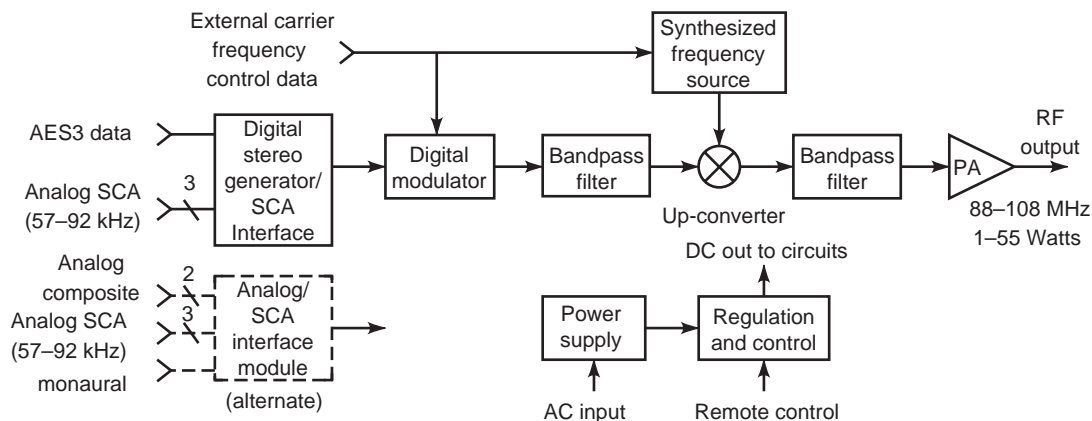

Figure 5. Harris DIGIT-CD DDS digital FM exciter.

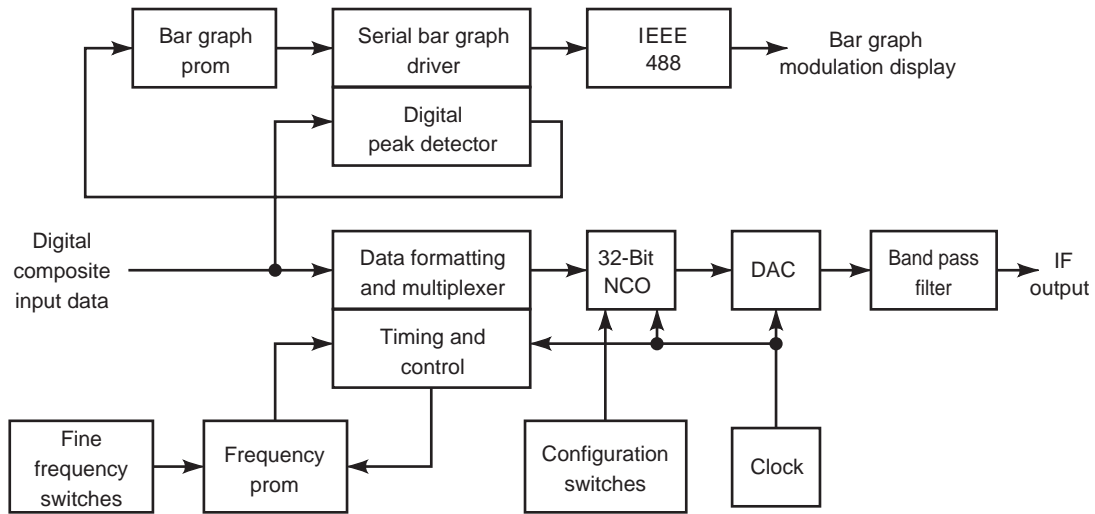

Figure 6. Digital modulator in the Harris DIGIT-CD FM exciter.

2.8. Digital Input and DSP Stereo Generator

DDS techniques are compatible with standard AES3 digital audio and provide the last link in maintaining a 100% digital audio path from the program source through the generation of the FM carrier with no intervening A/D or D/A conversions to add noise and distortion. The DDS exciter includes a built-in DSP stereo generator to convert the incoming AES3 digital stereo into the digital stereo modulation data needed for the NCO to generate FM stereo. Most DDS exciters also offer as an option a high-quality A/D converter that will convert the analog base-band output of an analog stereo generator into the digital data format needed by the NCO.

Auxiliary signals, such as SCA and RBDS/RDS (Radio Broadcast Data Service), are accepted as modulated analog waveforms from external devices, then A/D converted to digital data and applied to the NCO for simultaneous

transmission with normal stereo program material. Figure 7 shows the major signal blocks in the digital input module [7].

The digital input module provides the interface, monitoring, and control circuitry for these functions:

1. Accepts standard AES3 stereo digital data at any rate from 20.8 kHz to 56 kHz, normally 32 kHz. Rate conversion is automatic (self-clocking).
2. Accepts analog subcarriers in the range of 57 kHz to 92 KHz.
3. Converts all input signals to the composite digital format needed by the digital modulator.
4. Provides a 19 kHz output to synchronize an external RBDS/RDS generator.
5. Supplies digital composite limiting using *look ahead* digital technology.

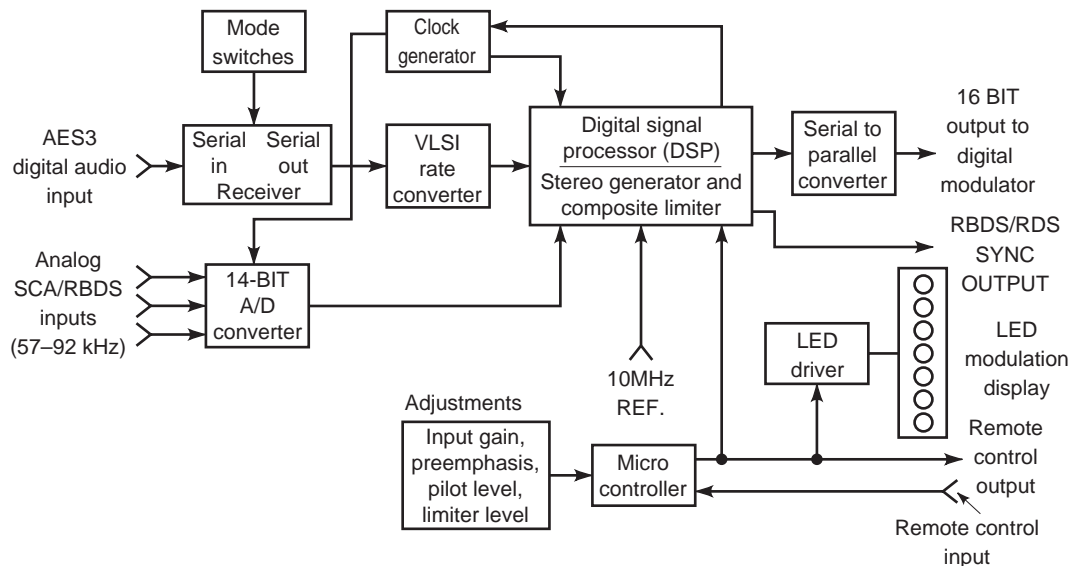

Figure 7. Harris DIGIT-CD digital input and DSP stereo generator.

6. Provides gain adjustment for SCA, overall deviation, limiting level, and pilot level.
7. Provides a switchable LED display showing either total peak deviation or limiting level.
8. Allows user selection of program channel mode (AES3/EBU or analog) (Audio Engineering Society/European Broadcast Union Digital Audio Transport Standard), preemphasis ON/OFF/time-constant, mono ON/OFF, and data error detection mode.

2.9. Exciter Metering

Metering of important operating parameters can be provided by a combination of analog metering and a digital LED display. Steady-state parameters are usually selected by a multi-position switch and displayed on an analog or LCD multimeter. Typical steady-state functions include regulated, preregulated, and unregulated supply voltages; the AFC control voltage; RF power amplifier collector voltage and current; forward output power; and reflected power.

A color-coded peak reading display is usually provided to constantly monitor the peak FM deviation. A high-speed peak detector gives accurate peak readings on signals from dc to 100 kHz. A one-shot multivibrator circuit provides a clear indication of short transient peaks exceeding 100% modulation. Digital exciters directly read the peak values of the modulation data producing the FM deviation in the NCO.

2.10. Exciter Output Stage

The broad-band RF amplifier in the exciter amplifies the output of the modulated oscillator from a power level of a few milliwatts up to an output level in the range of 5 W to 50 W. The output stage is usually protected against damage by an infinite VSWR at any phase angle.

The typical RF amplifier is designed to have a bandwidth of at least 20 MHz, using successive broadband impedance matching sections for each stage. Each group of matching sections consists of microstrip or lumped elements.

The broad-band performance of the RF amplifier eliminates the need for adjustments to any particular frequency within the FM band. The exciter output is transparent to the signal generated by the modulated oscillator, and the amplifier stability is enhanced under varying load conditions.

A microstrip directional coupler is often incorporated in the RF amplifier output network. This coupler supplies information to the exciter control circuitry that provides automatic control of power output level and provides protection against operation under high VSWR conditions.

All current generation FM exciters will produce at least 50 W of RF output so they can be used as complete transmitters for educational stations with the addition of a harmonic filter to the output. For higher power levels, the exciter is used to drive an external power amplifier.

3. RF POWER AMPLIFIERS

The remainder of the FM transmitter consists of a chain of power amplifiers, each having from 8 dB to 20 dB of power gain. Ideally, the transmitter should have as wide a bandwidth as practical with a minimum of tuned stages. Broad-band solid-state amplifiers are preferred to eliminate tuned networks in the RF path. Higher powered transmitters in the multikilowatt range may use multiple tube stages, each with fairly low gain, such as in the grounded-grid configuration or a single grid-driven PA stage with high gain and efficiency. The cost, redundancy, and wide bandwidth benefits of solid-state transmitters have made them attractive at power levels up to 20 kW. At higher power levels beyond 20 kW, the lower cost per watt of high-power, single-tube transmitters still make them attractive even though the modulation performance and reliability are less than those of a solid-state transmitter. Design improvements in tube-type power amplifiers have concentrated on improving bandwidth, reliability, and cost effectiveness, whereas design improvements in solid state amplifiers have focused on continuous cost reduction to make them competitive with tube technology at ever increasing power levels [8].

3.1. RF Power Amplifier Performance Requirements

The basic function of the power amplifier is to amplify the exciter output to the authorized transmitter power output level. Most of the overall performance characteristics of the transmitter are determined by the exciter, but a few are established or affected by the power amplifier characteristics:

1. The RF output level at harmonics of the carrier frequency is almost completely a function of the attenuation provided by the output matching circuit and output lowpass/notch filters. The FCC limit in decibels is $[43 \text{ dB} + 10(\log \text{ watts}) \text{ dB}]$ or 80 dB whichever is less (73 dB for 1 kW output or 80 dB for 5 kW and higher).
2. The major source of asynchronous AM noise usually originates in the last power amplifier stage. The FCC limit is 50 dB below 100% equivalent AM.
3. The RF power output control system that must keep the output within +5% and -10% of authorized output is usually achieved in the final power amplifier.
4. Inadequate power amplifier RF bandwidth, particularly with respect to phase linearity (constant time delay) across the signal bandwidth, can reduce stereo separation and cause SCA crosstalk.
5. The presence of standing waves on the transmission line to the antenna may also interact with the power amplifier to cause degraded stereo separation and SCA crosstalk.

The power amplifier should provide trouble-free service and be easy to maintain and repair. Good overall efficiency is also desirable to reduce the primary power consumption and heat load released into the transmitter room.

3.2. Power Amplifier Bandwidth Considerations

As mentioned earlier, the FM signal theoretically occupies infinite bandwidth. In practice, however, truncation of the insignificant sidebands (typically less than 1% of the carrier) makes the system practical by accepting a certain degree of signal degradation. The transmitter power amplifier bandwidth affects the modulation performance. Available bandwidth determines the amplitude response and group delay response. There is a tradeoff involved among the bandwidth, gain, and efficiency in the design of a power amplifier [9,10].

The bandwidth of an amplifier is determined by the load resistance across the tuned circuit and the output or input capacitance of the amplifier. For a single-tuned circuit, the bandwidth is proportional to the ratio of capacitive reactance to resistance:

$$BW \propto \frac{K}{2\pi f R_L C} = \frac{K X_C}{R_L} \quad (1)$$

where:

- BW = bandwidth between half-power points (BW3)
- K = proportionality constant
- R_L = load resistance (appearing across tuned circuit)
- C = total capacitance of tuned circuit (includes stray capacitances and output or input capacitances of the tube)
- X_C = capacitive reactance of C
- f = carrier frequency [11]

The load resistance is directly related to the RF voltage swing on the tube element. For the same power and efficiency, the bandwidth can be increased if the capacitance is reduced.

4. EFFECTS OF CIRCUIT TOPOLOGY AND TUNING ON FM MODULATION PERFORMANCE

FM broadcast transmitter RF power amplifiers are typically adjusted for minimum synchronous AM (incidental amplitude modulation with FM), which results in symmetrical amplitude response. This will assure that the transmitter's amplitude passband is properly centered on the FM channel. The upper and lower sidebands will be attenuated equally or symmetrically, which is *assumed* to result in optimum FM performance. This will be true if the RF power amplifier circuit topology results in simultaneous symmetry of amplitude and group delay responses.

Actually, symmetry of the group delay response has a much greater effect on FM distortion than has the amplitude response. Tuning for symmetrical group delay will cause the phase/time delay errors to affect the upper and lower sidebands equally or symmetrically. The group delay response is constant if the phase shift versus frequency is linear. All components of the signal are delayed equally in time, but no phase distortion occurs.

The tuning points for symmetrical amplitude response and symmetrical group delay response usually do *not*

coincide, depending on the circuit topology. Therefore, simply tuning for minimum synchronous AM (symmetrical amplitude response) does not necessarily result in the best FM performance [12].

Measurements taken on typical FM transmitters as well as computer simulations show that tuning the RF power amplifier for symmetrical group delay response results in minimum distortion and crosstalk. Group delay response asymmetry causes higher FM distortion and crosstalk than amplitude response asymmetry. The transmitter should be tuned for symmetrical group delay response, which results in the best FM performance, rather than for symmetrical amplitude response, which results in minimum synchronous AM [13].

4.1. Power Amplifier Output Source Impedance

At the milliwatt levels used in RF test equipment, it is customary to provide 50 Ω source and load impedances at both ends of a coaxial transmission line. This approach minimizes any reflections on the line because both the transmitter (source) and the termination (load) absorb reflected energy. A 50 Ω source impedance is usually provided by placing a 50 Ω build-out resistor in series with a low-impedance voltage source (Thevenin equivalent). The closed-circuit voltage with this configuration is exactly one half of the open-circuit voltage, meaning that half of the total available RF power is dissipated in the source resistance. The best possible efficiency for this system is 50% assuming that the voltage source is 100% efficient without the source resistance.

It becomes obvious that, although an FM transmitter is designed to drive a 50 Ω load, it does not have an output source impedance of 50 Ω . To achieve high efficiency, the transmitter must have a very low output source impedance so that nearly all of the power is delivered to the load. The plate dissipation indirectly represents some of the power lost within the low source resistance. Because the low source impedance of the transmitter provides a mismatch to reflected power from the load, this power is almost totally reflected back from the transmitter output stage toward the load again.

4.2. Intermediate Power Amplifiers

The intermediate power amplifier (IPA) is located between the exciter and the final amplifier in higher power transmitters that require more than about 50 W of drive to the final amplifier. The IPA may consist of one or more tubes or solid-state amplifier modules.

Most of the newer design, high-power transmitters with a tube in the final amplifier require between 150 W and 600 W of drive. This permits the use of solid-state, wideband, power amplifier modules to boost the exciter's power up to the level required to drive the grid of the final tube.

4.3. Interstage Coupling Circuits

The separate IPA output circuit and the final amplifier input circuit are often coupled together by a coaxial transmission line. Impedance matching is usually

accomplished at either end by one of the configurations shown in Fig. 8.

The interconnecting transmission line between the coupling circuits should be properly matched to avoid a high VSWR. Directional wattmeters are normally placed in the line to measure forward and reflected power from which a standing wave ratio can be established. The VSWR is established by the match at the load end of the transmission line.

Solid-state RF power devices possess a very low load impedance at the device output terminal, so that an impedance transformation that goes through the 50 Ω intermediate impedance level is required to couple these devices into the relatively high impedance of the final amplifier grid circuit. Therefore, virtually all solid-state IPA systems have a 50 Ω impedance point within the system that can be used to feed the antenna in an emergency.

4.4. Solid-State RF Power Amplifier Systems

A solid-state RF power amplifier almost always consists of a system of individual amplifier modules combined to provide the desired power output. Following are the advantages of using several lower power modules instead of a single high-power amplifier:

1. Redundancy is provided by isolating the input and output of each module, permitting uninterrupted

operation at reduced power if one or more of the modules fails.

2. The ability to repair or replace failed modules without having to go “off the air.”
3. More effective cooling of each power device junction by splitting the concentration of heat to be dissipated into several areas instead of one small area.
4. Better isolation between the amplifier modules and the input circuit of the final power amplifier or antenna is provided by the combiner/isolator.
5. Redundant power supplies and air cooling systems for each module improve overall reliability.

Each RF power amplifier module consists of one or more solid-state devices with broad-band impedance transformation networks for input and output matching. A new generation of class “C” MOSFET devices permits the design of broad-band amplifier stages with both high efficiency and the wide bandwidth necessary to cover the FM broadcast band.

The input impedance to the solid-state device is always lower than the desired 50 Ω input impedance, so a broad-band impedance transformation scheme is required. This is usually accomplished by a combination of coaxial baluns and push-pull coaxial line sections cross-coupled to provide 4:1 or higher transformation ratios over the FM band.

By operating two devices in push-pull, the input impedance (differential) is double that of a single-ended circuit, and the suppression of even order harmonics is enhanced. Two devices fed in this manner also provide some degree of redundancy within the module because partial RF output may be obtained when one device fails. Similarly, the low output impedance of these solid-state devices can be transformed up to the desired 50 Ω module output impedance where combining occurs. Figure 9(a) illustrates a simplified schematic of a broad-band, 350 W, MOSFET, RF amplifier module using the push-pull configuration. Figure 9(b) is a photograph of this RF amplifier module [14].

4.5. Solid-State Amplifier Splitting and Combining

The following are two frequently used types of splitting/combining schemes:

1. A 90° hybrid splitter or combiner ($N - 1$ hybrids are required to split or combine N inputs) (see section on transmitter output combining).
2. A Wilkinson N -way in-phase splitter or combiner.

Either type of splitter/combiner must provide isolation between the individual power amplifier modules and low-loss splitting or combining of the total power.

The cascaded 90° hybrid system shown in Fig. 10 provides double isolation between the power amplifiers and the load by first combining the two pairs of amplifiers and then combining the outputs of the first two combiners. A portion of the reflected power, caused by a mismatch at the output, will be dissipated in the reject loads so that the power amplifier modules will operate into a lower VSWR

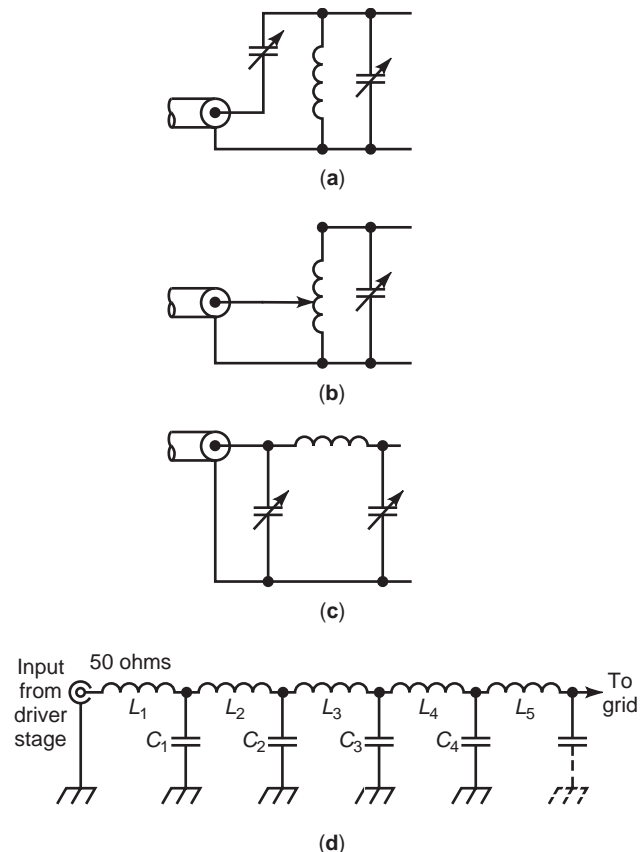

Figure 8. Interstage RF coupling circuits.

(a)

(b)

Figure 9. (a) Schematic of broad-band, 350 W, MOSFET, RF power amplifier module. (b) Broad-band, 350 W, MOSFET, RF power amplifier module.

than exists at the output. The unbalanced 50 Ω reject loads are accessible for monitoring of reject load power, which is useful in determining the balance of the system.

The Wilkinson system shown in Fig. 11 is a simple and effective way to split and combine modules operating in-phase but usually requires a balanced reject load that makes reject power measurements more difficult. By adding additional coaxial balun sections to the Wilkinson, it is

possible to use unbalanced reject loads [15]. This configuration is called Wilkinson–Gysel.

5. ADAPTIVE CONTROL OF THE COMBINER CONFIGURATION

Both the 90° hybrid and the Wilkinson combining systems require resistive RF power reject loads to provide isolation

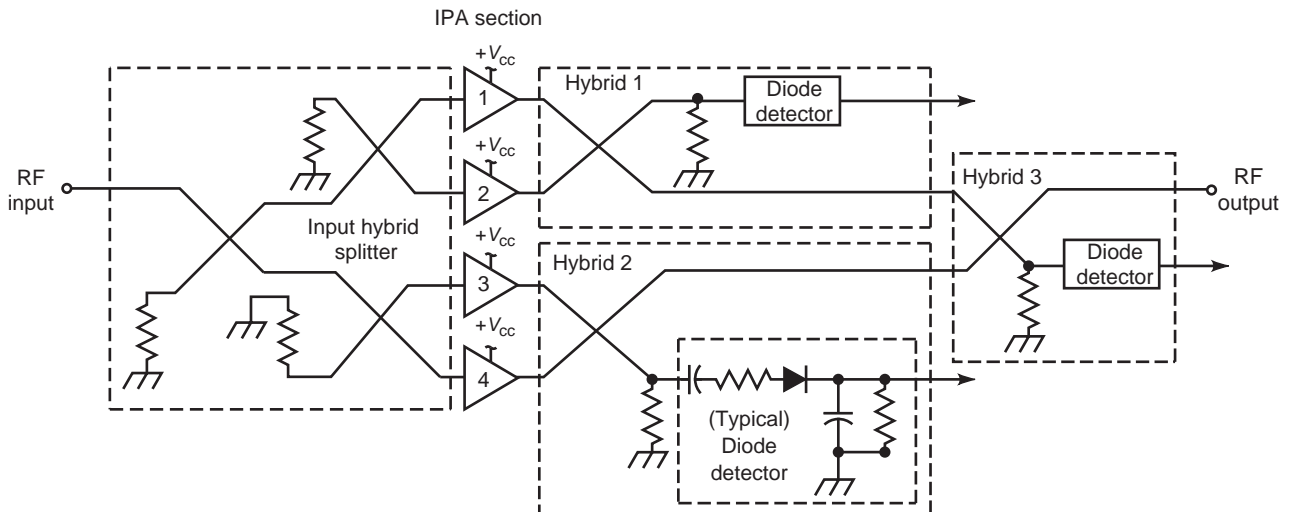

Figure 10. Cascaded 90° hybrid combiner.

Figure 11. Wilkinson-Gysel in-phase splitting/combining system with unbalanced reject loads.

between the amplifier modules in the event that one or more of the modules fail. A portion of the RF power from the remaining modules is wasted in the reject loads instead of being delivered to the output. Recent developments have made it possible for a microcomputer to monitor the degree of imbalance in the system and adaptively change the configuration of the combiner to losslessly compensate for the failure of one or more power amplifier modules. This is accomplished by having the microcomputer substitute the appropriate reactances in place of the resistive reject loads to maintain enough isolation for the remaining power amplifiers to work efficiently. This technique is used in the Harris "Z" plane combiner.

Because most splitter/combiner systems are designed around a 50Ω input and output impedance level, these systems can be easily used as low-power standby transmitters by routing the output to the antenna system. An RF lowpass filter (LPF) is required only when directly feeding the antenna system. The harmonic suppression of the IPA is not as critical when driving a nonlinear power amplifier that also generates harmonics, because this stage will have its own LPF.

6. SOLID-STATE FM BROADCAST TRANSMITTERS

The techniques used to construct IPA systems can also be used to construct a completely solid-state transmitter using arrays of combined modules for the final output stage.

An additional RF lowpass filter is usually required to meet FCC emission requirements.

6.1. Advantages of Solid-State Transmitters

The primary advantages of a solid-state transmitter are the built-in amplifier and power supply redundancy, superior FM performance, the ability to cover the entire FM band without the need for retuning, and elimination of tube replacement costs. A tubeless transmitter is nearly maintenance free.

6.2. Solid-State Transmitter Design Considerations

Several manufacturers offer solid-state FM broadcast transmitters with power outputs ranging from 100 W up to 20 kW, but present economic factors still favor the single-tube FM transmitter for power levels above 20 kW. For a solid-state transmitter to be competitive in cost and power consumption with a single tube transmitter, the efficiency of the solid-state RF power amplifiers and combining system have to approach the 80% efficiency obtainable from tube type RF amplifiers. This high efficiency has recently been achieved with MOSFET solid-state devices at VHF frequencies.

Recent solid-state designs have provided higher efficiencies, up to 80% dc to RF efficiency at the MOSFET device level and over 62% overall efficiency, from ac line in to RF output. This is actually better ac to RF efficiency at the 5 kW level than a typical single-tube transmitter.

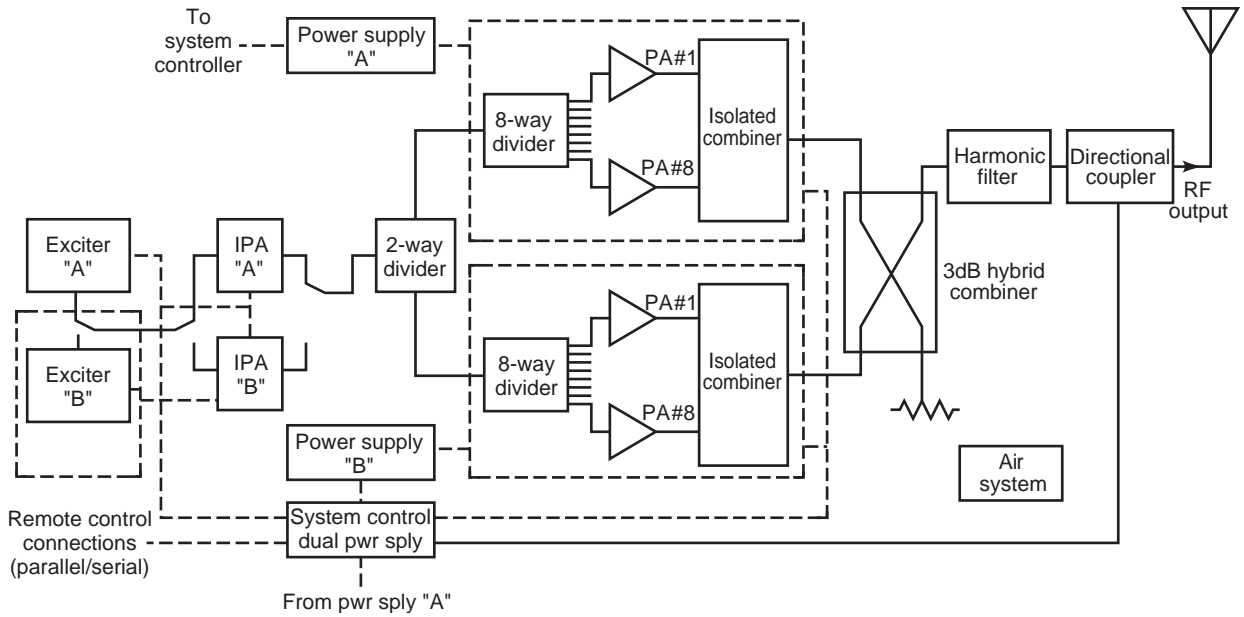

Figure 12. Harris Z 5 kW solid-state FM transmitter.

Some solid-state designs have added a few percent to their overall ac to RF efficiency by optimizing their RF circuits over narrowband sections of the FM band. This approach is beneficial to the user who is certain that there will be no need to change the transmitter's frequency or who is prepared to provide the transmitter modifications needed to do so.

Trends in the newest solid-state FM transmitters are to supply redundant RF, power supply, and control circuits so as to keep the transmitter on the air at reduced power in the event one or more components should fail. Identical and interchangeable IPA and PA modules offer additional redundancy. RF modules that can be removed and inserted in an operating transmitter also provide the advantage of not requiring an off-air period for some maintenance services.

Solid-state transmitter layouts with direct, cable-free connection of the RF modules to the RF combiner have also been introduced and further enhance transmitter reliability and stability. Another enhancement provided in some current solid-state FM transmitters is an advanced, microprocessor-based, control system that monitors detailed parameters within the transmitter and provides *intelligent control* of the transmitter system, including the RF combiner, so as to maximize output power and minimize reject load power under various combinations of active and inactive modules.

Figure 12 shows a block diagram of a 5 kW solid-state transmitter.

6.3. Vacuum-Tube Power Amplifier Circuits

The amplitude of an FM signal remains constant with modulation so that efficient, nonlinear, Class C, amplifiers can be used.

FM broadcast vacuum-tube power amplifier circuits have evolved into two basic types. One type uses a tetrode or pentode tube in a grid-driven circuit, whereas the other uses a high- μ triode in a cathode-driven (grounded grid) circuit.

6.3.1. Cathode-Driven Triode Amplifiers. The high- μ triodes being used in cathode-driven (grounded-grid) FM amplifiers were originally developed for linear SSB amplifiers. Their characteristics are well adapted to FM broadcast use because the circuit is very simple and no screen or grid bias power supplies are required. Figure 13 shows the basic circuit configuration. In this case, the grid is connected directly to chassis ground. Dc grid current is the difference between dc cathode current and dc plate current. The output tank circuit is a shorted coaxial cavity that is capacitively loaded by the tube output and stray circuit capacitance. A small capacitor is used for trimming

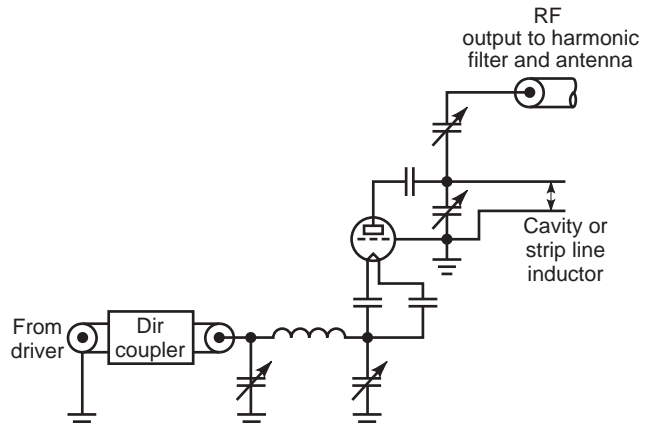

Figure 13. Cathode-driven, triode, power amplifier.

the tuning and another small variable capacitor is used to adjust the loading. A π -network matches the $50\ \Omega$ input to the tube cathode impedance.

The triodes are usually operated in the less efficient, class “B” mode to achieve maximum power gain, which is on the order of 20 (13 dB). They can be driven into high-efficiency, class “C” operation by providing negative grid bias. This increases the plate efficiency, but also requires increased drive power.

Most of the drive power into a grounded-grid amplifier is fed through the tube and appears in the stage’s output. This increases the apparent efficiency so that the efficiency factor given by the manufacturer may be higher than the actual plate efficiency of the tube. The true plate efficiency is determined by dividing the output power by the total input power, which includes both the dc plate input power ($I_p \times E_p$) and the RF drive power. Because most of the drive power is fed through the tube, any changes in loading of the output circuit also affect the input tuning and driver stage.

There is RF drive voltage on the cathode (filament) of the tube, so some means of decoupling must be used to block it from the filament transformer. One method employs high-current RF chokes because the inductance can be very low at this frequency range. The other commonly used method feeds the filament power through the input tank circuit inductor.

Cathode-driven stages are normally used only for the higher power stages. The first stage in a multitube transmitter is nearly always a tetrode because of its higher power gain.

6.3.2. Grid-Driven Tetrode and Pentode Amplifiers.

Transmitters with tetrode amplifiers throughout usually have one less stage than do those with triodes. Because tetrodes have higher power gain, they are driven into class “C” operation for high plate efficiency. Against these

advantages is the requirement for neutralization, along with screen and bias power supplies.

Figure 14 shows a schematic of a grid-driven tetrode amplifier. In this example, the screen is operated at dc ground potential and the cathode (filament) is operated below ground by the amount of screen voltage required. This is called grounded-screen operation. It has the advantage that stability problems due to undesired resonances in the screen-by-pass capacitors are eliminated. With directly heated tubes, it is necessary to use filament-bypass capacitors. During grounded-screen operation, these bypass capacitors need a higher breakdown voltage rating because they have the dc screen voltage across them. The filament transformer must have additional insulation to withstand the dc screen voltage.

The screen power supply provides a negative voltage in series with the cathode to ground and must have the additional capacity to handle the sum of the plate and screen currents. A coaxial cavity is used in the output circuit so that the circulating current is spread over large surfaces to keep the losses very low. This cavity is a shorted quarter-wavelength transmission line section that resonates the tube’s output capacitance. The quarter-wavelength cavity is actually shorter than a physical quarter-wavelength due to the electrical loading effect of the tube’s output capacitance across the open end of the transmission line. The length is preset to the desired carrier frequency, and then a small-value variable capacitor is used to trim the system to resonance. Capacitive output coupling is used to match from the high RF voltage point to the $50\ \Omega$ transmission line.

The $50\ \Omega$ input is capacitively coupled into the grid circuit inductor to provide the correct impedance match.

Pentode amplifiers have even higher gain than their tetrode counterparts. The circuit configuration and bias supply requirements for the pentode are similar to the tetrode because the third (suppressor) grid is tied directly to ground. The additional isolating effect of the (suppressor) grid eliminates the need for neutralization in the pentode amplifier [16].

6.3.3. Impedance Matching Into the Grid. The grid circuit is usually loaded (swamped) with added resistance. The purpose of this resistance is to broaden the bandwidth of the circuit by lowering the circuit Q and to provide a more constant load to the driver. It also makes neutralizing less critical so that the amplifier is less likely to become unstable.

Cathode or filament lead inductance from inside the tube through the socket and filament capacitors to ground can heavily load the input circuit. This is caused by RF current flowing from grid to filament through the tube capacitance and then through the filament lead inductance to ground. An RF voltage is developed on the filament, which in effect causes the tube to be partly cathode-driven. This undesirable extra drive power requirement can be minimized by series resonating the cathode return path with the filament bypass capacitors or by minimizing the cathode-to-ground inductance with a specially designed tube socket containing thin-film dielectric sandwich capacitors for coupling and bypassing.

Figure 14. Grid-driven, grounded-screen, tetrode, power amplifier.

High-power, grid-driven, class “C” amplifiers require a swing of several hundred RF volts on the grid. To develop this high-voltage swing, the input impedance of the grid must be increased by the grid input matching circuit. Because the capacitance between the grid and the other tube elements may be 100 pF or more, the capacitive reactance at 100 MHz will be very low unless the input capacitance is resonated in parallel with an inductor. Figures 15(a) and 15(b) show two popular methods of resonating and matching into the grid of a high-power tube. Both methods can be analyzed by recognizing that the desired impedance transformation is produced by an equivalent L network.

In Fig. 15(a), a variable inductor L_{in} is used to raise the input reactance of the tube by bringing the tube input capacitance C_{in} almost to parallel resonance. Parallel resonance is not reached because a small amount of parallel capacitance C_p is required by the equivalent L network to transform the high impedance Z_{in} of the tube down to a lower value through the series matching inductor L_s . This configuration provides an L -network lowpass filter by using part of the tube’s input capacitance to form C_p .

Figure 15(b) uses variable inductor L_{in} to take the input capacitance C_{in} past parallel resonance so that the

tube’s input impedance becomes slightly inductive. The variable series matching capacitor C_s forms the rest of the equivalent L network. This configuration is a high-pass filter.

6.3.4. Neutralization. Cathode-driven, grounded-grid amplifiers using triodes do not require neutralization. It is necessary that the grid-to-ground inductance, both internal and external to the tube, be kept very low to maintain this advantage. Omission of neutralization allows a small amount of interaction between the output circuit and the input circuit through the plate-to-filament capacitance. This effect is not very noticeable because of the large coupling between the input and output circuits through the electron beam of the tube. Cathode-driven tetrodes have higher gain and therefore require some form of neutralization.

Grid-driven, high-gain tetrodes need accurate neutralization for best stability and performance. Self-neutralization can be accomplished very simply by placing a small amount of inductance between the tube screen grid and ground, usually in the form of several short, adjustable-length straps. The RF current flowing from plate to screen in the tube also flows through the screen lead inductance. This develops a small RF voltage on the screen, of the opposite phase, which cancels the voltage fed back through the plate-to-grid capacitance. This method of lowering the self-neutralizing frequency of the tube works only if the self-neutralizing frequency of the tube/socket combination is above the desired operating frequency before the inductance is added. Feedback neutralization uses a small coupling capacitor, usually in the form of a small plate located near the anode of the tube. The sample of the RF voltage from the anode intercepted by this plate is coupled through a 180° phase-shift network into the grid circuit. This technique has the advantage of providing neutralization over a very broad range of frequencies if implemented correctly, and stray reactances are minimized. Special attention must also be given to minimizing the inductances in the tube socket by integrating distributed bypass capacitors into the socket and cavity deck assembly. Pentodes normally do not require neutralization because the suppressor grid effectively isolates the plate from the grid.

6.3.5. Power Amplifier Output Circuits. Usually, the output circuit consists of a *high-Q* (low-loss) transmission line cavity, strip line, or a lumped inductor that resonates the tube output capacitance. A means of trimming the tuning and a means of adjusting the coupling to the output transmission line must also be provided by the output circuit. The tank circuit loaded Q is kept as low as practical to minimize circuit loss and to maintain as wide an RF bandwidth as possible.

6.3.6. The Power Amplifier Cavity. The vacuum-tube power amplifier is constructed in an enclosure containing distributed tank circuit elements for minimum loss. The efficiency of the PA depends on the RF plate voltage swing, the plate current conduction angle, and the cavity efficiency. The cavity efficiency is related to the ratio of the

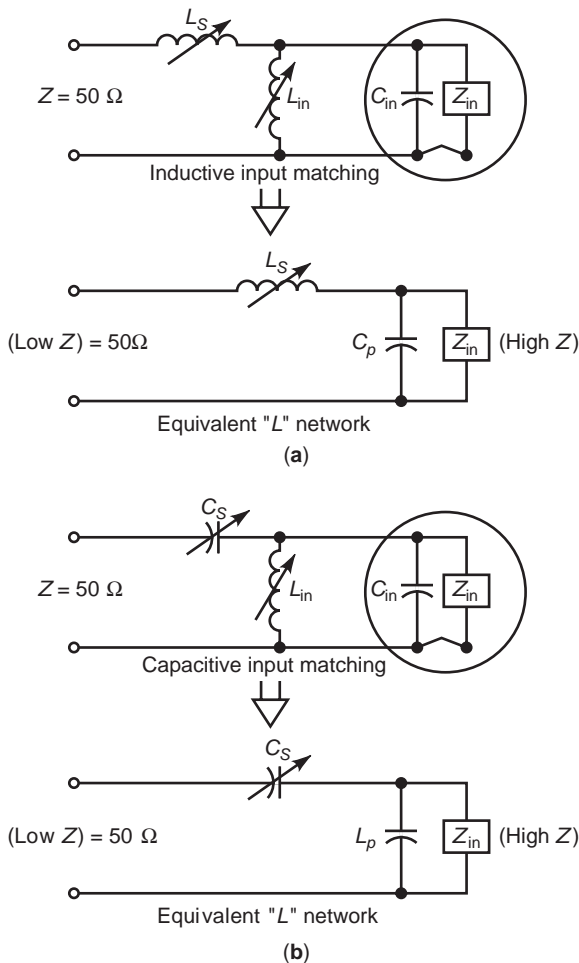

Figure 15. (a) Inductive input matching. (b) Capacitive input matching.

loaded to unloaded Q as follows:

$$N = 1 - \left(\frac{Q_L}{Q_U} \right) \times 100 \quad (2)$$

where N is the efficiency in percent, Q_L is the loaded Q of cavity, and Q_U is the unloaded Q of cavity.

The loaded Q depends on the plate load impedance and output circuit capacitance. Unloaded Q depends on the cavity volume and the RF resistivity of the conductors due to skin effects. A high unloaded Q is desirable, as is a low loaded Q , for best efficiency. As the loaded Q goes up, the bandwidth decreases. For a given tube output capacitance and power level, the loaded Q decreases with decreasing plate voltage and increasing plate current. The increase in bandwidth at reduced plate voltage occurs because the smaller load resistance is directly related to the RF voltage swing (for the same power) on the tube element. For the same power and efficiency, the bandwidth can also be increased if the output capacitance is reduced. Power tube selection and minimization of stray capacitance are areas of prime concern when designing for maximum bandwidth.

6.3.7. The Quarter-Wavelength Cavity. The “quarter-wavelength” coaxial cavity is the compact and popular output circuit illustrated in Fig. 16. The tube anode is coupled through a dc blocking capacitor to a shortened “quarter-wavelength” transmission line. The tube’s output capacitance is brought to resonance by the inductive component of the transmission line that is physically less than a quarter-wavelength long. Plate tuning is accomplished either by adding end-loading capacitance at the high-impedance end of the line with a variable capacitor or by changing the position of the ground plane at the low-

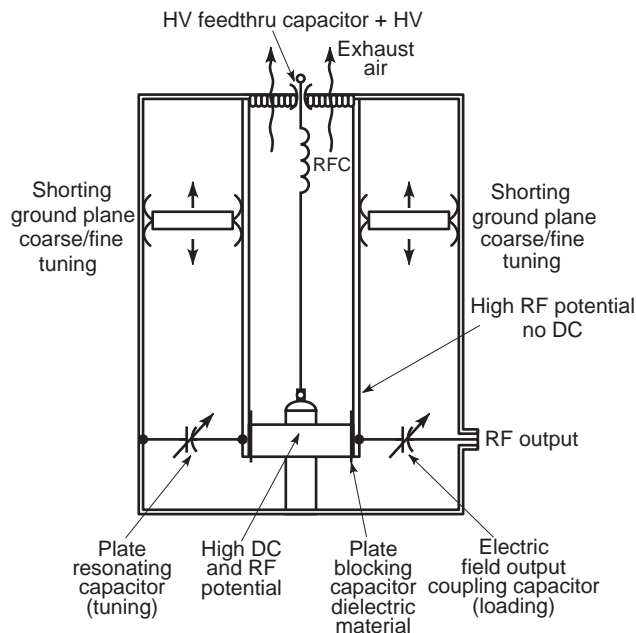

Figure 16. The quarter-wavelength cavity.

impedance end of the line. The plate-tuning capacitor may be a sliding or rotating plate near the anode of the tube. The center conductor of the transmission line (air exhaust chimney) is at dc ground, whereas the anode of the tube operates at a high RF and dc potential. Dc voltage is fed through an isolated “quarter-wavelength” decoupling network inside the chimney to the anode of the tube. The plate blocking capacitor prevents dc current flow from the anode into the chimney.

6.3.8. The Folded, Half-Wavelength Cavity. Another approach to VHF power amplification uses the reentrant, folded, “half-wavelength” cavity design illustrated in Fig. 17. The dc anode voltage is applied to the lower portion of the plate line through a choke at the RF voltage null point. The “half-wave-length” line is tuned by mechanically expanding or contracting the physical length of a flexible extension (bellows) on the end of the secondary transmission line stub, which is located concentrically within the primary transmission line (air exhaust chimney). Coarse frequency adjustment is accomplished by presetting the depth of the top secondary section of plate line into the tank cavity.

Other power amplifier configurations may use lumped components or hybrid combinations with distributed transmission line elements to achieve similar results. The discrete circuit elements are chosen for their individual inductance or capacitance, instead of being operated in a purely “quarter-wavelength” or “half-wavelength” mode. Stray inductance and capacitance add to the component values resulting in the hybrid nature of these circuits.

The RF voltage and current distributions for the “quarter-wavelength” and the folded, “half-wavelength” cavities are shown in Fig. 18.

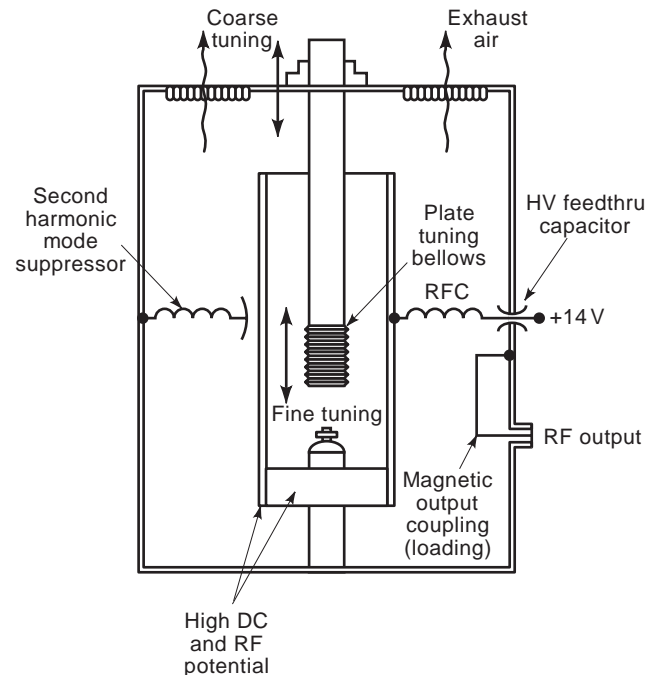

Figure 17. The folded, half-wavelength cavity.

Figure 18. Cavity RF voltage and current distributions.

Regardless of the specific configuration, the output circuit must transform the high resonant plate impedance down to the output transmission line impedance of $50\ \Omega$. The bandwidth of a transmission line cavity is optimized by choosing the highest characteristic impedance mechanically and electrically allowable.

6.3.9. Output Coupling. Power may be coupled from a “quarter-wavelength” cavity to the transmission line by a capacitive probe located near the high RF voltage point located at the anode end of the “quarter-wave” line as shown in Fig. 16. The amount of output coupling capacitance is determined by the RF power output required. The loaded Q of this circuit varies with the degree of capacitive coupling. Another method of coupling power from the “quarter-wavelength” cavity uses a tuned loop located near the grounded (high current) end of the line. In this case, the tuned loop operates both as an inductive and a capacitive pickup device. Power may be coupled from the “half-wavelength” line by an inductive loop located in the strong fundamental magnetic field near the center of the cavity, as shown in Fig. 17.

6.3.10. RF Output Low-Pass Filters. The high-efficiency, nonlinear RF power amplifiers used in FM broadcast transmitters generate significant amounts of energy on frequencies that are integral multiples (harmonics) of the desired fundamental frequency. The output circuit alone does not provide enough harmonic attenuation to meet FCC regulations. To comply with Part 73 of the FCC rules and regulations and to prevent interference to other services, a lowpass filter must be installed in the transmission line at the output of the transmitter. The FM band is narrow enough that one lowpass filter design can be used for any FM channel carrier frequency. These filters usually consist of multiple LC sections arranged so that frequencies within the FM band are passed with little attenuation (typically 0.1 dB or less), whereas frequencies above the FM band are highly attenuated (60 dB or more).

The most common type of filter in this application is called a *reflective* filter, meaning that the frequency components outside the passband are reflected back out of the filter toward the source because it provides a mismatch at these undesired frequencies. The filter can be constructed using either *lumped* inductors and capacitors or a section of nonconstant impedance transmission line to form *distributed* inductors and capacitors. The filters designed for low-power transmitters often employ *lumped* elements (coils and capacitors) because they are compact and can be integrated into the transmitter cabinet. The distributed type of filter is most often used with high-power FM broadcast transmitters because of its simplicity, extreme ruggedness, and ability to handle higher power levels. The distributed filter does have the disadvantage of having larger physical dimensions than a similar lumped filter, which may necessitate mounting the filter outside of the transmitter cabinet. Figure 19 shows a cutaway view of a typical distributed lowpass filter. Note that the areas where the center conductor for the transmission line is smaller than that required for the input Z_0 are inductive, whereas the areas where the center conductor is larger in diameter are capacitive.

When two filters (such as the output cavity and the harmonic filter) are connected by a transmission line, the total harmonic attenuation varies with interconnecting line length. The attenuation characteristics of the harmonic filter are specified for the condition where both the source and load impedances are equal to the desired transmission line impedance.

In actual use, the source impedance at the output of the tank circuit is much less than the $50\ \Omega$ load impedance presented by a properly terminated filter. At the operating frequency, the output impedance of the power amplifier

Figure 19. Cutaway view of a distributed lowpass filter.

and the input impedance of the lowpass filter become predominantly reactive at harmonic frequencies causing interaction between the two. If an unfortunate length of line is selected, the harmonic attenuation may be insufficient, and the transmitter tuning may be affected. This undesirable condition can be corrected by changing the line length by approximately one quarter-wavelength. At the operating frequency, the line length between the tank circuit and the harmonic filter is usually supplied precut to a value known to be satisfactory by the transmitter manufacturer.

6.3.11. Harmonic Notch Filters. In some cases, a second harmonic notch filter is required in addition to the lowpass filter because the second harmonic component from the amplifier is high and the cutoff slope of the lowpass filter is not steep enough to provide sufficient second harmonic attenuation. The additional attenuation required (typically 30 dB) can be provided by a notch filter that places a short circuit across the transmission line at the second harmonic while providing a high impedance at the fundamental. A one quarter-wavelength (at the fundamental frequency), shorted coaxial stub is often used for this function. The second harmonic energy is primarily reflected back toward the power amplifier and to a lesser extent dissipated in the equivalent series resistance of the series tuned circuit formed by the stub. This shorted stub provides a very low impedance and a dc path from the center conductor of the transmission line to ground providing a separate, protective, advantage by shunting static discharges, such as lightning, to ground.

7. COMBINED TRANSMITTERS

It is possible to combine the output of two RF power amplifiers for higher power levels. The important advantage is that the broadcast transmission is not interrupted if one amplifier fails. The radiated signal strength merely drops 6 dB until the failed amplifier is repaired and put back on the air. A dual-amplifier system costs more than a single amplifier for a given total power output, but there are the economic advantages of reducing lost air time and eliminating the need for a separate standby transmitter. Automatic or manual output switching can be used to route the full power of the remaining amplifier directly to the antenna, reducing the loss in radiated power from 6 dB to 3 dB.

Two methods may be used to bypass the output-combining hybrid to allow 100% of the power of the remaining transmitter to be sent to the antenna if one transmitter of a combined pair should fail.

The first method uses three motorized switches (or patch panels) to bypass the 3 dB hybrid while connecting the operating transmitter directly to the antenna and the failed transmitter directly to the test load. This allows recovery of the 50% power lost in the reject load when one transmitter is off the air. One disadvantage is that the system must be taken off the air for several seconds to operate the coax switches.

A second method provided by some transmitter suppliers uses a pair of 3 dB hybrids interconnected with one fixed and one variable RF phasing section. The phasing section is constructed to operate while under RF power and can redirect the full output of either transmitter directly to the antenna and place the other transmitter into the test load without taking the system off the air. A dedicated system controller allows automatic or manual control. This so-called *switchless* combiner offers the highest possible on-air availability for combined FM transmitters. With complete redundancy in the RF power amplifier chain, some stations go one step further and install dual exciters with automatic switching so that, if one exciter fails, the other unit is quickly switched into service.

7.1. 90° Hybrid Couplers

Hybrid couplers are reciprocal four-port devices used either for splitting or combining RF sources over a wide frequency range. Figure 20 shows an exploded view of a typical 3 dB, 90°, hybrid coupler. The coupler consists of two identical parallel transmission lines coupled over a distance of approximately one quarter-wavelength and are enclosed within a single outer conductor. Ports at the same end of the coupler are in phase, whereas ports at opposite ends of the coupler are in quadrature (90° phase shift) with respect to each other.

The phase shift between the two inputs or outputs is always 90° and is almost independent of frequency. If the coupler is being used to combine two signals into one output, these two signals must be fed to the hybrid coupler in phase quadrature. The reason this type of coupler is also called a 3 dB coupler is that when used as a power splitter, the split is equal or half-power (3 dB) between the two outputs.

7.2. 90° Hybrid Combiners

The output hybrid combiner effectively isolates the two amplifiers from each other. Tuning adjustments can be

Figure 20. Physical model of a 90° hybrid coupler.

made on one amplifier including turning it on and off without appreciably affecting the operation of the other amplifier. Good isolation is necessary so that if one transmitter fails, the other continues to operate normally instead of in a mistuned condition. Two of the ports on the hybrid coupler are the inputs from the power amplifiers, the sum port is the antenna output terminal, and the difference port goes to a resistive dummy load called the *reject load* because only the rejected power caused by imbalance appears here. When the power fed to each of the two inputs is equal in amplitude with a phase difference of 90°, the total power is delivered to the sum port (antenna). Very little of the power appears at the reject load if the phase relationship and power balance are correct. If the phase relationship is reversed between the two amplifiers, all the power is delivered to the reject load, so care must be taken to ensure that the proper one of the two possible 90° phase relationships is used. When all the ports on the hybrid combiner are properly terminated, isolation of 30 dB or more can be achieved between the power amplifiers. For perfect isolation between the amplifiers, the load impedance on the sum and difference ports must be exactly the same. This is approached in practice by providing a 1.0:1 VSWR with a resistive 50 Ω load for the termination (reject load) on the difference port and then reducing the VSWR on the antenna transmission line as low as possible by trimming the antenna match. This keeps the input port impedances from changing very much when one amplifier is not operating.

The input ports will present a load to each transmitter with a VSWR that is lower than the VSWR on the output transmission line because part of the reflected power coming into the output port will be directed to the reject load and only a portion will be fed back into the transmitters. Figure 21 shows the effect of output port VSWR on the input port VSWR and on the isolation between ports.

If the two inputs from the separate amplifiers are not equal in amplitude or exactly in phase quadrature, some of the power will be dissipated in the difference port reject load. The match in input power and phase is not extremely critical as shown in Figs. 22 and 23. The power lost in the difference port reject load can be easily reduced to a

Figure 21. Isolation and VSWR of a 90° hybrid coupler.

Figure 22. Loss due to power imbalance in 90° hybrid coupler.

negligible value by touching up the amplifier tuning and by adjusting the phase shift. For example, if one amplifier is delivering only half the power of the other amplifier, only about 3% of the total available power will be dissipated in the reject load and 97% is still fed to the output transmission line [17].

If one transmitter fails completely, half of the working amplifier’s output goes to the antenna, and the other half is dissipated in the difference port reject load. This is why the radiated output drops by 6 dB or to one fourth of the original combined power. The reject load must be rated to handle a minimum of one fourth of the total combined power, but often the reject load is rated to handle one half the total power, so that it can also be used a test load for one of the transmitters.

7.3. Hybrid Splitting of Exciter Power

Figure 24 shows a block diagram of a pair of combined amplifiers with dual exciters. The exciters cannot be operated in parallel like the amplifiers because their RF outputs would have to be on exactly the same carrier frequency and exactly in phase under all modulation conditions. An automatic or manual exciter switcher is used to direct the output of the desired exciter to the combined transmitter, and the other standby exciter is routed to a dummy load. The one exciter in use feeds a hybrid splitter/phase shifter, which transforms one 50 Ω input into two

Figure 23. Phase sensitivity in a 90° hybrid coupler.

Figure 24. Block diagram of a transmitter with two power amplifiers, a 90° hybrid combiner, and dual exciters with 90° power splitter.

isolated 50 Ω outputs that have a 90° phase shift between them with half the power going to each output. The operation of this hybrid splitter is the reciprocal of the hybrid combiner described above. The exciter must have enough power output capability to drive both power amplifiers. In some cases, an additional IPA is required between the exciter and the splitter to boost the drive level. The length of coax from the power splitter to each amplifier input must be cut to a precise length so that the amplifiers will be fed in the proper phase relationship.

Each of the power amplifiers is assumed to have equal gain and phase shift. In practice, it may be difficult to tune the amplifiers so that their gains and phase shifts are equal at the same time. For this reason, a line stretcher or variable phase-shift network is usually included with the exciter splitter so that the station engineer can adjust phasing independent of amplifier tuning.

7.4. Filterplexing

The practice of having several FM stations share a single broad-band antenna system has become more popular in recent years. To connect several transmitters on different frequencies together onto one antenna system, a special device called a filterplexer is required. The purpose of the filterplexer is to provide isolation between the various transmitters while efficiently combining their power into a single transmission line. This is usually accomplished by a system of bandpass filters, band-reject filters, and hybrid combiners. The isolation is required to prevent power from one transmitter from entering another transmitter with resulting spurious emissions and to keep the rest of the system running in the event of the failure of one or more transmitters.

An important consideration in designing a filterplexing system is the effect on the phase response (group delay characteristic in the passband) of each of the signals passing through the system because of individual bandwidth limitations on each of the inputs.

7.5. RF Intermodulation Between FM Broadcast Transmitters

Interference with other stations within the FM broadcast band and with other services outside the broadcast band can be caused by RF intermodulation between two or more FM broadcast transmitters. Transmitter manufacturers have begun to characterize the susceptibility of their equipment to RF intermodulation so this information

Third-order intermodulation products

$f_1 = 100.3 \text{ MHz.} \quad f_2 = 101.1 \text{ MHz.}$

$2f_1 - f_2 = [2(100.3) - (101.1)] = [200.6 - 101.1] = 99.5 \text{ MHz.}$

$2f_2 - f_1 = [2(101.1) - (100.3)] = [202.2 - 100.3] = 101.9 \text{ MHz.}$

OR

$[f_1 - (f_2 - f_1)] = [100.3 - (101.1 - 100.3)] = [100.3 - 0.8] = 99.5 \text{ MHz.}$

$[f_2 + (f_2 - f_1)] = [101.1 + (101.1 - 100.3)] = [101.1 + 0.8] = 101.9 \text{ MHz.}$

Figure 25. Calculation of intermodulation product frequencies.

will be available to the designers of filterplexing equipment.

The degree of intermodulation interference generated within a given system can be accurately predicted before the system is built if the actual mixing loss of the transmitters is available when the system is designed. Accurate data on *mixing loss* or *turnaround-loss* speed the design of filterplexing equipment and result in higher performance and more cost-effective designs because the exact degree of isolation required is known before the system is designed. Filterplexer characteristics and antenna isolation requirements can be tailored to the specific requirements of the transmitters being used. The end user is assured in advance of construction that the system will perform to specification without fear of overdesign or underdesign of the components within the system.

7.6. Mechanisms Which Generate RF Intermodulation Products

When two or more transmitters are coupled to each other, new spectral components are produced by mixing the fundamental and harmonic terms of each of the desired output frequencies. For example, if only two transmitters are involved,

Figure 26. Frequency spectrum of third-order IM products with the interfering level equal to the carrier level.

Figure 27. Typical frequency spectrum of third-order IM products of a broadcast FM transmitter.

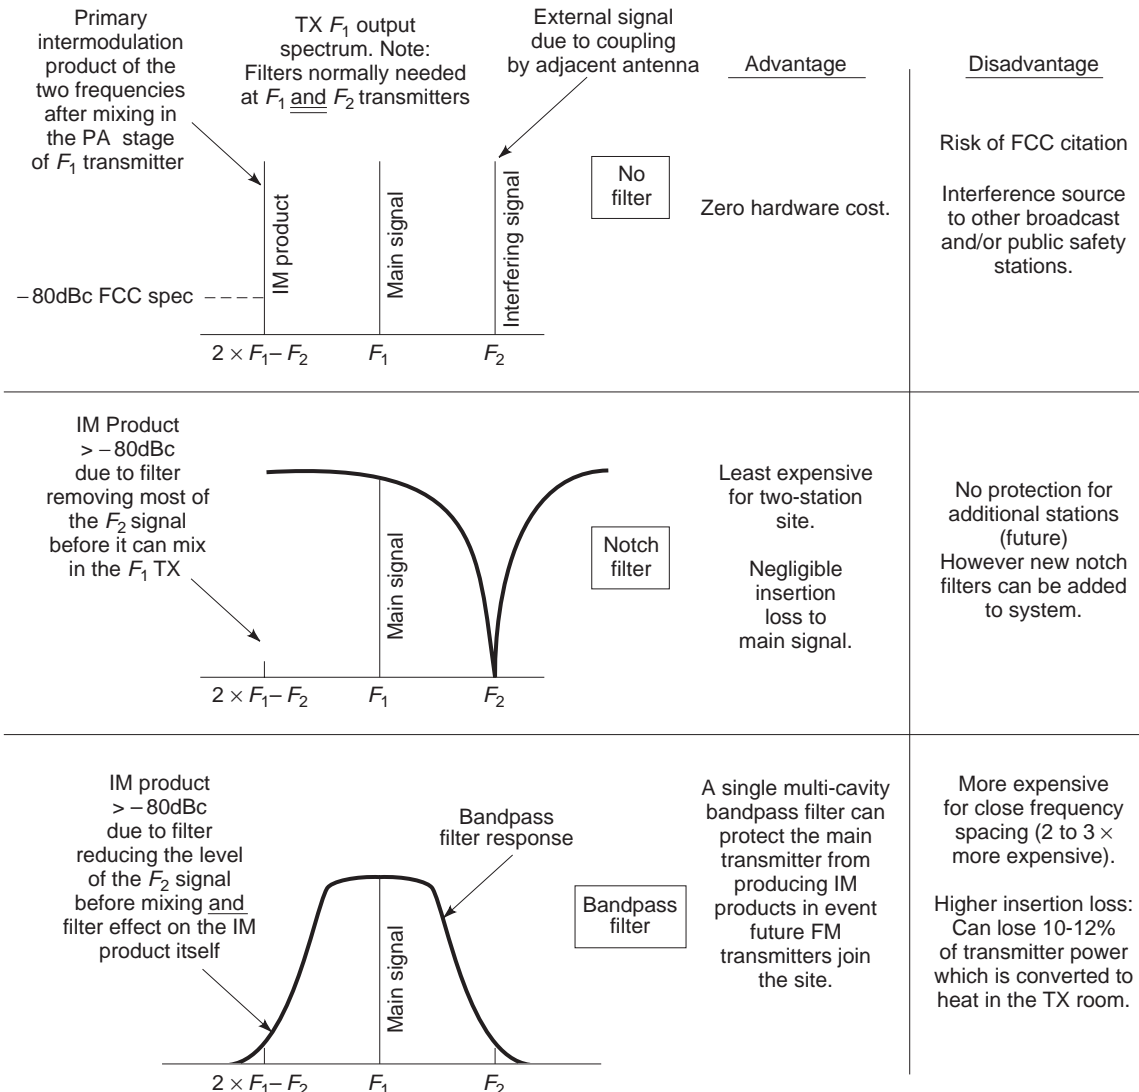

Figure 28. An overview of the various filtering options for preventing excessive IM3 products.

the third-order intermodulation (IM3) terms could be generated in the following way. The output of the first transmitter f_1 is coupled into the nonlinear output stage of the second transmitter f_2 because there is not complete isolation between the two output stages. f_1 will mix with the second harmonic of f_2 producing an in-band third-order term with a frequency of $[2(f_2) - (f_1)]$. Similarly, the other third-order term will be produced at a frequency of $[2(f_1) - (f_2)]$. This implies that the second harmonic content within each transmitter's output stage along with the specific nonlinear characteristics of the output stage will have an effect on the value of the mixing loss.

It is possible, however, to generate these same third-order terms in another way. If the difference frequency between the two transmitters $[(f_2) - (f_1)]$, which is an out-of-band frequency, remixes with either (f_1) or (f_2) , the same third-order intermodulation frequencies are produced.

Empirical measurements indicate that the $[2(f_2) - (f_1)]$ type of mechanism is the dominant mode generating third-order IM products in modern transmitters using a tuned cavity for the output network.

Figure 25 is an example of calculating intermodulation product frequencies. Figures 26 and 27 show the resulting frequency spectra.

7.7. Intermodulation As A Function of Turnaround Loss

Turnaround loss or *mixing loss* describes the phenomenon in which the interfering signal mixes with the fundamental and its harmonics within the nonlinear output device. This mixing occurs with a net conversion loss; hence, the term *turnaround loss* has become widely used to quantify the ratio of the interfering level to the resulting IM3 level. A *turnaround loss* of 10 dB means that the IM3 product fed back to the antenna system will be 10 dB below the interfering signal fed into the transmitter's output stage.

Turnaround loss increases if the interfering signal falls outside the passband of the transmitter's output circuit, varying with the frequency separation of the desired signal and the interfering signal because the interfering signal is first attenuated by the selectivity going into the nonlinear device and then the IM3 product is further attenuated as it comes back out through the frequency selective circuit.

Turnaround loss can be broken into three individual parts:

1. The basic in-band conversion loss of the nonlinear device.
2. The attenuation of the out-of-band interfering signal caused by the selectivity of the output stage.
3. The attenuation of the resulting out-of-band IMS products caused by the selectivity of the output stage.

As the *turnaround loss* increases, the level of undesirable intermodulation products is reduced, and the amount of isolation required between transmitters is also reduced.

The transmitter output circuit loading control directly affects the power amplifier source impedance and therefore

affects the efficiency of coupling the interfering signal into the output circuit where it mixes with the other frequencies present to produce IM3 products. Light loading reduces the amount of interference that enters the output circuit with a resulting increase in *turnaround loss*. In addition, the output loading control setting will change the output circuit bandwidth (loaded Q) and therefore affect the amount of attenuation that out-of-band signals will encounter passing *into* and *out of* the output circuit [18].

Second harmonic traps or lowpass filters in the transmission line of either transmitter have little effect on the generation of intermodulation products because the harmonic content of the interfering signal entering the output circuit of the transmitter has much less effect on IM3 generation than does the harmonic content within the nonlinear device. The resulting IM3 products fall within the passband of the lowpass filters and outside the reject band of the second harmonic traps. So these devices offer no attenuation to RF intermodulation products.

Figure 28 gives an overview of the various filtering options for preventing excessive IM3 products.

TRANSVERSE RESONANCE TECHNIQUES

ROBERTO SORRENTINO
 MAURO MONGIARDO
 University of Perugia
 Perugia, Italy

1. INTRODUCTION

The transverse resonance technique (TRT) can be regarded as an approach to the analysis, either rigorous or approximate, of guiding structures and their discontinuities, based on the simple idea of looking at the problem in the transverse rather than axial direction. This technique originated as an application of the microwave circuit formalism in the direction perpendicular to the actual power flow in a cylindrical waveguide, [1]. Over the years it has then been applied to evaluate the dispersion relation for the dominant mode of certain types of waveguides and also to evaluate the complete spectra of some nonseparable waveguides; more recent developments involve the modeling of discontinuities in closed or open transmission structures. Since the original concept of the TRT is now being used in a much broader sense, it is worth clarifying the basic ideas laying behind this technique.

As its name suggests, the TRT combines two different concepts. On one hand, the term *transverse* indicates, within a reference coordinate frame, a geometric direction to be preferred in contrast with the axial or longitudinal direction of propagation in a guiding structure (waveguide or other transmission line). The *resonance* concept, on the other hand, is associated with the stationary fields and the relevant reactive energy storage in a microwave structure. In the TRT, the structure under investigation may be a guiding structure, in which case its propagation characteristics are sought, or a discontinuity in a guiding structure, in which case the circuit characterization of the discontinuity (impedance, scattering parameters, etc.) are to be found. In either case, by expressing the resonance condition(s) in the transverse direction, the unknown parameters can be computed. For a number of practical geometries this approach proves to be computationally much more convenient than analyzing the structure in the axial direction.

The TRT concept will first be clarified in Section 2 with the example of simple guiding structures that can be treated analytically. The TRT will then be illustrated in

more involved cases in Section 3, where a certain degree of numerical processing becomes necessary. In the conventional formulation of TRT, a suitable transverse equivalent network is established to compute the cutoff frequencies and possibly some additional characteristics of the structure. An example of this procedure, making use of equivalent network representation of discontinuities, is illustrated in Section 3.1 by referring to a ridge waveguide. In a more elaborate and rigorous formulation, a full-wave analysis may be performed in order to find, via the dispersion equation, the modes of a nonseparable structure. Depending on whether the guiding structure is a closed or open one, different analytical formulations can be adopted. In the latter case, the approach will yield the bound (guided) modes of the waveguide, while in the former case the entire modal spectrum of the closed waveguide can be obtained. The procedure is illustrated in Section 3.2 for the computation of the slot-line spectrum.

As mentioned above, the TRT can also be applied for the characterization of discontinuities and junctions. In this case, the extraction of the discontinuity parameters is obtained by artificially inducing a resonance condition also in the longitudinal direction. The relevant procedure is briefly described in Section 4, where the characterization of circular posts in a rectangular waveguide using a hybrid mode-matching/FEM numerical technique is taken as an example.

2. TRANSVERSE RESONANCE TECHNIQUE: ANALYTICAL SOLUTIONS

2.1. Homogeneous Waveguides

To introduce the concept of transverse resonance, consider the cross section of a rectangular waveguide excited by the fundamental TE₁₀ mode (Fig. 1 depicts the wave propagation in this case); we remind the reader that the nonzero field components are E_y , H_x , and H_z . TE₁₀ mode propagation in the guide can be considered as a wave propagating with propagation constant β in the longitudinal z

Figure 1. TE₁₀ wave propagation in a rectangular waveguide of width a .

direction, and at the same time bouncing back and forth between the sidewalls at $x=0, a$ with propagation constant k_x . Wavenumber conservation imposes that

$$k_x^2 + \beta^2 = k_0^2 \tag{1}$$

Because of the round-trip condition $k_x = n\pi/a$.

The same results for k_x can be obtained by applying the transverse resonance condition. Let us consider the network equivalent of the round-trip condition as illustrated in Fig. 2. A short circuit is located at $x=a$ and an open circuit, at the symmetry plane $x=a/2$, with a transmission-line section in between; the latter has propagation constant k_x . A TE wave propagating in the positive z direction has a characteristic impedance given by the ratio between the fields transverse to the propagation direction:

$$Z_0^z = \frac{E_y}{-H_x} = \frac{\omega\mu_0}{\beta} \tag{2}$$

This wave is also TE if we consider propagation in the x direction; the characteristic impedance of the line, in this case, is given by the following ratio:

$$Z_0^x = \frac{E_y}{H_z} = \frac{\omega\mu_0}{k_x} \tag{3}$$

In the following, unless otherwise stated, we will consider the propagation in the x direction and the x apex will be omitted in the corresponding impedance. Resonance of the transverse equivalent circuit of Fig. 2 implies that a finite voltage response V_r ensues from zero current excitation I_e

$$I_e = YV_r = 0 \tag{4}$$

or vice versa; that is, a finite current response I_r follows from zero voltage excitation V_e :

$$V_e = ZI_r = 0 \tag{5}$$

Figure 2. By symmetry, we may place a magnetic wall, namely, an open circuit, in the midplane of the guide, thus obtaining the transverse equivalent circuit for even modes in a rectangular waveguide. The transverse equivalent circuit for odd modes is obtained by replacing the magnetic wall with an electric wall. Also shown is the electric field component for the fundamental mode.

In the circuit of Fig. 3, the total impedance, calculated at the x section, is

$$\vec{Z}(x) = \vec{Z}(x) + \overleftarrow{Z}(x) \tag{6}$$

and similarly for the admittance. The arrow points according to whether we take the impedance to the left or right of the observation point. The resonance condition implies that, at any point x along the line, we must have

$$\vec{Z}(x) = \vec{Z}(x) + \overleftarrow{Z}(x) = 0 \tag{7}$$

or

$$\vec{Y}(x) = \vec{Y}(x) + \overleftarrow{Y}(x) = 0 \tag{8}$$

Observe that condition (7) implies Eq. (8) and vice versa. In fact, by noting that

$$\vec{Y}(x) + \overleftarrow{Y}(x) = \frac{\vec{Z}(x) + \overleftarrow{Z}(x)}{\vec{Z}(x)\overleftarrow{Z}(x)} \tag{9}$$

it follows that resonances occur either when (7) is satisfied, or at common poles of $\vec{Z}(x), \overleftarrow{Z}(x)$, that is, when $\vec{Z}(x) = \infty$ and $\overleftarrow{Z}(x) = \infty$.

With reference to Fig. 2, placing the observation point at $x=a$ yields

$$\vec{Z}(a) = 0 \tag{10}$$

because of the short circuit at $x=a$, while, on the left, we obtain

$$\overleftarrow{Z}(a) = \frac{j\omega\mu_0}{k_x} \tan k_x a \tag{11}$$

Hence the resonance condition implies $\tan k_x a = 0$ or

$$k_x a = n\pi \tag{12}$$

which is the same condition we found from the round-trip phase difference. This procedure, of course, can be applied

Figure 3. At any point along the line it is possible to define an impedance looking at the left side \overleftarrow{Z} and an impedance looking at the right side \vec{Z} . The zeros of the total impedance $Z = \overleftarrow{Z} + \vec{Z}$ provide the circuit resonances (in addition to the common poles of \overleftarrow{Z} and \vec{Z}).

in less trivial cases such as, for example, a waveguide filled with one or more dielectric layers or a slab waveguide, as shown in the next subsections.

2.2. Waveguides Filled with Layered Dielectrics

A rectangular waveguide loaded with one dielectric slab is sketched in Fig. 4. For such a geometry, the boundary conditions at the dielectric interface can be individually satisfied by TM^x and TE^x fields. This becomes evident if one considers the simple discontinuity due to an abrupt change in the z direction of the dielectric constant filling the guide. The cross-sectional distribution of the electromagnetic field is not altered by the change of the dielectric; the only change is in the impedance.

By adopting the transmission-line formalism to represent the field propagation along the x axis, the boundary conditions can be represented in a straightforward manner as shown in the lower part of Fig. 4. Let us recall that, for TE^x modes, the characteristic impedances of the i -th transmission line is

$$Z_0^{(i)} = \frac{j\omega\mu_0}{k_x^{(i)}} \quad (i = 1, 2) \quad (13)$$

while the wavenumber conservation imposes that

$$k_x^{(i)2} + \beta^2 = k_0^2 \epsilon_i \quad (14)$$

The total impedance seen at $x = a_1$ is given by Eq. (6), where

$$\overleftarrow{Z}(a_1) = Z_0^{(1)} \tan k_x^{(1)} a_1 \quad (15)$$

$$\overrightarrow{Z}(a_1) = Z_0^{(2)} \tan k_x^{(2)} a_2 \quad (16)$$

The resonance condition (7) $\overleftrightarrow{Z} = 0$, together with Eq. (14), provides the dispersion relation for the waveguide. The cutoff frequencies can be obtained by setting $\beta = 0$.

This approach can easily be extended to more complicated cases where several dielectric layers are present. In such cases the transmission-line formalism can highly

Figure 4. Sketch of a dielectric-loaded waveguide; in the lower part the transverse equivalent network is represented.

Figure 5. A TE even field for a slab waveguide. The original slab of width $2d$ has been replaced by a slab of width d over an electric/magnetic wall.

simplify the computations by adopting the ABCD representation.

2.3. Slab Waveguide

Another interesting case is the slab waveguide (Fig. 5). The equivalent network appropriate for this structure is shown in Fig. 6 for the TE mode. In the even case, a magnetic wall is placed at the symmetry plane $x = 0$. Looking from $x = d$, the impedance Z is that of a line section open-circuited at the opposite end, while \overleftarrow{Z} is that of a TE wave in free space. The transverse resonance condition (7) is thus given by

$$\overleftarrow{Z} + \overrightarrow{Z} = -j \frac{\omega\mu_0}{q_s} \cot(q_s d) + j \frac{\omega\mu_0}{\gamma_x} = 0 \quad (17)$$

where q_s and γ_x are the propagation constants in the x direction in the slab and in the air, respectively. Hence, we

Figure 6. Equivalent network of a TE even field for a slab waveguide.

recover the dispersion relation

$$q_s \tan(q_s d) = \gamma_x \quad (18)$$

This equation is identical to that obtained by matching the fields.

Consider now the odd TE modes (electric wall at the symmetry plane $x=0$). Their x dependence is given by a sine function inside the slab and an exponential function outside. As a consequence, the total impedance seen at $x=d$ is

$$\vec{Z} = j \frac{\omega \mu_0}{q_s} \tan(q_s d) + j \frac{\omega \mu_0}{\gamma_x} = 0 \quad (19)$$

yielding the dispersion relation

$$q_s \cot q_s d = -\gamma_x \quad (20)$$

For a network interpretation of the cutoff it is instructive to consult Ref. 2, where the transverse resonance approach is also used to provide further insight into the nature of the continuous part of the spectrum.

3. TRANSVERSE RESONANCE TECHNIQUE FOR TRANSVERSELY DISCONTINUOUS WAVEGUIDES

The presence of any discontinuity in the transverse direction other than a dielectric interface perpendicular to the x or y direction would produce the coupling between different modal sets, that is, between TE^x and TM^x modes, so that the elementary solutions seen before cannot be obtained anymore. The presence of discontinuities normal to the transverse direction produces energy storage that can be taken into account by a proper lumped reactance. Once again the resonance condition of such networks provides the characteristic equation for the structure. Since the solutions for many practical discontinuity problems are available in classical textbook such as Ref. 3, the TRT proves extremely useful in providing the guide propagation properties with a minimal amount of computer effort. Naturally, this type of application of the TRT has some limitations: (1) the discontinuity must be noninteracting with the sidewall of the waveguide, (2) characterization of the discontinuity is typically available only for the fundamental mode incidence, and (3) this approach does not allow the field computation in the proximity of the discontinuity. These limitations are removed by the use of the *generalized TRT*. In Section 3.1 we will first describe the use of conventional TRT with equivalent circuits by means of the ridge waveguide example. In Section 3.2 we will describe the slotline hybrid spectrum computation by means of the generalized TRT.

3.1. Ridge Waveguide

Fig. 7 shows the cross-sectional geometry of a single-ridge waveguide whose dominant mode is a TE^z mode with even symmetry with respect to the plane $x=a/2$. Looking in the transverse x direction, the ridged waveguide is seen as a

Figure 7. Single-ridge waveguide cross section and its transverse equivalent network. Use has been made of symmetry by placing an electric/magnetic wall in the midsection $x = a/2$.

composite structure consisting of waveguides of different heights. Transverse step discontinuities produce TE^x and TM^x higher-order mode excitation. In practical cases these are well below cutoff; hence they contribute only to the reactive energy stored in the proximity of the ridge edges. If characterization of these step discontinuities is possible, the TRT provides a very simple way to compute the characteristic (dispersion) equation of the structure.

For ease of explanation, let us reduce the problem to a more familiar one by assuming two dominant TE^z modes traveling in opposite directions, thus creating a standing-wave pattern. We may now insert two perfectly conducting planes normal to the z axis, spaced $\lambda_g/2$ apart, that do not alter the field distribution in the ridge waveguide. By looking in the x direction the same closed resonator is seen as the cascade of three rectangular waveguides; the central one is of reduced height. By using symmetry and an appropriate equivalent network representation for the step discontinuity, we can obtain the equivalent circuit shown in Fig. 7. The shunt capacitance (susceptance B) accounts for the reactive energy associated with stray field at the discontinuity; a simple expression for the susceptance B can be found in Ref. 3. The transmission-line sections correspond to TE_{10}^x modes in the two waveguide sections having the same width $\lambda_g/2 = \pi/\beta$ and are therefore characterized by the same propagation constant

$$k_x^2 = k_0^2 - \beta^2 \quad (21)$$

where β is the longitudinal propagation constant. Characteristic impedances are chosen to be proportional to the waveguide heights. Because of symmetry considerations, in the transverse equivalent circuit an open- or short-circuit condition is established at $x = a/2$. In particular, the open-circuit condition (magnetic wall) provides the lowest resonance (fundamental mode). The resonance condition can be simply obtained by equating to zero the sum of the three admittances seen at the connection $x = (a-s)/2$ between the lines:

$$-jY_{01} \cot \frac{k_x(a-s)}{2} + jB + jY_{02} \tan \frac{k_x s}{2} = 0 \quad (22)$$

By using the fact that $Y_{02}/Y_{01} = b/d$ we obtain the dispersion equation for the ridge waveguide

$$\frac{b}{d} \tan \frac{k_x s}{2} - \cot \frac{k_x(a-s)}{2} + \frac{B}{Y_{01}} = 0 \quad (23)$$

It is worth noting that the analysis above could also be carried out at cutoff condition, when $\beta = 0$. In this case the problem would be that of a parallel-plate waveguide discontinuity. This type of technique can be used for semi-open waveguiding structures, slotted rectangular and circular waveguides, open groove guides, or other structures of interest in leaky-wave antennas.

3.2. Slotline Hybrid Modes

The TRT can also be applied in a rigorous manner in order to determine the spectrum of closed or open waveguides with nonseparable cross sections. We can, in fact, expand the transverse field at an interface in terms of two components (in turn each component will be expanded on a suitable basis). In addition we can also set up a rigorous relationship between the electric and magnetic transverse fields, hence obtaining a rigorous formulation.

As an example, we consider the fully hybrid problem of slotline characterization by application of the generalized TRT. We refer the reader to Refs. 1 and 2 for the analytical details relative to the closed and open configurations, respectively. Here we provide only the general framework.

The slotline geometry is shown in Fig. 8. With reference to this figure, from the continuity of the transverse-to-y electric and magnetic fields across the slot, we obtain a pair of coupled integral equations for E_x and E_z on the slot aperture in the form:

$$\begin{bmatrix} H_z \\ H_x \end{bmatrix} = \begin{bmatrix} \hat{Y}_{11} & \hat{Y}_{12} \\ \hat{Y}_{21} & \hat{Y}_{22} \end{bmatrix} \cdot \begin{bmatrix} E_x(x, 0) \\ E_z(x, 0) \end{bmatrix} = 0 \quad (24)$$

The integral operators \hat{Y} , for instance, denote the sum of the admittance operators of the two half spaces

$$\hat{Y}_{11} = \hat{Y}_{11}^a + \hat{Y}_{11}^s$$

where the “a” superscript stands for air half-space ($y > 0$) and the “s” superscript stands for substrate region ($y < 0$). The relative kernels are obtained as described, for example,

Figure 8. Slotline geometry and relative coordinate system.

in Ref. 2 for the open slotline. The integral operators \hat{Y}_{ij} play the same role as Y in Eq. (7). They represent the sum of the admittance operators of the two half-spaces \hat{Y}_{ij}^a and \hat{Y}_{ij}^s , which are the operator equivalent of Y and \hat{Y} in Eq. (7).

The integral equation (24) is the dispersion equation for the slotline discrete modes, which we solve by discretization in the space domain. By making use of the moment method approach, the integral equation (24) is reduced to the following matrix equation

$$\begin{bmatrix} \mathbf{Y}_{11}(\beta) & \mathbf{Y}_{12}(\beta) \\ \mathbf{Y}_{21}(\beta) & \mathbf{Y}_{22}(\beta) \end{bmatrix} \begin{bmatrix} \mathbf{X} \\ \mathbf{Z} \end{bmatrix} = 0 \quad (25)$$

where \mathbf{X} and \mathbf{Z} are vectors containing the electric field expansion coefficients. The vanishing of the determinant of (25) is therefore the generalization of Eq. (7); it gives the propagation constant β of the guide, whereas \mathbf{X} and \mathbf{Z} yield the transverse field distributions within a normalization constant that is fixed by the transverse normalization of the fields.

4. TRANSVERSE RESONANCE ANALYSIS FOR WAVEGUIDE DISCONTINUITIES AND JUNCTIONS

In the previous section we showed how to evaluate the propagation characteristics of a transversely discontinuous waveguide (e.g., a ridge waveguide): the resonant frequencies of a waveguide section are computed from knowledge of the equivalent transverse network and the network characterization of the discontinuity.

In this section we show how to derive the network characterization of a longitudinal discontinuity from the knowledge of the resonant frequencies of a waveguide section containing the discontinuity, using a transverse field formulation. Such a generalization of the TRT is a rigorous useful tool for characterization of a variety of discontinuity problems.

The method consists schematically of the following steps:

1. A resonant cavity is created by enclosing the discontinuity or junction by auxiliary reactive walls sufficiently apart from it.
2. A field analysis based on transverse field formulation is performed to compute the resonant frequencies and the corresponding field distributions.
3. The network matrix representation (scattering matrix, impedance matrix, etc.) of the discontinuity is evaluated by means of the resonant frequencies and/or field distributions.

It is noted that the determination of the equivalent circuit parameters of a two-port network via the resonant frequencies of the network inserted between two reactive terminations is equivalent to the experimental technique known as the tangent or Weissfloch method [3]. Analytical formulations based on a variational approach have also been presented [4].

Figure 9. Example of a structure to be simulated. The propagation direction is along the x axis.

This technique was used in Ref. 5 for characterization of finline discontinuities and is reported with a detailed example also in Ref. 1.

A more recent development of the technique is shown next as an example, this time using a hybrid technique, namely, a FEM modal analysis, for the electromagnetic analysis of the structure.

4.1. Example Based on Finite-Element/Modal Analysis Computations

This method is based on the use of the hybrid finite-element/mode-matching analysis and application of the TRT for evaluating the frequency response of the device under analysis from its natural resonances. Let us consider the structure in Fig. 9, which consists of a rectangular waveguide containing three circular posts, each post having two different diameters. The direction of propagation is assumed along the z axis. In order to avoid a time-consuming three-dimensional analysis, we analyze such a structure along the transverse direction (y axis). Input and output ports ($z=0$ and $z=c$) are terminated by metallic walls, obtaining a resonant cavity. Referring to Fig. 10, such a resonator can be seen, in the transverse y direction, as a waveguide step in which ports at $y=0$ and $y=b$ are short-circuited. The scattering matrix of the

Figure 10. Example of a structure to be simulated. The direction of propagation is along the x axis, but we analyze such a structure with a mode matching along the z axis.

waveguide step at $y=l_2$ can be evaluated using the mode-matching technique. The application of the mode-matching technique requires the evaluation of the coupling integrals

$$g_{n,m} = \iint_{\mathcal{S}_2} \mathbf{e}_n^{(1)}(x,z) \cdot \mathbf{e}_m^{(2)}(x,z) dx dz \quad (26)$$

where $\mathbf{e}_k^{(i)}(x,z)$ represents the transverse normalized modal electric field of the k th mode in the i th waveguide, while \mathcal{S}_2 is the transverse section of the waveguide with smallest cross-sectional area (waveguide 2). As the waveguide cross sections are nonseparable, waveguide modes are evaluated by using a two-dimensional finite-element method. A step-by-step procedure is summarized as follows (see Ref. 6 for further details and Fig. 11 for reference planes):

1. Insert shorting planes at distances d_1 and d_2 away from the reference planes 1 and 2.
2. Evaluate the resonant modes and corresponding field distributions at the reference planes in the frequency range where only the waveguide fundamental mode is propagating. The resonant modes frequencies of the cavity are the frequencies of our analysis.
3. Evaluate the characteristic admittance y_c and the propagation constant β of the input and output waveguides at the abovementioned frequencies.
4. By using the computed modal voltages and currents, solve the following system:

$$\begin{aligned} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} &= \begin{bmatrix} Y_{11} & Y_{12} \\ Y_{12} & Y_{11} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \\ &= \begin{bmatrix} V_1 & V_2 \\ V_2 & V_1 \end{bmatrix} \begin{bmatrix} Y_{11} \\ Y_{12} \end{bmatrix} \end{aligned} \quad (27)$$

hence obtaining the sought values for Y_{11}, Y_{12} . Note that we have considered a symmetric and

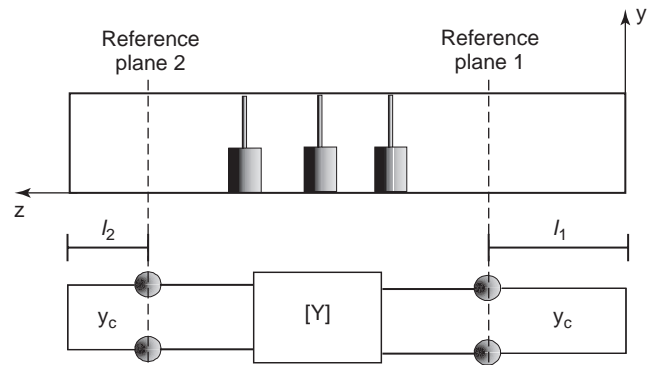

Figure 11. The device and its equivalent network (admittance representation) at the reference planes. Both device and equivalent circuit are short-circuited at distances d_1 and d_2 from ports 1 and 2, respectively.

Figure 12. Scattering parameters of a circular post in rectangular waveguide. Comparison between our data and those obtained by a 3D FEM [high-frequency structure simulator (HFSS)] (MTR=modified transverse resonance) [7].

reciprocal component: $Y_{11} = Y_{22}$ and $Y_{21} = Y_{12}$. Also observe that we need $V_1 \neq V_2$ for solving the system in (27).

5. For other frequency points, repeat the whole procedure by performing another finite-element/modal analysis by changing d_1 or d_2 or both of them.

As an example of application of the method described above, consider a single circular metallic post of radius $r = 5.64$ mm and height $h = 30.6$ mm inside a rectangular waveguide with the broad wall $a = 80$ mm and the narrow wall $b = 40$ mm. Note that analysis of this structure requires, with the present method, only the solution of a two-dimensional problem: finding the modes of the waveguides. By contrast, a typical solver considers the structure as three-dimensional, hence significantly increasing the operation count. This fact becomes more relevant as the geometric dimensions of the structure are increased. In the present case a discretization with about 1200 triangles has been used in order to find the modes with sufficient accuracy. By performing just six analyses it was possible to generate the results in the frequency band shown in Fig. 12. Results obtained by TRT have been compared with those obtained by a 3D FEM, as obtained by about 40 frequency analyses, as illustrated in Fig. 12.

TRAVELING WAVE ANTENNAS

ROD B. WATERHOUSE
Pharad LLC

1. INTRODUCTION

Probably one of the most diversified styles of antennas is a traveling wave antenna. From the IEEE Standard Definitions of Terms for Antennas (IEEE Std 145-1983) [1], traveling wave antennas are defined as, “an antenna whose excitation has a quasi-uniform progressive phase, as a result of a single feeding wave traversing its length in one direction only.” Thus any antenna that relies on this mechanism to radiate falls into this class, and as you can imagine, a plethora of antennas exist that do so. Examples include beverage antennas, horn antennas, reflectors, tapered slot antennas, and lens antennas. A more simplified interpretation of the above IEEE standard definition, which is not necessarily valid for all forms of traveling wave antennas, is that this form of radiator converts guided electromagnetic energy into radiated energy in a gradual or smooth transition. An example of a traveling wave antenna, whose form is obviously compliant with this statement, is a horn antenna where the flange of the waveguide is gradually opened to effectively match the impedance/mode of the guided wave to that of free space. Thus expanding this postulation on the nature of traveling wave antennas, one can almost make the statement that two fundamental forms of antennas exist; resonant and nonresonant (traveling wave) styles. Resonant antennas (also referred to as standing wave antennas) include dipoles, monopoles, microstrip patches, and slots, and are defined as [1], “antennas whose excitation is essentially equiphase, as the result of two feeding waves which traverse its length in opposite directions, their combined effect being that of a standing wave.” So, using these definitions we can make some generalizations that may help distinguish these classes of antennas. Traveling antennas tend to be electrically large (the size with respect to the wavelength of operation), whereas resonant antennas tend to be much smaller, as these antenna are usually operated at their lowest resonant mode. Thus versions of resonant antennas tend to be incorporated into applications where size is an issue, for example mobile/wireless communication terminals and scanning arrays (where grating lobes need to be avoided to ensure a highly efficient solution). On the other hand, traveling wave antennas generally give a better electromagnetic solution than their resonant counterpart, whether it be higher gain, larger impedance bandwidth, or more linear phase, and

therefore are applied in the more “high end” problems where the electromagnetic performance cannot be compromised: radio astronomy, ground penetration radar, and wideband scanning arrays. One can almost think of the comparison between the two classes of radiators as comparing a Volkswagen to a Rolls Royce, or in today’s culture, a Jeep to a Hummer.

Of course, once you draw a line in the sand, a certain grey/blurred zone associated with the demarcation exists. This issue is evident here as many traveling wave antennas incorporate resonant style antennas within their structure. Reflector and lens antennas commonly use dipoles (and patches) as their feeding elements. Yagi Uda antennas (TV antennas before cable and satellite services) also use resonant elements to achieve their appropriate responses. Simplistically, all these antennas on the macroscale are traveling wave antennas in that they are compliant with the aforementioned definition, namely they have a single feeding wave traversing its length in one direction only; however, on the microscale they rely on a standing wave antenna to help perform this function. Log periodic and spiral antennas further blur this definition.

In this article, we will review traveling wave antennas. We will briefly investigate the general characteristics of several versions of this class of antenna. We will summarize the physical layout and performance of wire (Section 2), waveguide (Section 3), reflector and lens (Section 4) traveling wave antennas, in particular looking at the general responses and some design strategies. In Section 5, we will look at some printed versions of traveling wave antennas, focusing on tapered slots, printed beverage antennas, printed quasi Yagi Uda, antennas, and reflectarrays. The objective of this article is to give the reader an overview of this antenna technology. More detail on the various traveling wave antennas presented can be found in the given references, and the reader is encouraged to read these to obtain a more complete understanding on the topics.

2. WIRE ANTENNAS

Probably one of the easiest traveling wave antennas to visualize the above mentioned definition is the Beverage, or long wire or wave, antenna. The antenna was invented in the early 1920s by Harold Beverage and variations of this form of radiator are very common, in particular in the MF (300 KHz–3 MHz) and HF (3–30 MHz) ranges. A simple schematic of the long wire antenna is shown in Fig. 1. In Fig. 1, a long wire mounted above the ground is excited at its leftmost point and terminated at the other end. Here, the antenna is designed to have uniform patterns in both current and voltage. To achieve this pattern, the wire antenna must be appropriately terminated to ensure no reflections occur. The length of this antenna ranges from one to many wavelengths. Several design parameters of the Beverage antenna exist that impact its response: the characteristics and dimensions of the material used to create the wire, the height of the antenna above ground, and the termination of the antenna. To achieve an “ideal” traveling wave response, this termination must be

Figure 1. Schematic of a wire beverage antenna.

matched to that of the impedance of the transmission line, or the long wire. Doing so will prevent reflections at the end of the wire and thereby reduce the likelihood of standing wave effects in both the radiation patterns and the impedance response of the antenna. However, as a consequence, these antennas do suffer from relatively low efficiencies as power is dumped into the load. In some cases, if the antenna is long enough, then much of the injected power may have leaked from the wire by the time the wave reaches the end of the wire, and so a termination may not be required. For more detail on this form of antenna, please refer to [2,3].

A variation of the long wire antenna that can overcome several of its shortcomings is the V-antenna, which can be formed by using two wires each with one of their ends connected to a feedline. A schematic showing an aerial view of this concept is shown in Fig. 2a. To maximize the directivity of this antenna, smaller included angles (θ) are required for longer V’s (L). To ensure a traveling wave response for this antenna, once again proper termination is required. One way to achieve this is to attach a load (equal to the open-end characteristic impedance of the V-wire transmission line). Another option (shown in Fig. 2b) is to terminate each wire to ground via an impedance of half of that of the characteristic impedance. Typical θ ’s and L ’s range from 30–80° and 1–3 λ_0 , respectively. For more details on this form of wire traveling wave antenna, please refer to [2,4]. Two V antennas can be connected at their ends to form a rhombic antenna [2,5,6]. The antenna is typically terminated with a 600–800 Ω resistor to minimize reflections, as shown in Fig. 3a. A common version of the rhombic antenna is shown in Fig. 3b, the inverted V antenna. The inverted V antenna is connected to ground via a resistor. The patterns and responses of all these

Figure 2. Schematic of terminated V antennas: (a) not grounded; (b) grounded.

Figure 3. Schematic of rhombic antennas: (a) formed by 2V antennas; (b) inverted V antenna.

variations of the V antenna can be controlled by varying the element lengths and the angles between the elements.

A very well established traveling wave wire antenna is the endfire helix (for examples, see [2,7]). The helix is an antenna that can actually be both resonant and nonresonant, depending on its electrical length. Short helices (normal mode) are resonant in nature as opposed to endfire (or axial mode) helices, which are electrically long and can readily provide circular polarization over a wide bandwidth (VSWR <2:1). For this reason, endfire helix antennas are commonly used for satellite communications. A schematic of an endfire helix is shown in Fig. 4. Here, the wire antenna is fed by a coaxial cable where the inner conductor is extended beyond the edge of the outer conductor. The outer conductor is connected to a groundplane of the antenna that is typically $\lambda/2$ in diameter. The helix consists of N turns of diameter D and spacing S between each turn. The total length of the antenna is $L=NS$. Another important parameter of a helix is the pitch angle, α , which is the angle formed by a line tangent to the helix wire and a plane perpendicular to the helix axis. For the endfire helix, one major lobe exists and its maximum radiation intensity is directed along the axis of the helix. To ensure the helix works in this mode of operation, the D and S must be large fractions of the wavelength. To

Figure 4. Schematic of an endfire helix antenna.

achieve circular polarization, the circumference of the helix with respect to wavelength should be near unity and S should be approximately quarter-wave. α should be approximately $12\text{--}14^\circ$.

Another very common traveling wave wire antenna is the Yagi Uda antenna [8]. These antennas are commonly used in the high frequency (HF), very high frequency (VHF), and ultra-high frequency (UHF) ranges. The antenna consists of a number of linear dipole elements, one of which is fed by a transmission line and the others act as parasitic radiators via mutual coupling. Figure 5 shows a schematic of a wire Yagi Uda antenna, where the parasitic elements in the forward direction (to the right of the driven element) act as directors and the elements in the rear behave as reflectors, and so the overall structure can be thought of as a traveling wave antenna. The driven element is typically of the order of 0.5λ . The director elements are usually $0.4\text{--}0.45 \lambda$ in length and can be of different size. The spacing between these elements is usually of the order of $0.3\text{--}0.4 \lambda$, although this may not always be the case. The length of the reflector element is greater than the fed element and is typically spaced approximately 0.25λ from the driven element. An excellent review of wire Yagi Uda antennas, including design procedures, can be found in [2].

3. WAVEGUIDE ANTENNAS

Probably the most widespread moderate gain traveling wave antenna in the microwave frequency range is the horn antenna [9]. Schematics depicting four types of horns

Figure 5. Schematic of a wire Yagi Uda antenna.

Figure 6. Schematics of conventional horn antennas: (a) E-plane; (b) H-plane; (c) Pyramidal, (d) Conical.

are shown in Fig. 6. As mentioned before, a horn antenna consists of a waveguide (typically rectangular or circular), which is then tapered (or flared) to a larger opening. The type, direction, and amount of flare can greatly impact the performance of the antenna. The four horns shown in Fig. 6 are: the E-plane horn, where the dimensions of the side walls of the waveguide remain constant whereas the top and bottom walls are flared to the appropriate angle; the H-plane horn, where the dimensions of the top and bottom walls are kept constant and the side walls are tapered; the pyramidal horn, a combination of the E-plane and H-plane horns; and the conical horn, where a circular waveguide is flared to a larger opening. Horn antennas became of intense interest in the late 1930s for radar applications because of their relative ease in design as well as their superior power handling capabilities. Nowadays, variations of the horn antenna are used in many applications ranging from feeds for radio astronomy to gain standards for accurate gain measurements of antennas.

Pyramidal horns are the most common form of horn antenna [2]. The design parameters of this antenna are the E- and H-plane aperture dimensions a_1 and b_1 , respectively) and the E- and H-plane axial horn lengths (ρ_E and ρ_H , respectively). Intuitively, as the a_1 and b_1 are increased (for constant lengths), the directivity of antenna should increase. The same should hold for increase of the

axial horn lengths while maintaining the aperture dimensions. These trends do hold to a degree until phase errors associated with the different path lengths the wave travels from the apex of the horn to the aperture distort the patterns. As the axial horn lengths increase (keeping the aperture dimensions constant), the phase errors decrease, whereas as the aperture dimensions increase (keeping the horn lengths constant), the phase errors increase. One means to mitigate the phase error issue is to use an exponential taper, as opposed to a linear taper. A photograph of such a pyramidal horn is shown in Fig. 7 [10].

Figure 7. Photograph of a pyramidal horn antenna.

Another frequently used horn antenna is the conical horn [11], which, unlike the pyramidal horn antenna, is fed with a circular waveguide. One obvious feature of the conical horn is the ease in which this antenna can generate dual/circular polarization, essential for satellite communications. The performance of a conical horn is similar to that of a pyramidal horn: as the flare angle increases, the directivity for a given axial length increases until it reaches a maximum beyond which it starts to degrade. Once again the degradation is because of the dominance of the phase error at the aperture.

As the applications for horn antennas grew in the 1960s and 1970s, it was apparent that the overall performance of these waveguide-based antennas needed to be improved. In particular, horn antennas suffered from spillover loss, cross-polarization generation, and impedance mismatch with respect to the feeding waveguide. It was found that the origin of these problems stemmed from diffraction from the aperture of the antenna. Two techniques were proposed and successfully demonstrated to mitigate these issues: the corrugated horn antenna [12,13] and the aperture-matched horn antenna [14]. A corrugated horn applies the principal that a corrugated surface can produce the same boundary conditions for both the electric and magnetic fields, thereby making the radiation pattern symmetrical. A photograph of an array of circular aperture corrugated horns used to feed a radio astronomy reflector is shown in Fig. 8. An aperture-matched horn consists of a smooth curved surface section connected to

Figure 8. Photograph of an array of circular aperture corrugated horns.

the outside of the aperture. This section provides continuous matching sections between the horn modes and free-space radiation and therefore can reduce the previously encountered diffraction problems of conventional horn antennas. An excellent review on horn antennas, including the theory of operation, can be found in [2].

4. REFLECTORS AND LENS ANTENNAS

The previously considered traveling wave antennas (with the exception of the Yagi Uda antenna) have a guided medium excitation. There are two types of antennas that still have traveling wave antenna traits; however, they are typically excited by a feed radiator. The two types of antennas are reflectors [15–17] and lenses [18,19]. Reflector antennas are extremely prevalent in today's communications (both satellite and terrestrial) and radio astronomy solutions. Reflector antennas are typically used when a high-gain solution is required as large arrays of other forms of radiating elements suffer from feed losses when attempting to develop a high-gain antenna. Of the many different shapes a reflector may have, the parabolic reflector is probably the most prevalent. A schematic of this antenna (a front-fed parabolic reflector) is shown in Fig. 9, highlighting the important design parameters: the diameter of the reflector (D) and the f/D ratio (where f is the focal point). There are some very simple relationships that can be established here: as the diameter of the reflector increases, so does the gain; as the f/D ratio increases, the lower the amplitude taper loss and phase loss, however, the greater the spillover loss. These f/D ratio relationships will depend on the radiation characteristics of the feed antenna. A photograph of a millimeter-wave (mm-wave) front-fed parabolic reflector is shown in Fig. 10. The choice of D (and f/D for that matter) really depends on how much gain is required for the system and also how much space is available for the antenna platform. For example, for a gain of 35 dBi, a reflector of diameter $21 \lambda_0$ is required for an f/D of 0.44. A problem with the front-fed reflector is the decrease in efficiency because of blockage (and cross-polarization generation) created by the feed antenna and the subsequent transmitter and receiver circuitry. To reduce the blockage, the circuitry can be located behind the

Figure 9. Schematic of a front-fed parabolic reflector.

Figure 10. Photograph of a mm-wave front-fed parabolic reflector.

reflector; however, the loss in the transmission lines to the feed antenna located at the focal point can be an issue. To overcome this problem, Cassegrain feeds (named after the astronomer) were introduced. Here, a secondary reflector (or subreflector), typically hyperbola in shape, is illuminated by a conveniently located feed antenna, and then this reflector excites the parabolic reflector (see for example [20]). Cassegrain feeding techniques are typically 10% more efficient than the front-fed procedure. In fact, the Cassegrain arrangement has the following features: the ability to place the feed in a convenient location; the reduction of spillover and sidelobe radiation; the ability to obtain an equivalent focal length much greater than the physical length; and the capability for scanning the main beam by moving one of the reflecting surfaces. A photograph of a variation of a Cassegrain feed arrangement and parabolic reflector is shown in Fig. 11. There are numerous review articles on reflector-style antennas, and some can be found in [2,15–17].

Another traveling wave antenna with an optical origin is the lens antenna. Lens antennas are an alternative to reflector antennas, although they are only really practical at very high frequencies, well into the mm-wave frequency band and beyond. Below these frequencies the size and weight associated with the lens material become too large if a high-gain solution is required. Lens antennas have similar advantages as reflectors over large arrays, namely the feed loss can be very low. It is well known that elliptical shaped lenses can focus a planewave to a point; however, in practice, typically extended hemispherical lenses are used to synthesize an elliptical lens [19,21–23]. Figure 12 shows the parameters of an extended hemispherical lens, the radius of the hemisphere (R_L), and the length of the extension (L_L). These dimensions are dependent on the material used to realize the lens, however, in general, the larger the R_L and L_L , the more gain. For example, for a gain of 32 dBi, R_L is approximately $6 \lambda_0$ and L_L is approximately $8 \lambda_0$. In a lens

Figure 11. Photograph of a Cassegrain feed arrangement and parabolic reflectors.

antenna configuration, reflections from the lens/air interface can cause unwanted radiation in the form of increased cross-polarization levels as well as increased sidelobe levels. A coating can be used on the interface to help reduce this effect similar to what is used on Light Emitting Diodes; however, at microwave (and even millimeter-wave) frequencies, this is impractical. Figure 13 shows a photograph of a mm-wave lens antenna designed for operation between 26–40 GHz [24]. The traveling wave antenna is fed by an aperture stacked patch (ASP) of sufficient bandwidth. The layers used to develop the ASP have a similar dielectric constant to that used for the creation of the lens (polyethylene) to ensure the overall efficiency of the antenna is maximized. Several reported articles exist on lens antennas that are available in the literature (for example, [18]).

Figure 12. Schematic of an extended hemispherical lens.

Figure 13. Photograph of a mm-wave aperture stacked patch mounted on an extended hemispherical lens.

5. PRINTED ANTENNAS

In this section, we will look at a few examples of traveling wave printed antennas, in particular tapered slots, printed quasi Yagi Uda antennas, printed beverage antennas, and reflectarrays. Interestingly, all of these printed traveling wave antennas have their analogies that can be drawn from the previous sections. Also, the printed antennas presented here are all relatively new concepts with

the oldest (the tapered slots) dating back to the early/mid 1980s.

The tapered slot antenna is undoubtedly the most common printed traveling wave antenna (see [25–28] for examples). These antennas can operate over multioctave bandwidths and can operate well in a phased array environment. Effectively, one can think of this form of printed radiator in the same manner as a horn antenna where a waveguide is flared out to “match” the electromagnetic wave to free space, although in this case the transmission medium is a slotline. However, unlike a conventional horn antenna, the fundamental mode of the slotline is TEM in nature, and so some of the issues associated with the wave matching of a horn antenna are mitigated here. Having said that, the tapered slot is a relatively complicated radiating element with many degrees of freedom. As is the case for a horn antenna, the profile of the taper (or flare) contributes to the input impedance behavior as well as the radiation performance of this printed traveling wave antenna. Common profiles include linear, exponential, and piece-wise linear. One particular challenge with a tapered slot antenna is the transition from the slotline to a more common transmission media used in microwave circuitry design. Figure 14 shows a photograph of a tapered slot antenna with a Coplanar Waveguide (CPW) feed. Incorporated in this design is a wideband balun (part of which is the large slotline cavity in the top left-hand corner of the photograph), which efficiently transfers energy from an unbalanced transmission line (CPW) to the balanced slotline. Figure 15 shows the predicted and measured return loss of the developed traveling antenna, as well as a typical radiation pattern.

The Yagi Uda antenna as described in Section 2 is an endfire antenna. However, only limited success has been achieved at adapting this antenna to microwave/millimeter wave operation. Figure 16 shows a schematic of the uniplanar quasiYagi antenna [29,30]. The antenna is

Figure 14. Photograph of a tapered slot antenna.

Figure 15. Characteristics of tapered slot antenna: (a) return loss; (b) radiation pattern at 10 GHz.

constructed on a single layer of microwave laminate with metallization on both sides. The top metallization consists of a microstrip feed, a broad-band microstrip-to-CPS (Coplanar Stripline) balun and two dipole elements, one of which is the driver element fed by CPS and the second dipole being the parasitic director. The metallization on the bottom plane is a truncated microstrip ground, which serves as the reflector element for the antenna. The parasitic director element on the top plane simultaneously directs the antenna propagation toward the endfire direction, and acts as an impedance matching element. Thus, the printed version of the Yagi Uda antenna in Fig. 16 is similar in operation to that of a wire version presented earlier. Figure 17 shows the return loss response and radiation patterns of a typical

Figure 16. Schematic of a printed Yagi Uda antenna.

printed quasiYagi Uda antenna [30]. Recently, a modification of this traveling wave antenna was presented that greatly simplifies the feed arrangement of the printed antenna [31].

It is also possible to realize a printed version of a Beverage (or long wire) antenna. Figure 18 shows the cross-sectional view of such an antenna where microstrip is used as the transmission medium. For this particular configuration, a probe soldered to the microstrip line is used to excite the antenna, and the characteristic impedance of the transmission line is designed as 50Ω , and so the termination resistance is also this value. The antenna is well matched over a very wide bandwidth (in excess of a decade), and a typical radiation pattern (including gain) is shown in Fig. 19. This pattern is consistent with a wire version of the antenna (see, for example, [2]). The printed Beverage antenna radiates better when the height of the substrate is increased; however, doing so can compromise the input impedance response because of the discontinuity associated with the feeding mechanism as well as that associated with the load.

The microstrip reflectarray is a traveling wave antenna that combines the mechanical advantages of printed antenna technology with some of the robust electrical characteristics of reflector antennas [32–34]. Its main mechanical advantage is that the geometrical constraint of the parabolic reflector is eliminated, and that printed antenna technology is used, providing repeatable, low-cost manufacture of the antennas. The microstrip reflectarray resembles an ordinary array of microstrip elements printed on a grounded dielectric substrate with two notable

Figure 17. Typical characteristics of a printed Yagi Uda antenna: (a) return loss; (b) radiation patterns.

exceptions: the array elements are excited by a feed antenna, replacing the microstrip-line feed network commonly used in large arrays, and secondly, the resonant frequency of each element is tuned slightly off the center operating frequency of the reflectarray. The patches are tuned in order to adjust the scattering phase of each ele-

Figure 18. Schematic of a printed Beverage antenna.

ment and therefore produce a main beam at a predetermined angle. The elimination of the microstrip-line feed network produces an antenna with larger bandwidth and lower loss, especially at millimeter-wave frequencies. A photograph of a reflectarray (including its feed element and support structure) is shown in Fig. 20.

6. CONCLUSIONS

In this article we have reviewed some of the most common traveling wave antennas. In particular, we have looked at wire, waveguide, and printed versions of this concept as well as briefly examined reflectors and lens antennas. Traveling wave antennas play a very important role in a variety of wireless communications and radar systems, and it appears this fundamental form of radiator will continue to do so for a long time to come. Traveling wave antennas are typically more complicated in nature (both electromagnetically and structurally) than their resonant-style counterparts; however, their overall performance usually justifies the increase in complexity. A summary of some of the traveling wave antennas discussed is presented in Table 1. Here, typical gain, bandwidth, and overall dimensions are given. Also, the cost of implementation is provided and some applications where these antennas can be used are summarized. An important note should be added here, which is that several commercially available electromagnetic simulation software packages exist that can greatly assist in the design of traveling wave antennas (for example, Ansoft’s HFSS™). These are typically computationally intensive simply because the structures to be analyzed are either complicated or electrically large. Some useful and yet relatively simple design software packages also exists, which are included in some of the references given here (for example, [2]). Finally, another useful book highlighting design trends of some traveling wave antennas can be found in [35].

Table 1. Summary of Some Traveling Waves

Antenna	Gain	Bandwidth	Dimensions	Relative Cost	Applications
Beverage	< 3 dBi	< 10 : 1	< 10 λ ₀	cheap	Ham radio
Yagi Uda	4 dBi–14 dBi	(depends on gain requirement)	0.5 λ ₀ × 1 λ ₀ –0.8 λ ₀ × 10 λ ₀	cheap	TV, Radar
Horn	7–18 dBi	< 1.3 : 1	< 10 λ ₀	expensive	Radar
Tapered slot	6–12 dBi	> 4 : 1	< 5 λ ₀	moderate	Radar
Reflector	< 60 dBi	< octave (feed dependent)	< 30 λ ₀	moderate	Point-to-point links, radio astronomy
Lens	< 50 dBi	< octave (feed dependent)	< 10 λ ₀ × 10 λ ₀	moderate	Point-to-point links

TRAVELING WAVE TUBES

CAROL L. KORY
ANALEX Corporation

The traveling-wave tube (TWT) is a vacuum device invented in the early 1940s [1,2] used for amplification at microwave frequencies. Amplification is attained by surrendering kinetic energy from an electron beam to a radiofrequency (RF) electromagnetic wave. The demand for vacuum devices has been decreasing largely owing to the advent of solid-state devices. However, although solid state devices have replaced vacuum devices in many areas, there are still many applications such as radar, elec-

tronic countermeasures, and satellite communications that require operating characteristics such as high power (watts to megawatts), high frequency (below 1 GHz to over 100 GHz), high efficiency (65% efficient, 100 Watt, Ka-band TWTs are commonplace), and large bandwidth that only vacuum devices can provide. Vacuum devices are also deemed irreplaceable in the music industry where musicians treasure their tube-based amplifiers, claiming that the solid-state and digital counterparts could never provide the same “warmth” [3]. The term traveling-wave tube includes both fast-wave and slow-wave devices. This article will concentrate on slow-wave devices as the vast majority of TWTs in operation around the world fall into this category.

1. TRAVELING-WAVE TUBE PRINCIPAL COMPONENTS

The TWT possesses four major components as shown in Fig. 1 [4]

1. An electron gun that produces an electron beam
2. A slow-wave circuit that slows an RF electromagnetic wave to a speed synchronous with the electron beam
3. A collector that collects the spent electron beam
4. The TWT package that provides cooling, beam focusing, and access to the RF input and output

Amplification is obtained by feeding the RF signal to be amplified into the slow-wave circuit while the electron beam is moving along the TWT axis. The slow-wave structure reduces the electromagnetic wave phase velocity so that it propagates near synchronism with the electron beam resulting in interaction between the wave and the beam and thus amplification of the RF signal. The spent electron beam is collected at the end of the tube by the collector.

1.1. Electron Gun

The electron gun is used to produce the electron beam. The electron guns used for nearly all TWTs mimic a section of a spherical diode as first derived by Pierce [5] and are consequently referred to as Pierce guns. The major components of the gun are the cathode, heater, focus electrode, and one or more anodes. The type of cathode used in TWTs is the thermionic cathode where electron emission is achieved by using a heat source to supply the electrons near the surface of the cathode with enough energy to escape from the surface. Cathode operation is a complex subject, and the reader can consult [6] or the article on cathodes in this encyclopedia for further detail. In a simplified description, the higher the temperature of the cathode, the greater the emission (current density), but the shorter the life. Because of the limited lifetime of cathodes, the electron gun design must be consistent with the expected life of the application. For example, if a lifetime of 12 to 15 years is required, as in commercial space applications, cathode current densities of 1 A/cm² or less are usually specified for an M-type cathode [7].

Figure 1. Basic TWT. The electron gun shown to the left encompasses the heater, cathode, focus electrode, and anode. A multistage depressed collector is shown on the right with electron beam trajectories.

A heater connected to a dc or ac power supply, consisting of a coil of tungsten or tungsten-rhenium wire adjacent to or embedded within the cathode body, is typically used to raise the temperature of the cathode to an adequate level for electron emission. The wire is formed into a contrawound coil to reduce the amount of magnetic field introduced into the electron gun by the current through the heater, thus reducing large perturbations in the electron trajectories that would make the beam difficult to focus or couple modulation onto the electron beam.

The anode is a positively charged electrode that attracts and accelerates the electrons emitted from the cathode. Because of electrostatic repulsion forces, the electrons are deflected as they are emitted so the focus electrode is used to produce equipotential lines with the same center of curvature as the cathode resulting in electron flow toward this center of curvature; therefore, the electrons are focused into a beam. TWTs used in pulsed applications often have a grid placed close to the cathode that permits the electron beam to be turned off and on with a small swing (relative to the cathode-to-ground potential drop) in the applied grid-to-cathode bias. The grid typically causes some perturbation of the electron beam so it is typically not used in high reliability devices.

1.2. Slow-Wave Circuit

The RF voltage to be amplified is fed into the slow-wave circuit through the input coupler. The purpose of the slow-wave circuit is to slow the axial velocity of the RF wave so that it propagates near synchronism with the electron beam. There are numerous possible slow-wave structures limited only by human inventiveness. Some of the more common are the helix, contrawound helix, coupled-cavity, ring-bar, cloverleaf, ladder, and grating circuits. The axial component of the electric field set up by the voltage on the circuit is somewhat sinusoidal in the vicinity of the electron beam so a force is directed to the left when the field is positive and to the right when the field is negative (see Fig. 1). This causes some of the electrons in the beam to decelerate (force is directed to the left) and others to accelerate (force is directed to the right), causing the electron beam to form bunches or be velocity modulated. The bunches drift into a decelerating region of the field, and

the electrons lose velocity and thus kinetic energy. The energy lost by the electrons is transferred to RF energy in the RF wave, thus amplifying the RF signal. Further down the length of the tube, the bunches become more compact leaving even more electrons in the decelerating region causing the RF wave to grow even more. As this continues, the electron velocities decrease and space-charge forces within the bunch increase. Eventually a portion of the bunch leaves the decelerating region of the circuit field and enters the accelerating region. These electrons extract energy from the circuit field. When the energy extracted from the circuit field becomes equal to the energy supplied, amplification of the RF wave stops and the interaction is said to reach saturation.

Backward wave oscillations (BWOs) can occur when power is reflected back to the input because of a mismatch in the slow-wave circuit, at the load or at the output coupler. Because of a mismatch at the input, a portion of the signal is again reflected to provide a feedback signal. To prevent these reflections, or backward waves, from reaching the input, it is common that a sever or distributed loss is added to the slow-wave circuit. A sever isolates the input wave from the output wave by physically separating the sections. Distributed loss usually consists of a lossy resistive coating that attenuates both forward and backward waves. Although the RF wave is severed or attenuated at this point in the slow-wave circuit, the bunching of the electrons has been established and will reestablish the RF wave on the circuit beyond the sever or region of attenuation, allowing interaction to continue.

A common method to increase efficiency by prolonging synchronism between the electron beam and the RF wave is to incorporate a velocity taper in the TWT design. A velocity taper is achieved by changing the dimensions of the slow-wave circuit near the output of the tube so that the RF wave velocity is slowed along with the electron beam. With this technique, even though the electron bunches are slowed as they lose energy to the circuit, they will remain in synchronism longer with the consecutively slowed RF wave and continue to deliver energy to the circuit fields. Velocity tapering has proved to significantly increase the efficiency of TWTs [8–10]. In addition, the technique can be used to enhance the linearity of the

power output versus power input [11] and to prevent BWOs [12–14].

1.2.1. Helix. The helix is the most common type of slow-wave structure. A typical modern helical structure embodies a metal tape wound into a helix supported by three or more dielectric support rods inside a conducting barrel. Figure 2 shows the cross-sectional view of a typical helical circuit and a three-dimensional view of the helical tape. Derived from a single-wire transmission line that has zero dispersion, the helix has a primarily constant phase velocity over a large bandwidth making it the widest bandwidth circuit of any structure available. This relatively low dispersion can be reduced further by incorporating dispersion shaping techniques into the circuit design. This is achieved by perturbing the circuit fields predominantly at low frequencies so that the phase velocity is decreased at the low frequency end while staying constant at high frequencies, thus reducing dispersion and increasing bandwidth. As the fields are concentrated between the helical turns at high frequencies and in the area extending from the helix to the barrel at low frequencies, this low-frequency perturbation is possible by including specially shaped dielectric support rods or longitudinally conducting metal vanes that anisotropically load the circuit [6,15]. Several loading methods are shown in Fig. 3.

1.2.2. Coupled-Cavity Circuit. Another common slow-wave structure is the coupled-cavity circuit that is used mostly for high-power applications. Because of its all-metal construction, it is able to dissipate a greater amount of heat compared with the helix, but can operate over only a comparatively narrow bandwidth. As shown in Fig. 4 for the cross-sectional and top views, the circuit includes a chain of cavities, typically made of copper, brazed together with a coupling slot alternating 180 degrees at adjacent

Figure 2. Cross-sectional view of typical helix slow-wave circuit and three-dimensional view of helical tape. The rectangular helical tape is supported by three rectangular dielectric support rods, all enclosed in a conducting barrel. The electron beam travels through the axial center ($r=0$) of the helical circuit.

Figure 3. Various dispersion shaping techniques for broad-band helical TWTs. (a) A metal coating is applied to the dielectric support rods. (b) The support rods are formed into T-shapes. (c) Loading vanes are added between the support rods.

cavities. Ferrules may surround the beam hole to concentrate the RF electric field in the vicinity of the electron beam for increased interaction.

Figure 4. (a) Cross-sectional view, (b) top view of ferruled coupled-cavity circuit. The coupled-cavity circuit employs an all-metal construction suitable for high-power TWTs.

1.3. Collector

After the amplified RF output is removed from the TWT, the spent electron beam passes through the end of the beam focusing section, so space charge forces cause the beam to expand as it enters the collector. Upon entering the collector, the beam is highly disordered with a broad spectrum of energies. The electron beam at this point still possesses a great deal of kinetic energy as only about 5% to 30% is extracted during interaction with the RF wave [16]. If the collector was at the same potential as the body of the tube, this kinetic energy would be dissipated as heat on the collector surface. By operating the collector electrode at a potential below that of the RF circuit, the beam is decelerated before it hits the collector surface. Thus, some of the remaining kinetic energy from the electron beam is converted to electric potential energy. This negative potential operation is known as depressing the collector. The greater the amount of recovered power, the higher the total efficiency of the tube. The impact of an efficient collector is made clear by considering the efficiency formula. Overall efficiency can be expressed as the ratio of the output power to input power or

$$\eta_{0v} = \frac{P_{out}}{P_{in}} \tag{1}$$

where P_{out} is the RF power output and P_{in} is the sum of the heater power, P_h , beam power from the gun, P_o , RF input power, P_{RFin} , and power to the magnetic focusing system, P_m , minus the power recovered by the collector, P_{rec} , or

$$P_{in} = P_h + P_o + P_m + P_{RFin} - P_{rec} \tag{2}$$

Figure 5(a) plots the current to the collector versus the amount by which the collector is depressed below ground potential (the slow-wave circuit potential). Assuming zero loss and zero interception between the beam and the slow-wave circuit, the area under the curve represents the maximum power that could possibly be recovered by the collector. The beam power converted to RF power is represented by the area above the curve less the cross-hatched area for voltages greater than the beam voltage. The beam current and voltage are represented by I_o and V_o , respectively. For a single-stage collector depressed to voltage V_1 , the maximum power that can be recovered is represented graphically in Fig. 5(a) by the shaded area, which is the product of the magnitudes of the collector current and collector voltage or

$$P_{rec} = V_1 I_o$$

Several phenomena complicate the collector operation including space-charge effects of the electrons already in the collector repelling those electrons entering, secondary electron emission from the surface caused by incident electrons, and electrons having different amounts of kinetic energy, thus traveling with different velocities. Multistage depressed collectors (MDC), where several electrodes are used at different depressed potentials, in-

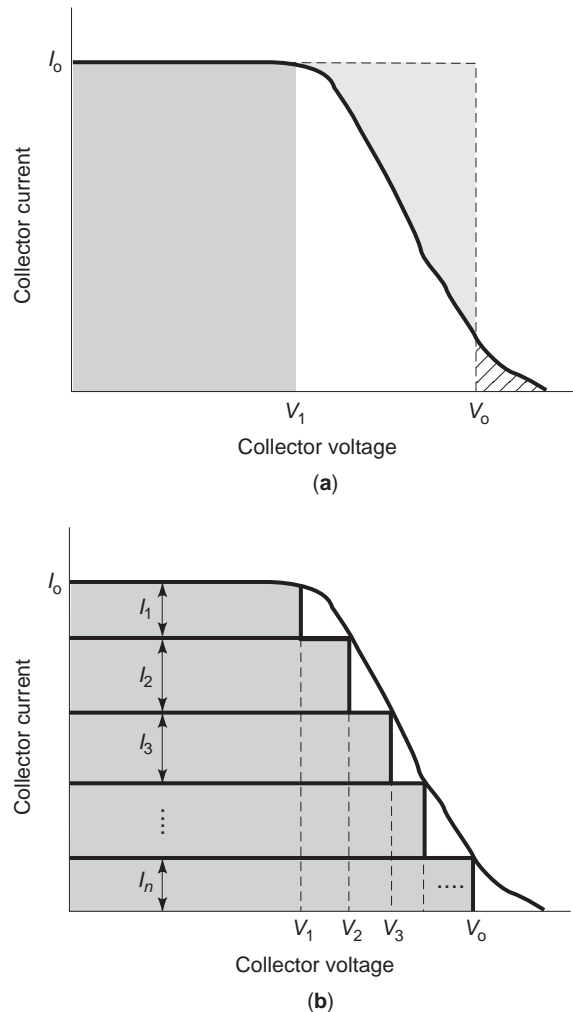

Figure 5. Collector current versus collector voltage. (a) The dark shaded area designates the maximum power that can be recovered by a single-stage collector. (b) The dark shaded area designates the maximum power that can be recovered by a multistage depressed collector with n stages.

corporate multiple velocity sorting stages. This directs high-velocity electrons to the stages having the greatest depression and the slow electrons to the stages with the least depression. This design has proven to greatly increase the overall efficiency of TWTs [17]. The reason for this becomes clear when the collector current versus voltage curve is again considered for the multistage collector. The total possible recoverable power for an n -stage MDC is represented by the shaded region in Fig. 5(b) where the n th electrode is at cathode potential, V_o . The possible recovered power is significantly greater compared with the single-stage collector given as

$$P_{rec} = \sum_{k=1}^n V_k I_k$$

In practice, this can never be exactly achieved because of secondary emission and imperfect energy sorting in the

collector. Considering Eqs. (1) and (2), it becomes obvious that the overall efficiency can be significantly increased. In practice, typical MDC designs incorporate no more than five collector stages as the law of diminishing returns starts to occur with regard to efficiency improvement versus fabrication and power supply complexity. A typical azimuthally symmetric four-stage MDC design is shown in two dimensions in Fig. 1.

1.4. Traveling-Wave Tube Package

The TWT package serves as a mechanical support structure for the TWT and RF input/output connectors, a thermal path for the conduction of waste heat, an electromagnetic interference (EMI) shield, and as a protective cover over the high-voltage connections and beam focusing magnets [4].

1.4.1. Beam Focusing. The electrons in the beam each possess negative charge; therefore, they repel one another causing the beam to diverge. To counteract this space charge effect and prevent the beam from diverging and being intercepted by the slow-wave structure as it flows through the length of the tube, external focusing is applied using an axial magnetic field. One way of doing this is to surround the TWT with a large solenoid that can be a permanent magnet or an electromagnet. Because of their size and large amount of stray magnetic field, solenoids are typically used only on very high-power (kilowatt level) TWTs with high current density beams.

A more commonly used method for focusing is to employ periodic permanent magnet (PPM) focusing that is lighter and more compact than an equivalent solenoidal magnet [18]. Alternating iron pole pieces and cylindrical magnets are placed side-by-side along the length of the tube, the polarity of adjacent magnets being reversed, as shown in Fig. 6. The PPM structure provides a nearly sinusoidal magnetic field at the beam axis with rms (root-mean-square) value about equal to the value of field required in a uniform field design.

1.4.2. Vacuum Envelope. It is necessary to operate the main components of the TWT under vacuum to ensure proper cathode operation and long cathode life, prevent formation of positive ions within the electron beam, and avoid high-voltage arcing at the electrodes. Thus, the gun, slow-wave structure, and collector are contained in a leak tight vacuum envelope. The beam focusing mechanism is usually mounted outside of the vacuum envelope, and this whole assembly is mounted in the TWT package.

2. BASIC FIELD THEORY

TWT gain is based on the surrender of energy from the electron beam to the RF electromagnetic wave. For this phenomena to occur, the phase velocity of the RF wave,* v , must be in near synchronism with the dc beam velocity, u_o ,

*The RF wave actually consists of space harmonics and the harmonic component of interest must be near synchronism with the dc beam velocity.

Figure 6. (a) Cross-sectional view, (b) top view of periodic permanent magnet focusing.

or

$$v = u_o \tag{3}$$

The gain of the tube depends on the strength of this interaction. A summary of the small-signal analysis for TWT gain is summarized by Gilmour [6], Gewartowski [19], and more succinctly by Wilson [20], based on the analysis done by Pierce [21]. The theory neglects space harmonics of the RF field other than that which is synchronous with the electron beam assuming these harmonics have no net effect.

First, the equation is derived for the ac current induced on the beam by the RF field (electronic equation). Next, the RF field resulting from the modulated beam is derived (circuit equation). These equations are solved simultaneously to determine the self-consistent relations for the circuit and beam quantities. The equations take on a neater form when several parameters are defined. Pierce's small-signal gain parameter C is defined as

$$C^3 = \frac{KI_o}{4V_o} \tag{4}$$

where K is the interaction impedance defined as

$$K = \frac{\int |E|^2 dS}{2\beta^2 PS} \tag{5}$$

where $|E|$ is the magnitude of the RF axial electric field, $\beta = \omega/\mu$ is the axial propagation constant, $\dagger P$ is the total RF power flow, and S is the cross-sectional surface area of the electron beam. I_o and V_o are the dc beam current and voltage, respectively. Pierce's space-charge parameter QC is defined as

$$QC = \frac{\omega_q^2}{4C^2 \omega^2} \tag{6}$$

where ω_q is the reduced plasma frequency and ω is the angular frequency ($2\pi f$), where f is the operating frequency.

A measure of synchronism between the electrons and the space harmonic wave is specified by Pierce's velocity

$\dagger K E$, and β are calculated for the space harmonic of interest.

parameter b defined as

$$b = \frac{u_o - v}{vC} = \frac{b_0 - N}{NC} \quad (7)$$

Pierce's loss parameter d is proportional to circuit attenuation and is defined as

$$d = \frac{\alpha\omega}{u_o C} \quad (8)$$

where α is the circuit attenuation including surface and attenuator losses. The various fields and beam quantities have a z dependence of the form

$$e^{-\Gamma z}$$

where Γ is the complex propagation constant for the circuit-beam coupled system. The allowed values for Γ are determined by simultaneously solving for the circuit and electronic equations. Doing so gives

$$\Gamma = j \frac{u_o}{\omega} (1 + jC\delta) \quad (9)$$

Making the appropriate substitutions and taking advantage of the fact that C is small,

$$\delta^2 = \frac{1}{-b + jd + j\delta} - 4QC \quad (10)$$

The solutions for Eq. (10) give three allowable propagation constants. Regardless of the values of d and QC , one will always obtain one growing wave that is responsible for the gain in the tube, one decaying wave, and one wave of nearly constant amplitude as long as the tube is operating near synchronism (small b).

The initial loss factor A_1 is defined as

$$A_1 = 20 \log \left| \frac{\delta_1^2}{(\delta_1 - \delta_2)(\delta_1 - \delta_3)} \right| \text{dB} \quad (11)$$

The space charge loss factor is defined as

$$A_2 = 20 \log \left| \frac{\delta_1^2 + 4QC}{\delta_1^2} \right| \text{dB} \quad (12)$$

Next we define

$$B = 54.6 \text{Re}(\delta_1) \quad (13)$$

and the electronic wavelength number N as

$$N = \frac{u_o l}{2\pi\omega} \quad (14)$$

where l is the length of the interaction circuit. The small-signal gain can now be expressed as

$$\text{Gain}_{s-s} = A_1 + A_2 + BCN - \text{sever loss dB} \quad (15)$$

The loss associated with each sever is typically about 6 dB. It should be noted that the small-signal gain analysis is valid only when the tube is operating well below saturation. Near or at saturation, the TWT behaves in a nonlinear manner and the small-signal theory is no longer valid.

3. TRAVELING-WAVE TUBE COMPUTER MODELING

Because of the complexity of operation, there are numerous codes that are used in the design, development, and analysis of TWTs. Some of the codes stand alone, and others are incorporated into the microwave and millimeter-wave advanced computational environment (MMACE), which is a vacuum electronics initiative directed at integrating existing codes into a compatible environment having a user-friendly interface [22]. A discussion of available codes follows that is grouped by TWT section. This is intended to point the reader to the appropriate references for each code.

3.1. Electron Gun

Numerous codes exist that will calculate electron trajectories in electrostatic and magnetostatic focusing systems. Electron gun (EGUN) is a widely used code that includes two-dimensional(2-D) fields and three-dimensional(3-D) particle trajectories [23]. In contrast to EGUN's rectangular mesh capability, DEMEOS uses a deformable triangular mesh that is efficient in modeling both the small and the relatively large dimensions of the electron gun [24]. The two-and-one-half-dimensional particle-in-cell (PIC) code MAGIC is also used in gun design [25].

3.2. Slow-Wave Structure

There is a large variety of codes available for the analysis of slow-wave structures. An important step in TWT design is to obtain the cold-test characteristics of the circuit. Cold-testing implies testing the circuit or a scale model of the circuit on the RF test bench without the electron beam to obtain dispersion, interaction impedance, and attenuation characteristics. Accurate results have been obtained in terms of cold-test parameters for several slow-wave circuits using codes like the 3-D electrodynamic PIC code MAFIA [26,27], the 3-D cold-test codes Micro-SOS [28,29] and ARGUS/ESP of MMACE [30], the 3-D cold-test code for helical structures TLM [31], and the 3-D cold-test code limited to axially symmetric cavities in cylindrical coordinates SUPERFISH [32].

It is also important to obtain information about the match from the slow-wave structure to the input/output couplers. Accurate results regarding the transmission characteristics of TWT couplers have been obtained using codes like Ansoft Eminence [33] and MAFIA [34].

3.3. Collector

There has been significant progress made in the computational modeling of collectors within the past several years. Typically an electron trajectory code such as EGUN was used to aid in collector design [35], but because it can simulate only azimuthally symmetric

structures with steady-state electron streams, three-dimensional codes that compute instantaneous conditions are also being used. Several 3-D codes have provided reasonably accurate results: the 3-D PIC code, MAFIA [36]; the 3-D PIC collector simulator integrated into the MMACE framework, C3D [37]; the 3-D PIC code, PIC3D [38]; and the 3-D electron trajectory collector simulator, LKOBRA [39].

3.4. Traveling-Wave Tube Interaction

As mentioned previously, the field theory for small-signal gain provides insight into TWT interaction, but when the tube is operated near or at saturation, this analysis is no longer valid. Near saturation the TWT behaves in a nonlinear manner referred to as large-signal operation. This means that when large-amplitude signals are present, higher order RF terms are no longer negligible as compared with the corresponding dc values. The analysis of the nonlinear system does not lend itself to neat solutions of closed-form equations, so computational modeling becomes crucial [40]. There are a number of codes available to simulate TWT interaction and thus provide characteristics such as gain, power transfer curves, and efficiency near and at saturation.

There are several codes devoted strictly to helical TWT interaction such as the one-dimensional (1-D) code, which predicts intermodulation distortion CHRISTINE [41], the 2-D code, which incorporates 3-D field vector components and beam velocities and which is part of the MMACE framework GATOR [42]; and the 2-D deformable disk model DDM HELIX TWT [43]. The NASA CC TWT code analyzes interaction between a 3-D electron beam and 2-D RF electromagnetic fields in coupled-cavity TWTs [44]. Fully three-dimensional PIC codes such as MAFIA, ARGUS, SOS, and 3DPIC offer the advantage of being able to simulate an entire TWT section in 3-D including modulation effects. Modeling the beam dynamics in just the TWT slow-wave section in 3-D has been accomplished with good accuracy [38,45] but an entire 3-D TWT model from gun to collector has not yet been accomplished because of the computational intensity of the problem.

4. FUTURE TRENDS

The microwave power module (MPM) is a recent development that has had a significant impact on microwave and millimeter-wave electronics system development by taking advantage of the best features of both vacuum electronics and solid-state devices. The MPM is a lightweight, miniaturized RF amplifier consisting of a low-noise, high-gain microwave monolithic integrated circuit preamplifier/signal conditioner, a high-efficiency vacuum power booster TWT, and a miniaturized high-efficiency integrated power conditioner. The MPM has proven to outperform conventional TWT technology in areas of power density (power per unit weight) and noise figure. Analyses also indicate improvement in reliability due to fewer components, lower typical operating temperatures, and improved interconnection technology [46], but data are not yet available to verify this.

Once thought to be a declining field, there is now a substantial opportunity for growth in the commercial demand for TWTs. Particularly, two types of systems are of interest, satellite communications and local multipoint distribution systems (LMDS) [47]. These commercial systems are close to turning the balance from a mostly military market to a commercial market. U.S. industry is proposing to invest more than U.S. \$35 billion in commercial Ka-Band satellite communications systems over the next 6 years, which will create a demand for thousands of TWT amplifiers. The LMDS concept would cover major metropolitan areas with a grid of cellular stations operating at Ka-Band and transmitting programming in competition with cable TV systems. One estimate suggests that 5000 to 6000 highly linear Ka-Band TWTs, probably operating at 28 GHz, would be required to implement LMDS in the continental United States [48].

TUNNEL DEVICES

EDWARD H. SARGENT
J. M. XU
University of Toronto

Tunnel devices take advantage of the wave-like properties of charge carriers in implementing a desired function. The term *tunneling* refers to the movement of matter from one side of an energetic barrier to the other even though it does not possess sufficient energy to overcome the potential barrier according to the laws of classical mechanics. Instead, the quantum-mechanical wave function of the particle penetrates inside the barrier and extends into the medium on the far side. Therefore, some probability exists for the particle to be on the other side. For these wave

properties of matter to be manifested, the particle mass and the tunneling distance must be small.

Tunnel devices typically possess nonlinear, nonmonotonic current-voltage characteristics and are characterized by very rapid fundamental propagation times. They find application in such diverse areas as microwave oscillators; multiple-level logic, switches, memory elements; and lasers. They are examples of functional devices whose underlying physical mechanisms are exploited and applied to meet a sophisticated demand simply. Often they replace a set of many interconnected devices in the form of a single device, which performs the desired function more naturally. In addition to playing an important role in modern electronics and optoelectronics, tunneling devices have played an important role in twentieth century science by offering direct, macroscopic evidence of microscopic quantum-mechanical phenomena.

1. TUNNELING CONCEPT

The quantum-mechanical concept of tunneling may be illustrated by a simple example. A particle with energy E impinges from the left on a potential barrier of height V , as illustrated in Fig. 1. The solution to the Schrödinger wave equation to the left of the barrier consists of traveling waves (the incident wave travels to the right and any reflected component travels to the left). As the particle energy is stated to be less than the barrier height, the wavevector inside the barrier is complex. The corresponding solution is a sum of decaying exponentials. To the right of the barrier, the solution is a wave traveling to the right. Continuity of the wave function and its derivative at the boundary specifies the overall solution to within a multiplicative constant. There is a nonzero probability of finding the particle on the far side of the barrier.

Associated with each particular choice of the energy E of the incident particle is a transmission coefficient $T(E)$, defined as the ratio of the current density of particles transmitted through the barrier to the current density of particles with energy E impinging on the barrier. As the wave function penetrating into the barrier decays expo-

Figure 1. A particle with energy E impinges from the left on a potential barrier of height V and width a . In the case considered, $E < V$, and the wavefunction inside the barrier takes the form of a decaying exponential. The wavefunction penetrates all the way through the finite barrier and emerges in the form of a traveling wave on the far side, and it is possible for the tunneling probability to be appreciable.

nentially, T will also decay exponentially with increasing barrier width and also with increasing difference between the barrier height and the energy of the incident particle. If T is much less than unity, it may be approximated as

$$T \sim 4 \left(\frac{E}{V} \right) \left(1 - \frac{E}{V} \right) \exp \left[-\sqrt{\frac{8m(V-E)}{\hbar^2}} a \right] \quad (1)$$

where m is the particle mass and \hbar^2 is Planck's constant divided by 2π . In Fig. 2, the transmission coefficient is shown as a function of barrier width for a typical electron at room temperature with energy 40 meV and effective mass $m_e = 0.05 m_0$. For this realistic range of parameters, the barrier width should be on the order of nanometers for T to be appreciable.

2. FUNCTIONAL DEVICES

Before the advent of tunnel devices, electronic devices (e.g., diodes, transistors) were dominated by physical mechanisms that gave rise to a monotonic dependence of outputs on inputs.

In 1965, J. A. Morton [1] of Bell Labs popularized the term *functional devices*, a family of which tunneling devices are natural members. Morton described traditional electronic circuits as consisting of vast numbers of interconnected transistors and other devices with simple, monotonic relationships between inputs and outputs. The equations that describe these relationships are mathematical approximations that develop out of physical interactions within matter. The relative simplicity and monotonicity of the resulting equations allows for representation using classic network equations employed in circuit function synthesis.

Morton argued that substantial inroads could be made by abandoning classic circuit concepts and exploiting instead the most basic interactions between energy and matter. Such functional devices would be designed to perform a desired function as simply as possible. The aim

Figure 2. The transmission coefficient for a typical room temperature electron ($E = 40 \text{ meV}$) through a finite potential barrier of various widths (a) and heights (V).

would be to reduce greatly the number of elements and process steps per function:

... the aim of electronics should be not simply to reproduce physically the narrow elegance of classical circuit theory; rather, it should be to perform needed system functions as directly, as simply, and as economically as possible from the most relevant knowledge of energy–matter interactions [1].

Despite such arguments for a natural and elegant approach to device innovation, in the 1960s, functional devices had only gained acceptance in fulfilling niche applications. The slow rate of incorporating the devices at that time is the result of at least two important factors. First, it had been possible until that time and has been possible until recently to continue to extract additional functionalities by making larger, denser circuits by interconnecting simple *black boxes* of traditional circuit elements. Technological inertia contributed to the success of this brute force approach to a point. It is believed, however, that present-day technology is approaching the practical limits of simple-minded miniaturization and densification, and therefore a more elegant and fundamental approach is necessary. A related factor is human inertia, wherein designers who employ electronic devices in creating circuits can manage complexity by conceptualizing device behavior in terms of sets of monotonic curves. They are not trained to manipulate the complicated hypersurfaces that mathematically describe the characteristics of functional devices.

As the demand for sophisticated functionality from a small number of densely packed devices grows and the limitations of traditional device and circuit approaches become more apparent, there will necessarily be a cultural shift in the area of circuit design. The complexities of functional devices will be recognized as a source of opportunities and challenges.

3. TUNNELING: EARLY DEVELOPMENTS

Through the development of the theory discussed later in this section, Fowler and Nordheim [2] are generally credited with one of the early triumphs of the quantum theory: explaining the ejection of electrons from a cold metal in vacuo subjected to a high electric field. They invoked the *new wave mechanics of Schrodinger* to show how electrons could tunnel through a sufficiently thin energetic barrier and escape into the vacuum.

Although Fowler and Nordheim were indeed the first to apply the Schrodinger mechanics specifically to the metal-

vacuum system, it was Oppenheimer [3], in a work concerning the ionization of hydrogen atoms via the tunneling process, who stated

...[the] pulling of electrons out of metal by [large] fields ... is probably to be accounted for in this way.

The history of the study of electron emission from metals is the background against which the advances attributed to Fowler and Nordheim may be understood. Schottky [4] studied the escape of electrons from a conductor via the process of thermionic emission, a purely classic process wherein a fraction of the electrons in the metal have sufficient energy to overcome the metal-vacuum barrier (Fig. 3). At higher temperatures, the average energy of electrons and the breadth of their statistical energetic distribution is increased, leading to a strong temperature dependence of the resulting current. When a weak field is applied to the metal, the Schottky formula describes the temperature T and electric field F dependence of the thermionic emission current:

$$J(F, T) = A_R T^2 \exp \left[- \frac{\phi - (e^3 F)^{1/2}}{k_B T} \right] \quad (2)$$

where A_R is a material-dependent constant, ϕ is the metal-vacuum barrier height in the absence of an applied field, and $(e^3 F)^{1/2}$ accounts for the lowering of the barrier height brought about by the application of the field. In the case where no field is applied, Eq. (2) reduces to the Richardson–Laue–Dushman equation, often called the Richardson equation, from which the Richardson constant A_R derives its name.

Thermionic emission theory did not adequately explain the behavior of strong currents that could be obtained at low temperatures if very high electric fields were applied. A number of experiments had shown that the current was independent of temperature over a broad temperature range. This led to attempts to distinguish between electrons *pulled out by fields* and those of a *thermionic character* in a way that Fowler and Nordheim thought artificial. A new empirical relationship was proposed [5], which was correct under high fields and low temperatures (*field emission*) and also at high temperatures (*thermionic emission*) but untested in the transitional region between these mechanisms and not motivated by fundamental considerations.

Fowler and Nordheim posited that the escape of electrons from a cold conductor under application of a sufficiently high electric field could be explained by a

Figure 3. Mechanisms of thermionic and field emission. In the case of (a) thermionic emission, a fraction of the electrons have sufficient energy to escape classically. In the case of (b) field emission, electrons may not have sufficient energy to escape classically, but may tunnel out quantum-mechanically for small enough potential height and barrier width.

quantum-mechanical description: electrons could tunnel through the field-deformed potential energy barrier to generate a current of field-emitted electrons [Fig. 1(b)]. They invoked de Broglie's description wherein electrons could be viewed as having wave-like properties, with a characteristic wavelength λ given by

$$\lambda = \frac{h}{(2mE)^{1/2}} \quad (3)$$

where h is Planck's constant, m is the electron mass, and E is the electron energy. The wave-like properties of the electron allow it to pass through an energetic barrier at an appreciable rate if the barrier is lowered below the level E_F in a distance comparable with the electron wavelength λ .

Fowler and Nordheim treated the matter of field-emission tunneling by solving the Schrodinger wave equation on either side of the barrier with appropriate boundary conditions. They obtained an expression for the quantum-mechanical transmission of electrons through the barrier as a function of electron energy and linked this with the rate of electrons impinging on the barrier as a function of energy. They obtained an electron field-emission tunnel-

ing current density J of

$$J(T, F) = AF^2 \exp\left(-\frac{B\phi^{3/2}}{F}\right) \quad (4)$$

where F is the electric field strength, ϕ is the conductor work function, and A and B are weaker functions of F and ϕ . Thus a plot of $\ln(J/F^2)$ versus $1/F$, the Fowler-Nordheim plot, is predicted to be a straight line, a fact that is borne out experimentally. The temperature-independence of the measured field-emission current is also predicted and explained by the Fowler-Nordheim theory.

4. THE TUNNEL, OR ESAKI, DIODE

In 1958, Leo Esaki [6] observed a negative differential resistance in the forward current-voltage characteristic of a Zener diode (Fig. 4). The devices under study were germanium p - n junctions with heavy dopant concentrations on the order of 10^{19} cm^{-3} . From capacitance measurements, Esaki found that the junction width was approximately 150 \AA . He accounted for the observed current-voltage characteristic in terms of tunneling of electrons in the conduction band of the heavily doped n -side through the narrow junction (whose width was comparable with

Figure 4. I - V characteristic of the tunnel diode of Leo Esaki's seminal work. The negative differential resistance characteristic—explained with the aid of Fig. 5—provides evidence of the importance of the tunneling mechanism and forms the basis for device applications of tunneling.

the electron wavelength, making the tunneling probability appreciable) into the valence band of the heavily doped p -type contact, and through the analogous process for holes.

To gain an understanding of the operation of the Esaki diode, one must consider the transmission coefficient for electrons and holes through the barrier as a function of their allowed energies and also the availability of states from which and into which to tunnel. Fermi's golden rule gives the transition rate from initial state i to final state m as

$$W_{i \rightarrow m} = \frac{2\pi}{\hbar} M_{im} \rho(E_m) \quad (5)$$

where M_{im} is called the matrix element for the transition and, in this case, is directly related to the tunneling transmission coefficient. The density of states $\rho(E_m)$ describes the availability of states into which the carriers may tunnel. To obtain the net tunneling current in a particular direction, the difference between $W_{c \rightarrow v}$ and $W_{v \rightarrow c}$ will be considered.

This concept and its consequences are illustrated schematically in Fig. 5. At zero bias [Fig. 5(a)], n -side electrons above the Fermi level can tunnel into vacant states on the p -side. However, because they do so at an equal rate in the opposite direction (and the same argument applies for holes), there is no net current. As a small forward bias is applied [Fig. 5(b)], electrons on the n -side become energetically aligned with unoccupied states on the p -side. As the bias is increased further [Fig. 5(c)], more of the electrons lie opposite the forbidden band on the p -side, so that tunneling (in this simple model) is not possible. At even higher biases [Fig. 5(c)], classic drift-diffusion processes dominate the I - V characteristic, and the diodes begin to obey the usual Shockley equation. It is essential that both sides of the junction be degenerately doped (i.e., that the Fermi level lie within the conduction band in the n -type contact and within the valence band in the p -type contact).

Esaki was a cowinner of the 1973 Nobel Prize for Physics for his experimental discovery regarding tunneling phenomena in semiconductors.

4.1. Excess Current

In many tunnel diode applications, a large ratio of peak current to valley current is required. For this reason, the *excess current*, the value of the current in the valley region of the I - V characteristic, where tunneling current is expected to drop to zero and before standard thermionic emission current takes over, is of practical significance. A number of hypotheses were put forth to explain this observation. Mechanisms whereby tunneling carriers could lose energy through photon, phonon, plasmon, or Auger processes were suggested but were not sufficiently important to explain the observed excess tunneling current. Starting from the hypothesis put forth by Esaki that electrons could not tunnel completely through the energy gap but only part of the way, making use of states in the energy gap, Chynoweth et al. [7] developed and experimentally corroborated a model for the excess current.

4.2. Desired Properties

One of the most prominent applications of the Esaki diode is as a high-speed component in oscillator circuits and switches. The preservation of the diode's negative resistance at high frequencies makes it a candidate for such applications. The switching speed is determined by the current available for charging the junction capacitance. To achieve high-speed performance, low capacitance is desired, and sufficient current must be supplied by the diode to charge the junction capacitance. Therefore, one simple figure-of-merit is the ratio of the peak current to the junction capacitance. Another important figure-of-merit is the ratio of the peak current to the valley current, known as the peak-to-valley ratio (P/V), which is related to the current gain obtainable. Maximizing the peak-to-valley ratio in Esaki diodes represents a compromise, primarily in the doping level. At lower (though still degenerate) dopings, the peak current is small because there is only a narrow energy range over which conduction-band electrons see unoccupied valence-band states (and analogously for holes in the valence band). At higher dopings, the density of bandgap states increases (as described above), and the valley current increases. The maximal P/V is found for some intermediate concentration. In either case, the

Figure 5. Schematic portrayal of the mechanism of Esaki diode negative resistance. Quantum-mechanical effects dominate the current at low forward bias (b); electrons and holes tunnel through the forbidden zone into the opposite band. As the bias is increased (c), fewer states are available into which carriers may tunnel, and the current decreases. The classic diode current takes over at higher biases (d).

requisite doping level is near the maximum level that can be activated in the semi-conductor, typically around 10^{19} cm^{-3} .

Although a remarkable device and one which provided a satisfying early example of engineering in the quantum domain the Esaki diode exhibits some intrinsic properties that limit its usefulness to certain regimes and application areas. Most importantly, the degenerate doping levels required to achieve a reasonable peak current give rise to a large shunt capacitance that limits high-speed performance and necessitates presenting the device with impedances properly matched to the capacitive reactance of the diode.

5. THE RESONANT TUNNELING DIODE

These fundamental limitations on the performance of the Esaki diode, taken together with the promising prospect that it demonstrated for devices based on tunneling, motivated the development of a structure whose performance was not fundamentally linked to heavy doping. This was first sought and realized in the form of the resonant (intra-band)-tunneling diode.

The history of resonant tunneling precedes the perception of its need in device implementations. The concept originally elaborated by Bohm [8] is illustrated in Fig. 6. The system of double barriers is characterized by a set of quantized energy states. If an incident particle impinges with energy equal to one of these bound-state energies, it is resonantly transmitted. If it differs substantially, it is resonantly reflected.

The first suggestions for resonant-tunneling devices were made by Davis and Hosack [9] and Ioganson [10]. Esaki and Tsu [11] proposed a superlattice implementation of the same basic concept and anticipated explicitly the negative differential resistance resulting from the strong energy dispersive effects that may develop in such a structure if the critical dimensions are on the order of the electron wavelength. In 1973, they extended their theoretical considerations [12] to the case of a multiple-barrier superlattice as opposed to a theoretically infinite one. In 1974, a superlattice was implemented using molecular beam epitaxy [13], with 45 Å GaAs wells clad by 40 Å AlAs barriers. The negative differential conductance characteristic of Fig. 7 was reported.

The mechanism of the intraband resonant-tunneling diode may be illustrated (Fig. 8) by considering one pair of barriers. The same principles apply in determining the conductance features of Fig. 7, the more complicated structure giving rise to the more intricate observed fea-

Figure 6. Resonant transmission in a double barrier system. The alignment of the incident particle energy relative to the energies of barrier-confined states determines the rate of transmission through the system.

Figure 7. Differential conductance of the first resonant intra-band tunneling structure of Esaki and Chang, 1974 [14].

Figure 8. Mechanism of negative differential conductance in resonant-tunneling diodes. At zero bias (a), the electron energy is less than that of the confined barrier states. Under increased bias (b), the incident and confined energies become aligned, and the states at this same energy in the collector are almost completely unoccupied, so that resonant transmission is achieved. As bias is further increased (c), electrons in the injector and the double barrier fall out of resonance.

tures. At zero bias, the energy of conduction-band electrons in the emitter is less than that of quantum-confined electrons between the barriers [Fig. 8(a)], and they are not resonantly transmitted. As the bias is increased, these energies become aligned [Fig. 8(b)]. The states at this same energy in the collector are almost completely unoccupied, so that resonant transmission is achieved, and the conductance is increased. As bias is further increased, however, the energies of the electrons in the injector and inside the well are out of resonance and the conductance is reduced [Fig. 8(c)].

It was not until the observation of fast intrinsic response times by Sollner et al. [14] and soon thereafter of room temperature negative differential resistance [15,16] that the field of superlattices and quantum wells began to grow rapidly. Sollner et al. obtained a P/V ratio of 6:1 at low temperatures, and although the negative differential resistance characteristic was not manifested at room temperature, the effect of resonant tunneling was nevertheless apparent in the room temperature differential conductance characteristic. In addition, Sollner et al. reported one of the first experimental manifestations of the anticipated high-speed response of the room temperature device (RTD). The authors concluded that the charge transport mechanisms are characterized by a time of 6×10^{-14} s. The room temperature NDR of Shewchuck et al. [15] was one of many incremental steps of progress in the direction of acceptably high room temperature peak-to-valley ratios that came with gradual technological improvements in molecular beam epitaxy [17]. In particular, very thin (~ 1 nm) high barrier layers were eventually obtained with precise thickness control and uniformity. Double-barrier RTDs operating at room temperature have been achieved with peak-to-valley ratios as high as 50:1 at 300 K [17]. With the benefit of such incremental technological progress, the experimentally observed fundamental oscillation frequency has improved approximately linearly with time.

6. RESONANT INTERBAND TUNNELING

It is remarkable that, with the benefit of the high-quality atomic-layer engineering made possible by molecular beam epitaxy, resonant-tunneling diodes achieved room temperature peak-to-valley ratios no better than those of the original Esaki diodes of thirty years earlier, which used much less sophisticated material engineering techniques. Had the abrupt interfaces and high doping of modern epitaxial crystal growth techniques been possible at that time, the Esaki diode would likely have provided still more competitive performance.

On the other hand, the RTD held the clear advantage of a much lower capacitance and more manageable technological challenges. In the light of these observations, in 1989, Sweeny and Xu proposed [18] a structure operating on both interband and resonant-tunneling principles with the objective of preserving the attractive features of each one. Their resonant interband tunnel diode concept was an otherwise ordinary p - n diode with quantum wells in the conduction and valence bands. Thus, although it was a

bipolar interband-tunneling device like Esaki's, it incorporated the resonance features of the RTD through the use of coupled quantum wells. The device did not rely on heavy doping to ensure tunneling, but instead took advantage of quantum wells (grown or induced) and exploited the resonance tunneling phenomenon. The operation of one such device is illustrated in Fig. 9. Regions I and IV of Fig. 9 have opposite doping and need not be degenerate. The well regions II and III have a lower bandgap and are doped the same as their higher bandgap outer neighbors. As in previous tunneling devices, the barrier must be sufficiently thin that there is significant interpenetration of the carrier wave functions in II and III. Using bandgap engineering, high carrier concentrations may be achieved in the wells without requiring degenerate doping at any point in the structure. When a bias is applied so that the conduction-band density of states in the n -type quantum well (II) is energetically aligned with the valence-band density of states in the p -type quantum well (III), resonant transmission of carriers through the barrier occurs. As the bias is further increased, no states are available for tunneling until the conduction band of (II) and (III) are aligned. These possibilities and the resulting I - V characteristic are illustrated in Fig. 10. The type-II heterostructural version in their proposal was later suggested independently and demonstrated the same year [19]. This very first implementation of the RIT achieved a room temperature P/V ratio of 20. Within four years, a room temperature peak-to-valley current ratio of greater than 100 had been demonstrated by Day et al. [20].

Figure 9. Resonant Interband Tunneling device operation. Resonant transmission occurs between the conduction to the valence bands, rather than within a single band as in earlier intraband tunneling devices.

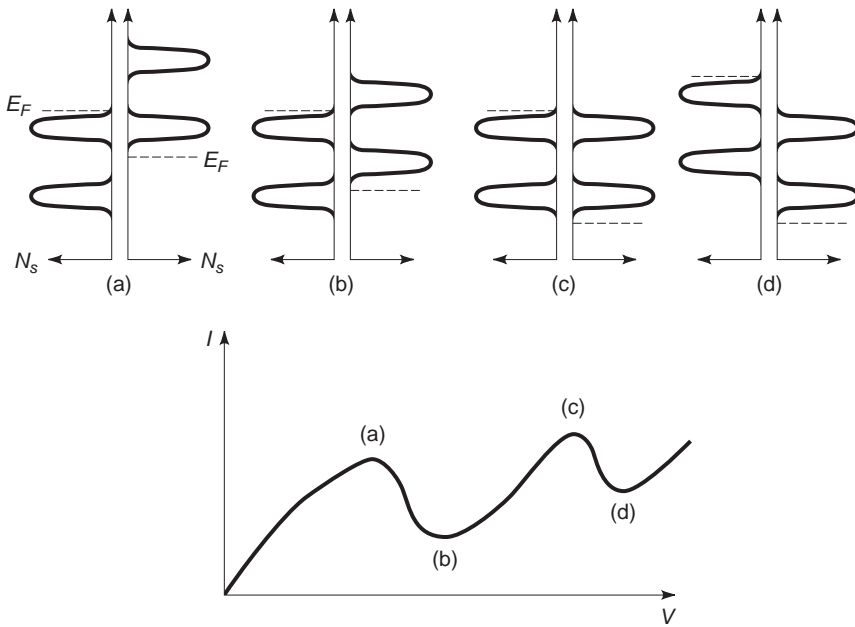

Figure 10. Mechanism of I - V characteristic of resonant intraband tunneling diode. The alignment of quantum-confined energetic states in the conduction and valence bands determines the rate of resonant transmission.

The two alternate implementations of the resonant interband tunneling concept work similarly [18]. The polytype heterostructural implementation exploits the fact that the conduction band of one material is below the valence band of the other in a type-II heterostructure. Resonant intraband tunneling could be realized in such a device [Fig. 11(a)] using very low doping, enabling ultra-high-speed performance not limited by significant contact capacitances. Another realization, a modulation-doped homostructure [Fig. 11(b)], also allows resonant intraband tunneling with a minimum of material doping.

7. SINGLE-ELECTRON TUNNELING: EFFECTS AND DEVICES

The preceding discussion centered around collective transport of many electrons through a system. Tunneling of individual electrons—known as single-electron tunneling—is difficult to observe and control, because thermal fluctuations in electron energy (of order kT) are typically larger than the Coulomb energy change of the system.

Substantial progress has nevertheless been made in this area [21–24]. The possibility of observing single-electron tunneling in very small systems was noted around the same time that Esaki observed the effects of macro-

scopic tunneling electron tunneling in semiconductors. To observe single-electron tunneling, it is not sufficient simply for the system to be small and to have a large effective capacitance, in turn giving rise to a large charging energy (much greater than kT). It must also be well isolated (electromagnetically decoupled) from the environment such that the electron is essentially localized within the system. This localization condition may be expressed in the requirement that the tunneling resistance (impedance) of the system be much greater than the quantum resistance.

Only recently—with the aid of technological advances and further important progress [25]—has broad interest been generated in this problem, and a wide range of investigations begun into single-electron tunneling effects. If the conditions described above are met, the effect may be observed in a number of ways. Because of the discrete nature of electrons, a staircase relation between system charge and voltage exists, so that conductance peaks may be observed at specified voltages. A Coulomb staircase I - V characteristic [25]—a dramatic manifestation of the effect of single-electron charging—develops in suitable structures in which one tunnel barrier is more strongly transmitting than the other [26]. One application area already demonstrated is in the use of controlled Coulomb blockade effects in realizing accurate current standards: by cycling tunneling barrier heights, individual electrons

Figure 11. (a) Polytype heterostructure implementation of the resonant interband tunneling diode. (b) Modulation-doped homostructure implementation of the resonant interband tunneling diode.

can be made to pass through the confined system at the applied frequency—resulting in an “electronic turnstile” [27]—and producing a current $I = ef$ (where e is the electronic charge and f the frequency of modulation).

The introduction of further tunneling junctions and more complex connections and coupling provide a rich variety of externally observable single-electron tunneling phenomena. Foreseeable applications in conventional electronics include memory cells, D/A converters, and sensitive analog transistors.

8. TUNNELING IN OPTOELECTRONICS

Laser technology has also benefited from innovative solutions to problems posed by new applications. Conventional semiconductor lasers are bipolar devices that rely on band-to-band transitions between the conduction and valence bands. The energy associated with these interband transitions and consequently the energy of the emitted photons is largely determined by the properties of the semiconductor material. By introducing quantum wells in which spatially confined electrons and holes have ground-state energies above the semiconductor bandgap, it is possible to tailor somewhat the energy of photon emission.

For a number of applications, mid- or long-wavelength lasers with photon energies ranging from 2 to 12 μm are desired. One solution that reduces the dependence on material choice takes advantage of transitions in quantum wells within a particular band, typically the conduction band. In these intraband devices, the photon emission energy may be selected by careful tailoring of well and barrier widths.

One fundamental requirement in lasers is that of population inversion. If photons are emitted during the stimulated transition from state 2 to state 1, then the population of state 2 must exceed that of state 1. Two dominant approaches have been adopted in achieving population inversion in intraband lasers, both of them based on tunneling.

The group of Capasso [28] realized the first intrasubband laser. In this device, population inversion within the conduction band was achieved via very careful design of the active region, which consists of sets of wells and barriers for injection, relaxation, and removal of carriers. Electrons are injected by resonant tunneling into one of the higher states of the active region quantum wells. By simultaneously making the lower state depopulation mechanisms resonant with other phonon and tunneling processes, the lifetime of the lower state is made less than that of the upper state, and population inversion may be achieved. Using this tunneling-based mechanism, room temperature quantum cascade lasers have been achieved [29].

Another approach to achieving population inversion was proposed by Yang and Xu [30]. As illustrated in Fig. 12, intraband tunneling or simply intraband transport may be used to inject carriers into the upper state (from I–II in the figure), and interband tunneling to remove carriers from the lower state (from II–III) to invert the populations in the first two states of the conduction

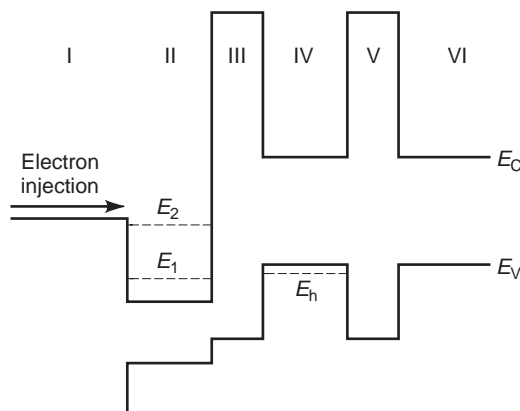

Figure 12. Illustration of resonant interband tunneling-assisted population inversion. Carriers are injected into the upper state (from I–II) and are removed from the lower state (from II–III) via interband tunneling. The population in the first two states of the conduction band is thereby inverted.

band. The structure is designed to prevent tunneling out of the upper state. Low-temperature operation of a device incorporating this concept was demonstrated by Yang et al. in 1997 [31].

9. TUNNEL DEVICE MODELING

Since the seminal work of Fowler and Nordheim [2], a variety of advances have been made in the accuracy of models of tunnel device operation [32]. An element common to these developments is the use of the effective mass approximation. In this approach, widely employed throughout condensed matter physics, an effective mass term (not generally equal to the true physical mass of the carrier) is used to account for the effects of the atomic potentials that the charge carrier encounters during its trajectory through a solid medium. The simplifications involved transform the modeling of interactions in a solid from what would be a daunting task, accounting individually for a large, complex set of potentials, into potentially tractable problems. The effective mass is used in an approximate Schrodinger equation, and the validity of the results vary according to structure and the region within a given structure.

The Bohm approximation (or the golden rule of Fermi) is usually invoked to quantify tunneling currents. Tunneling may be viewed as the scattering of an electron in an electric field in which the scattering potential is usually invariant in the transverse direction, so that the transverse momentum vector is conserved. (In more complex devices, one may take advantage of the transverse direction in further enhancing functionality.)

Although a number of simplifications have already been invoked to this point, further approximations are typically employed in modeling interband tunnel devices. In this case, the coupling between conduction and valence bands provides the central mechanism for device operation, and a singleband effective mass approximation does not yield physically correct results.

In such devices, interband coupling is strongest in the tunneling region. To a first-order approximation, the current-voltage relationship is obtained from a coupled-band effective mass equation. If spin is taken into consideration, there are two conduction-band contributions and six valence-band contributions. Within this eight-band framework, the $\vec{k} \cdot \vec{p}$ of Kane [33] is the most commonly employed and may also be the most exact. Altarelli [34] provides a review of the $\vec{k} \cdot \vec{p}$ treatment.

To gain physical insight into the problem without onerous computation, a two-band model is often used. By symmetry considerations of the Bloch functions, the conduction band and light-hole bands are most strongly coupled and must be retained. The other bands of the eight-band Luttinger–Kohn Hamiltonian [29] may be removed if the effective masses of the bands remaining are adjusted to ensure that their dispersion relationships agree reasonably with the known band structure over the energy of interest (for a review, see Datta [36]). Even this simplified two-band model provides coupling between the differential equations associated with different bands.

10. OVERVIEW, ASSESSMENT, AND OUTLOOK

Digital functional devices based on carrier tunneling take advantage of nonmonotonic I – V characteristics and fast intrinsic response times. Applications include high-speed analog-to-digital converters, parity bit generators, and multiple-valued logic elements. Three terminal devices, such as the resonant tunneling bipolar transistor proposed by Capasso and Kiehl in 1985 [37] have also been developed. This particular device, which uses a quantum well in the p -type base layer, exhibits a series of peaks in its collector current as a function of base-emitter voltage. For this device, applications include multiple-valued logic, parity generators, analog-to-digital converters, and multiple state memory, all implemented more naturally than using a collection of two-terminal devices. Three-terminal unipolar devices based on tunneling include the resonant hot electron transistor (RHET) of Yokoyama et al. [38] and the quantum wire transistor proposed in 1985 by Luryi and Capasso [39].

High-speed analog devices typically exploit the high-frequency negative differential conductance obtained from tunneling devices. Two-terminal oscillators are perhaps the simplest device examples, which take advantage of the fact that the negative differential conductance persists on timescales as short as the lifetime of the electron in the resonant state between the barriers of a resonant tunneling diode. RTDs may also be used as efficient mixers by exploiting the rapid variation in dynamic conductance with voltage near the negative differential resistance portion of the I – V characteristic.

RTDs find applications in switching when they are biased with a source resistance larger than the magnitude of their negative differential resistance. A stable bias point is no longer achievable in the NDR region, and switching occurs between the stable points outside of this region. Switching times as short as 2 ps have been measured [40,41].

The preceding list of applications covers those that could be thought of as niche roles for tunneling devices. They fulfill a specific role often very effectively but typically in isolation from general circuit applications. It has been argued that tunneling devices have a much more important role to play in the future.

Exponential improvements in circuit speed have been enabled by an exponential downward trend in minimum device geometries and switching power. This downscaling cannot continue indefinitely. Before fundamental physical limits are reached, ICs based on transistors will be rendered impossible or exorbitant by a combination of problems related to device technology, interconnection, noise, and reliability. A saturation in circuit density improvements is likely to imply a saturation in the historically downward trend in cost per bit or function.

Three-terminal devices based on tunneling would provide a means to continue this downward scaling and in fact to exploit it to the fullest. However, as argued previously, tunneling devices technologies will not gain acceptance if they cannot penetrate the culture of circuit design—if they do not become accessible to their users. This necessitates coordination between device creators and device users in matching physics with function, as per Morton’s vision of 1965.

Another possible trend is a further extrapolation of Morton’s functional device concept and of the desirability of device miniaturization. The inspiration is taken from biological systems and biochemical reactions and interactions, which possess the desired characteristics of being based on tunneling and, therefore are very fast; of being intrinsically multifunctional; and of possessing, in some instances, the potential to implement a *local learning function*. At least two approaches have been witnessed on this front. First, simple tunneling processes have been incorporated into otherwise standard bipolar transistors [42] and MOS transistors [43]. In the bipolar transistor, the large ratio of electron tunneling transmission to hole transmission (because of the large effective mass disparity in compound semiconductors) yields improved injected efficiency of homojunction BJTs with a more easily fabricated layer structure than traditional heterojunction BJTs. In the MOS case, tunneling into a floating gate structure enables functionality analogous to learning. A second approach, more revolutionary and therefore less mature in approach, involves developing devices that perform some of the basic electronic functions using human-engineered molecules, a field known as (bio)molecular electronics. Both approaches use tunneling, as a consequence of miniaturization and as a means for expanding and exploring new functionalities.

UHF RECEIVERS

CHARLES W. BOSTLAN
DENNIS G. SWEENEY
Virginia Tech

An ultra-high frequency (UHF) receiver receives radio signals with input frequencies between 300 MHz and 3000 MHz. Radio waves in this part of the spectrum usually follow line-of-sight paths and penetrate buildings well. The natural radio environment is significantly quieter at UHF than at lower frequencies, making receiver noise performance more important. UHF antennas are small enough to be attractive for vehicular and handheld applications, but are not as directional or expensive as microwave antennas. Many radio services use UHF, including land mobile, TV broadcasting, and point-to-point. The point-to-point users are rapidly disappearing, and the greatest current interest in receiver design centers on cellular and personal communications system (PCS) applications in bands from 800 MHz to 950 MHz and 1850 MHz to 1990 MHz.

UHF receiver design was once a specialized field incorporating parts of the lumped-circuit techniques of radio-frequency (RF) engineering and the guided-wave approach of microwave engineering. Recent trends in circuit integration and packaging have extended RF techniques to the UHF region, and there are few qualitative distinctions between UHF receivers and those for lower frequencies. UHF receivers differ from their lower-frequency counterparts primarily by having better noise performance and by being built from components that perform well at UHF.

1. UHF RECEIVER OPERATION

1.1. The Role of a UHF Receiver in a Radio Communications System

Radiofrequency communications systems exist to transfer information from one source to a remote location. Figure 1 is a system block diagram of a simple radio communications system. A transmitter takes information from an

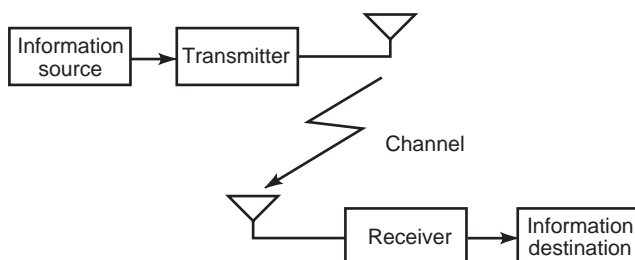

Figure 1. Block diagram of a UHF communications system showing the role of the receiver.

external source, modulates it onto an RF carrier, and radiates it into a radio channel. The radiated signal grows weaker with distance from the transmitter. The receiver must recover the transmitted signal, separate it from the noise and interference that are present in the radio channel, and recover the transmitted information at some level of fidelity. This fidelity is measured by a signal-to-noise ratio for analog information or by a bit error rate for digital information.

1.2. Receiver Characteristics

The following characteristics describe receiver performance:

- *Sensitivity* is a measure of the weakest signal that the receiver can detect. The ideal receiver should be capable of detecting very small signals. Internally generated noise and antenna performance are the primary factors limiting the sensitivity of UHF receivers.
- *Selectivity* describes the receiver's ability to recover the desired signal while rejecting others from transmitters operating on nearby frequencies.
- *Stability* is the receiver's ability to remain tuned to the desired frequency over time with variations in supply voltage, temperature, and vibration, among others.
- *Dynamic range* is a measure of the difference in power between the strongest signal and the weakest signal that the receiver can receive.
- *Image rejection* measures the receiver's ability to reject images, incoming signals at unwanted frequencies that can interfere with a wanted signal.
- *Spurious response protection* measures the receiver's freedom from internally generated unwanted signals that interfere with the desired signal.

1.3. The Superheterodyne Architecture

The most widely used receiver topology is the superheterodyne or superhet. A block diagram of this topology is shown in Fig. 2. It provides amplification both at the incoming radiofrequency and at one or more intermediate

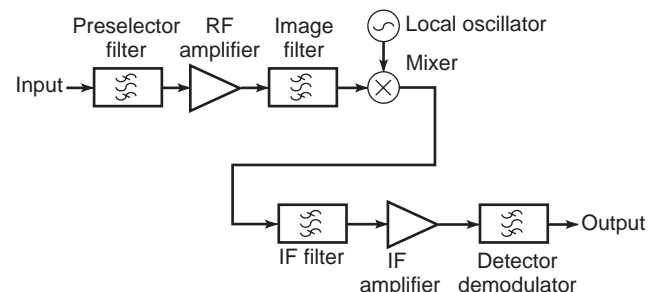

Figure 2. The architecture of a superheterodyne receiver.

THIN FILMS

KIYOTAKA WASA
Yokohama City University
KENTARO SETSUNE
Matsushita Electric
Industrial Co.

1. THIN FILM MATERIALS

Thin film ferroelectric materials and hexagonal piezoelectric materials are essential for fabrication of electronic and/or photonic devices. Historically ferroelectric materials were discovered in a form of bulk single crystals of Rochelle salt in 1920. Since then, a number of ferroelectric materials, including $\text{NH}_4\text{H}_2\text{PO}_4$ (ADP), KH_2PO_4 (KDP), LiNbO_3 (LN), LiTaO_3 (LT), BaTiO_3 (BT), PbTiO_3 (PT), and $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$ (PZT), were developed in a form of bulk single crystals or bulk ceramics. Among these ferroelectric materials, perovskite (ABO_3) with oxygen octahedral structures has become an important ferroelectric material.

Ferroelectric materials are dielectrics that have a spontaneous polarization with nonlinear hysteretic properties and show several unique properties including high dielectric permittivity, high piezoelectricity, high pyroelectricity, and high electrooptic characteristics.

Bulk ferroelectric materials were widely used to manufacture discrete electronic components including ceramics capacitors, bandpass filters, resonators, ultrasonic transducers, and positive temperature coefficient (PTC) thermistors. Novel ferroelectric materials such as optical transparent ferroelectric $(\text{Pb},\text{La})(\text{Zr},\text{Ti})\text{O}_3$ (PLZT) ceramics were developed by Haertling and Land in 1971. A high-speed electrooptical shutter was realized using hot-pressed transparent PLZT ceramics. The bulk-type ferroelectric devices, however, could not meet recent requirements of miniaturization and/or integration with Si and/or GaAs semiconductive devices.

Thin film ferroelectric materials have a high potential for miniaturization and/or integration with the semiconductive devices. Thin films are also important to the understanding of ferroelectricity. Thin films are commonly fabricated by depositing individual atoms on a substrate. The film thickness is typically less than several micrometers. The structure of thin films is essentially homogeneous on an atomic scale. Thin films exhibit the following useful aspects including thin film effects:

1. Unique material properties resulting from the atomic scale growth
2. Size effects at ultrathin films
3. Unique functional properties at layered structure including human-made superlattice and tailored ferroelectric materials

Polycrystal and/or single-crystal thin films of ferroelectric/piezoelectric materials are used for the fabri-

cation of thin film devices. The polycrystal thin films are commonly deposited on a noncrystalline substrate such as fused quartz, borosilicate glass, and passivated Si substrates. The single-crystal thin films are heteroepitaxially grown on a foreign single-crystal substrate such as sapphire, MgO , SrTiO_3 (ST), LaAlO_3 , and YSZ substrates. At the early stage, the ferroelectric thin films were considered to be a simple substitution of bulk dielectric materials by thin films, such as a fabrication of thin film discrete capacitor for an electronics system.

Since the 1970s, several kinds of thin film ferroelectric and/or piezoelectric films were developed for a fabrication of bulk acoustic wave (BAW) devices, surface acoustic wave (SAW) devices, thin film ferroelectric memory, acoustooptical (AO) devices, and electrooptical (EO) devices. Among these thin films, piezoelectric ZnO and CdS thin films of hexagonal structure were extensively studied for a fabrication of the thin film SAW devices and the thin film AO devices, although the piezoelectric hexagonal ZnO and/or CdS were not ferroelectric materials. The technology for a production of ZnO thin film SAW devices was established, and the ZnO thin film SAW devices are used in practice. Since the 1980s, much attention has been paid to the application of ferroelectric thin films such as PZT and $(\text{Pb},\text{La})\text{TiO}_3$ (PLT) to thin film optical waveguide devices, an integrated pyroelectric sensor, a memory capacitor of high dielectric permittivity at megabit dynamic random access memory (DRAM), the ferroelectric random access memory (FERAM) combined with Si and/or GaAs integrated circuits, and a thin film microactuator. Two-dimensional integrated optical devices are made by electrooptic thin films. The multilayer structures tailor SAW materials with designed acoustic velocity, electromechanical coupling, and temperature stability. The electromechanical coupling for the generation of SAW is enhanced at the layered structures. High electromechanical coupling with zero temperature coefficient of delay time (TCD) could be achieved at the layered structure of ZnO/glass substrate. The electrostrictive properties are also of interest for making a microelectromechanical system (MEMS). A MEMS provides integration of sensors, actuators, and electronic circuits in a single chip. Table 1 shows typical thin film ferroelectric materials and their devices including hexagonal piezoelectric thin films [1–3].

2. THIN FILM FABRICATION

Thin films of ferroelectric materials are fabricated by a thin film deposition process including physical vapor deposition (PVD), chemical vapor deposition (CVD), and chemical solvent deposition, as shown in Table 2.

Thin films of ferroelectric materials were first fabricated by Feldman in 1955 for BaTiO_3 by PVD using a simple vacuum evaporation. In the 1960s, others tried to deposit thin films of PbTiO_3 by cylindrical magnetron sputtering. The controlled deposition of the perovskite

ferroelectric materials of ABO₃ and A(B1,B2)O₃ structure could not be attained because of their complex chemical composition. Since the middle of the 1970s, rapid progress has been observed in the thin film deposition processes, including planar magnetron sputtering, molecular beam epitaxy (MBE), and metal organic chemical vapor deposi-

tion (MOCVD). After the discovery of high-Tc superconductors of layered perovskite in 1986, rapid progress has been seen in the development of the deposition process for complex perovskite with atomically controlled crystal structure using sputtering, MBE, laser ablation, and MOCVD.

Table 2. Thin Film Deposition Process

Classification	Deposition System	Source Materials	Film Structure
<i>Vapor phase deposition</i>			
PVD	Thermal evaporation	Individual metals Individual oxides Multisource	Uniaxial crystal by epitaxial growth (poly/single)
	EB crucible MBE		
	Laser ablation	FE compounds Individual oxides Multitarget	Tailoring FE by layer-by-layer deposition <i>In situ</i> poling
CVD	Sputtering	FE compounds Individual metals Individual oxides Multitarget	
	Low-pressure CVD MOCVD Plasma-assisted MOCVD	Individual halide Metal organic gas	Uniaxial crystal by epitaxial growth (poly/single) <i>In situ</i> poling
	<i>Chemical solvent deposition</i>		
	MOD Sol-gel deposition	Individual Metal organic gas	Multiaxial (polycrystal) <i>Ex situ</i> poling (porous)

Typical configuration of deposition systems are shown in Fig. 1. A conventional thermal evaporation process provides inhomogeneous and nonstoichiometric thin films. A multisource MBE system is used for the deposition. The laser ablation is carried out by the direct evaporation of source ferroelectric materials resulting from the irradiation of high-intensity pulsed excimer laser. The mechanism of laser ablation includes photo and thermal evaporation. The pulsed evaporation by high-intensity laser improves the inhomogeneity and/or nonstoichiometry, although the laser ablation includes the thermal evaporation process. The phenomenon of sputtering consists of a nonthermal evaporation. The sputtering process essentially provides homogeneous and stoichiometric thin films of complex ferroelectric materials because the sputtering mechanism consists of removing source materials (target) on an atomic scale by an impact of energetic ions through the momentum transfer mechanism. Multitarget magnetron sputtering is used for the deposition of layered structures and/or human-made superlattices. The sputtering process has a high potential for the fabrication of complex ferroelectric thin films. In the plasma-assisted MOCVD, energetic electron in gas plasma enhances the chemical reaction. At present, these thin film processes provide the thin films of perovskite with an accuracy of 1 nm corresponding to two or three of their crystal units. The chemical solvent deposition provides a simple fabrication process. However, the deposited thin films are essentially porous because the growth process is governed by

a conventional thick film technology including dipping and/or spinning of sol-gel precursor solution followed by annealing for sintering.

The deposition, chiefly by sputtering, of transducer quality ZnO thin films has been studied since the 1970s. The technology to fabricate ZnO thin films has already been established. The *c*-axis-oriented polycrystalline thin films are deposited on a glass substrate by direct sputtering from the ZnO target. The *c*-axis orientation on the glass substrate is quite reasonable because the film growth of a hexagonal structure is governed by Bravis's empirical law for crystal growth, where the most densely packed plane (*c*-plane) will be the most preferable surface of crystal growth. Single-crystal ZnO thin films are epitaxially grown on a sapphire substrate. The *a*-axis-oriented ZnO thin films are epitaxially grown on *R*-plane sapphire.

It is particularly important to understand the structure of thin films because it can have a profound influence on the operation of the thin film devices.

Thin films of polycrystalline phase comprise a column geometry with an interfacial layer between the thin films and a substrate. Low dielectric permittivity of the interfacial layer apparently reduces the permittivity of the ferroelectric thin films and/or increases a coercive field (extrinsic thickness effect). The decrease of dielectric permittivity for ferroelectric thin films with the decrease of their film thickness is also governed by the depolarization phenomenon (intrinsic thickness effect).

Figure 1. Typical configuration of thin film deposition systems: (a) multisource MBE, (b) laser ablation, (c) multitarget sputtering, (d) plasma-assisted MOCVD.

The epitaxial ferroelectric thin films show different microstructures depending on the degree of lattice match between the thin films and substrates. It is generally believed that, under an excellent lattice match, the thin films such as PT on ST show a single domain; under a poor lattice match for both *a*- and *c*-axes, the thin films such as PT on MgO show a multi-axial crystal structure; and under a fairly good lattice match, the thin films such as PT on KTaO₃ (KTO) constitute a periodic domain structure. These microstructures are grown primarily to minimize the total energy of the heterostructure. The phenomena are understood by linear-elasticity theory and a Landau–Ginzburg–Devonshire type phenomenological theory.

The actual epitaxial thin films of ferroelectric materials commonly constitute inhomogeneous microstructures including an interfacial layer that resembles polycrystalline thin films on a glass substrate as a result of the inhomogeneous nucleation at the initial stage of film growth. A selection of substrate materials is important for the control of thin film growth. Typical structural properties of substrates are shown in Table 3 [4–6].

3. THIN FILM DEVICES

3.1. Thin Film SAW Devices

The use of thin film SAW devices is an example of a successful application using piezoelectricity of hexagonal thin films and perovskite ferroelectric thin films. In the quasistatic approximation, the acoustic fields associated with plane waves in a piezoelectric medium are obtained by solving the stiffened Christoffel equation. In the case of a half-space medium with a free boundary surface, the boundary conditions must be satisfied and the mechanical stress and electric displacement must be calculated from the piezoelectric constitutive equations. These procedures give the solution as a SAW, which acoustic vibration energy concentrates near the surface of elastic solid materials. The Rayleigh wave and Love wave are obtained as the typical solutions of SAWs. The particle displacement of the former is in the sagittal plane, which is

Figure 2. Interdigital transducer formed on the surface of the piezoelectric substrate.

perpendicular to the surface and parallel to the wave-propagation direction, and that of the latter is parallel to the surface and perpendicular to the direction of propagation. The SAW makes possible acoustoelectronic devices including the SAW filter for cellular phone/PCS/pager.

3.1.1. Generation of SAWs. The SAW modes can be generated by an interdigital transducer (IDT) formed on the surface of the piezoelectric substrate shown in Fig. 2. In the bulk SAW devices, bulk single crystals such as the LiNbO₃ and/or LiTaO₃ are adopted as the piezoelectric substrate. Whereas in the thin film SAW devices, a layered structure consisting of a piezoelectric thin film on the nonpiezoelectric medium is used as the piezoelectric substrate. Figure 3 shows the calculated result of an effective electromechanical coupling constant k^2 for four types of electrode configurations of a *c*-axis-oriented ZnO film on fused quartz. These electrode configurations for a thin film SAW transducer are also illustrated in Fig. 7. Each configuration consists of an IDT with or without a counter electrode. The value of k^2 is determined by the relation $k^2 = \Delta V_p / V_p$ where ΔV_p is the variation of SAW phase velocity V_p by the short condition of the surface electric field. The k^2 is simply evaluated by the equation $k^2 = \pi\omega_0 C_T / 4NG_a$, the inline model of Smith’s equivalent circuit model for electromechanical bulk wave, where ω_0 ,

Figure 3. Calculated result of an effective electromechanical coupling constant k^2 for each configuration in the case of c -axis-oriented ZnO film on fused quartz. Four types of thin film electrode configurations are illustrated [7].

C_T , G_a , and N are the synchronous frequency, capacitance, radiation conductance, and number of finger pairs of IDT, respectively. The inline model (the major electric field component is parallel to the surface) becomes almost equal to the crossed-field model (the major electric field component is perpendicular to the surface) under the rough condition of $k^2 N > 1$. Figure 3 shows that k^2 varies with the ZnO film thickness, and the variations show a double-peaked character for the IDT structures including the counter electrodes. Note that the k^2 for thin films is higher than the bulk value at optimum film thickness.

3.1.2. Temperature Stability. SAW-layered structures have flexibility in that substrate materials can be chosen to adjust the temperature coefficient of a center frequency (TCF) and a delay time (TCD). The temperature stability of TCF or TCD is given by the equation, $(1/f)(dt/dT) = (1/t)(dt/dT) = (1/v)(dv/dT) - \beta$, where β denotes the thermal expansion coefficient of the substrate. The tendency of the phase velocity change $(1/v)(dv/dT)$ varies with the layered film thickness and elastic properties of the substrate materials. A suitable film thickness and a pertinent selection of substrate materials result in a zero TCD. Figure 4(a) shows one example of such a temperature deviation of the center frequency of the SAW IDT, which consists of the ZnO thin film, the SiO₂ or fused quartz layer, and the Si substrate. In this structure, the TCF of ZnO has a negative value of about -30 ppm/°C, and that of fused quartz has a positive value of $+60$ ppm/°C. These opposite values cancel the TCF while controlling the thickness of the SiO₂-layered film. Another example is shown in Fig. 4(b). Here the borosilicate-glass substrate can control TCF by controlling the composition ratio of the elements added to the glass.

3.1.3. SAW in Layered Media. The Rayleigh wave and Love wave are the solutions for a half-space medium with a free boundary surface. In layered structures, which

(a)

(b)

Figure 4. Temperature deviation of the center frequency of the SAW IDT constructed by the ZnO thin film: (a) the SiO₂ or fused quartz layer and the Si substrate; (b) the borosilicate-glass substrate [8].

include the thin plate rigidly bonded to the half-space (or substrate) having different material properties, the solutions for propagating waves must satisfy the appropriate wave equation in the layer and in the substrate as well as the boundary conditions imposed by the interface and the free surface. We know that fundamental and higher order modes of both Rayleigh and Love waves can propagate when the bulk shear wave velocity of the layer is lower than that of the substrate. This condition corresponds to that of the heavier and less stiff layer loads on

the substrate and will tend to confine the propagation energy to the layer. In this case, the propagating wave nodes are regarded as the modified plate modes. Sezawa discovered that a second fundamental mode may also exist in layered media. The Rayleigh modes and Sezawa modes correspond to symmetric and antisymmetric modes of a free plate modified by the contact of the surface with the substrate. In addition to these, the layer on an infinite half-space is open on one side, and there is a possibility of radiation or energy leakage out of the layer into the half-space. This condition gives the leaky wave solution for SAW.

The particle displacement of the SAW in the sagittal plane degrades with the depth from the surface. Also in the case of the layered substrate, almost the same situation exists in the half-space substrate. However, the degradation of that area in or near the top layer is different from the monotonous degradation of the zeroth Rayleigh mode. The amplitude distribution of the particle displacement is calculated for each propagating mode. Figure 5 shows the depth profiles of the particle displacement in the sagittal plane for the fundamental mode and higher four modes of the Rayleigh-type wave. More complex profiles and deeper penetration are shown for the particle displacement of higher order modes. Moreover, Fig. 5 shows that the higher order modes have a large displacement component in the substrate. So, it can be understood qualitatively that the higher order modes have a higher phase velocity because the phase velocity of the substrate is higher than that of the layer.

In Fig. 6, the solid lines and broken lines show the phase velocity V_p and the effective coupling coefficient k^2 of the Rayleigh-type and Love-type wave modes as a function of h/λ , respectively, where h is the layer thickness. These numerical results were obtained for the SAW directed to [1000] ZnO axes in the layered structure with the ZnO layer on the R -plane sapphire substrate. The first mode of the Rayleigh-type (zero Sezawa mode) shows an exceedingly large maximum value of k^2 with very high phase velocity at relatively small h/λ . These computer solutions were experimentally confirmed. For higher Rayleigh-type

Figure 5. Depth profiles of the particle displacement in the sagittal plane for the fundamental mode and higher four modes of the Rayleigh-type wave.

Figure 6. Rayleigh-type and Love-type wave mode solutions as a function of h/λ on the [1000] direction of the single-crystal (11 $\bar{2}$ 0) ZnO thin film epitaxially grown on the (01 $\bar{1}$ 2) sapphire surface. Solid lines and broken lines show the phase velocity V_p and the effective coupling coefficient k^2 [9].

modes, responses were still observed above the mode cutoff frequency as leaky mode responses.

3.1.4. Thin Film SAW Filters. Thin film SAW devices are constructed by the thin film IDTs on nonpiezoelectric substrates, by high-frequency propagation of the higher order modes of layered SAW, the substrate selected for the temperature stability, and so on. These distinguishing characteristics can realize the high performance of bandpass filters, resonators, delay lines, convolvers, integrated devices, and acoustooptic devices. The video intermediate frequency (VIF) filters for color TV sets were the first thin film mass-production devices. The frequency range of a VIF filter of 50–60 MHz is low enough for the SAW propagation loss of polycrystalline piezoelectric thin films such as c -axis-oriented ZnO films on a borosilicate-glass substrate. The thin film SAW filter shows excellent long-term stability. The long-term drift of the center frequency is less than 100 ppm after 1000 hours of exposure to 125°C in the air. The long-term stability of the ZnO thin film SAW filter is higher than that of bulk single-crystal LiNbO₃ SAW filters because of the absence of subsurface damage inflicted during sawing and polishing, which is unavoidable for bulk SAW devices. Figure 7 shows one example of the configuration of SAW VIF filters with two normal output IDTs and one apodized input IDT.

Another example is the high-frequency filter of epitaxially grown single-crystal thin film, which has low propagation loss of higher order Rayleigh wave modes in the gigahertz range. The ZnO single-crystal film on sapphire substrate is the typical construction of devices that

Figure 7. IDT configuration of SAW VIF filters with two normal output IDTs and one apodized input IDT on the layered substrate.

provide 4.37 GHz filters with a phase velocity of 5327 m/s and an insertion loss of 16 dB by 0.27 μm thick ZnO film, 3-IDT of 50 nm thick Al electrodes, and third-order response of double electrode-type IDTs. These excellent properties of thin film SAW filters are able to provide the high performance of information communication systems [7–17].

3.2. Ferroelectric Nonvolatile Memory

The basic operation of ferroelectric nonvolatile memory is switching of polarization states in a ferroelectric ABO_3 structure. Figure 8 shows a typical configuration and

Figure 9. Schematic circuit of 256-bit FESRAM (Ramtron Corp. [18]).

schematic circuit of ferroelectric nonvolatile memories, dynamic random access memory (FEDRAM). The FEDRAM resembles a conventional dynamic random access memory (DRAM). The memory capacitor C_s of DRAM is replaced by a ferroelectric thin film capacitor. The C_s is in series with a MOS (metal-oxide-semiconductor) transistor whose source is connected to the bit line, the gate to the word line, and the drain to the pulsed 5 V common plate. In the FEDRAM, the polarization of the ferroelectric thin films switches to the opposite polarity on application of an electrical field higher than the coercive force when the MOS transistor is turned on by the appropriate voltage on

the gate. In the hysteresis loop of memory capacitor C_s , the position *A* is taken to be a bit 1 state and *B*, a bit 2 state. The switching signal is detected by the voltage change at the bit line V_b . The V_b is given by $V_b = Q_s/C_b$, where Q_s denotes change of charge at switching on the capacitor C_s and C_b denotes the storage capacitor at the bit line. The Q_s is given by $Q_s = 2P_r$, where P_r denotes remanent polarization for ideal ferroelectric thin films having a symmetric hysteresis loop. For memory capacitors, PZT thin films are widely used. The P_r is 20–30 $\mu\text{C}/\text{cm}^2$ for typical PZT thin films. The value of Q_s for each memory cell is 400–600 fC for a cell area of $1 \mu\text{m}^2$, which is enough for the switch

memory operation because the minimum detectable value of Q_s for each cell is 20–30 fC at the conventional DRAM. The switching speed is essentially governed by the switching time of polarization reversal. The switching time is 1 ns for typical ferroelectric materials. The FEDRAM has some definite advantages, including a permanent memory and radiation hard characteristics. However, there are disadvantages of switch fatigue resulting from domain switching. Historically, the ferroelectric memory was proposed in the first part of the 1970s and first developed in 1987 by Ramtron Corp., Colorado Springs, and Krysails Corp., Albuquerque. The first developed ferroelectric

Figure 11. Schematic configuration of a linear array IR sensor for (a) a smart air conditioner and (b) its fabrication process [20].

memories look like the six-transistor static random access memory (SRAM) except that they include an additional pair of ferroelectric thin film capacitors, as shown in Fig. 9. Presently, the FEDRAM with a single transistor, where the ferroelectric thin films make a conventional DRAM nonvolatile, has been extensively studied to improve long-term stability. The ferroelectric thin films placed in the gate area of a MOS transistor provide another type of ferroelectric memory—the ferroelectric memory field effect transistor (FEMFET). Depending on the polarization of the gate materials, the source-to-drain current is increased or decreased significantly. The 1 or 0 state is detected by monitoring the source-to-drain current without switching the remanent polarization. This type of switch gives a nondestructive read out. This type of memory is under research because the interface control between the ferroelectric thin film and semiconductor is not completed.

Apart from the FEDRAM, the high dielectric permittivity of ferroelectric films is used for the local capacitor in highcount DRAM to reduce the area of the memory capacitor and/or eliminate the complex trenching and/or corrugation structures for the increased capacitive area. The high permittivity of the ferroelectric thin films achieves the flat structure of the memory cell. In the mega-/gigabit DRAM, the requirement for ferroelectric thin films is a permittivity of 200–2,000 at a film thickness of 100 nm

Figure 12. Cross-sectional view of thin film optical channel waveguide: (a) raised-strip type, (b) ridge type, (c) embedded type, and (d) strip-loaded type. n_1, n_2, n_3, n_4 are refractive index of waveguide, substrate, environment, and loaded strip, respectively.

without remanent polarization. The ferroelectric thin films should be used above their Curie temperature. If ferroelectric thin films are used, their operating coercive field should be large [18,19].

3.3. Thin Film Pyroelectric Infrared Detectors

Ferroelectric materials have been used for making pyroelectric infrared detectors by measuring the pyroelectric

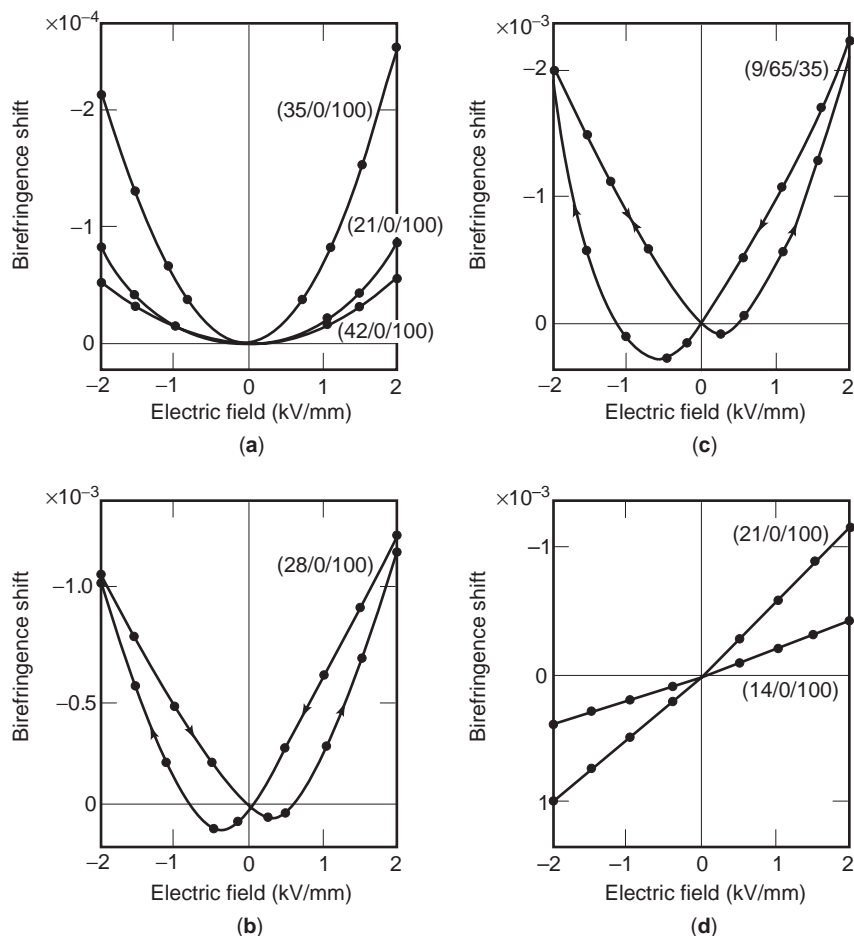

Figure 13. The effective birefringence shift as a function of transverse electric field for PLZT thin film of 0.4 mm in thickness [22].

current because they exhibit a large pyroelectric effect. The pyroelectric effect is described by the pyroelectric coefficient γ , which relates the change of polarization to the change in temperature. Pyroelectric current i_p will be detected by the temperature change of the detector materials generated by absorbed infrared radiation. The i_p is given by $i_p = \gamma(dT/dt)$. Bulk ferroelectric single crystals TGS (triglycine-sulphate) and LT, ferroelectric polymer PVDF (polyvinyl-di-fluoride), and ferroelectric ceramics PT and PbZrO_3 (PZ) are widely used for making pyroelectric infrared detectors. The pyroelectric materials are evaluated by figures of merit; $F_1 = \gamma/C_v$, $F_v = \gamma/C_v \cdot \varepsilon$, $F_M = \gamma/C_v(\varepsilon \cdot \tan \delta)^{1/2}$, where C_v denotes a volume-specific heat, ε denotes a dielectric constant, and F_1 , F_v , and F_m denote the figure-of-merit related to a current response, an output voltage response, and a detectivity, respectively. Perovskite thin films of PT and/or PLT are epitaxially grown on a Pt-metallized MgO substrate. The MgO substrate is removed after deposition of perovskite thin films. The as-deposited thin films show a highly oriented structure, which results in excellent pyroelectric properties without poling treatment after deposition. The single-domain structure with a low dielectric constant in the c -axis direction improves the figure-of-merit of conventional ceramic pyroelectric materials. Figure 10 shows the typical pyroelectric properties of bulk and thin film PLT. The integrated infrared sensor array shown in Fig. 11 was created using thin film infrared detector technology. The sensor array, manufactured by Matsushita Elec. Ind., Osaka, Japan, is used for a room air conditioner. The array detects the position and number of persons and their body temperatures to create a comfortable space [20,21].

3.4. Thin Film Optical Waveguide Devices

Thin film optical waveguide devices commonly consist of a sandwich structure of a thin film waveguide and a substrate. The refractive index of the thin film waveguide is larger than the substrate value so that a guided light beam propagates in the thin film waveguide. The direction of a propagated light beam is controlled by the channel waveguide shown in Fig. 12. The waveguide thin films comprise functional materials including EO or AO materials such as LN, PLZT, and ZnO. The PLZT thin films exhibit a linear EO effect or a quadratic EO effect depending on their composition. Typical EO properties of PLZT thin films are shown in Fig. 13. The birefringence shift $\delta\Delta n$ is several times larger than for conventional LN crystals. The linear EO coefficient r is given by the relation $\delta\Delta n = -\frac{1}{2} \times n^3 r E$ and the quadratic E/O coefficient R is given by the relation $\delta\Delta n = -\frac{1}{2} \times n^3 R E^2$, where n is the refractive index and E is the applied electric field. The value of R is $0.6 \times 10^{-16} (\text{m/V})^2$ and r is $0.81 \times 10^{-10} \text{ m/V}$. The light beam is introduced using an optical coupler such as a prism, micrograting coupler, and microlens directly connected to the optical fiber. The thin film waveguide is fabricated by deposition of the functional thin films on a substrate followed by microfabrication. The surface treatment, such as doping of a foreign element on the functional crystal substrate (i.e., Ti doping on LN),

is also used for the fabrication of thin film waveguides. Typical thin film waveguide devices are shown in Figs. 14–16.

Figure 14(a) shows the Mach–Zehnder interferometric modulator. The input light signal is equally divided into two waves by the branching guide and fed through two parallel arms of guide. In each arm, the waves are electrooptically modulated by the applied field. The intensity of guided light of TE_0 mode is strongly modulated because of a large EO effect. A typical sinusoidal pattern is observed as the applied electrical field is varied as shown in Fig. 14(b). The Bragg diffraction switches comprise PLZT epitaxial thin films on sapphire for the EO switch and ZnO epitaxial thin films on sapphire for the AO switch, respectively. The guided light, chiefly TE_0 mode, is diffracted as a result of a periodic grating with refractive index by applying a periodical electrical field for the EO switch using an interdigital electrode and by applying SAW for the AO switch using an interdigital SAW transducer. The angle of diffraction is governed by the Bragg diffraction, and the diffraction angle 2θ is given by $2\theta = \lambda_0/n\lambda_s$, where θ denotes the Bragg angle, λ_0 denotes

Figure 14. (a) Configuration of a thin film Mach–Zehnder interferometer using PLZT thin film on sapphire and (b) the variation of output light intensity with applied voltage [23].

Figure 15. (a) Configuration of thin film AO Bragg deflector using ZnO thin film waveguide on sapphire and (b) a deflected light beam as a function of applied frequency at IDT driven by the first-order Sezawa mode of SAW [24].

the wavelength of light, n denotes the effective refractive index of the waveguide, and λ_s denotes the wavelength of the interdigital electrode. Figure 15 shows a typical operation of the ZnO thin film AO deflector. The Bragg deflector is driven by the first-order mode of SAW (Sezawa mode) with a phase velocity of 5700 m/s. The IDT is designed for 2 GHz operation. The TE_0 mode of a guided He–Ne laser beam is effectively deflected by the high-frequency SAW.

The total internal reflection (TIR) switch, which was first proposed by C. S. Tsai, is composed of a pair of crossed channel PLZT (20/0/100) waveguides, quadratic EO, with four terminals on sapphire as shown in Fig. 16(a). The intersecting angle of the channel waveguide θ satisfies the relation, $\theta < 90 - \theta_c$, $\theta_c = 1/\sin(1 - \frac{1}{2}n^2RE^2)$, where θ_c denotes the critical angle of total reflection, R denotes the quadratic EO coefficient, and E denotes the electrical field at the crossed area. At the crossed area, a pair of control electrodes are deposited to apply a control electrical field. Figure 16(b) shows a typical operation of the PLZT TIR switch. The TE_0 mode of the guided He–Ne laser beam directly coupled from port 1 propagates to port 3 without applying a control voltage, but the guided light is switched to port 4 as a result of the decreased refractive index at the interaction area under the application of control voltages. The switching voltage is less than 5 V because of the high EO coefficient of PLZT. The switching speed is expected to be as high as 100 GHz.

Thin film waveguide devices are flourishing. A number of promising devices are proposed for optical communication systems and integrated optical circuits, including optical computing [22–29].

 Kingdom

1. INTRODUCTION

The study of III-V compounds dates back to the dawn of semiconductor technology, when in 1952 Welker [1] suggested that gallium arsenide (GaAs) showed potential as a semiconductor material. The key aspect of this class of

materials that makes them of particular interest is their properties, which make them particularly suitable for high-frequency electronic and photonic devices. In the case of GaAs the electron velocity of bulk material, which determines the frequency limits of devices, is significantly higher than that found in silicon (Si). Furthermore, the low field mobility of electrons in many III-V materials is higher than that of Si. Diodes fabricated from III-V materials have demonstrated cutoff frequencies of several terahertz; transistors have demonstrated cutoff frequencies (f_T) higher than 300 GHz [2] and monolithic microwave integrated circuits (MMICs) operating above 200 GHz [3]. This has led to the use of GaAs and InP in a wide variety of high-frequency semiconductor devices operating in applications as diverse as low-noise amplifiers, mixers, power amplifiers, RF switches, and oscillators at frequencies up to 240 GHz. The wide operating temperature range of III-V semiconductors, typically from -200 to 300°C, coupled with superior radiation hardness compared to Si, led to GaAs and InP becoming key materials for space and defence requirements. In more recent years the photonic properties of III-V materials, arising from their direct bandgap energy band structures, have been extensively exploited for solid-state lasers, light-emitting diodes, photodetectors, and optical modulators, with the potential for fully integrated optoelectronic integrated circuits. To date these properties are unrivalled by Si, which is an indirect bandgap semiconductor.

Although many III-V materials are routinely used in microwave and optoelectronic semiconductor devices today, it wasn't until the early 1970s that the first semiconductor devices became widely available, and even then it was restricted to two terminal devices and simple transistors. The relatively slow progress in developing commercially viable technologies was partly due to the challenging problems in establishing high-quality material growth and the development of processing techniques that allow reliable devices to be fabricated. The key step to achieving volume production and widespread use of cost-effective devices is the availability of larger-diameter wafers, from which the semiconductor devices are fabricated. Early work was restricted to very small samples (parts of wafers) or small-diameter wafers of 2 in. or less. Gradually, high-quality 3- and 4-in.-diameter wafers became available and discrete devices and integrated circuits were introduced for military and commercial applications. Significant advances since the early 1980s have led to the introduction of 6-in. (150-mm) very-high-quality GaAs substrates and epitaxy suitable for high-volume production of semiconductor devices. Similarly, other materials such as InP are now well established and production is supported by 4-in.-diameter substrates.

The advent of high-quality reproducible epitaxy, provided by molecular-beam epitaxy (MBE) and organic metal vapor-phase epitaxy (OMVPE, MOCVD), led to a shift in interest from bulk III-V devices to heterostructure semiconductor devices, based on bandgap engineering, which allow higher performance to be obtained. In particular, the development of ternary and quaternary compounds, such as AlGaAs, GaInAs, and GaInAsP, were key steps forward for new transistor technologies,

Table 1. III-V Semiconductor Materials

Compound Type	III-V Material
Binary	BAs, BP, AlSb, BN, GaSb, AlAs, AlP, GaAs, InSb, GaP, InAs, InP, AlN, GaN
Ternary	AlGaAs, AlGaIn, InGaAs, InGaP, GaAsP, InAsP, GaInSb, GaInAs
Quaternary	InAlGaAs, GaInAsP, InAlGaP, InAlGaSb, AlGaAsSb

high-electron-mobility transistors (HEMTs), heterojunction bipolar transistors (HBTs), and long wavelength optoelectronic devices. The exploitation of lattice-matched (usually to InP) and strained (usually to GaAs) crystal structures using these compounds is an essential element of today's III-V technology. More recently the use of material systems such as GaN/AlGaN for high-voltage, high-power-density transistors has led to increased interest in examining the growth on nonnative layers using epitaxy to create III-V active layers on SiC, sapphire, or more recently silicon substrates. Record performance power density levels are being achieved with GaN HEMTs, reporting over 30 W/mm gate periphery, compared with less than 1 W/mm from conventional MES-FETs and HEMTs [4].

In the mid-1980s GaAs integrated circuit technology was costly and reserved only for the most demanding system requirements. Contemporary III-V semiconductor device technology is able to provide microwave monolithic integrated circuits (MMICs) at a cost of less than 20 cents per square millimeter in some very high volumes, supporting a market approaching a billion die per annum. III-V transistor technology is the foundation of high-efficiency power amplifier and low-loss RF switch MMICs in today's cellular handsets. The advent of heterostructure technologies using Si, notably SiGe, which have demonstrated the potential for very fast devices, is likely to displace III-V in some very-high-volume RF and microwave applications.

This article aims to provide a basic introduction and an overview of contemporary III-V semiconductors. Many of the topics touched on in these pages are expanded in detail elsewhere in this encyclopedia, but the reader is encouraged to explore the wealth of material available in this exciting area of semiconductor technology.

2. III-V SEMICONDUCTOR MATERIAL PROPERTIES

III-V semiconductor materials are alloys formed from elements in group III and group V of the periodic table. They are grown as single crystals and as either binary, ternary, or quaternary alloys (Table 1).

2.1. Crystal Structure

All III-V semiconductors are alloys, and unlike the elemental semiconductors silicon (Si) and germanium (Ge), which exhibit diamond cubic crystal structures, generally crystallize in more complex structures. GaAs and InP have cubic zincblende structures (sphalerite structures), with a tetrahedral arrangement of the atoms, with each group III atom bonded to four group V atoms (Fig. 1). The tetrahedral structure is characteristic of directional covalent

bonding in semiconductors, with eight valence electrons per pair of atoms (in sp^3 -hybridized orbitals). In the case of GaAs and InP, unlike diamond cubic semiconductors, there is some charge transfer between the two types of atom giving rise to the partial ionic character of the bond. Generally speaking, these partly heteropolar bonds are stronger than homopolar bonds such as those found in Si. Heteropolar bonds also tend to be associated with lower amplitude lattice vibrations and wider energy bandgaps.

The properties of crystal structures, including their electrical behavior, vary according to the plane considered. The most commonly used method of defining planes in crystals is the use of Miller indices [5], which are obtained by determining the intercepts of each plane on the three Cartesian coordinates in terms of the lattice constant and then taking their reciprocals and reducing them to the smallest three integers having the same ratio (Fig. 2). The lattice parameter is usually denoted a , for sphalerite structures. The resulting Miller indices are expressed in parentheses (hkl). For example, a plane that intercepts the x axis on the negative side of the origin is (100) . Extensions of this notation allow for planes of equivalent symmetry, defined as $\{hkl\}$; for example, $\{100\}$ for cubic symmetry. Crystal direction is defined using the notation $\langle hkl \rangle$; for example, $\langle 100 \rangle$ for the equivalent set of directions $[100], [010], [001], [100], [010], [001]$. Crystal direction is used to define the orientation of wafers for the

Figure 1. Cubic zincblende (sphalerite) crystal structure of GaAs [based on diagram from S. M. Sze, *Physics of Semiconductor Devices*, Wiley-Interscience (1981)].

Figure 2. Miller indices [based on diagram from S. M. Sze, *Physics of Semiconductor Devices*, Wiley-Interscience (1981)].

fabrication purposes, since the electrical properties and chemical etching properties differ according to orientation. Notches or “flats” are created on the edge of wafers to precisely indicate the orientation of the wafer with respect to the crystal structure.

In the case of GaAs cleaved along the (111) plane, the surface consists of either Ga atoms, which have three bonds with the crystal or As atoms that have one bond with the crystal. In fact, the bonds between the nearest Ga and As atoms are in the $\langle 111 \rangle$ directions. Gallium nitride GaN has a wurtzite crystal structure, which has two lattice parameters a and c .

2.2. Energy Band Structure

The electronic and vibrational states in crystals are usually described in reciprocal space or k space. The smallest unit cell in reciprocal space is called the *first Brillouin zone*. The first Brillouin zone in cubic semiconductors is a truncated octahedron with symmetry points and lines denoted Γ , X , L , K , U ($K=U$), W , Δ , Λ , and Σ . A very good detailed description is given in Ref. 6. The Γ point at $k=0,0,0$ in Cartesian coordinates is the point of highest symmetry in the Brillouin zone.

The energy band theory of semiconductors assumes that the lattice features perfect translational symmetry, that one electron at a time is considered, and that the influence of all electrons is represented by the average over their wavefunctions. The Schrödinger equation for the one-electron case is used to define the functional dependence of energy $E(k)$ on the wavevector k for the various bands. This model is modified to form the Sommerfeld free-electron model by introducing the idea of effective mass. The nearly free-electron approximation provides a basis for developing energy band theory, and the origin of the energy bandgap between the valence and conduction bands. It also introduces the concept of effective mass, which is defined as the reciprocal of the curvature of the E - k diagram. The band structure for a semiconductor is calculated using the well-known $\mathbf{k}\cdot\mathbf{p}$ method [7]. The $\mathbf{k}\cdot\mathbf{p}$ representation results from the complete set of eigen functions that are obtained from the substitution of Bloch functions [6] in the one-electron Schrödinger equation. Spin-orbit interaction is also included in the full definition of the energy-wavevector relationship, which leads to a formulation based on a series of Hamiltonians.

Valence band maxima occur at the Γ point for semiconductors with tetrahedral structure. Many semiconductors with this structure, such as GaAs and InP, also have conduction band minima at this point. In GaAs and similar semiconductors, the conduction band structure close to Γ is essentially parabolic. The lowest conduction band minimum occurs at $k=0$ with further minima in the Δ $\langle 100 \rangle$ and Λ $\langle 111 \rangle$ directions. Other important conduction and minima occur at 0.31 and 0.52 eV above the first Γ minima for X and L . The valence band structure has heavy hole and light hole bands that degenerate at $k=0$ and spin-orbit split bands at 0.34 eV below this level. The energy band structure for GaAs are shown in Fig. 3. The direct energy bandgap is the difference in energy between the conduction band minima and the valence band maxima.

The energy band structure of other III-V semiconductors such as ternary and quaternary alloys is dependent on the mole fractions x and y (e.g., $\text{Al}_x\text{Ga}_{1-x}\text{As}$ and $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$). The direct energy bandgap $E_0(x,y)$ is usually expressed as a quadratic function of the mole fraction, characterized by the coefficient of the second-order term, also known as the “bowing parameter.” The

bowing parameter typically varies from 0.2 for AlGaAs to 0.88 for GaInP. Positive bowing parameters imply that the energy band bows downward. In contrast to the energy bandgap, the lattice constant of ternary alloy semiconductors generally varies linearly with composition. The lattice constant behavior for quaternary compounds is more complex with a higher-order dependence on the mole fractions. The energy bandgap, lattice constant, and other parameters of binary III-V semiconductors are shown in Table 2.

The energy bandgap is a very important parameter in device design. The temperature dependence of the bandgap E_g , which decreases with increasing temperature, is generally expressed as

$$E_g(T) = E_g(0) - \frac{\alpha T^2}{T + \beta}$$

where $E_g(0)$ is the energy bandgap at 0 K and α and β are constants; α typically lies in the range $2.5\text{--}6 \times 10^{-4}$ eV K⁻¹, β in the range 75–600. In the case of GaAs $E_g(0)$, α and β have the values 1.519, 5.405×10^{-4} eV/K, and 204.

The bandgap of ternary and quaternary III-V alloys depends on their composition and mole fraction [8]. The lattice matching criteria and compositional factors (Vegard's law) limits the range of mole fractions. In the case of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ and $\text{In}_x\text{Ga}_{1-x}\text{As}$ the bandgap dependence on mole fraction x (at 300 K) is described by simple quadratic equations:

$$\text{Al}_x\text{Ga}_{1-x}\text{As} : E_g = 1.424 + 1.429x - 0.14x^2 \text{ eV}$$

$$\text{In}_x\text{Ga}_{1-x}\text{As} : E_g = 1.425 - 1.501x + 0.436x^2 \text{ eV}$$

In the case of ternary compounds such as InAlGaAs, the energy bandgap is a function of two mole fractions x and y such that at 300 K:

$$\begin{aligned} \text{In}_{1-x-y}\text{Al}_x\text{Ga}_y\text{As} : E_g(x, y) = & 0.360 + 2.093x + 0.629y + 0.577x^2 \\ & + 0.436y^2 + 1.013xy - 2.0xy \\ & (1 - x - y)\text{eV} \end{aligned}$$

Additionally in the case of InAlGaAs, it is necessary to account for the lattice-matching condition $0.98x + y = 0.47$ and the compositional parameter z where $x = 0.48z$ and

$$E_g(z) = 0.76 + 0.49z + 0.20z^2 \text{ eV}$$

The range of mole fraction compositions in III-V ternary and quaternary semiconductors is limited by the requirement to achieve lattice matching to GaAs, InP or GaSb substrates. Figure 4 shows the variation in lattice parameter with energy bandgap for a range of III-V semiconductors [6]. The shaded regions show the range of parameters for quaternary alloys $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{Sb}_{1-y}$ and $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$.

Figure 4. Variation of lattice parameter with energy bandgap associated with a variety of III-V semiconductors at 300 K [Landolt-Bornstein, “Numerical Data and Functional Relationships” in *Science and Technology*, Vol. 22, *Semiconductors*, Subvol. A., O. Madelung and M. Schulz, eds., Springer, New York (1987)].

2.3. Crystal Growth

Ideally, integrated circuits require an insulating substrate to provide electrical isolation between the various circuit elements. Silicon does not have a native insulating or semiinsulating state, although the more recent silicon-on-insulator (SoI) technology facilitates a suitable substrate for silicon RF and microwave integrated circuits. On the other hand GaAs and many other III-V semiconductors can be grown as semiinsulating materials. The active (conductive) regions of the circuit are defined by combinations of epitaxy, ion implantation, and mesa etching (or isolation by ion implantation).

Active devices and integrated circuits are fabricated on semiinsulating wafers that may have epitaxial layers grown on the surface. Some devices such as diodes may use bulk doped substrates. The wafers are obtained by sawing single-crystal boules along predetermined planes. These single crystal boules may be grown using a variety of techniques, including horizontal or vertical Bridgman, Czochralski, liquid-encapsulated Czochralski (LEC), magnetic LEC, liquid-encapsulated Kryopoulos (LEK), horizontal gradient freeze, or by float-, horizontal- or vertical-zone melting [9]. Bridgman techniques are the most commonly used methods of growing semiinsulating substrates.

The horizontal Bridgman technique involves the progressive crystallization of a molten bar of material as it is passed through a carefully controlled temperature gradient. The semiconductor crystal is grown in a quartz boat using a seed crystal and the constituent materials. In the case of GaAs, the boat containing the GaAs seed crystal and Ga is placed in a sealed quartz ampoule, with an overpressure of arsenic produced from a separate charge of arsenic at the opposite end of the ampoule. A temperature difference is produced along the tube, ensuring that one end of the boat is at the melting point (1238°C for Ga) while the arsenic, at the other end of the ampoule, is maintained at 614°C. Stoichiometry is ensured by precise control of the temperature and by accurate weighing of the Ga and As. Precise temperature control is required, ensuring horizontal thermal uniformity within 0.1°C. Long crystals of up to 1 m in length have been produced using this method. Very-good-quality material is produced using the horizontal Bridgman technique, and dislocation densities approaching 10^5 m^{-3} have been achieved for low-chromium-doped GaAs. The horizontal gradient freeze technique is similar to the horizontal Bridgman method; the main difference is that the former method induces crystallization from the seed by carefully controlled cooling of a melt. Both the Bridgman and gradient freeze techniques tend to have Si as impurities in the finished GaAs crystal as a consequence of the quartz boat.

The Czochralski technique is often used to grow large-diameter boules, suitable for wafers up to 6-in. in diameter. This pulling method uses a chamber with heated walls to maintain the required arsenic pressure. The LEC method is the more common than the basic Czochralski approach since it avoids arsenic loss and atmospheric contamination. The LEC system consists of a growth chamber housing a vertical puller with a seed crystal at

the tip of a rotating tip, which, in the case of GaAs growth, is immersed in a Ga melt, which in turn is fed with arsenic vapor from a separately heated quartz ampoule of arsenic. The susceptor containing the crucible with the Ga melt is heated with an RF coil. A molten B_2O_3 encapsulating layer on the surface of a Ga melt is used to prevent arsenic loss and contamination. An inert gas, such as nitrogen, is used to pressurize the growth chamber to a level higher than the As partial pressure. The rotating seed crystal is slowly withdrawn vertically upward, and the GaAs crystal boule is grown from the melt. The magnetic LEC method is a variation on the LEC technique that reduces the thermal convection currents found in the conventional LEC approach, improving the boule's homogeneity.

2.4. Epitaxy and Implantation

Semiinsulating substrates, available as wafers usually in the region of 600 μm thickness, are usually used as the basis for fabricating devices and integrated circuits in most III-V technologies. The conductive regions required for the active devices are formed using either epitaxial layers grown on the surface of the semiinsulating substrate, or by selective ion implantation.

Ion implantation techniques, which are used widely in Si technology to define conductive regions, were used widely to form the channel regions for MESFETs, bipolar junction transistors, varactor diodes, and IMPATT diode structures, especially in earlier integrated circuit designs. This low-cost approach, which is still widely in use today, can provide devices with moderate low-field channel mobilities ($0.35 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$) associated with channel doping densities of up to the mid- 10^{23} m^{-3} range for GaAs. High doping densities of up to $2 \times 10^{25} \text{ m}^{-3}$ are achievable for ohmic contacts, but have very low mobilities ($0.03 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$) [10].

Ion implantation is achieved by bombarding the semiconductor substrate with high-energy ions of the required dopant species. These ions displace semiconductor atoms from their sites in the crystal structure. In order to avoid extreme surface damage, which would render the surface amorphous, GaAs substrates are usually heated to 150°C during implantation. Fabrication of FETs and diodes with ion-implanted active profiles usually requires several implantations with energies tailored to produce the required doping profile. Each implantation produces an almost Gaussian profile of implanted ions as a function of depth from the semiconductor surface. This allows a selective three-dimensional doping profile to be produced in planar devices with localized highly doped regions for ohmic contacts. The wafers require annealing at a temperature in the range 800–950°C (for GaAs) after implantation to reduce the damage (defects) caused by the high-energy ion bombardments and achieve activation of the donor species. The doping efficiency is a function of the type of ion, implantation dose, and annealing temperature. Annealing is performed using either annealing furnaces, infrared radiation from halogen lamps, pulsed laser beam or electron-beam, techniques. The surface of GaAs loses arsenic at temperatures above 600°C, and hence annealing is performed either under arsenic overpressure

(“capless” annealing) or encapsulated using Si_3N_4 or AlN . The implanted dopants diffuse during annealing. Implantation can be used to produce either n- or p-type materials. Materials such as S, Se, Te, Si, and Sn are used to produce n-type GaAs. Dopants for p-type GaAs include Be, Zn, Cd, Mg, and C.

Ion implantation is widely used as an alternative to etched mesa isolation in integrated circuit designs to isolate the active regions of individual devices, allowing a more planar fabrication technology. In this scenario, semiinsulating material is produced locally by ion induced damage using proton bombardment or oxygen implantation, followed by annealing at a temperature between 650 and 800°C.

The advent of heterostructure devices, including high-electron-mobility transistors (HEMTs) and heterojunction bipolar transistors (HBTs), coupled with the demand for higher mobilities, higher channel carrier densities, lower-noise-figure FETs, and higher power densities from existing devices, has led to widespread use of epitaxial layer growth techniques. Although there are four potential candidates, vapor-phase epitaxy (VPE), liquid-phase epitaxy (LPE), molecular-beam epitaxy (MBE), and metallorganic chemical vapor deposition (MOCVD, also known as OMVPE), only the latter two techniques provide the necessary abruptness of interface and quality of growth necessary for most contemporary III-V semiconductor devices. MBE allows precise thickness and dopant control and is widely used as the basis of material for HEMTs, while the thicker layers found in HBTs are normally grown using MOCVD. Both techniques have been shown to produce very-high-quality material on high-quality semiinsulating substrates, achieving high mobilities and low defect densities [11].

MBE requires an ultra-high-vacuum growth chamber in a system that has multiple ultra-high-purity sources, achieving stoichiometric growth [12]. The growth rate is relatively slow, achieving 0.1–10 $\mu\text{m}/\text{h}$, but allowing very precise control of the film thickness, material composition, and dopant density. Highly abrupt interfaces are easily achieved and pulse (or delta) doping layers are readily grown, with layer thicknesses as thin as 5 Å. Heated crucibles, known as *Knudsen cells*, containing the elements or compounds used to form the various material layers are used as the sources. Contemporary multiwafer MBE production systems are capable of simultaneously growing high-quality material, with excellent uniformity on up to seven 6-in.-diameter wafer substrates (or a larger number of smaller-diameter substrates). This has led to widespread use of MBE grown wafers in modern III-V fabrication facilities. A wide range of compound semiconductor material systems can be grown using MBE and the same system can contain a range of Knudsen cells with ultra-high-purity Ga, In, Al, As, P, and Sb, as well as smaller cells for doping such as Si. It is common practice to have the most heavily used cells, such as Ga, duplicated. Growth is carried out on a single-crystal substrate—most commonly GaAs, which is heated to a temperature in the range 540–650°C. Faster growth rates tend to occur at the higher temperatures, and require careful control of the ratio of arsenic to gallium. The upper limit on growth

temperature is generally limited by the availability of the group V element over pressure.

MBE is used to grow highly complex multilayer heterostructures such as those found in quantum-well lasers and optical guides. Indeed, it is common for over 10 layers to be grown to form the active region of HEMTs, pseudomorphic HEMTs (PHEMTs), and metamorphic HEMTs (MHEMTs). MBE is used to produce the epitaxial material for a wide range of other microwave devices, including HBTs, MESFETs and resonant tunneling diodes. Superlattices, consisting of alternating layers of wide- and narrower-bandgap materials, are often used in these structures, and MBE is ideally suited to forming these abrupt interfaces [13].

The basic configuration of an MBE system requires a stainless-steel growth chamber, analysis chamber, and a load lock for transporting wafers into and out of the system (Fig. 4). The growth chamber is maintained at an ultrahigh vacuum and requires extreme cleanliness to ensure low defect densities during crystal growth. In addition to the Knudsen cells, the growth chamber houses shutters, substrate-handling equipment (which is robotic in many production systems), cryoshrouds, and surface analysis equipment to monitor growth. The effusion cell shutters regulate the emission of material from the cells. Normally, an additional “main” shutter is placed in front of the rotating substrate. The substrate is mounted on a heated holder, which rotates at speeds of up to 150 rpm for smaller holders, although lower rates of 5 rpm are normally used. This rotation and heating assist in maintaining uniformity in doping and thickness. The cryoshroud, which requires liquid nitrogen, encloses the entire growth area and minimizes water vapor and other unwanted gases during growth. Cooling of the regions surrounding the Knudsen cells also ensures that cross-contamination is minimized. In addition, each cell is usually water-cooled. The cells themselves, which are contained in stainless-steel housings, are made of graphite or boron nitride. The flux emitted from the cells is regulated by the shutters and monitored by an ion gauge behind the wafer holder. In more recent times, many systems use additional “cracker cells” placed between the Knudsen cells and the substrate. The cracker cells operate a high temperature (850–1000°C), and as effusion beams of arsenic or phosphorus pass through the region occupied by these cells, the As_4 and P_4 tetramers form As_2 and P_2 dimers. Dimer sources have been shown to reduce the density of deep levels and have a higher “sticking” coefficient, reducing the arsenic flux required during growth. Finally, surface analysis tools are normally incorporated into the system, including a scanning electron microscope (SEM), reflective high-energy electron diffraction (RHEED), Auger electron spectroscopy, secondary-ion mass spectroscopy (SIMS), and X-ray photoelectron spectroscopy. The RHEED analysis instrument plays a crucial role in determining substrate quality, growth condition and monitoring the thickness of the layer growth.

The molecular-beam epitaxial growth process (Fig. 5) for III-V materials requires precise control of the beam fluxes from the Knudsen cells and careful control of the surface temperature on which crystal growth is required.

Figure 5. Schematic diagram of a molecular-beam epitaxy system [based on A. Y. Cho, *Molecular Beam Epitaxy and Heterostructures*, L. L. Chang and K. Ploog, eds., Kluwer, Academic Press (1985)].

Prior to initiating III-V growth, the substrate is heated to absorb the oxide layer on the surface, to ensure that the surface is atomically clean. This occurs at temperatures in the region of 590°C for GaAs and 520°C for InP. The process itself involves adsorption of the constituent atoms and molecules, surface migration and dissociation of the adsorbed molecules and incorporation of the atoms into the substrate, leading to nucleation and growth. In the case of GaAs, stoichiometric growth requires that an excess of arsenic be available at the growing surface, and that any excess that does not incorporate with gallium reevaporate. The growth of ternary (e.g., $\text{Ga}_x\text{In}_{1-x}\text{As}$) and quaternary compounds (e.g., $\text{Al}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$) is achieved with MBE using precise control of the ratios of the beam fluxes to ensure that growth occurs with the required mole fractions. A high-volume multiwafer MBE system for production purposes is shown in Fig. 6.

In contrast to the MBE, the metallorganic chemical vapor deposition growth (MOCVD) technique involves chemical reactions between gases that occur at tempera-

Figure 6. High-volume MBE production system capable of simultaneously growing epitaxial layers on seven 150-mm wafers (Veeco Applied Epitaxy GEN2000 system at Filtronic plc).

tures far below the melting point of the growing material. A typical MOCVD process involves a pyrolysis reaction between a metal alkyl vapor, such as trimethylgallium (TMGa), trimethylindium (TMIn), or trimethylaluminum (TMAI), and a hydride such as arsine (AsH_3) or phosphine (PH_3), in proximity to a heated substrate (Fig. 7). Epitaxial growth occurs on the crystal surface of the substrate as a result of the deposition. Common substrates used for growth include semiinsulating GaAs and InP. In MOCVD, all the constituents of the process are in the vapor phase. This allows for easy control of gas flowrates and partial pressures in the vicinity of the growth surface. Also since the pyrolysis reaction is relatively insensitive to growth temperature, MOCVD achieves highly reproducible deposition of thin layers and can also produce very good abrupt interfaces between the various deposited layers.

MOCVD systems are available in a range of configurations, including high-volume 150-mm substrate growth systems. The hydrides, including arsine and phosphine are highly toxic and require special handling. The choice of source material is critical to the efficient operation of the MOCVD process. In particular, the group V sources must possess high vapor pressures, pyrolysis at temperatures above 395°C, and low temperature stability. They must also be available with very high purity and not prone to parasitic reactions with the group III sources. Group V sources used in MOCVD include the elemental, hydride, trimethyl, triethyl, and tertiarybutyl materials; As, AsH_3 , TMAs, TEAs, TBAs, P, PH_3 , TMP, TEP, IBP, and TBP. Although arsenic and phosphorus require heating to be used as sources, arsine and phosphine have high vapor pressures of 760 torr at -55 and -88°C, respectively. TMAs and TMP have vapor pressures of >250 torr at room temperature, but both these sources have the disadvantage of requiring high pyrolysis temperatures. Similarly, TEP is not an effective phosphorus source since it is stable at normal growth temperatures and TEA has a relatively low vapor pressure, despite its ability to pyrolyze at normal growth temperatures. Metallorganic sources used for MOCVD typically have the lowest molecular

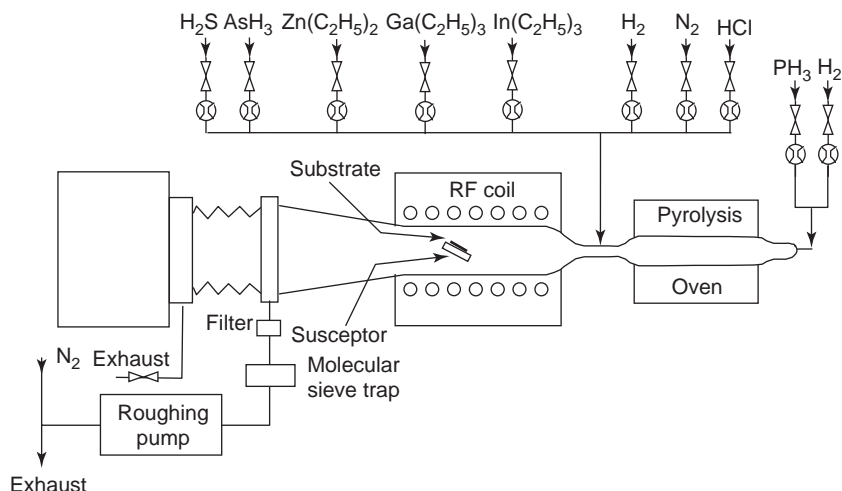

Figure 7. Schematic of a typical horizontal MOCVD system [derived from J. P. Hintz, M. Razeghi, M. Bonnet, and J. P. Duchemin, *GaInAsP Alloy Semiconductors*, T. P. Pearsall, ed., Wiley (1982)].

weights possible with vapor pressures in the region of 1–100 torr at temperatures from -25 to 25°C , and decompose thermally at the required growth temperatures of 550 – 800°C [14]. Generally, trimethyl compounds are used in preference to triethyl materials because of their higher vapor pressures promoting faster growth rates. Typical group III organometallic sources used in MOCVD include TMGa, TMAI, TMIIn, and TMSb. Group III alkyls used in MOCVD readily pyrolyze at low or atmospheric pressures.

The purity of III–V material grown using MOCVD is dependent on the quality of the substrate and the purity of the starting materials (the metal alkyls and hydrides), growth temperature, and the ratio of the constituents in the reactor. In the case of GaAs grown using TMGa and AsH_3 , the purity decreases with increasing growth temperature, probably due to the incorporation of carbon and silicon at higher temperatures. Carbon impurities usually take the form of acceptors, and Stringfellow has shown that a large increase in carbon incorporation occurs at higher growth temperatures [14]. In the case of AlGaAs growth, carbon contamination can lead to significant degradation in mobility, especially with increasing aluminum mole fraction. Doping of MOCVD grown material is usually performed using either Si, Ge, Se, S, or Te for donor impurities and Zn, Cd, Mg, and Be as acceptor impurities. Zinc (p-type) and selenium, tellurium or silicon (n-type) are the most common dopants. Hydrogen selenide H_2Se , SiH_4 , or DETe are used as sources for the donors, and dimethyl or diethyl zinc (DMZn or DEZn) as the p-type dopants.

2.5. Defects and Traps

Semiconductor crystals contain three types of defect: dislocations (or line defects), point defects, and volume defects (precipitates). Line defects occur as the melt crystallizes and shortly after solidification, and are associated with polygonization and slip interactions. The dislocation density is nonuniform and typically lies in the range 10^5 – 10^9 m^{-2} . High values of dislocation density

are detrimental to device performance and are extremely undesirable. Point defects are due to either native defects or chemical impurities. Native defects are usually associated with energy levels deep in the bandgap (known as deep levels) [15,16]. Chemical impurities often originate from the crucible or B_2O_3 encapsulant in LEC material and may include Si, C, or B. Other unwanted impurities, including Fe, Mg, Mn, S, Se, Te, and Zn, may also be found at concentrations of up to 10^{21} m^{-3} . Impurities, such as Cr, may be added to increase the resistivity of the semiinsulating material, with densities in the region of 10^{19} m^{-3} . Volume defects are often found in association with dislocations. Hexagonal precipitates of arsenic and GaAs microparticles create volume defects in some circumstances. Heat treatment of ingots reduces the effect of volume defects.

Point defects are usually characterized as either electron or hole traps. A particularly important point defect is the EL2 deep donor level, common in LEC grown GaAs. Traps play a key role in producing semiinsulating behavior in GaAs substrates [15]. Semiinsulating GaAs has intrinsic behavior in addition to high-resistivity properties, and is remarkably tolerant of small variations in impurity concentrations, retaining good uniformity throughout the ingot. It is important to appreciate that the presence of the deep donor (acceptor) and an excess of shallow acceptors (donors) are required for semiinsulating behavior. If these conditions are not satisfied, it is extremely difficult to achieve semiinsulating behavior [15]. In order to significantly reduce the concentrations of deep traps required to produce semiinsulating material, the concentrations of shallow donors and acceptors must be reduced, requiring material of very high chemical purity. In the case of bulk material, this is most easily achieved for LEC bulk material where the dominant shallow levels are acceptors, possibly due to Zn, Mg, Be, and carbon introduced in the growth process. These compensate the deep donor EL2. Bridgman material tends to be n-type, probably attributable to silicon introduced during growth. Semiinsulating material can be obtained from Bridgman by adding acceptors to compensate

the deep-level EL2 or adding chromium to introduce a deep acceptor, which, along with compensation with excess shallow donors, behaves in a manner analogous to EL2 [15].

Semiinsulating GaAs substrates (undoped and lightly Cr-doped) are often characterized using only one or two deep level traps: the EL2 midgap trap around 0.72 eV, dominant for LEC undoped substrates, and a shallower trap with an activation energy of approximately 0.39 eV. The EL2 level has been found to have an emission time constant that has a strong dependence on electric field [17]. The ionisation of the EL2 level produces an ionized EL2 center and an electron in the conduction band. Spectra associated with hole-type trap behavior have been observed bulk GaAs substrates [18].

The presence of the EL2 level, located near the middle of the bandgap, is essential to avoid nonuniformity and to ensure semiintrinsic behavior. The presence of the EL2 level and its concentration in GaAs ingots is dependent on the melt stoichiometry, and is minimized by having a slightly arsenic-rich content. The arsenic atom fraction in the melt stoichiometry during growth of the ingot determines whether the material is semiinsulating, for fractions in the range 0.475–0.535 with resistivity typically above $10^5 \Omega \cdot \text{m}$, or whether it is p-type in behavior for fractions in the range 0.43–0.47 with resistivities of the order of $10^{-2} \Omega \cdot \text{m}$. The association of semiinsulating behavior with the EL2 level suggests that the electrical properties of the material are due to the deep donor EL2 level and additional residual compensating acceptors, such as carbon.

A comprehensive survey of electron and hole traps was published in Refs. 18 and 19, in which over 33 electron and 22 hole trap levels were tabulated from various sources. It was suggested that some of these observations related to the same traps levels in differing materials. Even so, if this is the case, over 20 separate electron and 11 separate hole trap energies exist. A number of different transient spectroscopy methods have been developed to characterize traps in GaAs; the most commonly used is deep-level transient spectroscopy (DLTS) [10]. These include voltage-pulsed stimulated current and capacitive DLTS [e.g., 18,20], thermally stimulated current and capacitance techniques TSC, TSCAP [e.g., 21], and optically stimulated methods.

The presence of traps in active-device structures can have a profound effect on their transient electrical behavior. Many III–V devices suffer from adverse transient effects such as “gate and drain lag” in FETs, where the drain current responds with a transient of typically many hundreds of microseconds in response to a step excitation in the gate or drain voltages, respectively. The origin of these effects is associated with combinations of surface, bulk, and substrate traps. Surface traps, which are responsible for surface charge, play a particularly important role in determining the transient response of planar devices such as FETs. The transient behavior of these traps gives rise to dispersion phenomena in the drain current, transconductance, output resistance, and gate–drain capacitance. Surface charge can also have a profound impact on the breakdown voltage of these

transistors (which can consequently be a time-dependent phenomena). Ladbroke [22] provides a detailed insight into the impact of surface charge effects and dispersion in III–V MESFETs.

2.6. Substrates and Wafers

Although doped (and unintentionally doped) substrates were commonly grown in the past, for vertically oriented devices such as diodes, today the majority of substrates are semiinsulating. In 2003 over 13 million III–V substrates were manufactured worldwide. The rapid growth in III–V technology demand over the period 2001–2006 is expected to see a threefold increase in substrate supplies with a shift to increase wafer diameter [23].

As in all semiconductor technologies, wafer diameter plays a key role in the economics of manufacturing III–V devices. Since it is proportionately cheaper to fabricate devices on larger wafers than on smaller wafers, there has been a progression over the years from 1-in.-diameter wafers through to the current 6-in.-diameter wafers used for GaAs technologies. Up until 2000, 3- and 4-in.-diameter wafer processes dominated the industry. However, with the successful introduction of 6-in. semiinsulating substrates and associated epitaxial processes (MBE initially, followed by MOCVD), by 2004 there were over 10 large-scale 6-in. fabrication facilities worldwide, gradually displacing the less cost-effective smaller diameter fabrication facilities. This migration to larger wafer sizes can be compared with the movement from 2- through to 12-in.-diameter silicon wafers. The prospect of larger-diameter wafers for GaAs needs to be considered in the context of the level of demand and return on investment in the fabrication equipment as well as the fact that boules of GaAs have a density of more than double that of Si, presenting substantial challenges for growing boules for wafers of over 150 mm (6 in.) diameter.

Generally speaking, in applications where very low defect densities are required (e.g., laser diodes), or for more specialised materials, smaller diameter wafers are used. For example, at the time of writing high-quality GaN is usually grown on 2-in. wafers, and while GaAs is well established on 6-in. wafers, InP technology is still based on 3-in.- and more rarely 4-in.-diameter wafers. Continual improvements in epitaxy have led to dramatic improvements in defect density and epitaxial wafer quality, and this is reflected in the impressive yields, of over 95%, which can be achieved routinely on 150-mm (6-in.-) diameter GaAs wafers [24].

The quality of substrates and epitaxial layers is examined using a range of material characterization techniques, including X ray, photoluminescence, SEM/EDAX, and classical Hall mobility and sheet resistance measurements. In the case of epitaxial layers, the aim is to determine layer thicknesses, uniformity, surface morphology, chemical composition, carrier mobility, Hall factor, defect density, doping profile, and sheet carrier densities. A wide variety of techniques are used and cannot be covered in this article; the reader should consult Refs. 10 and 25. Surface and layer analysis is performed using a

range of spectrometry systems, including X-ray spectroscopy, secondary-ion mass spectrometry, Auger electron spectrometry, and X-ray photoelectron spectroscopy. Defect density and trap density and type are investigated using X-ray spectrometry systems, supported by DLTS. Sheet resistance and Hall mobility are often determined using van der Pauw measurements, based on Schottky gate patterns [26] and magnetoresistance measurements [27]. The doping density and in some cases the doping profile is determined for bulk doped materials, using tests such as C - V profiling, or evaluation from a combination of C - V and I - V data on long-gate length FETs. In the case of heterostructure layers, such as those used in HEMTs, the material is also characterized in terms of its sheet carrier concentration.

3. CARRIER TRANSPORT PROPERTIES

The carrier transport properties of materials determine a material's electrical behavior. The key properties that characterize carrier transport in semiconductor materials are the mobility and velocity of the electrons and holes, which are dependent on the scattering mechanisms in the particular material. The main scattering processes, which influence the mobility of electrons and holes, are acoustic phonon, nonpolar optical mode, polar mode, and ionized impurity scattering. Ionized impurity scattering dominates at low temperatures (< 100 K). Alloy scattering is a limiting process at room temperature in some material systems, such as in AlGaIn/GaN used in HEMTs. The bulk electrical conductivity is then expressed in terms of the mobilities and carrier densities in the bulk material. The low field mobilities of electrons and holes are a strong function of lattice temperature, carrier, and doping density. The transport properties have fundamental dependence on the electric field within the device structure, and are further modified by nonequilibrium behavior in small-scale structures, where rapid changes in the electric field can occur quickly changing the energy of the carriers leading to "hot" carrier transport phenomena.

The mobility in III-V semiconductor samples is normally determined from Hall effect measurements [5], where bulk samples of the material are characterized under the influence of a strong magnetic field. The hole mobility μ_p for p-type material in a small electric field is determined from the Hall mobility μ_H according to the relationship,

$$\mu_H = \sigma R_H = r_H \mu_p$$

where σ is the conductivity, R_H is the Hall constant, and r_H is the Hall factor, which tends to unity for strong magnetic field conditions ($B\mu_p \gg 1$). Similarly for electrons mobility μ_n for n-type material in a small electric field is determined from the Hall mobility μ_H according to the relationship

$$\mu_H = |\sigma R_H| = r_H \mu_n$$

where the Hall factor r_H is close to unity for strong magnetic fields and greater than 1 for medium or weak magnetic fields. Electron and hole mobilities are strongly temperature-dependent, showing approximately $(300/T)^{2.3}$ behavior above 100 K for GaAs. Below 70 K ionized impurity scattering reduces the mobility with decreasing temperature. Mobilities are also a function of carrier density. Typical values of hall mobility for p-type GaAs are in the region of $0.04 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ for hole densities below 10^{22} m^{-3} , falling to $0.005 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ for densities above 10^{25} m^{-3} . The Hall mobility of the electrons in GaN/AlGaIn HEMTs at 300 K has been found to be as high as $0.14 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ in high-quality material for sheet carrier concentrations of 10^{17} m^{-2} .

The electron and hole drift velocities are defined by the product of the mobility and electric field \mathbf{E} . Hence, for electrons, the drift velocity v_d is given by $\mu_n \mathbf{E}$. In the case of low doped n-type GaAs μ_n is in the region of $0.8 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 300 K for low values of electric field. At low values of electric field the velocity increases with increasing electric field. However, as the electric field increases and the electrons gain energy, the mobility decreases slightly. Increasing the electric field still further results in the most energetic electrons transferring from the central Γ valley to the first satellite valley X, which has a higher effective mass and reduced mobility. Eventually, a value of electric field is reached where the velocity attains a peak value, in the region of $2 \times 10^5 \text{ m/s}$ for GaAs. Beyond this value the drift velocity decreases with increasing electric field, asymptotically approaching the saturated value of $7 \times 10^5 \text{ m/s}$ at very high values of electric field. The steady-state electron velocity-electric field characteristics for several III-V semiconductors compared with silicon at 300 K are shown in Fig. 8 [28–32]. The region of negative-differential mobility beyond the peak velocity in each characteristic, where the velocity decreases with increasing electric field, is due to the transferred electron effect where electrons are transferring from the high-mobility central (Γ) valley to the low-mobility satellite (X) valley in the energy band structure. This phenomenon can give rise to oscillations in samples of InP and GaAs, and forms the basis of the Gunn diode (transferred electron device) [5].

The transient (nonequilibrium) carrier transport properties of semiconductors may be markedly different from their steady-state (equilibrium) characteristics [33,34]. In the case of many III-V semiconductors, the change in velocity experienced by electrons entering a high-electric-field region can lead to a phenomenon known as "velocity overshoot," where the electron is accelerated in the electric field, rapidly gaining energy, to a velocity significantly higher than the peak steady-state value, for a short interval (usually less than 0.1 ps). In the case of GaAs the transient velocity of these hot electrons may reach values in excess of $5 \times 10^5 \text{ m/s}$ over a short distance ($< 0.1 \mu\text{m}$) until scattering, energy, and momentum relaxation lead to a reduction in velocity that subsequently approaches the steady-state value over a short interval in time and distance [33,34]. Velocity overshoot in III-V devices can enhance their high-frequency performance

Figure 8. Steady-state velocity–electric field characteristics for GaAs, InP, $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$, and GaN, compared with Si at 300 K.

and is significant for short-gate (submicrometer)-length FETs.

The conductivity of semiconductors is given by

$$\sigma = \sigma_n + \sigma_p = q(n\mu_n + p\mu_p)$$

where n and p are the electron and hole densities (n_0, p_0 for intrinsic condition). In the case of GaAs doped with shallow donors or acceptors, the ratio of n/p is far from unity at 300 K, and the conduction is essentially unipolar depending on the dopant type. GaAs can be engineered to achieve a high value of resistivity, close to the intrinsic state, by the use of chromium doping, which introduces EL2 centers (see Section 2.5), creating semiinsulating GaAs. The room temperature resistivity of semiinsulating GaAs is typically in the range 10^3 – $10^7 \Omega \cdot \text{m}$, which makes an ideal substrate for integrated circuits.

4. PROCESSING AND DEVICE FABRICATION

The fabrication of semiconductor devices using either semiinsulating wafers with ion implantation of epitaxial layered wafers requires several stages of lithography, selective etching, deposition, and passivation, finishing with die separation, final test, and packaging. It is not possible to provide a detailed description of processing in this article, but an outline is a useful aid in understanding the design constraints and properties of the finished semiconductor devices. Williams provides a useful introductory text for GaAs processing [11].

4.1. Lithography

One of the most fundamental elements of device processing is the definition of the active and passive regions of the device, electrical contacts, bondpads, implantation regions, passivation areas, and interconnecting lines. This process of transferring patterns, made up of geometric shapes, to a thin layer of radiation sensitive material (*resist*) deposited on the surface of a semiconductor wafer is known as *lithography*. The resist is usually

deposited on the wafer by spinning a few drops of resist fluid into thin film at very high speeds, on to the surface of the wafer. The resist is then patterned (exposed) using photolithography, ultraviolet light lithography, electron-beam lithography, or in special cases X-ray or ion-beam lithography. The resist is then developed, selectively removing either the exposed or unexposed areas. The remaining pattern is then used to define areas for etching, deposition, or implantation. The resists are classified as either positive or negative depending on whether the exposed region is removed (positive) or whether the unexposed regions are removed (negative). An additional technique is based on image-reversal, which can provide enhanced resolution, which is particularly useful for submicrometer photolithography.

The photolithography techniques used in III–V processing include contact printing, proximity printing, projection printing, and stepping. Contact printing, which is frequently used for initial research development and for backside processing, is a straightforward process where the mask is aligned on the wafer and the resist exposed using a beam of ultraviolet light. Resolutions down to the region of one micrometer are possible as a result of the direct contact between the mask and the wafer. The two main disadvantages of this approach are (1) abrasion of the mask through direct contact, which reduces mask lifetime, and (2) *runout* due to any lack of planarity between the mask and wafer, preventing contact. Runout, due to curvature in either the mask or wafer, results in misalignment in areas of the pattern. Contact printing systems are significantly lower in cost than steppers or other precision lithography systems. Proximity printing places the mask in close proximity to the wafer, but avoids direct contact. Diffraction at edges in the pattern produces a slightly blurred image. This technique cannot achieve high resolutions and is not widely used in modern fabrication processes.

Optical steppers are the mainstay of silicon fabrication and are becoming widely used in III–V fabrication. The mask consists of the patterning for device and integrated circuit designs and is known as a *reticule*. The reticule is projected onto the wafer, which has previously been coated

in resist. A typical reticle is 20×20 mm. Many reticle patterns can be accommodated on a wafer. After the first reticle pattern is exposed, the wafer is moved very precisely and a second image is created. This process repeats across the wafer until the whole wafer is exposed. This step and repeat process is well established and is precisely indexed to allow multiple mask sets to be used, achieving precise alignment between layers. Steppers normally allow reduction of the reticle pattern on the mask by factors of 5 or 10, although in some circumstances unity reduction is used. Steppers achieve optical imaging using either lenses (refractive optics) or mirrors (reflective optics). The limitations of the optics are constrained by diffraction, where the optical surfaces must be accurate to within a quarter-wavelength. Steppers achieve a highly repeatable pattern, where any runout or misalignment is generally confined to the reticle. As a result, steppers have become established as a key element of high-yield processing, producing very-high-quality, highly repeatable lithographic patterning. Contemporary steppers for III-V lithography are available that achieve feature sizes of 0.35, 0.18, and 0.12 μm ; the cost of the system increases with increased resolution. Excimer laser (KrF) sources are used for the high-resolution steppers in the 0.18 μm range. Even higher resolutions are possible today, but the cost of the stepper is prohibitive for anything other than very-high-volume Si applications (microprocessors and memory). More recently there has been increased interest in using phase-shifting masks [35], which improve optical resolution by using interference to cancel diffraction effects. Steppers are available for 3, 4, 6, 8, and 12 in. wafer sizes.

Electron-beam (e-beam) lithography is widely used in III-V processing, as a means of both precisely patterning the masks used in photolithography and directly exposing (direct *writing*) patterns on wafers. Submicrometer gates were first written on GaAs using e-beam systems, although more recently, gate lengths above 0.35 μm are more routinely written using steppers, and it can be expected that 0.25- and 0.15- μm gates will in due course be written using steppers. At the heart of e-beam systems is the electron gun, which operates continuously, and beam-blanking plates that turn the beam on and off. The beam is moved over the surface of the wafer, within the scanned region, using deflection coils. The wafer is coated in a resist such as polymethylmethacrylate (PMMA). The wafer is positioned using a precision mechanism to move from one scanning field to the next. The pattern is generated in e-beam systems using computer controlled raster or vector scanning techniques. Electron-beam systems can achieve very high resolutions (currently below 70 nm), excellent registration, and great flexibility and do not require masks. Wafer flatness is not a problem for e-beam systems as they have a greater depth of field than do steppers. However, the throughput of e-beam systems is significantly slower than steppers at present. Also, on larger wafers e-beam systems can suffer from degradation of alignment accuracy, especially toward the edge of the wafers, away from the initial scanning fields. E-beam systems for III-V processing are available that will handle wafer sizes up to 6 in. (150 mm).

III-V processing has a number of significant differences to silicon device fabrication and in some respects is simpler — generally requiring fewer steps for monolithic microwave integrated circuits (MMICs) than for silicon ICs. A key stage in semiconductor device fabrication is the metal patterning, where, following evaporation of the required metal, the unwanted metal regions are removed. The metals used with silicon processing (typically Al) are usually fairly easy to etch, whereas the metallization schemes used in III-V processing (frequently TiPtAu, AuGeNi) are often difficult to etch. In silicon, this is achieved by depositing the metal first and then coating the metal with resist and lithographically defining the pattern. The unwanted metal, which is not protected by resist, is then removed by etching after developing the resist pattern. The resist is then removed using a solvent. In the case of III-V semiconductors a process known as “lift-off” is normally used, where the resist pattern is produced using lithography prior to evaporation of the metal. The desired metal pattern is then obtained by removing (“lifting off”) the resist (with metal evaporated on its surface) using a solvent, leaving the metal deposited on the semiconductor surface in the regions where the resist was originally removed following the development stage. The liftoff process is very sensitive to the pattern defined by the resist and an undercut in the resist profile is usually used to help define the desired metal regions.

It is convention to include a process control monitor (PCM) site in the reticle. This important element of the patterning includes a range of test devices, such as simple contact structures, transistors, and diodes and if it is a MMIC, a small range of transmission-line structures resistors, capacitors, and inductors. The purpose of these structures is to monitor the key parameters against the expected values as the wafer goes through each stage of the processing. This allows the quality of the processing to be closely monitored and assists in process control and yield optimization. The PCM sites are usually tested after each processing stage or at suitable intervals. The PCM site usually occupies only a small area of the reticle — often less than 1%.

4.2. Etching Techniques

III-V semiconductors can be etched using either wet- or dry-etch techniques or a combination of both. Prior to processing and at stages during the fabrication, it is necessary to clean the wafer surfaces. Exposure of GaAs to the atmosphere leaves an oxide layer on the exposed surface of the material, which can be 50 Å thick, which is removed using a highly diluted acid such as HCl. Highly pure deionized water is used extensively in processing to avoid contamination. Wet and dry etchings are used as a means of forming patterns and defining features in the surface of the semiconductor wafer, and for polishing (e.g., after thinning of wafers during backside processing).

Wet etching techniques have been established since the early days of fabrication and normally have the properties of providing selective and preferential etching depending on the crystallographic orientation of the wafer. In the case of Si, this allows distinctive etching that is exploited

in MEMs, and, for example, allows “V” grooves to be readily defined. Etching of III-V compounds is usually crystallographic, and key features and critical dimensions can be defined by ensuring proper alignment with the lattice planes. In the case of GaAs, (111) Ga faces etch up to 5 times slower than do (100), (110), and (111) As faces. Wet etches are categorized either as electrolytic or nonelectrolytic. Electrolytic etches require an electrical contact to the wafer and in the case of GaAs have an anodic oxidation mechanism. One advantage of electrolytic etches is that they can be used to provide accurate technical depth control. Nonelectrolytic etching rates are either diffusion or chemical-reaction-limited. Diffusion-limited etches are generally isotropic and are well suited for polishing wafers after mechanical grinding. Chemical-reaction-limited etches are often anisotropic are particularly suitable for defining patterns. Wet etches generally contain an oxidizing agent, such as Br_2 or HNO_3 , a complexing agent, such as NH_4OH , NaOH , HC , citric acid, or H_2SO_4 and water. The complexing agent ensures that the relatively insoluble oxidized layer is dissolved in the water. The etch is chosen to remove areas of the wafer that are not protected by the exposed resist pattern.

Dry etching techniques have become increasingly popular for use in III-V device fabrication in more recent years. They are widely used in III-V processing to produce recesses (e.g., single- and double-gate recesses), mesas for isolation, and via holes through the substrate that are metallized to connect the top surface to the metallized back surface of the wafer. These reactive plasma etching techniques have several important advantages over wet-etch methods, including better directional control of the etch and improved anisotropy of the etch. Specifically, the laterals etch rates in plasma etching are very low indeed, preventing undesirable undercutting of the resist pattern. Dry etching utilizes an ionized gas to achieve plasma-driven chemical reactions or use highly energetic ion beams to remove material that is not protected by the resist pattern. Dry etching can be classified as plasma etching, reactive-ion etching (RIE), ion milling, or reactive-ion-beam etching (RIBE). Inductively coupled plasma etching is also widely used in III-V device fabrication. Control of the plasma by varying the system electrode configuration, gas composition, pressure, and bias voltages allows the characteristics of the etching process to be tailored to the particular semiconductor material and the required shape of the etched region.

Plasma etching systems often use chlorine, HCL , PCl_3 as sources of chlorine ions. O_2 and Ar are often added. CH_4/H_2 systems have been used for InP and GaAs. The system itself in its basic form consists of two parallel plates with a DC and RF ionizing source (100–600 V at 13 MHz) attached to the top plate and the wafers clamped to the lower water-cooled plate. The plasma is formed between the plates and energetic ions perpendicularly impact the surface of the exposed semiconductor material. The resist prevents the ions penetrating the unexposed surface of the semiconductor. Plasma etching can give rise to radiation damage and in some circumstances leaves residues that require subsequent removal (often using a light wet etch). RIE is in many ways similar to plasma

etching, with the reactive species generated from the plasma, but with greater directionality of the ions. RIE systems typically operate at low pressures and the substrates are mounted on the powered electrode. Reactive-ion etching is usually used to etch GaN/AlGaN because of the difficulty in finding suitable wet etches. BCl_3/Ar is found to produce surfaces smoother than those obtained with Cl_2/Ar for GaN/AlGaN. Finally, the electrodes themselves are often asymmetric with the chamber forming the grounded electrode. In RIE the semiconductor is etched through a combination of chemical reaction and sputtering. Similar ion species can be used to plasma etching, but a smoother surface is obtained using H_2 , BCl_3 , or CCl_3F . Again O_2 is added to CCl_3F and CCl_4 to increase etch rates, and Ar to increase anisotropy.

Ion-beam milling is a high-energy (~ 1000 eV) etching process, where inert ions (Ar) are allowed to impinge on the target substrates in a uniform beam. Ion-beam milling can achieve relatively high resolutions, and can be used to define structures smaller than $0.01\ \mu\text{m}$. It is a highly anisotropic process, and the profile of the etched sidewall can be determined by positioning the relative angle of the substrate and by using shadow masking. Ion-beam milling can be used to etch metals, including Ti, Pt, and Au metallization layers and will etch materials that are challenging for plasma or wet-etch systems. The main disadvantages are damage from ion bombardment, poor sensitivity, and redeposition of materials. Focused ion-beam etching can be used to define small-scale structures. The final dry etching process, reactive-ion-beam etching (RIBE) takes advantage of both chemical reaction and ion bombardment to etch material. Unlike ion beam milling it uses a reactive gas although the etch characteristic are very similar. Redeposition of the etched material is avoided in RIBE by using a vacuum removal system.

4.3. Deposition and Metallization

It is usually necessary to provide insulating coatings on the surface of semiconductors at various stages in processing, either to planarize the surface for additional processing (e.g., metallization) or as a dielectric for capacitors in integrated circuits, or as a passivation to protect the surface of the semiconductor. The type of materials deposited can be either inorganic, such as silicon nitride or silicon dioxide, or organic, such as BCP. Plasma-enhanced chemical vapor deposition (PECVD) techniques, which use RF excited plasmas, are often used to deposit these films, as they can achieve this at relatively low temperatures (typically 250 – 350°C). This low temperature capability is very important for III-V processing, where higher temperatures would lead to changes or decomposition of the semiconductor material. PECVD films are amorphous, and the density and quality of the material depend strongly on growth conditions. In particular, the frequency of the RF stimulated discharge, which may lie between 50 kHz and 13 MHz, directly influences the stress in the film (the higher the frequency, the lower the compressive stress). PECVD layers are usually deposited in thickness between $1000\ \text{\AA}$ and $1\ \mu\text{m}$, with growth rates typically of the order of $300\ \text{\AA}/\text{min}$.

Plasma deposition is usually carried out in either a planar (parallel-plate) or barrel (tubular) reactor. The best uniformity is achieved in radial flow planar reactors, where the substrates are positioned on the lower electrode of the two parallel plates. Deposition is performed under a vacuum to minimize contamination, and a wide variety of highly reactive chemical species are used, including chlorine, fluorine, hydrogen, oxygen, silane (SiH_4), and ammonia. Silicon nitride, which is one of the most frequently used insulating materials, is often deposited using electron cyclotron resonance systems, which operate at 2.45 GHz.

Silicon nitride Si_3N_4 is used widely in III-V processing as a dielectric layer in capacitors, an encapsulant (to prevent diffusion) or for passivation to protect the surface of the semiconductor or die from the environment. It is normally grown using silane as a source of silicon and ammonia (or nitrogen in some cases) as the nitrogen source. The silane is mixed with an inert gas (argon). The dielectric constant of the amorphous silicon nitride is a function of film thickness and silane concentration. The film thickness dependence is due to the impact of stress and nonuniform growth of the layer. Thin films (below 1000 Å) can achieve relative dielectric constants of up to 11, whereas thicker films typically have dielectric constants in the region of 8. Silicon dioxide has a lower dielectric constant than silicon nitride and is often used as a spacer layer in metal cross-overs to minimize parasitic capacitance. Again, silane is usually used as the silicon source, and the oxygen source is selected from CO , O_2 , or N_2O .

Some III-V processes utilize aluminium nitride as an insulator or passivation layer. AlN for these purposes is grown either by sputtering, vapor phase, or MBE. Single-crystal films may be grown at temperatures in the region of 1150°C, although amorphous AlN films can be grown at lower temperatures or using plasma CVD. Other dielectric films such as silicon oxynitride are used in some circumstances.

The final element in processing is the provision of metallization on the surface of the semiconductor to act either as contacts or interconnections. Two types of metal-semiconductor contact can be fabricated in III-V devices: ohmic contacts and Schottky contacts. Ohmic contacts have the property that they possess very low resistances across the metal-semiconductor interface, while Schottky barrier contacts have a more complex rectifying contact behavior, representative of a diode, where in reverse bias the interface demonstrates very high resistance (ideally no current flow) and capacitance associated with the charge developed in the depletion region below the contact. In contrast in forward bias, the interface behaves like a diode, with the potential for significant current flow, but only supporting relatively low forward voltages across the interface. In addition to the contacts, first- and second-level metallization is used to interconnect the various elements of the active devices, and circuits, where the metal is chosen to possess high conductivity, excellent adherence, and conformal coating, coupled with compatibility with the Schottky and ohmic contacts. Additionally, via holes that connect between levels or between the top and backside metallized surfaces of the substrate.

Schottky contacts can be formed with III-V semiconductors using sputter or evaporation deposited multi-layer metal contact structures such as TiPtAu, TiW, TiWSi, Pt, Al, WSi, WAl, and TiPdAu. Metal silicides, such as tungsten silicide, widely used in silicon VLSI, can achieve low contact resistances for III-V devices when annealed at high temperatures and may be deposited using RF cosputtering. Schottky contacts on AlGaN can be achieved using Ni/Au. The barrier height of the Schottky barrier varies with the semiconductor material composition, crystal orientation, and the contact metal. In the case of GaAs and gold, for example, the barrier height varies from 0.82 eV for (100) orientation to 0.97 eV for (110) crystal orientation at the interface [36]. The range of barrier height for Schottky contacts on several III-V binary semiconductors is shown in Table 3 [5,36,37].

Ohmic contacts are formed with III-V semiconductors using n^+ or p^+ layers immediately below the contact metallization. Very high doping levels above $5 \times 10^{24} \text{ m}^{-3}$ are used with multilevel metal-alloyed contacts. In the case of GaAs, alloys based on Au or Ag are popular choices. In the case of contacts made on p-type material, zinc is usually added to the alloy, which acts as a dopant in the semiconductor. In the case of n-type contacts germanium and tin are used in the alloy. AuGeNi contacts provide among the lowest contact resistances and high reliability in III-V devices. Other GaAs metal alloy ohmic systems include Au-Zn, Au-Zn-Sb, Au-Be, and Au-Be-Ni. Ohmic contacts to InP are achieved using Au-Ge-Ni, Au-Sn, Ag-Sn-In, In-Zn, Au-Mg, and Au-Be. AlGaAs ohmic contacts are made with Al, Au-Zn, and Au-Ge-Ni; GaInAs, with Au-Zn, Au-Sn, and Au-Ge-Ni. Ohmic contacts to AlGaN/GaN devices are usually made with alloys based on Ti/Al annealed at 850–875°C. Rapid thermal annealing is usually employed for ohmic contacts. “Balling” of the metals on the contact surface can be avoided by including a thin cover layer of Ni/Au over the Ti/Al prior to annealing at 900°C. It should be noted that it is hard to form ohmic contacts to AlGaN when the mole fraction exceeds 33%.

A first-level metal used as part of the interconnection metallization has the characteristic of good adhesion to ohmic and Schottky barrier metals. Gold-based alloys are generally used for interconnection first metallization — the most common are TiPtAu and TiPdAu, using e-beam deposition systems. Copper, with its very high conductivity, which is used with silicon, diffuses in several III-V semiconductor materials and cannot be used. Aluminum

Table 3. Schottky Barrier Heights for n-Type III-V Semiconductors

Material	Barrier Heights (eV)						
	Ag	Al	Au	Ni	Pt	Ti	W
GaAs	0.88	0.80	0.90	0.79	0.85	0.82	0.79
GaP	1.20	1.07	1.30	1.27	1.45	1.12	—
AlAs	—	—	1.20	—	1.00	—	—
InAs	—	—	0.47	—	—	—	—
InP	0.65	—	0.65	—	—	—	—
$\text{Al}_{0.14}\text{Ga}_{0.86}\text{As}$	—	0.90	1.02	—	—	—	—
$\text{Al}_{0.32}\text{Ga}_{0.68}\text{As}$	—	1.09	1.10	—	—	—	—
$\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$	0.20	—	0.20	0.20	—	0.15	—

interacts adversely with gold, with high-resistance intermetallic products. Silver is very reactive and is rarely used in III-V devices. First metallization is usually in the region of $0.5\ \mu\text{m}$ thickness. Second-level metallization is usually based on gold (Ti/Au), due to its low tendency to electromigration [38] and ability to handle very high current densities. Airbridges are also formed in the second-level metal. Metallization is achieved using sputtering, evaporation or electroplating. An evaporation system for 150-mm-diameter wafers is shown in Fig. 9. Thicker layers ($> 1\ \mu\text{m}$) are usually deposited using RF sputtering systems. Via holes may be plated using either electroplating or electroless plating (based on gold–cyanide solutions) or magnetron sputtering or by evaporation of TiAu.

4.4. Backside Processing

The final stage of the fabrication process is backside processing and die separation. After completing the frontside with the devices, metallization, contacts, and circuit elements, the reverse side of the wafer is processed. At this stage the wafer is usually thinned to its final thickness, which usually lies in the range $30\ \mu\text{m}$ (for high power) to $150\ \mu\text{m}$ (Fig. 10). A mechanical grinding process is used to remove the bulk of the material, which is then finished with a chemical etch. If there is a requirement for via holes to connect the top surface to the backside, vias will be etched, usually using dry etching techniques (Fig. 11). If a ground plane is required, the backside is metallized with gold (as in the case of vias). After completion of processing, the wafer may be attached to a film frame to facilitate temporary die retention during the on-wafer test and die separation processes. The die on the wafer are then subject to visual inspection and electrical testing. The process control monitor (PCM) sites receive their final electrical tests to complete the process data for the wafer. The die may be probed using DC and RF testing to determine whether they meet the specification (and hence determine the final yield). After on-wafer testing the final stage is to separate the die, which is achieved using either a diamond scribe (“scribe and break”) or a

Figure 9. Evaporation system for metallizing semiconductor wafers.

Figure 10. Cross section of a die, showing thinning of the GaAs to $30\ \mu\text{m}$ and gold metallization of the backside ($\sim 10\ \mu\text{m}$). The FET structure can be seen on the frontside (Filtronic plc).

diamond saw. Laser separation techniques are beginning to appear that also show promise. The die are retained on the film in preparation for packaging using robotic pick-and-place instruments.

5. RF AND MICROWAVE DEVICE TECHNOLOGY

III-V RF and microwave devices may be fabricated as unipolar or bipolar designs. The early interest in GaAs and InP centred around the properties of these materials that demonstrated negative-differential resistance as a consequence of their velocity–electric field relationships. J. B. Gunn demonstrated microwave oscillations in 1963, using a simple GaAs two-terminal structure. This phenomena forms the basis of the *transferred electron effect*

Figure 11. A via hole etched in a $125\text{-}\mu\text{m}$ substrate and plated in gold (light color) (Filtronic plc).

[5], which is characterized by the behavior of the Gunn diode. GaAs and InP Gunn diodes have found widespread application as the active devices in microwave oscillators ranging from 1–100 GHz.

The most common transistor technologies in use today are based on unipolar field-effect transistor (FET) or heterojunction bipolar transistor technologies [39,40]. GaAs and Si bipolar transistors were widely used prior to the advent of higher-frequency FETs [41]. In 1971 Turner reported a 1- μm -gate-length FET with gain of ≤ 18 GHz [42]. By 1980, GaAs metal semiconductor field-effect transistors (MESFETs) were established as the device of choice in microwave low-noise and medium-power amplifiers, achieving noise figures of less than 1 dB at 4 GHz and output powers of up to 25 W [43]. Although MESFETs were employed in oscillator designs, especially varactor tuned designs, from their introduction in the mid-1970s [44], relatively poor $1/f$ noise performance in early MESFETs led to the continued use of bipolar junction transistors in low-noise oscillators up to 6 GHz. The advent of AlGaAs/GaAs high-electron-mobility transistors (HEMTs), also known as *modulation-doped FETs* (MODFETs), in the 1980s with their improved noise performance displaced MESFETs in low-noise amplifiers and wider use in oscillators and mixers, although still with some remaining $1/f$ noise limitations. AlGaAs/GaAs heterojunction bipolar transistors (HBTs) were introduced in the early 1980s, but were not widely used until the advent of mobile communications and the widespread development of low-voltage, high-efficiency power amplifiers for cellular handsets. By 2000 pseudomorphic HEMTs (PHEMTs) had become the established high-frequency transistor, operating at frequencies up to 200 GHz and achieving noise figures below 0.2 dB at 2 GHz. HBTs based on AlGaAs/InGaAs/GaAs, and InGaP structures demonstrating maximum frequencies of oscillation f_{max} above 100 GHz, are now readily available. GaAs-based PHEMTs have demonstrated high power and high efficiency operation up to X band [45]. The state of the art is now occupied by gallium nitride transistors, with AlGaN/GaN FETs achieving power densities above 10 W/mm gate periphery and capable of over 170 W at high efficiencies [46], and power densities of over 4 W/mm at 30 GHz [47]. Similarly, GaN/AlGaN HBTs show potential for high-power high-frequency operation and demonstrate high emitter injection efficiencies.

6. APPLICATION OF TRANSISTOR TECHNOLOGIES

Up until 1985, the MESFET dominated as the preferred choice of microwave transistor, with some usage of silicon bipolar remaining for niche applications below 8 GHz (such as low-noise oscillators). By 1990, the PHEMT had begun to displace MESFETs for low noise amplifiers, and the AlGaAs/GaAs HBT had begun to emerge as a candidate for low-voltage power amplifier applications (such as in the emerging cellular handset market). Up until this time, MESFET technology had been dominated by ion-implanted designs, utilizing semiinsulating GaAs substrates. Improvements in epitaxial growth (MBE and MOCVD/OMVPE) allowed higher performance FETs to be designed, with improved gain, current, and power handling. By 2000, MESFET technology was being displaced in many applications by PHEMT and HBT, because of the superior gain and power handling of these technologies. Nevertheless, the simpler fabrication technology MESFETs remains attractive for low-cost applications where the performance is undemanding. At the present time, HBTs are the most common choice for power amplifiers in cellular handsets, while PHEMTs power FETs are being introduced in many microwave and millimeter-wave power amplifier applications and are even challenging silicon LDMOS in some specialized applications at 2 GHz. By 2006 GaAs-based HEMTs are expected to be found in over 35% of microwave applications, while HBTs provide another 30%, with MESFETs falling to around 20%.

The maximum electric field sustainable before the material breakdown determines the maximum voltage sustainable across the device, which in turn directly influences the power handling of the device. The electron and hole mobilities impact the resistivity, frequency limit, and current handling (and thus power handling) of the device. The saturation velocity determines the current handling and frequency limitations. The thermal conductivity limits the temperature of operation and thus the power-handling and frequency limits. Table 4 lists these parameters for a range of semiconductors used or potentially available for power devices. The potential for newer materials such as GaN, SiC, and diamond is still being evaluated. It should be noted that the reported data for more recent materials varies in the literature. The Johnson and Baliga figures of merit are frequently used to compare the potential of materials for power device applications [48,49]. Baliga's figure of merit is a measure of the

Table 4. Material Properties for Power Devices at 300 K

Property	GaAs	InP	GaN	Si	4 HSiC	Diamond	Units

Table 5. Johnson Figure of Merit Normalised to Silicon

Material	Johnson Figure of Merit
Si	1.0
GaAs	1.9
InP	2.3
GaN	233.0
4 HSiC	455.0
Diamond	37,000.0

ON resistance of the drift region of a transistor (usually applied to vertical FETs) [50]. The Johnson figure of merit (JFM) is a measure of the ultimate high frequency capability of the material and is given by the product of critical breakdown field E_{Br} and saturated electron drift velocity v_{sat} :

$$JFM = \left(\frac{E_{Br} v_{sat}}{2\pi} \right)^2$$

The Johnson figure of merit is shown for a range of power semiconductors in Table 5. It should be noted that practical limitations encountered in fabricating power transistors limits the actual performance of devices, although the more mature technologies of Si and GaAs can approach these limits in some applications. InP has demonstrated excellent performance in applications, including MMICs, above 100 GHz, although it is still mainly applied to small-signal transistor applications and a limited range of relatively low-power millimeter-wave devices such as Gunn diodes (75 mW at 94 GHz).

7. APPLICATIONS AND MARKETS FOR MMICs AND DIGITAL ICs

Historically, the market for III-V integrated circuits grew steadily up until 2000, without the cyclical behavior often seen in the silicon digital IC market. In 2000 over \$2 billion MMICs and digital GaAs ICs were sold and despite the technology recession observed in 2001/02, the market for these products is expected to grow to over \$4 billion by 2006. Wireless communications represented over 70% of this market in 2000, but by 2006 this is expected to fall to around 60% as the use of MMICs in automotive applications increases. Interestingly, despite the intense interest in optoelectronics, the total share of the GaAs IC market in this application (for modulators, switches, driver ICs, detectors, and high-speed processing) is not expected to exceed 12% in the foreseeable future (indeed, its market share fell to 8% in 2002). Although digital GaAs was originally seen as a major growth element of the industry in the late 1990s, the collapse in the optoelectronic market in 2000 and the increase in CMOS Si and SiGe capabilities, have seen the GaAs largely displaced for digital applications below 2.5 Gbps. Analogue applications now dominate for III-V MMICs with increased usage in mobile terminal products (cellular handsets, personal digital assistants wireless LANs, etc.), principally for power amplifiers and low-loss RF switches (Fig. 12). The emer-

**Figure 12.** A microwave switch MMIC (1 × 1 mm) (Filtronic plc).

gence of automotive radar applications has led to forecasts of significant growth for chipsets at 17, 24 and 77 GHz, possibly reaching 5 million chipsets per annum by 2007.

1. COMMUNICATION SYSTEMS

The ability of electromagnetic radiation to provide almost instantaneous communication without any interconnecting wires has been a major factor in the explosive growth

of mobile communications, especially cellular and personal communications during the latter half of the twentieth century. The vacuum tube made the radio practical and affordable during the earlier half of the twentieth century. The invention of the transistor and highly complex yet cheap integrated circuits have allowed the development of ever complex digital communication systems that operate quite close to theoretical limits on channel capacity, spectrum efficiency, and so on.

The word *transceiver* is actually a combination of two words, *transmitter* and *receiver*. Figure 1 shows the block diagram of a general radio transceiver. Below each system block is a list of some of the popular techniques used. A modern digital transceiver uses most, if not all, of the system blocks in Fig. 1. Based on the direction of information transfer, radio systems are of three general types: simplex, half-duplex, and full-duplex systems. A *simplex* system transmits information in only one direction from a transmitter to a receiver. Examples of simplex systems are commercial audio and television broadcast systems organized in a *star* configuration. A *half-duplex* system is one in which transmission is bidirectional but only one transmitter at a time can transmit. A *full-duplex* or duplex system is one in which bidirectional communication can occur at any time. Although all communication systems are either some kind of simplex or duplex system, a variety of communications architectures exist dependent on the end application.

Section 2 points out the important characteristics of radio transceivers. Section 3 is devoted to the evolution of transceiver architecture. The characteristics of various different architectures are discussed in detail. Section 4 describes the implementation of important transceiver components with special emphasis on digital processing. Section 5 concludes by looking at the future.

2. TRANSCIEVER CHARACTERISTICS

2.1. Radio Transmitter Characteristics

This section details the important characteristics and performance issues for a transmitter.

2.1.1. Out-of-Band Emissions. There are stringent requirements as part of the standards for out-of-band power emissions. For example, the interim standard IS-54 for digital cellular radio specifies that power emission in adjacent and alternate channels must be 26 dB and 45 dB below the mean output power, respectively. Spectral shaping to maintain out-of-band emissions below those required by the standards is usually achieved through a combination of baseband pulse shaping, IF/RF filtering, and proper operation of the radiofrequency (RF) power amplifier.

2.1.2. Output Power, Distortion, and Efficiency of the Power Amplifier. In the early days of radio, power was amplified by vacuum tubes. With the invention of the transistor, solid state circuits have replaced vacuum tubes. The power amplifier should provide adequate output power with the least distortion and maximum possible efficiency [1]. The gain, efficiency, distortion, and power of the transistors typically used in solid-state power amplifiers depend on the choice of the bias point and the drive mechanism through the familiar designation of the operating class (Class A, B, AB, C, or E). The distortion introduced by the amplifier is specified by its AM-AM and AM-PM transfer characteristics.

The two most important parameters of the power amplifier, namely, efficiency and distortion, are incompatible with one another. Linear power amplifiers provide the least distortion but have quite large quiescent currents, resulting in poor efficiency. Nonlinear amplifiers, like

Figure 1. General block diagram of a modern transceiver. Abbreviations are listed at the end of the article.

Class C amplifiers, are highly efficient but cannot be used for linear modulation because of the distortion introduced by the amplifier. The type of power amplifier used depends on the requirements of the modulation used. Constant envelope modulation like frequency modulation (FM) can be amplified with nonlinear Class C amplifiers. However, in recent years, increasing demand for RF spectrum usage is forcing the use of spectrally efficient linear modulation techniques. These signals have a fluctuating envelope, and nonlinear amplification results in spectral spreading and intermodulation products. Therefore highly linear power amplifiers are required. One way to achieve linear amplification is to back off the amplifier from saturation and operate in the linear region of its transfer function. However, such amplifiers have poor dc-to-RF conversion efficiency. A major challenge in designing a high-power amplifier is to maintain linearity without compromising power efficiency [2].

2.2. Radio Receiver Characteristics

This section details the important characteristics and performance issues for a receiver.

2.2.1. Antenna and Input Characteristics. The main function of a radio receiver is to pick up electromagnetic radio energy at the antenna and transfer it efficiently to the processing section of the receiver. The important characteristics of an antenna are its efficiency, impedance, 3 dB beam width, bandwidth, and gain. Other characteristics are null-fill, upper sidelobe suppression, and performance versus specification. All antenna characteristics are functions of the physical antenna dimensions relative to the operating wavelength. Another important component is the coupler between the antenna and the input circuit of the receiver, which typically is a filter or an amplifier. Maximum energy is transferred if the impedance of the input circuit matches that of the antenna throughout the band of interest. Some of the antenna matching problems in a radio receiver are as follows:

1. The problem of matching the antennas at certain frequencies may be limited by component availability.
2. The impedance of antennas used in mobile applications or in locations where the environment changes with time due to foliage or traffic.

The problem of antenna matching is often solved by the system designer taking into account and compensating for a range of mismatch losses that might occur in practice. Other input characteristics that need to be taken into account are as follows:

1. The input RF circuits may be balanced, unbalanced, or both.
2. Protection from high-voltage discharges due to lightning.
3. Ability to handle high-power cochannel and adjacent channel transmissions

2.2.2. Gain and Sensitivity. Radio receivers typically process signals with a wide range of powers. The extent to which the signals can be received and processed usefully depends on the noise levels received at the antenna and those generated by the circuits within the receiver itself. The receiver is also required to produce a certain level of output power suitable for the application. Receivers are designed so that the gain is distributed among the various stages as required. Modern receivers are usually not gain-limited, and the weakest signal that can be processed is usually noise-limited. This signal level is known as the *sensitivity* of the receiver. A measure of sensitivity is the *minimum detectable signal* (MDS), which is the power of a sinusoidal signal that just equals the noise power at the intermediate frequency (IF) output of the receiver. MDS [1] can be expressed in decibels as

$$\text{MDS} = KTB_n F$$

where K is Boltzmann's constant (1.38×10^{-20} mW/°K), T is the reference temperature (typically 290°K), B_n is the noise bandwidth of the receiver, and F is the noise figure.

2.2.3. Noise Figure. The noise figure compares the total receiver noise with the noise that would be present if the receiver generated no noise. This ratio is called the *noise factor* F , and, when expressed in decibels, the noise figure (NF). It is thus a measure of the amount of noise introduced by the circuits within the receiver itself.

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}}$$

where (S/N) is the signal-to-noise ratio.

2.2.4. Selectivity. Selectivity is the ability of a receiver to separate a signal at one frequency from signals at other frequencies. Selectivity is defined as the bandwidth for which a signal x dB stronger than the minimum acceptable signal at a nominal frequency is reduced to the level of that minimum acceptable signal. Two important characteristics are required in establishing the selectivity of a receiver. One is that the selective components of the receiver must be sufficiently sharp to suppress unwanted interference from adjacent channel transmissions and spurious responses. The other is that the components must be sufficiently broad to pass the highest frequency of interest with acceptable gain and phase distortion.

2.2.5. Dynamic Range. Dynamic range is used to indicate the ratio between the strongest and weakest signals that a receiver can handle with acceptable noise or distortion. The weakest signal commonly considered is the minimum detectable signal. This definition is of limited value especially when the desired signal is surrounded by other signals with varying signal power. The selectivity of a receiver provides protection against many of the unwanted signals. The strong unwanted signals, however, can still cause degradation because of nonlinearities in the receiver chain. Therefore it is important to consider the

definition of the strongest signal component when determining the dynamic range of the receiver.

2.2.6. Characterization of Spurious Outputs. A modern receiver typically has a synthesizer and possibly several local oscillators, especially if superheterodyne architecture is used. It is possible for these frequencies to interact and produce spurious outputs without any inputs present. The following are other sources of spurious signals:

1. Parasitic oscillations in amplifiers because of parasitic feedback
2. Intermediate frequency subharmonics
3. Power supply harmonics

2.2.7. Frequency/Clock Generator Characteristics

2.2.7.1. Accuracy and Stability. Modern transceivers have a frequency synthesizer to which all other local oscillators are slaves. Earlier radios had free running oscillators that have largely been replaced by digital synthesizers because of the superior frequency accuracy, stability, flexibility, and cost performance of digital circuitry. Once the synthesizer has been set to operate at a specified frequency, its frequency must remain unchanged for a period sufficient for nominal operation despite temperature and environmental changes. Modern transceivers use temperature-compensated crystal oscillators as clocks for their digital circuitry. These oscillators typically are accurate to about 1 part per million. Higher accuracies are provided by oven-stabilized crystal oscillators and rubidium oscillators when sufficient power is available. In certain applications, such as mobile handsets where cost and power are at a premium, less expensive clocks with accuracies of approximately 3 to 10 parts per million are used.

2.2.7.2. Settling Time. Modern receivers typically span large frequency ranges and might be required to retune to a different frequency of operation. Because the frequency synthesizer used is typically based on a phase-locked loop, the loop goes out of lock for a short period whenever the receiver retunes. The settling time of the loop is important as any loss of lock results in degraded receiver performance.

2.2.8. Digital Receiver Characteristics. In addition to the characteristics previously mentioned, these are other important characteristics useful for systems using digital modulation.

2.2.8.1. Eye Diagram. The eye diagram [3], the traditional way of displaying digital data, is obtained by displaying the received demodulated digital data signal in successive symbol intervals on top of each other. The eye pattern provides the following wealth of information:

1. The width of the eye opening defines the time interval over which the received signal can be sampled without error from intersymbol interference.

2. The sensitivity of the system to timing error is determined by the rate of closure of the eye, as the sampling time instant is varied.
3. The height of the eye opening at any specified time defines the margin over channel noise.

2.2.8.2. Bit Error Rate (BER). The BER [1] is the primary measure of the quality of a digital communication system. The BER is defined as

$$\text{BER} = \frac{N_E}{N}$$

where N_E is the number of bit errors and N is the total number of bits transmitted.

3. RADIO ARCHITECTURES

3.1. Evolution

Radio architectures have remained relatively unchanged since the invention of the homodyne and superheterodyne receivers in the early part of the twentieth century. With the advent of integrated processors during the 1970s and 1980s, there was a migration from analog to digital processing in almost every aspect of radio systems engineering. The only radio system block that survived this migration was the RF front end, which by its function has to be analog. However, the basic radio architecture has remained the same. The word *digital* in digital radio has a double meaning. First, it refers to the fact that information is carried in digital form and second that the radio uses digital processing to recover the transmitted signal after it has been downconverted by an analog front end. The following are the advantages of using digital processing [1,4]:

1. The repeatability and temperature stability of digital processing are substantially better than analog processing.
2. Certain functions that cannot be or are difficult to implement in analog hardware, such as sharp rolloff linear phase filters, can easily be implemented with digital processing.
3. Once engineered, digitally implemented system functions do not require the tuning or tweaking typically required in analog systems.

The software radio [5] can be thought of as the next logical evolution of the digital radio, where software control of radio functions is pushed as close as possible to the antenna in the conventional digital radio architecture. Here, the entire RF band of interest is digitized right at the operating RF band by high-speed analog-to-digital converters (ADCs). The rest of the radio functions, such as downconversion, equalization, demodulation, and decoding, would be carried out by reprogrammable logic, typically digital signal processors (DSPs).

Software radio architecture has the following advantages over conventional hardwired digital radio architecture:

1. A highly flexible and reconfigurable transceiver can be implemented.
2. The transceiver can be easily adapted to any particular environment by changing the modulation, filtering, demodulation, and so on.
3. Because of open architecture, future upgrades can easily be made without reengineering the entire radio.
4. Software radio architecture benefits readily from concentration, where multiple radio channels share the same RF front end, whereas analog systems need a separate RF front end for each channel.

Applications that already use or are likely to use digital/software radio architectures include cellular and personal communications systems, satellite communications, digital television, digital audio broadcasting, navigation and position location systems, and test equipment.

3.2. Transmitter Architectures

The earliest analog radio transmitter architecture was the direct conversion transmitter. Figure 2 shows the general block diagram of an analog direct conversion architecture. Although this architecture is simple, it has the following disadvantages [6].

1. The analog implementation of precise modulators at the operating RF is difficult.
2. When used as an analog quadrature modulator, gain and phase imbalances between the mixers require compensation because unwanted sidebands are generated.
3. The filtering required to reduce out-of-band emissions to conform to government-mandated spectral masks must be carried out completely at the RF

band of interest. Designing high rolloff RF filters that introduce minimal amplitude and phase distortion across the frequency band of interest is difficult.

The superheterodyne architecture shown in Fig. 3 was intended to overcome some of the disadvantages of the direct conversion architecture. Here, modulation is carried out at a low IF. Then the desired signal band is filtered to conform to the desired spectral mask, and the filtered signal is upconverted to the desired RF band. The main disadvantage of the superheterodyne architecture is that the one or more IF stages used increase power consumption, space, and cost.

The advent of digital modulation and digital integrated circuits has resulted in the ever increasing use of digital processing in the transmitter chain. Digital processing can alleviate most of the problems associated with analog direct conversion transmitters, and as a result there is a resurgence of interest, especially for low-power mobile handsets where space and power are at a premium. Following are the advantages of digital architecture [7]:

1. Design and implementation are flexible.
2. Digital implementation overcomes the problems of gain and phase, dc offsets, and performance drifts in analog implementations.
3. Multichannel digital IFs especially at base stations eliminate the multiple analog IF chains required in analog architecture. With digital upconversion, all digital IF signals can be combined in a digital summer and then transformed into a single analog signal by a digital-to-analog converter (DAC).
4. Manufacturing is reliable.

Some of these combined analog-digital architectures are shown in Fig. 4.

The advent of software radio architecture will result in almost complete replacement of the RF system by programmable digital processing. Figure 5 shows the block diagram of an ideal software radio. In this ideal architecture, except for the final RF power amplifier and filter, the

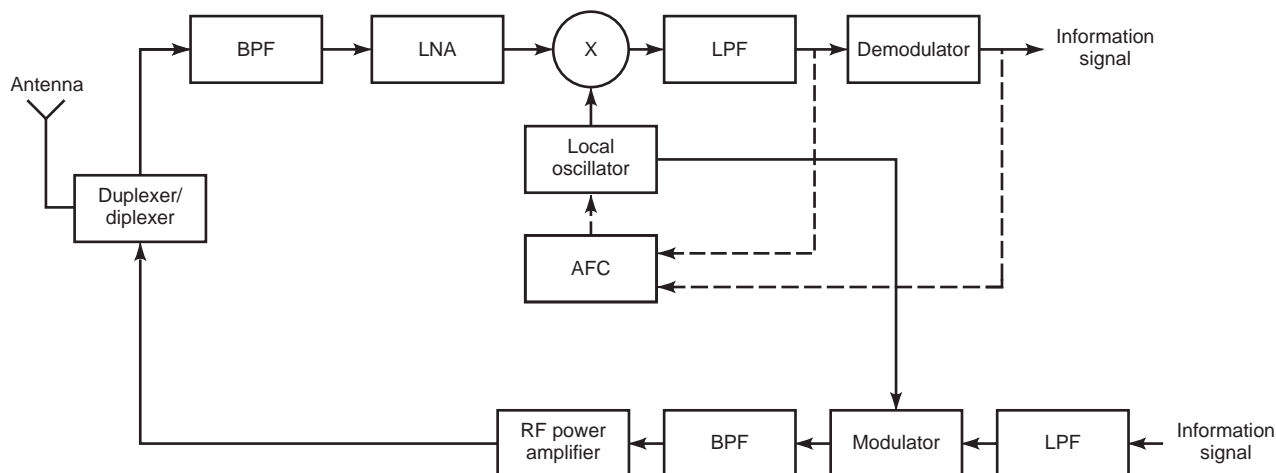

Figure 2. General block diagram of an analog homodyne transceiver.

Figure 3. General block diagram of an analog superheterodyne transceiver.

analog upconversion chain has been replaced by digital IF upconversion. Limitations on the maximum sampling rate by currently available technology, however, permits replacing only the first analog IF strip.

3.3. Receiver Architectures

The earliest analog receiver architecture was the homodyne or the direct conversion architecture, as seen in Fig. 2. The receiver consists of a bandpass filter (BPF) following the antenna for noise and interference rejection

followed by a low-noise amplifier (LNA). Then the signal is downconverted to baseband by a pair of analog mixers. The in-phase and quadrature components are low-pass filtered to remove the mixer products and are demodulated. Following are the advantages of direct conversion architecture:

1. Reduced hardware complexity as there are no IF stages
2. No image frequencies

Figure 4. General block diagram of combined analog-digital upconversion architectures.

Figure 5. General block diagram of an ideal software radio architecture.

Following are the disadvantages of the direct conversion receiver, *especially* with an analog implementation:

1. Amplitude and phase mismatches between the mixers distort the signal.
2. Sharp rolloff analog low-pass filters (LPF) also distort the desired signal.
3. Carrier leakage, $1/f$ noise in the mixers, and bias in the filters all contribute to an unpredictable time-varying dc offset in the recovered signal.
4. All signal amplification has to be done at the carrier frequency. Building high-gain RF amplifiers at such high frequencies is difficult and expensive.
5. Carrier recovery for coherent reception has to be carried out at the carrier frequency. Precise control of high-frequency oscillators is difficult.

The superheterodyne receiver shown in Fig. 3 was developed to alleviate some of the disadvantages of the direct conversion receiver. In this architecture, the RF signal is downconverted to an intermediate frequency before being downconverted to baseband. This is known as the single IF stage superheterodyne receiver. Various versions of this general architecture with multiple IF stages have been developed. The most common version is the dual IF stage architecture. Following are the advantages of superheterodyne architecture compared with the direct conversion receiver:

1. Most of the signal amplification is done at relatively lower IFs, where it is easier to build high-gain amplifiers.
2. Automatic frequency control is usually carried out at the lower IFs and hence is easier to implement.

With the advent of digital modulation, high-speed ADCs, and digital integrated circuits, digital processing started to replace segments of the analog receiver architecture especially in demodulation and baseband processing. This led to the development of digital radio architecture. Both direct conversion and superheterodyne RF front-end architectures have been used in digital radios. The direct conversion digital radio requires two ADCs to digitize the in-phase and quadrature components of the downconverted signal. Superheterodyne digital radios have used both low-pass and bandpass digitization. The advantage of bandpass digitization is that it can replace the last analog downconversion stage. In addition, because the final

downconversion to center the chosen spectral image around dc is done digitally, all problems associated with quadrature analog downconversion disappear. Some of the digital receiver architectures are shown in Fig. 6.

Although the digital radio provides superior performance, its architecture is still based on the direct conversion or the superheterodyne architectures. Recently, a more fundamental change in receiver architecture occurred with the advent of software radio architecture, made possible by technological advances in ADC technology, computing technology, and software engineering. The software radio architecture looks similar to that of the digital radio with one crucial difference. In software radio architecture, programmable digital processing is pushed as close to the antenna as technology permits. The block diagram of an ideal software radio architecture is shown in Fig. 5. In this architecture, the only analog RF components are the preselection bandpass RF filter and the low-noise RF amplifier. Then the RF signal is directly digitized using bandpass subsampling, and the rest of the receiver functions are carried out in embedded software modules running on high-speed DSPs. This architecture is still a few years away from commercial implementation because high-speed ADCs that operate with sufficient resolution at the desired RF band are unavailable. Current software radio architectures use at least one IF stage.

4. TRANSCIEVER IMPLEMENTATION

4.1. Transmitter

The design and implementation of transmitters involves the following:

1. Filtering
2. Modulation and frequency upconversion
3. Power amplification

4.1.1. Filtering. In analog radios, analog filters are the only way to achieve frequency selectivity and to limit out-of-band emissions. In digital radios, digital filters in addition to analog filters are used to shape the spectrum of the transmitted signal. Analog filters are discussed in detail later. Some of the popular digital filters used for pulse shaping to achieve a compact modulated spectrum are the raised cosine and Gaussian filters [8]. The advantages of using digital filters are discussed in Section 4.2.7.2.

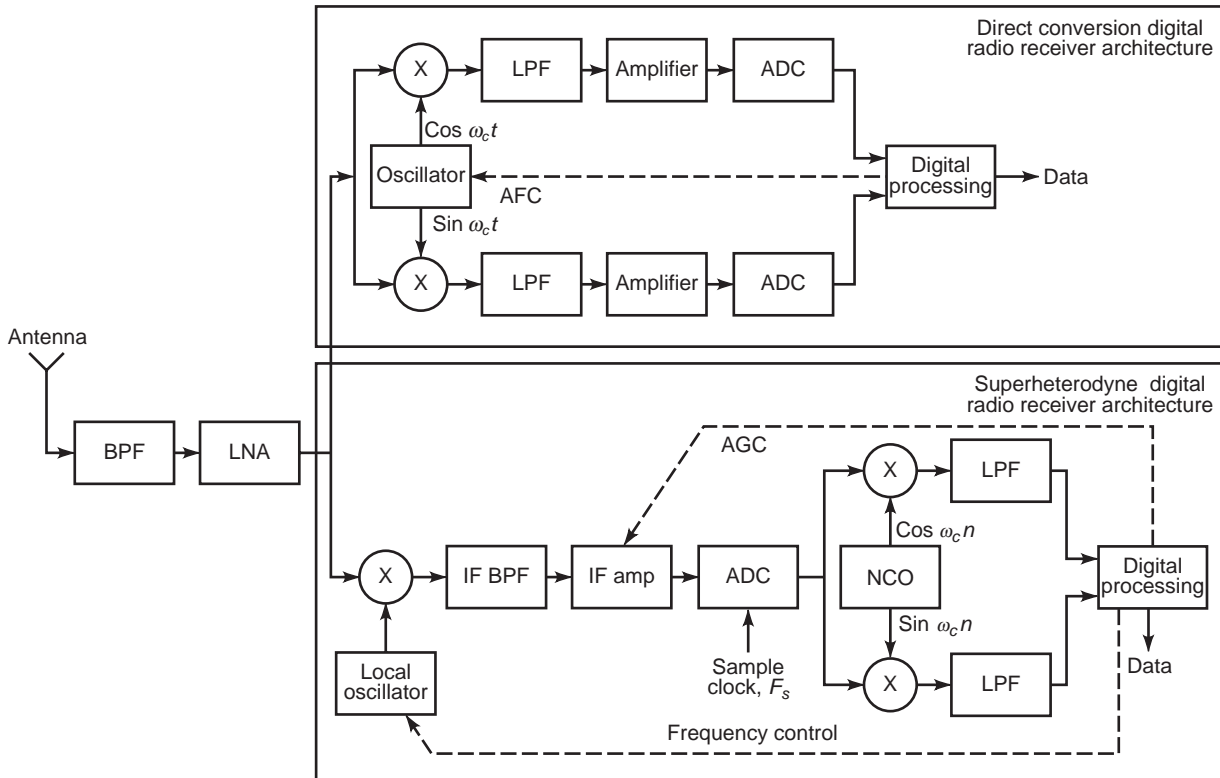

Figure 6. Some digital receiver architectures.

4.1.2. Modulation. Modulation [8] is the process of encoding information from a message source onto a format suitable for transmission. The process involves translating the baseband message signal, called the modulating signal, onto a bandpass signal at a much higher frequency, called the carrier. This process is called modulation. Modulation is usually carried out by varying the amplitude, frequency, phase, or any combinations of these three parameters of a carrier signal. Based on whether the message information signal is analog or digital, modulation is classified as analog or digital modulation.

4.1.2.1. Analog Modulation. In analog modulation, the modulating signal is analog and can assume an infinite number of amplitude values. Analog modulation is broadly classified into two categories, amplitude modulation and angle modulation.

In amplitude modulation (AM), the amplitude of a high-frequency carrier signal is varied in accordance with the instantaneous amplitude of the modulating information signal [3,8]. The amplitude-modulated signal is expressed as

$$S(t) = A_C[1 + m(t)] \cos 2\pi f_C t$$

where A_C is the amplitude of the carrier, f_C is its frequency, $m(t)$ is the modulating information signal, and $S(t)$ is the modulated signal. The spectrum of an AM signal contains a component at the carrier frequency and two sidebands that replicate the original information spectrum.

An AM signal is generated by a nonlinear device, such as a diode or transistor. Many variations of amplitude modulation exist based on what percentage of the sidebands is transmitted. Some of these variations are single-sideband AM (SSB-AM), pilot-tone-sideband AM, and vestigial-sideband AM (VSB-AM).

Angle modulation [3,8] varies the angle of the carrier signal according to the amplitude of the modulating signal. There are two important classes of angle modulation, FM and phase modulation (PM).

In FM, the instantaneous frequency of the carrier is varied with the information signal $m(t)$, as shown by the following equation:

$$S(t) = A_C \cos \left(2\pi f_C t + 2\pi k_f \int_{-\infty}^t m(l) dl \right)$$

where k_f is the frequency deviation constant measured in units of hertz per volt. There are two basic methods for generating an FM signal, the *direct method* and the *indirect method*. In the direct method, voltage-controlled oscillators vary the frequency of the carrier signal directly in accordance with the amplitude of the information signal. Such oscillators commonly use devices, such as varactor diodes, whose reactance can be varied in accordance with the modulating signal's voltage level. The indirect method is based on approximating a narrowband FM signal as the sum of a carrier signal and a single sideband signal where the sideband is 90° out of phase with the carrier.

PM is a form of angle modulation where the phase of the carrier is varied according to the information signal $m(t)$. A PM signal can be generated by first differentiating the information signal $m(t)$ and then outputting it to a frequency modulator.

4.1.2.2. Digital Modulation. Modern communication systems use digital modulation. In digital modulation, the modulating information signal is represented as a time sequence of symbols in which each symbol has m finite states. Each symbol represents n bits of information, where $n = \log_2 m$ bits/symbol. Digital modulation offers many advantages over analog modulation, including greater noise immunity, robustness to channel impairments, and easier multiplexing of various forms of information, such as voice, data, and video. Furthermore, digital transmissions use error-correcting codes and support complex signal conditioning and processing techniques, such as source coding/compression, encryption, and equalization to improve the performance of the communications. Advancements in very large-scale integration and digital signal processing technology have made it possible to implement digital modulators and demodulators easily. The use of embedded software to do most of the signal processing allows alterations without having to replace the hardware.

Some of the widely used digital modulation techniques are m -ary amplitude-shift keying (ASK), m -ary frequency-shift keying (FSK), m -ary phase shift keying (PSK), combined amplitude and phase modulation, combined coding and modulation, and multicarrier modulation.

In ASK, the amplitude of the carrier signal is varied in accordance with the instantaneous amplitude of the modulating information signal, which can take one of several discrete amplitudes. In FSK, the frequency of the carrier signal is varied in accordance with the instantaneous discrete amplitude of the modulating information signal. In PSK, the phase of the carrier signal is varied in accordance with the instantaneous discrete amplitude of the modulating information signal. In a general sense, ASK, FSK, and PSK can be thought of as special cases of AM, FM, and PM, respectively, where the modulating signal is discrete in amplitude. In combined amplitude and phase modulation, both the amplitude and phase of the carrier are varied according to the amplitude of the modulating signal. Ungerboeck [9] realized that error-correction coding and modulation can be combined at a fundamental level to realize performance gains greater than with the conventional method of coding and modulating separately. Combined coding and modulating is more commonly known as *trellis-coded modulation*. The basic concept of multi-carrier modulation is dividing a given RF bandwidth into many narrowband subchannels that are transmitted.

4.1.3. Frequency Upconversion. Frequency conversion is usually achieved by devices called *mixers*. A mixer is a component that acts as a frequency converter by mixing two input signals together to produce a desired signal. A mixer can be implemented by a variety of semiconductor devices, such as diodes (typically Schottky

diodes), bipolar-junction transistors, and field-effect transistors. Mixers are generally of two types, single-balanced and double-balanced. The single-balanced mixer improves port-to-port isolation and reduces the magnitude of some of the spurious signals. It consists of two single-ended mixers interconnected in a configuration that greatly reduces some spurious products. A double-balanced mixer further improves port-to-port isolation and suppresses spurious inter-modulation products even further.

4.1.4. Amplifiers. The triode vacuum tube amplifier was the mainstay for many communication systems before the transistor was invented. Because of transit time limitations, triodes were limited to VHF and UHF. For operation at higher microwave frequencies, the magnetron was invented in the early 1940s. The invention of the transistor was a boon for developing low-cost, reliable, handheld, low-power mobile communication systems. Since then, solid-state amplifiers have replaced vacuum tube amplifiers in almost all communication systems. Systems requiring extremely high power at microwave frequencies, such as deep space and radar systems, continue to use tube amplifiers.

All commercial communication systems use solid-state transistor amplifiers. Solid-state amplifiers come in four main types: discrete, hybrid, integrated (ICs), and application-specific IC (ASIC). A discrete amplifier is one built with discrete transistors and passive components. Hybrid modules, also known as microwave integrated circuits (MICs), have a substrate and discrete devices, including RF matching and bias circuitry. RF ICs, also known as microwave monolithic ICs (MMICs), have all bias and RF matching circuitry on the same substrate, whereas MICs use different materials to achieve optimum matching. The advantage of using a single substrate is that components can be closely matched in value. The difference between an IC and an ASIC is that an IC typically integrates only a few transistors together with transmission line filters and inductors, whereas ASICs, on the other hand, contain several hundred or thousands of transistors.

Several amplifier configurations are based on operating classes A, B, AB, C, D, E, or F. Silicon (Si) bipolar, heterojunction-bipolar, and field-effect transistors (FET) have been used most often to date in RF circuits. Gallium arsenide (GaAs) and complementary metal oxide semiconductor transistors have been gaining interest. GaAs amplifiers offer simple functionality with some biasing and matching components around a chain of transistors. One of the advantages of GaAs versus silicon is that GaAs is an insulator, whereas silicon is a conductor at RF frequencies. As a result, GaAs can integrate several RF components monolithically, facilitating closer components and better matching.

High-power amplification at microwave frequencies, especially those used for satellite communications, are usually handled by traveling-wave tube amplifiers (TWTAs). Other tube amplifiers are the magnetron, coupled-cavity TWT, continuous-wave TWT, helix TWT, klystron, and crossed-field amplifier (CFA).

4.2. Receiver

The main function of the receiver is to pick up the RF energy transmitted at its antenna and efficiently and effectively recover the original information signal transmitted. The design and implementation of receivers involves the following:

1. Antennas
2. Amplification
3. Filtering
4. Downconversion
5. Automatic gain control
6. Demodulation and other associated signal processing functions

Antennas, amplification, analog filtering, and downconversion are common to both analog and digital/software radios. The rest of the receiver functionality depends on its implementation, whether analog or digital. Because these implementations are quite different, they are discussed in different sections with special emphasis on digital implementation.

4.2.1. Antennas. The type of antenna used in a transceiver depends on its application. Handheld or backpacked transceivers require integral antenna structures. Vehicular transceivers must use antennas of limited size and relatively short wavelengths. Antennas that operate at frequencies substantially below their first resonance are called small antennas. Large point-to-point systems use large antennas. Some of the most popular antennas used in commercial communication systems are the vertical whip antenna, the loop antenna, and the dipole array.

4.2.1.1. Whip Antenna. For operating frequencies below the quarter-wave resonance of the antenna, the whip input impedance appears as a small capacitance in series with a resistance. The radiation resistance R_R of a short vertical whip is given by [1]

$$R_R = 40\pi^2 \left(\frac{h}{\lambda}\right)^2$$

where h is the antenna height and λ is the operating wavelength. The whip is also used as a quarter-wavelength monopole antenna for applications, such as cellular and PCS handsets. The whip antenna has an omnidirectional antenna pattern in azimuth.

4.2.1.2. Loop Antennas. Loop antennas have been used in portable broadcast receivers and radio direction finders. When the dimensions of the loop are small compared with the wavelength, the loop is said to be small and its impedance is an inductance in series with a resistance. The radiation resistance R_R for a loop with N turns is given by

$$R_R = 320\pi^4 \left(\frac{AN}{\lambda^2}\right)^2$$

where A is the area of the loop. The loop antenna responds as the cosine of the angle between its face and the arrival direction of the electromagnetic wave. This results in a figure-eight antenna pattern with the null for waves arriving perpendicularly to the loop face.

4.2.2. Amplification. The RF signal picked up by the antenna is very weak and has to be amplified before it can be processed. Typically the very first amplifier used is a specially designed, low-distortion, low-noise amplifier. The operating characteristics of the amplifier are important, as its noise performance dominates the noise figure of the receiver. Both bipolar-junction and FET amplifiers have been used. In recent years, the use of GaAs instead of Si has been gaining interest.

4.2.3. Analog Filters. The selectivity of an analog radio receiver is achieved solely by bandpass and low-pass analog filters. Even in digital and software radio architectures, the analog bandpass filter is an important component and is used both for preselection and antialiasing. Digital radios also use analog filters in their RF front end to implement some selectivity.

The most important characteristics of a filter are its amplitude and phase response. The various characteristics of a filter are interrelated because they are completely determined by the poles and zeros of the transfer function of the filter. Following are some of the common filter families:

1. Butterworth
2. Chebychev
3. Elliptic
4. Equiripple

Analog filters are implemented with a number of different resonators. Following are the available technologies:

1. Inductor–capacitor (LC) resonators
2. Mechanical resonators
3. Quartz crystal resonators

Another important filter implementation is the surface acoustic wave (SAW) filter, of interest because it can be implemented with integrated circuit techniques and can use finite impulse response designs, similar to those for digital filters.

4.2.4. Downconversion. Downconversion is the process of shifting the received RF signal to baseband. Both direct conversion and superheterodyne architectures are used. The basic components of downconversion are mixers, bandpass and low-pass filters, and oscillators.

4.2.5. Automatic Gain Control (AGC). The large dynamic range of signals that must be handled by radio receivers requires gain adjustment to prevent overload or intermodulation of the stages to adjust the demodulator input level for optimum operation. Gain control is generally distributed over several stages throughout the receiver architecture. AGC typically measures the signal level into the

demodulator and tries to keep the level in the desired range by a feedback control loop. The control should be smooth and cause a generally logarithmic variation with the input variable.

4.2.6. Other Analog Radio Receiver Functions. The remaining functionality of the analog radio receiver is demodulation. Double-sideband AM signals are usually detected by an envelope detector. An envelope detector is any rectifier circuit that produces a component at the modulating frequency that is then recovered by a low-pass filter. The rectifier is generally implemented by diodes and by bipolar and field effect transistors. Other AM transmissions, such as SSB-AM and VSB-AM, are demodulated by a coherent demodulator. The coherent demodulator uses a mixer circuit with a local oscillator signal synchronized to the AM input carrier. Carrier synchronization is achieved through a carrier recovery circuit, such as the Costas loop. Common FM demodulators are the slope detector, quadrature detector, phase-locked loop (PLL), demodulator, and zero-crossing detector. The slope detector uses linear circuits to convert the frequency variations to envelope variations that can then be detected by an envelope detector. The quadrature detector consists of a network that shifts the phase of the FM signal by an amount proportional to its instantaneous frequency and uses a phase detector to detect the phase difference between the original FM signal and the signal at the output of the phase shift network. The output of the phase detector is proportional to the instantaneous frequency of the FM signal. In this manner, a frequency-to-amplitude conversion is achieved and the FM signal is demodulated. Phase detectors are generally implemented by diode-based mixer circuits. Because a PM signal can be modeled as an FM signal where the modulating signal has first been differentiated, PM demodulation is achieved by passing the PM signal through an FM demodulator and integrating its output.

4.2.7. Other Digital/Software Radio Receiver Functions. The rest of the digital/software radio receiver can be split into two distinct segments: signal digitization and signal processing.

4.2.7.1. Signal Digitization. Signal digitization, implemented by ADCs, is a two-step process [10], signal sampling followed by quantization. The sampling process is critical in signal digitization. There are two types of sampling, uniform and nonuniform sampling. In uniform sampling, signal samples are taken at uniform intervals, whereas in nonuniform sampling, the samples are non-uniformly spaced. The ADCs in communication systems use uniform sampling, and so the rest of the discussion concentrates on uniform sampling ADCs. The sampling methods for uniform sampling are Nyquist sampling, oversampling, quadrature sampling, and bandpass sampling.

The general sampling theorem for a bandlimited analog signal with no spectral components above f_M Hz

requires that the sampling rate F_S satisfies

$$F_S \geq 2f_M$$

$F_S = 2f_M$ is known as Nyquist sampling, and at this rate, the replicas of the spectrum of the original analog signal do not overlap. Two practical problems develop when implementing Nyquist sampling. The first is defining what a truly bandlimited signal is, and the second is antialiasing filtering before the ADC. In general, an RF signal has components at all frequencies. It is desirable that the distortion of the desired signal be dominated by ADC nonlinearities, not by spectral overlap. This requires that signals higher in frequency than $F_S/2$ be lower in power than the largest spurious response of the ADC. Bandlimiting is usually carried out by the analog antialiasing filter before the ADC. Unfortunately, practical analog filters cannot provide the kind of "brickwall" filter response required. Also, as the steepness of the filter rolloff increases, the phase response of the filter becomes more nonlinear, introducing more distortion.

Sampling the signal at a rate higher than the Nyquist rate is called oversampling. The benefit of oversampling is that the spectral replicas of the original analog signal in the sampled signal spectrum become increasingly separated as the sampling rate is increased beyond the Nyquist rate. Hence, a simpler antialiasing analog filter with a more gradual transition band can be used.

In quadrature sampling, the signal to be digitized is split into two signals. One of the signals is multiplied by a sinusoid to downconvert the signal to a zero-center frequency and then filtered to form the in-phase component of the analog signal. The other signal is multiplied by a 90° phase-shifted version of the sinusoid and filtered to form the quadrature component. Because each of these two signals occupies only one half the bandwidth of the original RF signal, the sampling rate can be reduced by one half at the expense of requiring two ADCs.

Bandpass sampling is based on the bandpass sampling theorem, which states that a bandpass signal with no frequency components below f_L Hz and none above f_H Hz can be determined uniquely by sampling the signal at a rate F_S Hz, where

$$\frac{2f_H}{k} \leq F_S \leq \frac{2f_L}{k-1}$$

where k is restricted to integral values that satisfy

$$2 \leq k \leq \frac{f_H}{f_H - f_L}$$

and

$$(f_H - f_L) \leq f_L$$

Bandpass sampling provides an image of the desired signal at multiples of the sampling frequency, and the spectral replica of the original analog bandpass signal closest to dc is usually chosen for further processing.

Once sampling is over, the sampled analog signal with its infinite range of amplitudes has to be converted to a finite set of discrete amplitudes. This is known as quantization. There are two general quantization methods, uniform and nonuniform quantization. In uniform quantization, the voltage difference between each quantization level is the same. In nonuniform quantization, the quantization levels are nonlinearly spaced in voltage. The ADCs used in RF and IF digitization typically use uniform quantization. In uniform quantization, some error is introduced into the quantized signal because the analog signal cannot be represented exactly by a finite number of discrete amplitude levels. Statistically, it can be assumed that the error signal is uniformly distributed within a quantization level.

4.2.7.2. Signal Processing. Signal processing is the core of the radio receiver and is the segment where the original transmitted information signal is recovered. Many operations are carried out by this system. These operations are quite application specific and may include some or all of the following:

1. Downconversion
2. Filtering, either spatial or temporal or both
3. Equalization
4. Despreading
5. Synchronization
6. Demodulation
7. Automatic gain control
8. Carrier recovery
9. Error-correction decoding
10. Source decoding
11. Decryption
12. Timing recovery

Some of the most important signal processing functions of a receiver are examined here in further detail.

Downconversion. When bandpass subharmonic digitization is used, spectral replicas of the original analog signal are found at multiples of the sampling frequency. However, there is generally no spectral replica centered around the zero-center frequency. To generate the complex baseband signal centered around the zero-center frequency, the output of the ADC is sent to a pair of digital multipliers. The reference inputs for the digital multipliers come from a quadrature-output, numerically controlled oscillator (NCO). The multipliers shift the spectral replica to the zero-center frequency. Then the outputs of the multipliers are sent to low-pass digital filters, which are typically finite impulse response (FIR) filters, to recover the baseband signal and filter out the other mixer products.

Filtering. Digital filters [11] are widely used in communication signal processing for tasks, such as digital downconversion, equalization, interference suppression, and pulse shaping. Following are the advantages of digital filters:

1. Exact linear phase filters can be implemented easily.

2. Filters with almost any desired frequency and phase response can be designed and implemented easily.
3. Changes in filter responses due to component variations caused by aging are eliminated.
4. Changes to the filters can be carried out easily because most of the filtering is implemented in software running on programmable processors.

Digital filters are of two general types, FIR filters and infinite impulse response (IIR) filters. Finite impulse response filters are the most common digital filters in radio receivers mainly because of the following advantages:

1. Filters with exactly linear phases can be easily designed.
2. There are efficient recursive and nonrecursive realizations of FIR filters.
3. FIR filters realized nonrecursively are always stable.
4. Round-off noise inherent in finite precision arithmetic implementations are easily made small for non-recursive realizations.

Following are the disadvantages of FIR filters:

1. A large filter order is required for sharp cutoff filters.
2. The delay of linear phase FIR filters need not always be an integral number of samples.

The main advantage of IIR filters is that sharp cutoff filters can be realized in relatively small filter orders. Following are the main disadvantages:

1. IIR filters generally do not possess linear phases.
2. IIR filters are more prone to be unstable because of quantization and round-off noise.

Carrier Recovery. Coherent demodulation requires that the phase and frequency of the transmitted carrier be known. Carrier recovery is the process of estimating the phase and frequency of the carrier to establish a reference for demodulation at the receiver. Any error in estimating the phase and frequency of the carrier causes significantly degraded performance. The information signal may be modulated onto the RF carrier so that a residual component at the RF exists in the overall transmitted signal spectrum. This residual RF component can be easily tracked by a narrowband PLL and provides the desired reference signal. However, this residual component represents power unavailable to transmit the information. Techniques that conserve power are of interest especially in mobile applications where power is at a premium because batteries supply power to the radio. As such, suppressed carrier transmissions are widely used. Following are some of the popular suppressed carrier recovery techniques:

1. Squaring loop
2. Costas loop
3. Decision feedback loop

Demodulation. The ultimate function of the radio receiver is to recover the original information signal that modulated the transmitted carrier. This process is known as *demodulation*. The portion of the receiver system that implements demodulation is known as the *demodulator*.

Some of the popular FSK demodulators are the limiter-discriminator, the PLL, and noncoherent and coherent demodulators. Noncoherent demodulation is carried out by a bank of bandpass filters whose outputs are envelope-detected. The largest output is selected as the transmitted symbol. The bandpass filters used to detect the tones are implemented either as FIR or IIR filters. Coherent demodulation compares the received signal with all reference frequencies. The comparison is done by multiplying the received signal by all the reference signals and then low-pass filtering the outputs of the bank of multipliers. The largest output is selected as the demodulated symbol. The locally generated reference signals must be synchronized in phase and frequency to the transmitted signal states.

Common PSK demodulators are the coherent demodulator and the differential demodulator. PSK can also be demodulated by using a frequency demodulator, such as a limiter-discriminator or a PLL, and integrating the output before the decision stage. The block diagram of a coherent PSK demodulator is shown in Fig. 7. Differential demodulators determine the cosine and sine of the phase difference and then decide on the phase difference accordingly. Differential demodulation shown in Fig. 7 is implemented by taking the product of the signal and a delayed version of the same signal. The output of the multiplier is low-pass filtered, usually by a FIR filter, to recover the information symbol transmitted. The transmitted symbols need to be encoded differentially to use differential demodulation.

Differential demodulators are often used in highly mobile applications where fading in the channel makes it impossible to get a robust coherent estimate of the transmitted carrier.

Processing Implementation. The processing elements that implement the functions in a radio are crucial, especially in software radio architecture, as they implement virtually all of the functions of the radio transceiver except the frequency conversion and RF amplification. The main attraction of the software radio concept, namely, its flexibility and ease of adaptation, is possible because signal processing is implemented in software modules. The software requires a hardware platform to run on, and the capability of the hardware architecture of the processing platform is critical.

Typically digital signal processing functions are implemented on special digital processors called DSPs [12]. Although DSPs are also microprocessors, there are several crucial differences between general multipurpose microprocessors and DSPs. General microprocessors are typically built for a range of general functions and normally run large blocks of software. The DSP, on the other hand, is built for a small dedicated group of tasks, the most important being the multiply-accumulate arithmetic operation that forms the core of any digital filter. DSPs contain large, high-speed data busses and use direct memory access to transfer large amounts of data, thereby avoiding communication bottlenecks. In addition, DSPs contain dedicated hardware blocks, such as multipliers, to speed up the arithmetic-intensive signal processing steps.

Some of the signal processing functions are so complex that parallel and sequential partitioning of algorithms is required to get the required processing power. DSPs are getting faster but are currently incapable of implementing

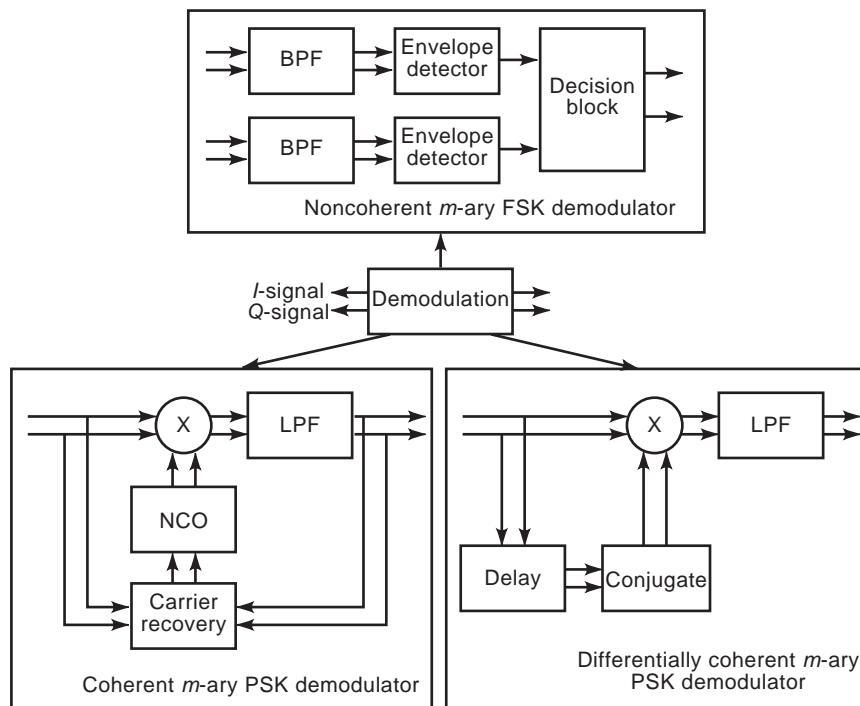

Figure 7. Some general demodulator architectures.

everything possible on a single chip. One approach has been to use multiprocessing to share the computational burden. The traditional approach to multiprocessing has been to integrate various DSPs on a board. Modern DSPs contain various hooks to simplify multiprocessing, such as simplified addressing across processors. A recent approach has been to integrate multiple processors within a single chip. This within-the-chip approach benefits from having closely coupled memory and cache, which improves communication efficiency.

To keep the flexibility of a programmable solution and the efficiency of a dedicated solution, field-programmable gate arrays (FPGAs) are increasingly becoming another viable option to implement highly complex signal processing functions. FPGAs are logic devices whose hardware architecture can be programmed before use. Techniques, such as distributed arithmetic for array multiplication, can increase the data bandwidth and throughput of an FPGA-based solution by orders of magnitude beyond those possible with general-purpose DSPs. It is projected that DSP cores will have onchip FPGA sections to provide configurable accelerators.

5. CONCLUSION

This article has presented an overview of the radio transceiver, its architecture, and the implementation of its most important system blocks. Several other specialized functions are not present in all transceivers and have not been discussed here. Some of these circuits are noise limiting and blanking, squelch, diversity reception, and adaptive antenna array processing.

Traditionally, transceivers have used analog circuits for implementation. The capabilities and advantages of digital processing have allowed replacing many of these analog functions. The movement of the digital portions of the processing closer to the antenna has resulted in the development of software radio architecture. The software radio is a powerful architectural framework that helps to deliver advanced radio services by leveraging the economics of contemporary micro-electronics and software technologies. Although much technological progress has been made in the field of digital processing, technology is not currently available to implement the ideal software radio. Following are some of the challenges and issues that face radio designers today:

1. To engineer low-cost, low-loss, and low-distortion wideband antennas
2. To engineer low-cost, low-loss, and low-distortion wideband RF front ends
3. To develop high-efficiency linear power amplifiers
4. To develop low-power integrated RF front ends
5. To develop low-cost, high-resolution (> 14 bits), and high-speed ADCs
6. To develop low-cost, high-speed reconfigurable digital processors

The development of the software radio transceiver is by no means over. Further technological advances are required,

especially in the hardware implementation of ADCs and reconfigurable processors. There will be further development toward integrating the analog RF front end into a single integrated circuit. The development of low-power RF and digital circuits is another challenge. The ultimate goal of implementing a radio on a chip, although not yet a practical reality, is not far away.

TRANSIENT ANALYSIS

ORLA FEELY
 BRIAN MULKEEN
 University College Dublin
 Dublin, Ireland

1. INTRODUCTION

Transient circuit analysis is used to find transient currents and voltages in a circuit. The word “transient” describes a quantity that is fleeting rather than permanent, and distinguishes this branch of circuit analysis from steady-state analysis, which is concerned with the long-term or settled behavior of a circuit. Transient circuit analysis asks not just “Where will my circuit end up?” but also “How will it get there?” The charging of a capacitor is one of the classic examples, but we might also consider what happens when a short pulse is applied to a transmission line (perhaps an interconnection on a high-speed digital integrated circuit), or when a burst of radiofrequency energy is applied to the antenna in a radar system. In this article, we review the basic principles of transient circuit analysis, which is a long-established branch of circuit theory with a wide range of applications. We will not consider the many techniques that are used in the simulation of transient behavior in circuits—these are an enormous topic in their own right, and are covered elsewhere.

Before proceeding, it should be noted that the circuits to be considered in this article in fact form only a subset of the universe of circuits—they are all linear and time-invariant. A linear circuit is one in which each element (except the sources that drive the circuit) is described by one or more linear equations involving its current(s) and voltage(s). For example, the resistor defined by $v = Ri$ is linear, but the diode defined by $i = I_s(e^{v/V_T} - 1)$ is nonlinear, and any circuit containing the diode is therefore nonlinear. Nonlinear circuits can exhibit highly complex behavior

and cannot be handled by the techniques described in this article. A time-invariant circuit is one in which the equations defining the elements (except the independent sources) do not change with time.

The equations describing a circuit arise from two sources: (1) Kirchhoff’s laws tell us how the elements in the circuit are interconnected, and then (2) each element in the circuit has an individual equation (or equations) describing its behavior. If all of the circuit elements are described by algebraic equations (i.e., ones in which no derivatives appear) involving their currents and voltages, these equations can be combined with Kirchhoff’s equations to give a set of algebraic equations that completely describe the circuit. These equations are linear equations in terms of the currents and/or voltages in the circuit, and can be solved by any of the techniques of linear algebra. The power of linear algebra means that these circuits, known as *resistive circuits*, are (relatively) easy to analyze. The behavior of these circuits is quite simple; if a linear resistive circuit is driven by a 1-V battery, then changing to a 2-V battery will cause all voltages and currents in the circuit to double. There is no time delay in this response—the doubling of voltages and currents occurs at the precise instant when the 2-V battery is inserted into the circuit. If the battery is replaced by a more complicated voltage source that varies with time, each voltage and current in the circuit will also vary with time as a scaled replica of the new voltage source.

Although easy to analyze, the limited behavior of a linear resistive circuit means that such circuits are not hugely useful. Instead of producing a scaled replica of the signal that drives them, most circuits are required to convert a signal into a more useful form. For example, the ignition circuit in a car is “driven” by a battery with almost constant voltage, but its output is a short, sharp spark; the circuits in a radio receiver are “driven” by a jumble of signals from many different sources, but must select the signal of interest and extract some information from it. These effects rely on the use of capacitors and/or inductors. These circuit elements are defined by equations involving not only their currents and voltages but also the rate of change (or derivative) of these quantities with time. Specifically, the current through a capacitor is proportional to the derivative of the capacitor’s voltage with respect to time, and the voltage across an inductor is proportional to the derivative of the inductor’s current with respect to time. Capacitors and inductors are known as *dynamic circuit elements*, conveying the importance to them of time variation, or energy storage elements, since they are capable of storing energy for later release.

Dynamic elements can be placed deliberately in a circuit, or they can be unwanted parasitic elements, modeling, for example, the capacitance between wires in the circuit. If a circuit contains even a single dynamic element, it is in general described no longer by a set of algebraic equations, but by one or more differential equations, in which the variables are not only the voltages and currents but also the derivatives of certain of these quantities with respect to time. A dynamic circuit is one that contains at least one dynamic element.

At higher frequencies, there is an additional complexity to consider in our circuit analysis, namely, the appearance of distributed circuit effects. Distributed circuits, unlike lumped circuits, have voltages and currents that vary not only with time but also with position within the circuit. The basic distributed circuit element is the transmission line, an incremental length of which is commonly modeled by a series resistance and inductance and a shunt capacitance and conductance. The inductance and capacitance in the model give rise to time derivatives in the equations that describe the line, while the distributed nature of the element gives rise to derivatives with respect to position along the line. Thus circuits of this nature are described by differential equations containing derivatives with respect to position as well as derivatives with respect to time. This gives rise to new forms of transient behavior in a circuit.

The goal of transient circuit analysis is to solve the differential equations that describe a dynamic circuit and thus to come up with expressions predicting the way in which the voltages and currents in the circuit will vary with time. It is often concerned in particular with the response of the circuit to changes, such as when a source is inserted, removed, or suddenly changed in some way, or a switch is closed and the makeup of the circuit thereby changed.

Dynamic circuits can exhibit more interesting behavior than resistive circuits, but they are also more difficult to analyze. One of the simplest dynamic circuits contains a single capacitor in series with a resistor and a constant voltage source that is switched on at some specified time. This circuit is described by an equation involving the capacitor voltage v_C and its derivative with respect to time dv_C/dt . The absence of any higher derivatives gives this equation the description “first order.” A circuit containing just a single dynamic element is described by a first-order differential equation and is called a *first-order circuit*.

The solution of a first-order differential equation will contain an unknown constant. To find this constant, it is necessary to apply some additional information about the value of the solution at a specified time instant. Since we are in general concerned with finding the response of the circuit to changes that occur at a certain time instant, we often know the state of the circuit just before the change occurs and can apply this information in order to find the unknown constant. The value of the capacitor voltage (or inductor current, if the circuit contains an inductor rather than a capacitor) just before the change occurs, is known as the *initial condition*.

Solving the first-order circuit just described yields the result shown in Fig. 1. The capacitor voltage plotted as a function of time is of exponential form, moving from its initial value toward the value of the constant voltage source and eventually settling there. (Certain assumptions have been made here, and are discussed in the next section.) This is intuitively plausible—once the voltage source has been inserted, the resistor voltage and capacitor voltage must sum to equal the voltage of the source. If the capacitor voltage does not initially equal that of the source, the voltage difference must be developed across the resistor by a current flowing through it. This current

Figure 1. Capacitor voltage in a first-order circuit increasing exponentially from its initial value to its final value.

charges the capacitor, bringing its voltage closer to that of the source, and the net effect is to cause the capacitor voltage to approach that of the voltage source.

Already in this simple circuit we can see how dynamic circuits behave in ways that would be impossible for a resistive circuit. If the circuit described above had been resistive, all voltages and currents would have been scaled versions of the source. In this circuit, however, the capacitor voltage takes on a form quite unlike that of the source—it varies exponentially with time, whereas the source is constant. The action of the resistor and capacitor has processed the source signal, with the capacitor voltage resisting the sudden change when the source was inserted, but retaining the steady behavior of the source. The resistor voltage, on the other hand, captures the change in the source very well, but eventually dies away to include nothing of the steady behavior of the input. This behavior is an example of the filtering behavior of this simple resistor–capacitor combination, which is useful in a variety of communications applications.

The exponential nature of the voltage observed in this simple circuit is not unusual—in fact, as we shall see, exponential functions appear in various guises in the solution to linear differential equations. Possibly the most widely known example of an exponential function appears in the analysis of radioactive decay, where the rate of decay of a substance is proportional to the amount of the substance present, and so the amount remaining decays exponentially to zero at a rate depending on the half-life of the substance.

A circuit that contains two dynamic elements in general gives rise to a second-order differential equation (containing the second derivative of the variable with respect to time) and is termed a *second-order circuit*. If all sources in the circuit are DC (constant) sources, this equation can be solved by application of standard theory of linear differential equations, with the aid of two initial conditions, one for each dynamic element. Instead of the single exponential transient of the first-order circuit, this circuit contains two exponential transients that are added to give the overall transient. The relationship (via complex numbers) between the exponential and sinusoidal functions can give rise to new types of behavior arising from these transients, as shown in Fig. 2. If the arguments of these exponentials are complex, as may turn out to be the case, then they can

Figure 2. Two possible responses of a second-order circuit, made up of the sum of two exponentials.

be added to give a transient that oscillates sinusoidally. In most circuits the magnitude of this oscillation decays exponentially with time. A common example of such a decaying oscillation is produced when a tuning fork is struck or a child's swing given a single push. If there are no losses in the circuit (not a practical requirement), the oscillation could persist indefinitely without decaying, and if the circuit is unstable, it is possible that the oscillation can actually grow.

In a radiofrequency system, a circuit would normally be “driven” by a more complicated signal, but the same basic principles apply. We can consider a simple example, where a short burst of a sinusoidal signal is applied to a second-order system. Such a signal might arise in a radar system or in a digital communication system. The resulting transient, shown in Fig. 3, is essentially sinusoidal in form, but its amplitude changes with time in a way that is similar to the transients shown earlier, first increasing in response to the start of the burst of sinusoidal signal, eventually settling to a steady amplitude, and then decaying exponentially following the end of the burst.

While it is possible to analyze simple first- and second-order dynamic circuits by applying standard theory of differential equations, such solution becomes rapidly more difficult when the order of the circuit increases or when the sources become more complicated. When faced with

Figure 3. Example transient response of a second-order circuit in response to a short burst of a sinusoidal signal.

such a problem, one might look enviously back at the much simpler process of solving a resistive circuit. In fact, it is possible to apply techniques of resistive circuit analysis to dynamic circuits with the aid of a variety of transforms. A *transform* is a method of changing a problem into a different form, solving it in the new form (where the solution is easier to obtain) and then changing the solution back to the original form. For example, a student unfamiliar with binary arithmetic, when asked to add two binary numbers, might convert the numbers to decimal form (presumably with the aid of a table), add the decimal numbers, and then convert back to binary. The transforms to be applied in this context change a system of differential equations to a system of algebraic equations that are significantly easier to solve.

The most important and most widely used of these transforms in circuit analysis is the Laplace transform. A second transform, the Fourier transform, is particularly useful in analyzing circuits designed for applications in communication systems. These transforms convert a set of differential equations involving the time variable into a set of algebraic equations involving a new variable called the *frequency* (in the case of the Fourier transform) or the *complex frequency* (in the case of the Laplace transform). Application of these transforms allows us to analyze a circuit by transforming it into an equivalent form in the frequency domain, where its equations are purely algebraic, analyzing the circuit in this frequency domain using the techniques of linear algebra, and then applying the transform in reverse to convert the result of this analysis into a function of time. We will see how the Laplace transform can be applied to distributed circuits as well as lumped circuits.

Once again, Laplace transform analysis shows up the special role of the exponential function (and its complex cousin, the sinusoid) in the behavior of circuits. Every dynamic circuit favors certain exponential (including sinusoidal) modes of behavior whose rate of decay (and frequency of oscillation, if applicable) is governed by the so-called natural frequencies of the circuit. These natural frequencies tell us whether the currents and voltages in a circuit will, of their own accord, tend to exhibit exponential or oscillatory decay, constant behavior or steady oscillation, exponential or oscillatory growth, or some

combination thereof. When an input signal is applied to the circuit, the currents and voltages may contain components controlled by the natural frequencies as well as a component controlled by the input. In many practical circuits it is desirable for the output to depend on the input, and the prospect of a growing oscillation in the circuit is a designer's nightmare. (This effect is similar to that demonstrated by sound systems when a microphone is placed in the path of a loudspeaker and an unwanted tone appears and swamps the desired signal.) In other cases, a sustained oscillation is the objective, and the designer's aim is to fix the frequency and amplitude of this oscillation. The issue here is one of *stability*. An asymptotically stable system is one in which all exponential transients die away, leaving only the effect of the input signal. Laplace transform techniques allow us to analyze a system to determine whether it is asymptotically stable, or whether a sustained oscillation is possible.

The effects of transients are seen in a huge range of electronic and electrical engineering applications, from the transmission of tiny pulses between parts of a communication system to the behavior of an electrical power system struck by lightning. The techniques described in this article provide the reader with the ability to understand and analyze transient behavior in a wide variety of circuits.

2. TIME-DOMAIN ANALYSIS

2.1. Natural Response and Step Response of a First-Order Circuit

Consider the circuit shown in Fig. 4a. Until the time $t = 0$, the switch S is in position 1, and the resistor R and capacitor C are connected in a loop. At time $t = 0$ the switch is moved to position 2, connecting the DC voltage source E in series with R and C . We assume that the switch closes instantaneously and that it presents a short circuit between the terminals that it connects. Mathematically, we say that the voltage applied to the RC series combination is $EU(t)$, where $U(t)$ is the unit step function given by

$$U(t) = \begin{cases} 0 & \text{for } t < 0 \\ 1 & \text{for } t \geq 0 \end{cases} \quad (1)$$

The circuit of Fig. 4a can, therefore, also be drawn in the form shown in Fig. 4b.

The analysis of the circuit for $t \geq 0$ in Fig. 4 will require knowledge of the initial voltage across the capacitor just after the switch is thrown, $v_C(0^+)$, where $0^+ = \lim_{\epsilon \rightarrow 0} \epsilon$.

Figure 4. (a) The switch S moves from position 1 to position 2 at time $t = 0$, so the voltage applied to the RC series combination is 0 for $t < 0$ and E thereafter. The switch/voltage source combination is represented in (b) by the single voltage source $EU(t)$.

We generally know, or can find from analysis of a previous regime, $v_C(0^-)$, the voltage at the instant just before the switch is thrown: ($0^- = \lim_{\epsilon \rightarrow 0} -\epsilon$). If the capacitor current is finite, $v_C(0^+)$ must equal $v_C(0^-)$, and we can refer to both as $v_C(0)$. Similarly, if the voltage across an inductor is finite, its current waveform must be continuous. We will assume these continuity conditions throughout this analysis. The alternative case, where the capacitor current or inductor voltage can be infinite, is not practical but turns out to be mathematically interesting and useful in analysis. It can be handled by an extension of our analysis in this section (see Ref. 1 for details), but we will postpone consideration of this possibility until Section 3, where it can be handled more conveniently.

For $t \geq 0$, Kirchhoff's voltage law gives the equation

$$v_C(t) + i(t)R = E$$

or, applying the constitutive relation $i(t) = C \frac{dv_C(t)}{dt}$ for the capacitor

$$RC \frac{dv_C(t)}{dt} + v_C(t) = E \quad (2)$$

This is a first-order differential equation in the capacitor voltage v_C , and so this circuit is referred to as a *first-order circuit*. It can be solved by a number of methods to give an expression for v_C as a function of time. One such method is to recast the equation in the form

$$\frac{d(v_C(t) - E)}{dt} = -\frac{1}{RC}(v_C(t) - E)$$

This equation is of the familiar form

$$\frac{dx(t)}{dt} = ax(t)$$

which has the solution [2]

$$x(t) = x(0)e^{at}$$

where $x(0)$ is the value of x at time $t = 0$. This initial condition must be known if the equation is to be solved for $x(t)$. Thus Eq. (2) has the solution

$$v_C(t) - E = (v_C(0) - E)e^{-t/RC} \quad (3a)$$

or

$$v_C(t) = v_C(0)e^{-t/RC} + E(1 - e^{-t/RC}) \quad (3b)$$

The response of the series RC circuit with zero initial capacitor voltage to the application of a voltage source given

by the unit step function is known as the *step response* of the series RC circuit. (Note that we will use the word “response” to signify any current or voltage in the circuit, or any set thereof, including, for example, the set of all currents and voltages. Throughout this article the variables that constitute the response in any given instance will be clear from the context in which the term is used.)

It is clear from Eq. (3a) that the difference between v_C and E varies exponentially with time, and when the product RC is positive (a condition that will be assumed to hold unless otherwise stated), this difference tends to zero as t tends to infinity. v_C is plotted as a function of time in Fig. 5, where, as expected, v_C is seen to converge exponentially to E . The rate of this convergence is governed by the value of RC , which is termed the time constant of the waveform and denoted by the symbol τ . The smaller the time constant, the faster the rate of convergence. After one time constant has elapsed (i.e., at $t = \tau$), $v_C(t) - E$ has decreased to $e^{-1} = 36.8\%$ of its value at $t = 0$, and at time $t = 5\tau$ this difference has decreased to $e^{-5} = 0.7\%$ of its initial value. Although v_C does not reach E within any finite time (unless, of course, it started out at E), after five time constants have elapsed, the difference between v_C and E has been reduced to less than 1% of its initial value. The time constant is a useful measure of the response speed of a first-order circuit. For more general circuits, the risetime is used as a measure of response time. This is defined as the time taken for the step response to rise from 10% to 90% of the steady-state value. For the first-order circuit analysed in this section, the risetime can be found to be $\tau \ln 9 \approx 2.2\tau$.

The value E to which the capacitor voltage converges is termed the *steady-state value* of this voltage. It is the only value of capacitor voltage at which the circuit can settle, or in other words it is only when $v_C = E$ that all currents and voltages in the circuit cease to vary with time. Clearly, when a quantity ceases to vary with time, its derivative with respect to time is zero, and so the steady-state value of v_C can be found directly from the differential equation (2) by setting the term dv_C/dt to zero (or, in circuit terms, replacing the capacitor by an open circuit), yielding the

Figure 5. The capacitor voltage in the circuit of Figure 1 varies exponentially from its starting value $v_C(0)$ to its steady-state value E , with time constant $\tau = RC$.

equation $v_C = E$, as expected. The overall waveform $v_C(t)$ is the sum of this steady-state component and a second component that dies away with time. This second component is known as the transient component (or just the transient). The exponential form of the transient in this circuit is, as we will see later, particularly common in linear circuits and other linear systems.

Note, however, that the procedure just outlined yields the value of v_C at which the circuit variables (currents and voltages) can remain constant, but it does not guarantee that the circuit will actually converge to this state. For example, if $RC < 0$, Eq. (3a) implies that v_C will diverge exponentially away from E and the circuit has no steady-state response. [The only exception to this divergence is when $v_C(0) = E$, in which case it will theoretically remain fixed at E for all time. The word “theoretically” is important—in practice, any noise in the circuit that causes v_C to differ even infinitesimally from E will result in its diverging exponentially from E .] This distinction relates to the issue of the stability of equilibria of differential equations [2].

Another useful view of the solution waveform (3b) for $v_C(t)$ is that it is composed of two components: one caused by the initial condition $v_C(0)$, and the other caused by the voltage source E . If $E = 0$, the response (3) reduces to $v_C(t) = v_C(0)e^{-t/RC}$, which is termed the “natural” or “unforced” response of the circuit. This is a viewpoint to which we will return later.

Any circuit consisting of a single capacitor in an otherwise resistive circuit containing only DC sources is generally analyzed by transforming it to single-loop form by means of a Thévenin transformation [3], as shown in Fig. 6. The analysis described above is then applicable, where E is the Thévenin equivalent voltage source, and R the Thévenin equivalent resistance. (The small number of circuits that do not have a Thévenin equivalent can be handled separately.)

Before leaving the single-loop first-order circuit of Fig. 4, we note that the analysis of this section can be used to find the response of a first-order circuit to a voltage source that is piecewise-constant, that is, constant over certain time intervals with discontinuous jumps between these constant levels. One important such waveform is the pulse

$$p(t) = \begin{cases} 0 & \text{for } t < 0 \\ E & \text{for } 0 \leq t < t_0 \\ 0 & \text{for } t \geq t_0 \end{cases}$$

Figure 6. A circuit consisting of a single capacitor in an otherwise resistive circuit is simplified by replacing the resistive one-port seen by the capacitor by its Thévenin equivalent.

The response of the first-order RC circuit to this source waveform is found by an extension of the analysis just performed. For $0 \leq t < t_0$, the analysis proceeds as before and $v_C(t)$ is given by Eq. (3b):

$$v_C(t) = v_C(0)e^{-t/RC} + E(1 - e^{-t/RC}) \text{ for } 0 \leq t < t_0 \quad (3c)$$

For $t \geq t_0$, the response is just the natural response found previously; the only difference is that since this phase of the analysis commences at $t = t_0$ instead of $t = 0$, the initial condition is $v_C(t_0)$ instead of $v_C(0)$. Applying this initial condition in the usual way, we find that

$$v_C(t) = v_C(t_0)e^{-(t-t_0)/RC} \text{ for } t \geq t_0 \quad (4)$$

$v_C(t_0)$ is, by our assumption of bounded currents, equal to $v_C(t_0^-)$, the capacitor voltage just before the source waveform drops to zero. Since Eq. (3c) gives $v_C(t)$ for all times in the range $0 \leq t < t_0$, it can be used to find that

$$v_C(t_0^-) = v_C(0)e^{-t_0/RC} + E(1 - e^{-t_0/RC})$$

Substituting this value for $v_C(t_0)$ in (4) completes the analysis of the response of the series RC circuit to the voltage pulse. This response is plotted in Fig. 7 for two different values of the time constant. The response of a circuit to a pulse is particularly important in communication systems where such pulses are used to carry information and must be clearly identifiable at the receiver. An RC combination of the type studied here often occurs in such transmission systems, formed by the output resistance of the part of the system where the signal originates and the input capacitance of the part of the system into which the signal is fed, and thus exponential distortion will inevitably ensue. Clearly the “smearing” of the pulse evident in Fig. 7 when the time constant is large limits the rate at which pulses can be transmitted if they are to be separated at the receiver.

The response of the series RC circuit to any piecewise-constant source waveform is found by an extension of the

Figure 7. The response of a first-order RC circuit to a voltage pulse of amplitude E and duration t_0 . The solid line shows the response if $\tau = t_0/50$; the dashed line, the response if $\tau = t_0/5$.

analysis performed above. The circuit is analysed using the standard method over each of the time intervals in which the source is constant, starting with the first time interval. The initial condition for the n th time interval, commencing at time $t = t_n$, is found by evaluating the response from the previous time interval at time $t = t_n^-$.

The second type of first-order circuit is one in which the single energy storage element in the circuit is an inductor rather than a capacitor, and by application of a Norton transformation (where possible) is of the form shown in Fig. 8, where the constant current source I is connected in parallel with conductance G and inductance L for $t \geq 0$. Kirchhoff’s current law applied to this circuit gives the following differential equation in the inductor current i_L for $t \geq 0$

$$GL \frac{di_L(t)}{dt} + i_L(t) = I$$

which can be solved as before to find

$$i_L(t) - I = (i_L(0) - I)e^{-t/GL}$$

or

$$i_L(t) = i_L(0)e^{-t/GL} + I(1 - e^{-t/GL})$$

Thus the inductor current waveform for the circuit of Fig. 8 takes the same form as the capacitor voltage waveform for the circuit of Fig. 4b, with time constant GL and steady-state value I . This is a consequence of the fact that the circuit of Fig. 8 is the dual of that of Fig. 4b. The response to a piecewise-constant source waveform can be found by applying the method previously described for the series RC circuit.

2.2. Natural Response of Second-Order Circuits

The circuit in Fig. 9 consists of a resistor and two energy storage elements—a capacitor and an inductor. Kirchhoff’s voltage law gives the equation

$$v_C(t) + L \frac{di_L(t)}{dt} + Ri_L(t) = 0$$

which on application of the relation $i_L(t) = C[dv_C(t)/dt]$ becomes

$$LC \frac{d^2v_C(t)}{dt^2} + RC \frac{dv_C(t)}{dt} + v_C(t) = 0 \quad (5)$$

Figure 8. First-order circuit consisting of the parallel combination of current source $IU(t)$, conductance G , and inductor L .

Figure 9. Second-order circuit consisting of resistor R , capacitor C and inductor L .

This is a second-order differential equation, and so the circuit is termed a *second-order circuit*. The exponential waveform

$$v_C(t) = Ae^{st}$$

is a solution to Eq. (5) provided

$$LCs^2 + RCs + 1 = 0$$

which yields

$$s = \frac{-R}{2L} \pm \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}$$

If these two values, s_1 and s_2 , are distinct (i.e. $s_1 \neq s_2$), then the general solution of Eq. (5) is of the form

$$v_C(t) = A_1 e^{s_1 t} + A_2 e^{s_2 t} \quad (6)$$

Since there are no sources in the circuit, this is the natural or unforced response of the series RLC circuit. The constants A_1 and A_2 will be determined by applying the initial conditions $v_C(0)$ and $i_L(0)$ and solving the resulting simultaneous equations:

$$v_C(0) = A_1 + A_2$$

$$i_L(0) = C \left. \frac{dv_C}{dt} \right|_{t=0} = CA_1 s_1 + CA_2 s_2$$

We will now consider the nature of the natural or unforced voltage waveform represented by Eq. (6). We will use the following shorthand form for s_1 and s_2

$$s_1 = -\alpha + \sqrt{\alpha^2 - \omega_0^2} \quad \text{and} \quad s_2 = -\alpha - \sqrt{\alpha^2 - \omega_0^2}$$

where

$$\alpha = \frac{R}{2L} \quad \text{and} \quad \omega_0 = \frac{1}{\sqrt{LC}}$$

We will assume for now that $\alpha \geq 0$.

The first case to be considered is the case where $\omega_0^2 < \alpha^2$ and s_1 and s_2 are real and distinct. In this case the circuit is said to be overdamped and the response $v_C(t)$ is the sum of two exponentials with time constants $1/|s_1|$ and $1/|s_2|$.

An example of an overdamped response is plotted in Fig. 10a.

The second case occurs when $\omega_0^2 > \alpha^2$ and s_1 and s_2 are complex conjugates of the form $-\alpha \pm j\omega_d$, where $\omega_d = \sqrt{\omega_0^2 - \alpha^2}$. In this case the circuit is said to be underdamped. Equation (6) remains valid but can be expressed more clearly in the form

$$v_C(t) = e^{-\alpha t} [(A_1 + A_2) \cos \omega_d t + j(A_1 - A_2) \sin \omega_d t]$$

where A_1 and A_2 are complex conjugates, and so the coefficients $B_1 = (A_1 + A_2)$ and $B_2 = j(A_1 - A_2)$ are real and can once again be found from the initial conditions. The underdamped response takes the form of an oscillation of frequency ω_d multiplied by an exponential envelope $e^{-\alpha t}$. If $\alpha > 0$, the amplitude of the oscillation decreases exponentially with time, with the rate of this decrease, known as “damping”, controlled by α . If $\alpha = 0$, the response is an oscillation of constant amplitude and frequency $\omega_d = \omega_0 = 1/\sqrt{LC}$. This is the case of the well-known LC oscillator, which arises when $R = 0$ and there is no dissipation in the circuit. The underdamped response is plotted in Figs. 10b and 10c for the two cases $\alpha > 0$ and $\alpha = 0$. Note that the underdamped response is always characterized by oscillation, sometimes termed “ringing”.

If $\omega_0^2 = \alpha^2$, then $s_1 = s_2 = -\alpha = -R/2L$. In this case the general solution of Eq. (5) is no longer given by Eq. (6) but instead by [2]

$$v_C(t) = (D_1 + D_2 t) e^{-\alpha t}$$

and is said to be “critically damped”. The constants D_1 and D_2 are once again found by application of the initial conditions. An example of a critically damped response is plotted in Figure 10d.

2.3. Step Response of Second-Order Circuit

The circuit in Fig. 11 is identical to that of Fig. 9 but for the addition of the voltage source E at $t = 0$. Applying Kirchhoff’s voltage law for $t \geq 0$ gives the equation

$$v_C(t) + L \frac{di_L(t)}{dt} + Ri_L(t) = E$$

which on application of the relation $i_L(t) = C[dv_C(t)/dt]$ becomes

$$LC \frac{d^2 v_C(t)}{dt^2} + RC \frac{dv_C(t)}{dt} + v_C(t) = E \quad (7)$$

To solve this equation, we apply the fact that the general solution to a differential equation is the sum of two components, which are known in mathematics as the “homogeneous solution” and a “particular solution” [2]. The homogeneous solution is the solution to the differential equation obtained when all input terms (i.e., all terms not involving the variable or its derivatives) are set to zero. In circuit terms, this is just the response obtained when all independent voltage and current sources are removed, namely, the natural or unforced response. A particular

Figure 10. Examples of the natural response of the series *RLC* circuit: (a) overdamped; (b) underdamped; (c) underdamped and lossless; (d) critically damped.

solution is any solution to the differential equation. This decomposition may seem to be of no particular benefit, since it states that to solve the differential equation, one must obtain a solution to the differential equation. The benefit lies in the ability to choose a particularly simple form for the particular solution, which can then be extended to yield the general solution by the addition of the homogeneous solution. The simplest particular solution is the constant solution, which is obtained by setting all derivatives to zero.

The particular solution to Eq. (7) obtained by setting all derivatives to zero is $v_C(t) = E$. Adding this solution to the homogeneous solution that has already been found in Eq. (6) yields the general solution, which is of the form

$$v_C(t) = A_1 e^{s_1 t} + A_2 e^{s_2 t} + E \text{ if } \omega_0^2 < \alpha^2 \text{ (overdamped)} \quad (8a)$$

$$v_C(t) = e^{-\alpha t} [B_1 \cos \omega_d t + B_2 \sin \omega_d t] + E \text{ if } \omega_0^2 > \alpha^2 \quad (8b)$$

(underdamped)

$$v_C(t) = (D_1 + D_2 t) e^{-\alpha t} + E \text{ if } \omega_0^2 = \alpha^2 \text{ (critically damped)} \quad (8c)$$

The appropriate constants A_1 and A_2 , B_1 and B_2 , or D_1 and D_2 are found by applying the initial conditions. If the initial conditions are zero, Eqs. (8) represent the step response of the series *RLC* circuit, and are plotted in Fig. 12.

Depending on the system in which a circuit is to be used, different demands may be made of its step response. In some applications, for example, there may be a requirement that the voltage reach its steady-state value as soon as possible, while in others it may be necessary that the

Figure 11. Second-order circuit consisting of resistor *R*, capacitor *C*, inductor *L*, and voltage source $EU(t)$.

Figure 12. Examples of the step response of the series RLC circuit: (a) overdamped; (b) underdamped; (c) critically damped.

voltage never exceed its steady-state value by more than some specified percentage, to avoid driving circuit elements into saturation. A number of figures of merit have been defined to characterize the step response of a circuit in order to test its suitability for a given application [1]. The risetime has already been defined. The *settling time* is the time beyond which the step response does not differ from its steady-state value by more than 2%. The *delay time* is the time taken for the step response to reach 50% of its steady-state value. The *overshoot* is defined as the difference between the peak value and the steady-state value of the step response, expressed as a percentage of the steady state value.

3. LAPLACE TRANSFORM CIRCUIT ANALYSIS

The analyses described above have found the circuit variables as a function of time by directly solving the differential equations that describe the circuit. While such a procedure is reasonably straightforward for first- and second-order circuits with simple source waveforms, it becomes significantly more difficult as the order of the circuit increases and as the source waveforms become more complex. It is desirable, therefore, to have a more powerful method of finding a solution. In the special case where all sources in the circuit are sinusoidal of the same frequency, the transformation of circuit variables into phasor or complex number form [3–5] allows the circuit to be handled using purely algebraic equations instead of differential equations. Although extremely useful in certain circumstances, this is not a general circuit analysis method: it can handle only sinusoidal sources, it is applicable only if the circuit is stable, it finds only the steady-state component of the waveform and does not allow consideration of initial capacitor voltages and inductor currents.

3.1. The Laplace Transform

A more general transform than the phasor transform is the Laplace transform, named after the French mathematician Pierre-Simon Laplace (1749–1827) [3–6]. This transform method retains the fundamental advantage of the phasor transform, which is the ability to transform a system of differential equations into a system of algebraic equations, but has the additional advantages of being able to handle a much broader class of source waveforms

(including all that are of any practical interest), accommodating initial conditions, and yielding solutions that incorporate both transient and steady-state components without requiring that the circuit be stable.

The Laplace transform is discussed in the article on linear systems, and we will merely summarize its properties here. Given a function of time $f(t)$, its Laplace transform is

$$F(s) = \mathbf{L}\{f(t)\} = \int_{0^-}^{\infty} f(t)e^{-st} dt \quad (9)$$

where the variable s is complex and is termed the (*complex*) *frequency*. Thus the Laplace transform converts a function $f(t)$ from the time domain into a function $F(s)$ in the frequency domain. There exist functions that do not have a Laplace transform, since the integral in (9) fails to converge, but all functions of interest in circuit theory have a Laplace transform. Since the interval of integration is from 0^- to ∞ , the transform defined by Eq. (9) is sometimes called the “one-sided Laplace transform”, to distinguish it from another version in which the integration is from $-\infty$ to ∞ , but we will not need to draw this distinction here and will refer to it simply as the *Laplace transform*. The lower limit of integration of 0^- is chosen in order to accommodate functions with infinite spikes at $t = 0$. Such functions will prove extremely useful in our analysis.

Some of the properties of the Laplace transform that make it so useful in circuit analysis are the following [3,6], where $F(s)$ denotes the Laplace transform of $f(t)$, $F_1(s)$ the Laplace transform of $f_1(t)$ and $F_2(s)$ the Laplace transform of $f_2(t)$:

Uniqueness: $f_1(t) = f_2(t)$ for all $t \geq 0 \Leftrightarrow F_1(s) = F_2(s)$ (More precisely, if $F_1(s) = F_2(s)$ then $\int_{0^-}^{\infty} |f_1(t) - f_2(t)| dt = 0$, but for our purposes it will suffice to assume that $F_1(s) = F_2(s) \Rightarrow f_1(t) = f_2(t)$ for all $t \geq 0$)

Linearity: $\mathbf{L}\{k_1 f_1(t) + k_2 f_2(t)\} = k_1 F_1(s) + k_2 F_2(s)$, where k_1 and k_2 are scalars.

Differentiation: $\mathbf{L}\{(d/dt)f(t)\} = sF(s) - f(0^-)$.

Integration: $\mathbf{L}\left\{\int_{0^-}^t f(\tau) d\tau\right\} = (1/s)F(s)$.

Time shift: $\mathbf{L}\{f(t - \tau)U(t - \tau)\} = e^{-s\tau}F(s)$, where $\tau > 0$ and $U(t)$ is the unit step function given by Eq. (1).

Frequency shift: $\mathbf{L}\{e^{-\alpha t}f(t)\} = F(s + \alpha)$.

The first three of these properties are particularly important. The uniqueness property guarantees that if a system of differential equations is solved by transforming to the frequency domain, solving in the frequency domain and transforming back to the time domain, the solution obtained will be the same as would have been obtained if the solution had been carried out entirely in the time domain. The linearity property guarantees that a system of linear equations in the time domain will remain linear in the frequency domain, allowing powerful linear analysis techniques to be applied in both domains. The differentiation property allows differentiation in the time domain to be replaced by multiplication in the frequency domain, together with the addition of a term related to the initial condition. It is this property that allows a system of differential equations in the time domain to be replaced by a system of algebraic equations in the frequency domain, which can be solved by a variety of powerful and elegant techniques. The Laplace transforms of some important functions are given in Table 1, in which $\delta(t)$ is the delta function defined by

$$\begin{aligned} \delta(t) &= 0 \text{ for } t \neq 0 \\ \int_{-\infty}^{\infty} \delta(t) dt &= 1 \end{aligned} \tag{10}$$

Three steps are to be taken in solving a set of differential equations using Laplace transform analysis: (1) the system of differential equations in the time domain is transformed to a set of algebraic equations in the frequency domain; (2) this set of algebraic equations is solved in the frequency domain, using standard linear techniques; and (3) the solution is transformed from the frequency domain back to the time domain. Step (1) involves application of the definition of the Laplace transform (9) together with certain of its properties (notably the differentiation property). Step (2) involves standard techniques from linear algebra. The third step involves the application of the inverse Laplace transform, which converts a function $F(s)$ in the frequency domain to a function of time $f(t) = \mathbf{L}^{-1}(F(s))$ in such a way that $\mathbf{L}(f(t)) = F(s)$. Note that the function $f(t)$ is unique only for $t \geq 0$, since two functions of time that

differ for $t < 0$ but are identical for $t \geq 0$ will have the same Laplace transform.

3.2. The Inverse Laplace Transform

There is a closed-form equation for the inverse Laplace transform (see Ref. 6 for details), but it is rather difficult to apply (involving contour integration) and is rarely used in circuit analysis applications. Instead, the inverse Laplace transform of a function is generally found by writing the function as the sum of simpler functions, each of whose inverse Laplace transform is known. A technique that is particularly useful here is the partial fraction expansion [2,6]. This is a technique that allows the decomposition of a function $F(s)$ that is the ratio of two real polynomials in s into the sum of simpler terms. It is assumed that the degree of the numerator of $F(s)$ is less than that of the denominator—if this is not the case, then $F(s)$ can be expressed in the form $F(s) = r(s) + \hat{n}(s)/\hat{d}(s)$, where $r(s)$ is a polynomial in s and the degree of $\hat{n}(s)$ is less than that of $\hat{d}(s)$. The inverse Laplace transform of $R(s)$ can be found from Table 1, leaving only the component $\hat{n}(s)/\hat{d}(s)$ to be handled by the partial fraction expansion. Thus, without loss of generality, we can assume that the degree of the numerator of $F(s)$ is less than that of the denominator. The first step in the partial fraction expansion is the factorization of the denominator polynomial:

$$F(s) = \frac{n(s)}{d(s)} = \frac{n(s)}{(s - p_1)^{\alpha_1} (s - p_2)^{\alpha_2} \cdots (s - p_m)^{\alpha_m}}$$

The quantities p_i , the zeros of the denominator $d(s)$ of $F(s)$, are known as the *poles* of $F(s)$, and the multiplicity of the pole p_i is the number of times α_i that it appears as a zero of $d(s)$. A pole of multiplicity 1 is called a *simple* pole. If all poles are simple, then

$$\begin{aligned} F(s) &= \frac{n(s)}{(s - p_1)(s - p_2) \cdots (s - p_m)} \\ &= \frac{k_1}{s - p_1} + \frac{k_2}{s - p_2} + \cdots + \frac{k_m}{s - p_m} \end{aligned}$$

where $k_i = [(s - p_i)F(s)]_{s=p_i}$.

The term k_i is the *residue* of $F(s)$ at the pole p_i . If $F(s)$ has a pole of multiplicity α_j at p_j , the partial fraction expansion takes the form

$$\begin{aligned} F(s) &= \frac{n(s)}{(s - p_j)^{\alpha_j} \hat{d}(s)} = \frac{k_{j1}}{s - p_j} \\ &\quad + \frac{k_{j2}}{(s - p_j)^2} + \cdots + \frac{k_{j\alpha_j}}{(s - p_j)^{\alpha_j}} + \frac{\hat{n}(s)}{\hat{d}(s)} \end{aligned}$$

where

$$k_{ji} = \left\{ \frac{1}{(\alpha_j - i)!} \frac{d^{\alpha_j - i}}{ds^{\alpha_j - i}} [(s - p_j)^{\alpha_j} F(s)] \right\} \Big|_{s=p_j}$$

Since the numerator and denominator of $F(s)$ are real polynomials in s , poles appear in complex conjugate pairs,

Table 1. Some Important Laplace Transforms

$f(t)$	$F(s) = \mathbf{L}(f(t))$
$\delta(t)$	1
$U(t)$	$\frac{1}{s}$
t^n	$n! \frac{1}{s^{n+1}} \quad n = 1, 2, \dots$
e^{-at}	$\frac{1}{s+a}$
$\sin \omega t$	$\frac{\omega}{s^2 + \omega^2}$
$\cos \omega t$	$\frac{s}{s^2 + \omega^2}$

Figure 13. Transformation of a capacitor with initial voltage $v_C(0^-)$ into the frequency domain.

as do their residues. This allows the combination of any complex term in the expansion with its conjugate to give a real term.

The inverse Laplace transform of each of the terms in the partial fraction expansion is known:

$$\mathbf{L}^{-1}\left\{\frac{k_{j\alpha_j}}{(s-p_j)^{\alpha_j}}\right\} = k_{j\alpha_j} \frac{t^{\alpha_j-1}}{(\alpha_j-1)!} e^{p_j t}$$

In this way it is possible to find the inverse Laplace transform of any function consisting of the ratio of two polynomials in s by decomposing the function via the partial fraction expansion and taking the inverse Laplace transform of each of the constituent functions. This method relies fundamentally on the uniqueness and linearity properties of the Laplace transform. Clearly the method applies only to a restricted range of functions, those which can be expressed as the ratio of two polynomials in s . As will be seen, however, functions of this type are particularly important in circuit analysis, and so this is not a significant limitation.

3.3. Circuit Analysis

The first step in the Laplace transform analysis of a circuit is the transformation of the circuit from the time domain to the frequency domain. All branch voltages $v(t)$ and currents $i(t)$ that appear as variables in the differential equations describing the circuit will appear in the transformed equations as variables $V(s) = \mathbf{L}\{v(t)\}$ and $I(s) = \mathbf{L}\{i(t)\}$. Independent voltage and current sources are transformed from known functions of time $v_s(t)$ and $i_s(t)$ to known functions of frequency $V_s(s) = \mathbf{L}\{v_s(t)\}$ and $I_s(s) = \mathbf{L}\{i_s(t)\}$. A resistor is described in the time domain by the linear equation $v(t) = Ri(t)$ and so is defined in the transformed circuit by the relation $V(s) = RI(s)$. Similarly the linear equations describing all resistive two-ports (including ideal transformers, gyrators and controlled sources), and indeed resistive n -ports, are unchanged in the transformation from time domain to frequency domain. The

capacitor is defined in the time domain by the equation

$$i_C(t) = C \frac{dv_C(t)}{dt}$$

Applying the differentiation property of the Laplace transform yields the frequency-domain equation for the capacitor:

$$I_C(s) = sCV_C(s) - Cv_C(0^-)$$

Thus the capacitor C with initial voltage $v_C(0^-)$ appears in the transformed circuit as the parallel combination of the independent current source $Cv_C(0^-)$ and the linear element defined by the relation $V(s) = (1/sC)I(s)$. This second element can be regarded as a generalized resistance (known as an *impedance*) $1/sC$ and throughout the analysis in the frequency domain can be handled as if it were a resistance. Figure 13 shows the transformation of a capacitor from the time domain into the parallel combination of an impedance and an independent current source in the frequency domain or, by Thévenin's theorem, into the series combination of an impedance and an independent voltage source. In a similar manner, the inductor defined in the time domain by the relation

$$v_L(t) = L \frac{di_L(t)}{dt}$$

is defined in the frequency domain by the relation

$$V_L(s) = sLI_L(s) - Li_L(0^-)$$

Thus, as shown in Fig. 14, the inductor appears in the transformed circuit as the series combination of an impedance sL and voltage source $Li_L(0^-)$ or the parallel combination of the same impedance and current source $[i_L(0^-)]/s$. Note that once again this circuit transformation could have been obtained from Fig. 13 by application of the

Figure 14. Transformation of an inductor with initial current $i_L(0^-)$ into the frequency domain.

principle of duality. Coupled inductors can be transformed in a similar manner.

When all the elements in the circuit have been transformed into the frequency domain, the first step of the analysis process is complete. The second step is to analyze the circuit in the frequency domain, employing any of a wide variety of techniques such as loop current analysis, node voltage analysis, modified nodal analysis, and sparse tableau analysis. The analysis of a circuit in the frequency domain is described in the article on frequency-domain circuit analysis, and also in most circuit theory textbooks, such as Refs. 3–5. The third step is then to transform the results of the analysis back to the time domain via the inverse Laplace transform.

Example 1. The circuit of Fig. 4 can be transformed into the Laplace transform domain, yielding the circuit of Fig. 15. Analysis in the frequency domain, followed by partial fraction expansion, yields the result that

$$V_C(s) = \frac{v_C(0^-)}{s + \frac{1}{RC}} + \frac{E}{s} \frac{1}{\left(s + \frac{1}{RC}\right)} = \frac{v_C(0^-)}{s + \frac{1}{RC}} + \frac{E}{s} - \frac{E}{s + \frac{1}{RC}}$$

The inverse Laplace transform is then applied to find

$$v_C(t) = v_C(0^-)e^{-t/RC} + E(1 - e^{-t/RC}) \text{ for } t \geq 0$$

which agrees with the time domain analysis performed earlier.

3.4. Laplace Transform Analysis of Distributed Circuits

Laplace transform techniques can also be applied to the analysis of distributed circuits. Consider the example of a transmission line modeled as in Fig. 16 by incremental series inductance L and resistance R and shunt capacitance C and conductance G , all per unit length. Applying Kirchhoff's laws and taking the limit of vanishing line length gives the telegrapher's equations

$$\begin{aligned} \frac{\partial i(x, t)}{\partial x} &= -Gv(x, t) - C \frac{\partial v(x, t)}{\partial t} \\ \frac{\partial v(x, t)}{\partial x} &= -Ri(x, t) - L \frac{\partial i(x, t)}{\partial t} \end{aligned}$$

Figure 15. Laplace transform of the circuit of Figure 4.

Figure 16. Basic model of a length Δx of transmission line.

The current and voltage now vary not only with time t but also with distance x along the line. The appearance of distance in this fashion, and also of the derivative with respect to distance, does not occur in lumped circuits.

The new parameter x can be shown explicitly in the definition of the Laplace transform:

$$\mathbf{L}[f(x, t)] = \int_0^\infty f(x, t)e^{-st} dt = F(x, s)$$

There is now a second differentiation property:

$$\mathbf{L}\left[\frac{\partial f(x, t)}{\partial x}\right] = \frac{\partial F(x, s)}{\partial x}$$

Then taking

$$I(x, s) = \mathbf{L}[i(x, t)]$$

$$V(x, s) = \mathbf{L}[v(x, t)]$$

the telegrapher's equations become

$$\begin{aligned} \frac{\partial I(x, s)}{\partial x} &= -GV(x, s) - sCV(x, s) + Cv(x, 0^-) \\ \frac{\partial V(x, s)}{\partial x} &= -RI(x, s) - sLI(x, s) + Li(x, 0^-) \end{aligned}$$

If, for simplicity, we assume zero initial voltage and current along the line, these equations can be solved for $V(x, s)$ and $I(x, s)$:

$$\begin{aligned} V(x, s) &= V^+(s)e^{-\gamma x} + V^-(s)e^{\gamma x} \\ \Rightarrow I(x, s) &= \frac{1}{Z_0} [V^+(s)e^{-\gamma x} - V^-(s)e^{\gamma x}] \end{aligned}$$

where $Z_0 = \sqrt{(R + sL)/(G + sC)}$, $\gamma = \sqrt{(R + sL)(G + sC)}$ and V^+ and V^- are as yet unknown constants of integration. Z_0 is called the characteristic impedance of the line, and γ is the propagation constant. If the line is lossless, $R = G = 0$, and so $Z_0 = \sqrt{L/C}$, which is purely real (generally denoted R_0) and $\gamma = s\sqrt{LC}$. We define $u = 1/\sqrt{LC}$, and so $\gamma = s/u$. (We shall shortly see the physical significance of this variable.)

Inserting typical terminations for a line of length L , consisting of the series combination of voltage source $V_0(s)$

and generator impedance Z_g at $x = 0$, and load impedance Z_L at $x = L$, we can solve these equations for V^+ and V^- to find

$$\frac{V^-}{V^+} e^{2\gamma L} = \frac{Z_L - Z_0}{Z_L + Z_0} = \Gamma_R$$

where Γ_R is the receiving end reflection coefficient, and in a similar manner we define the generating end reflection coefficient

$$\Gamma_g = \frac{Z_g - Z_0}{Z_g + Z_0}$$

We can substitute for V^+ and V^- to find the expressions for the voltage and current along the line in the frequency domain:

$$V(x, s) = \frac{Z_0 V_0}{Z_0 + Z_g} \left[\frac{e^{-\gamma x} + \Gamma_R e^{-\gamma(2L-x)}}{1 - \Gamma_R \Gamma_g e^{-2\gamma L}} \right]$$

$$I(x, s) = \frac{V_0}{Z_0 + Z_g} \left[\frac{e^{-\gamma x} - \Gamma_R e^{-\gamma(2L-x)}}{1 - \Gamma_R \Gamma_g e^{-2\gamma L}} \right]$$

In the important case of a lossless line, these equations can be rewritten as

$$V(x, s) = \frac{V_0 R_0}{R_0 + Z_g} \left[\frac{e^{-(sx/u)} + \Gamma_R e^{-s(2\tau - (x/u))}}{1 - \Gamma_R \Gamma_g e^{-2s\tau}} \right] \tag{11}$$

$$I(x, s) = \frac{V_0}{R_0 + Z_g} \left[\frac{e^{-(sx/u)} - \Gamma_R e^{-s(2\tau - (x/u))}}{1 - \Gamma_R \Gamma_g e^{-2s\tau}} \right]$$

where $\tau = L/u$ is the delay of the line. (Once again, we shall shortly see the physical significance of this variable).

We will now consider the solution of these equations in three cases of increasing complexity. It suffices to consider the voltage equation (11), since the current follows easily.

3.4.1. Matched Lossless Line. If the load impedance Z_L equals the characteristic impedance R_0 of the line, then $\Gamma_R = 0$ and Eq. (11) becomes

$$V(x, s) = \frac{V_0 R_0}{R_0 + Z_g} e^{-(sx/u)}$$

In the time domain, applying the time-shift property of the Laplace transform, we get

$$v(x, t) = \mathbf{L}^{-1}[V(x, s)] = f\left(t - \frac{x}{u}\right) U\left(t - \frac{x}{u}\right)$$

where $U(t)$ is the unit step function given by (1) and

$$f(t) = \mathbf{L}^{-1}\left[\frac{V_0 R_0}{R_0 + Z_g}\right]$$

The voltage at the generator end of the line, that is, at $x = 0$, is

$$\frac{V_0 R_0}{R_0 + Z_g}$$

which agrees with the result expected by voltage division. The voltage at any point x along the line is an undistorted

replica of the voltage at $x = 0$ delayed by the time interval x/u , where u is the velocity at which the waveform propagates along the line.

3.4.2. Lossless Line with Matched Source and Unmatched Load. If the lossless line is matched at the source end but unmatched at the load end (i.e., $\Gamma_g = 0$ and $\Gamma_R \neq 0$), the voltage in the frequency domain is given by

$$V(x, s) = \frac{V_0}{2} \left[e^{-(sx/u)} + \Gamma_R e^{-s(2\tau - (x/u))} \right]$$

The inverse Laplace transform gives the voltage in the time domain:

$$v(x, t) = f_1\left(t - \frac{x}{u}\right) U\left(t - \frac{x}{u}\right) + f_2\left(t - 2\tau + \frac{x}{u}\right) U\left(t - 2\tau + \frac{x}{u}\right) \tag{12}$$

where

$$\mathbf{L}^{-1}\left[\frac{V_0}{2}\right] = f_1(t) U(t)$$

and

$$\mathbf{L}^{-1}\left[\Gamma_R \frac{V_0}{2}\right] = f_2(t) U(t)$$

The voltage given by Eq. (12) is the sum of two terms. The first of these is a waveform that starts from the generator end of the line ($x = 0$) at $t = 0$ and travels along the line toward the load with velocity u . This waveform reached the load at time $L/u = \tau$. The second, or reflected, term originates at the load end of the line ($x = L$) at time $t = \tau$, and travels to the left with velocity u .

3.4.3. Lossless Line with Unmatched Source and Unmatched Load. The voltage equation (11) can be expanded to the form

$$V(x, s) = F(s) \sum_{n=0}^{\infty} \Gamma_R^n \Gamma_g^n e^{-s(2n\tau + (x/u))} + F(s) \sum_{n=0}^{\infty} \Gamma_R^{n+1} \Gamma_g^n e^{-s(2(n+1)\tau - (x/u))}$$

where

$$F(s) = \frac{V_0 R_0}{R_0 + Z_g}$$

Defining

$$F_1^{(n)}(s) = F(s) \Gamma_R^n \Gamma_g^n = \mathbf{L}\left[f_1^{(n)}(t) U(t)\right]$$

and

$$F_2^{(n)}(s) = F(s) \Gamma_R^{n+1} \Gamma_g^n = \mathbf{L}\left[f_2^{(n)}(t) U(t)\right]$$

we get

$$V(x, s) = \sum_{n=0}^{\infty} F_1^{(n)}(s)e^{-s(2n\tau + (x/u))} + \sum_{n=0}^{\infty} F_2^{(n)}(s)e^{-s(2(n+1)\tau + (x/u))}$$

Taking the inverse Laplace transform, we get the time-domain voltage

$$v(x, t) = \sum_{n=0}^{\infty} f_1^{(n)}\left(t - 2n\tau - \frac{x}{u}\right)U\left(t - 2n\tau - \frac{x}{u}\right) + \sum_{n=0}^{\infty} f_2^{(n)}\left(t - 2(n+1)\tau + \frac{x}{u}\right)U\left(t - 2(n+1)\tau + \frac{x}{u}\right)$$

Hence the voltage waveform consists of a sum of two types of terms. The first type has the form

$$f_1^{(n)}\left(t - 2n\tau - \frac{x}{u}\right)U\left(t - 2n\tau - \frac{x}{u}\right) \tag{13}$$

which represents a waveform traveling toward the load with velocity u . This expression is zero for $t < 2n\tau + (x/u)$. Since $0 \leq x \leq L$, $0 \leq x/u \leq \tau$, and so the term (13) is zero everywhere on the line if $t < 2n\tau$. Thus this term represents a waveform that starts at the generator end of the line at time $t = 2n\tau$ and travels to the load, reaching it at time $t = (2n + 1)\tau$.

The second type has the form

$$f_2^{(n)}\left(t - 2(n+1)\tau + \frac{x}{u}\right)U\left(t - 2(n+1)\tau + \frac{x}{u}\right)$$

which represents a waveform traveling to the left with velocity u . This expression is zero for $t < 2(n+1)\tau - (x/u)$, and is zero everywhere on the line if $t < 2(n+1)\tau - x/u$. Thus this term represents a waveform that starts at the load at time $t = (2n + 1)\tau$ and travels toward the generator end of the line, reaching it at time $t = (2n + 2)\tau$.

4. NATURAL RESPONSE AND ZERO-STATE RESPONSE

When converted into the frequency domain, a (lumped or distributed) circuit contains independent sources of two types. The first are the transformed versions of the independent sources from the time domain. These sources drive the circuit in the time domain, and are often termed the “inputs” to the circuit, borrowing a viewpoint from system theory. The second group of independent sources in the frequency-domain circuit are those that are introduced during the transformation of energy storage elements and account for the initial conditions in the circuit, specifically, the capacitor voltages and inductor currents at time $t = 0^-$. We will call these sources the “initial” condition generators, to distinguish them from those sources that represent the independent sources from the time domain. By superposition, the response of the circuit to these sources (by which we mean any current or voltage in the circuit, or any collection thereof) is the sum of two components: one due to the independent sources acting alone, with the initial condition generators removed, and the

other due to the initial condition generators acting alone, with the independent sources removed. Since these two components of the response arise from different mechanisms, it is often useful to treat them separately. The component of the response due to the independent sources, with the initial conditions set to zero, is called the *zero-state response*, and the component due to the initial conditions, with the independent sources set to zero, is the *natural or unforced response* (also called the *zero-input response*).

4.1. Natural Response and Natural Frequencies

We will consider first the natural response of a circuit. Application of any of the standard frequency-domain analysis techniques will yield a matrix equation of the form [3]

$$\mathbf{M}(s)\mathbf{X}(s) = \mathbf{U}(s)$$

where $\mathbf{M}(s)$ is a matrix each element of which is a polynomial in s ; $\mathbf{X}(s)$ is a vector containing some subset of the unknown branch voltages, branch currents, node voltages, and loop currents; and $\mathbf{U}(s)$ is a vector, each nonzero element of which is a linear combination of the initial condition generators. If the circuit has a unique solution, that solution is given by [2]

$$\mathbf{X}(s) = \mathbf{M}^{-1}(s)\mathbf{U}(s) = \frac{1}{\det(\mathbf{M}(s))} \text{Adj}(\mathbf{M}(s)) \cdot \mathbf{U}(s)$$

where the existence of a unique solution guarantees that the determinant $\det(\mathbf{M}(s))$ is not identically zero. We assume, unless otherwise stated, that all zeros p_1, p_2, \dots, p_m of $\det(\mathbf{M}(s))$ are simple. Each component $X_i(s)$ of the vector $\mathbf{X}(s)$ is the ratio of two polynomials in s , and so the partial fraction expansion can be applied to yield the expression

$$X_i(s) = \frac{k_1}{s - p_1} + \frac{k_2}{s - p_2} + \dots + \frac{k_m}{s - p_m}$$

The time-domain response $x_i(t)$ is therefore

$$x_i(t) = k_1e^{p_1t} + k_2e^{p_2t} + \dots + k_me^{p_mt}$$

for $t \geq 0$. [If some of the zeros of $\det(\mathbf{M}(s))$ have multiplicity greater than one, the time response will contain terms of the form $t^2e^{p_it}$.]

Clearly the zeros p_i of $\det(\mathbf{M}(s))$ play a crucial role in determining the natural response of the circuit. These quantities are known as the *natural frequencies* of the circuit. The number of natural frequencies in a circuit is less than or equal to the number of energy storage elements in the circuit. The contribution of each natural frequency to the natural response depends on its location in the complex plane. A natural frequency at zero contributes a constant term to the natural response. A real and positive natural frequency p_i contributes a term $k_ie^{p_it}$ that grows exponentially with time. A real and negative natural frequency p_i contributes a term $k_ie^{p_it}$ that decays exponentially with time. Complex natural frequencies occur in conjugate pairs, and their contributions add to make a

real contribution to the response waveform. If the natural frequencies in question lie on the imaginary axis at $\pm j\omega$, their composite contribution to the time response is of the form $k_i e^{j\omega t} + \bar{k}_i e^{-j\omega t} = 2|k_i| \cos(\omega t + \angle k_i)$, an oscillation of constant amplitude. If the complex natural frequencies lie in the right half-plane at $\alpha \pm j\omega$, their composite contribution is of the form $k_i e^{(\alpha + j\omega)t} + \bar{k}_i e^{(\alpha - j\omega)t} = 2|k_i| e^{\alpha t} \cos(\omega t + \angle k_i)$, an oscillation whose amplitude grows exponentially with time. Finally, if the complex natural frequencies lie in the left half-plane at $\alpha \pm j\omega$, their composite contribution is of the form $k_i e^{(\alpha + j\omega)t} + \bar{k}_i e^{(\alpha - j\omega)t} = 2|k_i| e^{\alpha t} \cos(\omega t + \angle k_i)$, an oscillation whose amplitude decays exponentially with time. (If some of the natural frequencies have multiplicity greater than one, their contribution to the time response will be more complicated, with polynomials times exponentials in place of exponentials, but can be handled by an extension of the preceding analysis.)

The preceding discussion leads to the important conclusion that if all natural frequencies of a circuit lie in the open left half-plane (i.e., if their real parts are less than 0), then for any set of initial conditions the natural or zero-input response of the circuit decays to zero as $t \rightarrow \infty$. This decay may be oscillatory, depending on the presence of complex natural frequencies. A circuit is said to be asymptotically stable or exponentially stable if all of its natural frequencies lie in the open left half-plane. If any natural frequency lies in the open right half-plane, then the initial conditions can cause certain currents and voltages to grow exponentially with time, which is clearly undesirable. Obviously in a real circuit this growth cannot continue indefinitely as the circuit elements will eventually cease to function, possibly in dramatic fashion. Also obvious is the fact that this behavior cannot occur in a circuit made up entirely of passive elements, since the exponential growth requires that energy be supplied to the circuit by an active element such as a controlled source or negative resistance.

While the natural frequencies determine the possible natural modes of behavior of a circuit, the actual response that will be observed in a circuit with zero input depends on the values of the initial conditions. Certain sets of initial conditions will excite one mode only, which means that all circuit variables will exhibit the same exponential or oscillatory behavior, but for most sets the response will be the combination of various modes. Also, not all modes can be observed in any given circuit variable—it may be that certain variables are not susceptible to the influence of one or more natural frequencies.

Example 2. To find the natural frequencies of the circuit of Fig. 17, the voltage source can be set to zero and the resulting circuit analyzed by any of the usual methods. In this case node voltage analysis is possible, yielding the matrix equation

$$\begin{pmatrix} \frac{1}{R_1} + sC_1 & 0 \\ -g_m & \frac{1}{R_2} + sC_2 \end{pmatrix} \begin{pmatrix} V_1(s) \\ V_2(s) \end{pmatrix} = \begin{pmatrix} C_1 v_1(0^-) \\ C_2 v_2(0^-) \end{pmatrix}$$

Figure 17. Circuit to be analyzed in Examples 2 and 3.

The natural frequencies are the values of s for which the determinant of the matrix in this equation is zero, and therefore equal $(-1)/R_1 C_1$ and $(-1)/R_2 C_2$. Solving explicitly for $V_1(s)$ and $V_2(s)$, we find that

$$V_1(s) = \frac{V_1(0^-)}{s + \frac{1}{R_1 C_1}} \quad \text{and} \quad V_2(s) = \frac{\frac{g_m}{C_2} V_1(0^-) + \frac{1}{C_1} V_2(0^-)}{\left(s + \frac{1}{R_1 C_1}\right) \left(s + \frac{1}{R_2 C_2}\right)}$$

Thus the voltage v_1 (natural or zero-input component) exhibits only the behavior controlled by the natural frequency at $(-1)/R_1 C_1$ and is unaffected by the natural frequency at $(-1)/R_2 C_2$.

4.2. The Zero-State Response and Transfer Functions

The zero-state response of a circuit is its response to one or more independent sources (inputs) with all initial capacitor voltages and inductor currents set to zero. It suffices to consider the response to a single input, since superposition can then be applied to calculate the response due to multiple inputs. Application of any of the standard frequency-domain analysis techniques to a single-input zero-state circuit will yield a matrix equation of the form

$$\mathbf{M}(s)\mathbf{X}(s) = \mathbf{U}(s)$$

where $\mathbf{M}(s)$ is a matrix, each element of which is a polynomial in s ; $\mathbf{X}(s)$ is a vector containing some subset of the unknown branch voltages, branch currents, node voltages, and loop currents; and $\mathbf{U}(s)$ is a vector, each nonzero element of which is a term involving the independent source, say, $V_s(s)$ (although the theory applies equally to the case where the input is a current source). It follows from linear algebra [2,3] that

$$X_i(s) = \frac{n(s)}{\det(\mathbf{M}(s))} V_s(s) = H(s) V_s(s) \quad (14)$$

where $n(s)$ is a polynomial in s and $\det(\mathbf{M}(s))$ is nonzero, by our standing assumption of unique solvability. Thus the zero-state response to a source $v_s(t)$ is obtained by multiplying its Laplace transform $V_s(s)$ by the appropriate function $H(s) = n(s)/\det(\mathbf{M}(s))$ and taking the inverse Laplace transform to return to the time domain. This function is known as a transfer function or network function. Note that the poles of a transfer function are zeros of $\det(\mathbf{M}(s))$ and are therefore natural frequencies of the circuit.

However, not all natural frequencies need show up as poles of a given transfer function, due to cancellations with numerator terms.

Once again we see that the natural frequencies play a crucial role in determining the response of the circuit—even, as in this case, when the initial conditions are zero. From (14) the poles of $X_i(s)$ will be some subset (determined by numerator cancellations) of the poles of $V_s(s)$ and the natural frequencies. Therefore, $x_i(t)$ will in general, contain terms related to the input together with exponential, constant, or oscillatory terms governed once again by the natural frequencies. If the circuit is asymptotically stable, the contributions governed by the natural frequencies will die away, leaving only the component governed by the input.

The simplest application of Eq. (14) occurs when $V_s(s) = 1$, that is, when the independent source $v_s(t)$ is the delta function or impulse function defined by (10). Although this function is physically unrealizable, it proves extremely useful in circuit and system analysis. When $v_s(t) = \delta(t)$, then $X_i(s) = H(s)\mathbf{L}\{\delta(t)\} = H(s)$, and so the zero-state response is $x_i(t) = h(t) = \mathbf{L}^{-1}\{H(s)\}$. The zero-state response to an impulse function is known as the *impulse response*, and so we have found that the Laplace transform of the impulse response equals the transfer function. The expression

$$X_i(s) = H(s)\mathbf{L}\{v_s(t)\}$$

giving the frequency-domain response of the system with transfer function $H(s)$ to an input $v_s(t)$ can be expressed in the time domain as

$$x_i(t) = h(t) * v_s(t) = \int_{0^-}^{t^+} h(t - \tau)v_s(\tau)d\tau$$

where $h(t) = \mathbf{L}^{-1}\{H(s)\}$ is the impulse response and the asterisk $*$ is the convolution operator [3,6].

If the input is the unit step function $U(t)$, which has Laplace transform $1/s$, that is, $X_i(s) = H(s) \cdot \mathbf{L}\{u(t)\} = H(s)/s$, and so the step response is $x_i(t) = \mathbf{L}^{-1}\{H(s)/s\}$. It is easy to see that the impulse response is the derivative of the step response.

Example 3. The transfer function $V_2(s)/V_s(s)$ of the circuit of Fig. 17 is

$$\begin{aligned} H(s) &= \frac{\frac{g_m}{C_2}}{\left(s + \frac{1}{R_1 C_1}\right)\left(s + \frac{1}{R_2 C_2}\right)} \\ &= \frac{\frac{g_m}{C_2}}{R_2 C_2 - R_1 C_1} \left[\frac{R_2 C_2}{\left(s + \frac{1}{R_1 C_1}\right)} - \frac{R_1 C_1}{\left(s + \frac{1}{R_2 C_2}\right)} \right] \end{aligned}$$

and so the impulse response is

$$\begin{aligned} h(t) &= \frac{g_m R_2}{R_2 C_2 - R_1 C_1} e^{-t/R_1 C_1} \\ &\quad - \frac{g_m R_1 C_1 / C_2}{R_2 C_2 - R_1 C_1} e^{-t/R_2 C_2} \text{ for } t \geq 0 \end{aligned}$$

The step response is

$$\begin{aligned} \mathbf{L}^{-1} \left\{ \frac{\frac{g_m}{C_2}}{\left(s + \frac{1}{R_1 C_1}\right)\left(s + \frac{1}{R_2 C_2}\right)} \right\} \\ = \frac{g_m R_1 C_1 R_2}{R_2 C_2 - R_1 C_1} \left[-e^{-t/R_1 C_1} + e^{-t/R_2 C_2} \right] \text{ for } t \geq 0 \end{aligned}$$

Note the exponential modes corresponding to the natural frequencies in both the step response and the impulse response. Note also that the impulse response is the derivative of the step response.

5. FOURIER TRANSFORM CIRCUIT ANALYSIS

The power of the Laplace transform in finding the transient and steady-state response of a circuit, the variety of source waveforms that it can handle and its ability to accommodate initial conditions make it the method of choice in transient circuit analysis. Despite these advantages, another transform, closely related to the Laplace transform, is preferred in certain situations. This is the Fourier transform [4–6], named after the French mathematician Jean Baptiste Joseph Fourier (1768–1830). The close relationship between the Fourier transform of a signal and the frequency content of that signal make it particularly useful in applications such as communications and signal processing where this frequency content is of paramount importance. However, the Fourier transform is defined for a smaller class of source waveforms than the Laplace transform, and it cannot handle initial conditions. The latter condition in particular makes it poorly suited to transient circuit analysis and so we will merely give a brief discussion of its properties here, with the intention of (1) explaining why it is unsuited to transient circuit analysis and (2) providing a link to other forms of transient circuit analysis for circuits such as filters that are more usually handled using Fourier analysis.

The Fourier transform is closely related to the Fourier series [4–6], in which a periodic function with period T is decomposed into the weighted sum of sinusoids whose angular frequencies are integer multiples of $2\pi/T$. By superposition, the response of a circuit to a periodic function could be obtained by decomposing the function into the sum of sinusoids, finding the response to each of these sinusoids via phasor analysis, and summing these responses to find the overall response. The main disadvantage to this Fourier series method of analysis is that many source waveforms of interest are not periodic, and since the

method is based on phasor analysis, it finds only the steady-state component of the response. The fundamental idea underlying this method, however, namely, the idea of a sum of input sinusoids being processed (i.e., altered in magnitude and phase) in different ways by a circuit and then added to form the response, is a very useful one and underlies the more general Fourier transform analysis.

The Fourier transform is a generalization of the Fourier series to accommodate nonperiodic functions. A nonperiodic function can be viewed as the limit of a periodic function as the period T tends to infinity. The Fourier series of this periodic function consists of weighted sinusoids spaced in frequency at integer multiples of $2\pi/T$. As T tends to infinity, the separation of these sinusoidal frequency components tends to zero, and in the limit we have the nonperiodic function represented by a continuum or spectrum of sinusoidal components. This spectrum of sinusoidal components constitutes the Fourier transform of the function. The Fourier transform of a signal $f(t)$ is found, as in the preceding discussion, by taking the limit of the expression for the Fourier series of a periodic function as the period tends to infinity, which turns out to be

$$F(j\omega) = \mathbf{F}\{f(t)\} = \int_{-\infty}^{\infty} f(t)e^{-j\omega t} dt \tag{15}$$

and exists if the integral in (15) converges. Once again we say that the Fourier transform converts a function from the time domain into the frequency domain, with $F(j\omega)$ indicating the frequency content of the signal at frequency ω . If $f(t) = 0$ for $t < 0$ and the integral shown above converges, the Fourier transform of f is just the Laplace transform with $j\omega$ substituted for s . Given $F(j\omega)$, the function $f(t)$ such that $F(j\omega) = \mathbf{F}\{f(t)\}$ is found by application of the inverse Fourier transform

$$f(t) = \mathbf{F}^{-1}\{F(j\omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(j\omega)e^{j\omega t} d\omega$$

One important feature of the Fourier transform is the differentiation property, which states that differentiation in the time domain is equivalent to multiplication by $j\omega$ in the frequency domain. Thus the Fourier transform can, like the Laplace transform, be used to transform a system of differential equations in the time domain to a system of algebraic equations in the frequency domain.

In Fourier transform analysis a circuit is transformed into the frequency domain by replacing all independent sources by their Fourier transforms, replacing each inductor L by an impedance $j\omega L$ (and replacing any time-domain coupling M between inductors by the frequency-domain coupling $j\omega M$), replacing each capacitor C by an impedance $1/j\omega C$ and leaving resistive components unchanged. Note the lack of any initial condition generators—this is a consequence of the fact that the lower limit of integration in the definition of the Fourier transform is $-\infty$ rather than 0^- . Analysis in the frequency domain proceeds as described in the article on frequency-domain analysis or in Refs. 4 and 5, using the standard tools, and

the frequency-domain response is converted back to the time domain by application of the inverse Fourier transform. Once again there is a transfer function—in this case a function of frequency $H(j\omega)$ —relating input and output in the frequency domain. Note that the response obtained through Fourier transform analysis is the zero-state response only, since the method contains no provision for handling initial conditions.

Given a circuit with input $\sin(\omega_0 t)$ and transfer function $H(j\omega)$ [which is in general complex and, for the circuits in which we are interested, has the property that $H(-j\omega)$ is the complex conjugate of $H(j\omega)$], the output is obtained by taking the inverse Fourier transform of $H(j\omega) \cdot \mathbf{F}\{\sin(\omega_0 t)\}$, which turns out to be $|H(j\omega_0)| \sin(\omega_0 t + \angle H(j\omega_0))$. In other words, the sinusoidal input appears at the output as a sinusoid of the same frequency, with amplitude multiplied by the magnitude of the transfer function at that frequency and phase incremented by the phase of the transfer function at that frequency. If the input to the circuit is more general, it can be viewed as the finite or infinite sum of sinusoids, which will be altered in magnitude and phase by the action of the circuit and then recombined to form the output of the circuit. The magnitude and phase of the transfer function will generally vary with frequency, and when plotted against frequency are called the *amplitude* (or *magnitude*) *response* and *phase response* plots.

Frequency-selective circuits that pass certain ranges of frequencies from input to output while blocking other ranges are known as *filters* [7]. For example, an ideal low-pass filter would pass to the output all frequency components of its input up to a certain cutoff frequency, and pass no higher frequency components. This ideal lowpass filter cannot be realized and is therefore approximated by a variety of functions such as the Butterworth and Chebyshev approximations. Figure 18 plots the amplitude response of the ideal lowpass filter with cutoff frequency at 1 rad/s, together with the amplitude responses of the normalized Butterworth filters of orders 2,3,4,5. The amplitude response of each of these Butterworth filters is 0.7071 or -3 dB at $\omega = 1$ rad/s, which is to say that their 3 dB bandwidth is 1 rad/s.

In a communication system designed to transmit pulses, the step response of a filter is crucial. Too slow a risetime leads to neighboring pulses in a pulsetrain being smeared over one another, rendering them indistinguishable at the output. Too high an overshoot can drive circuit elements into saturation. The step response of a filter can be found by Fourier transform methods, by taking the inverse Fourier transform of the function $H(j\omega)\mathbf{F}\{u(t)\}$, but there is in general no reason to prefer the Fourier transform over the Laplace transform in this situation, and it is usual to take instead the inverse Laplace transform of the function $H(s)\mathbf{L}\{u(t)\}$. For example, the normalised third order Butterworth lowpass filter has transfer function $H(s) = 1/(s^3 + 2s^2 + 2s + 1)$, and so its step response is $\mathbf{L}^{-1}\{1/[s(s^3 + 2s^2 + 2s + 1)]\}$, which can be found by the partial fraction decomposition to be

$$1 - e^{-t} - \frac{2}{\sqrt{3}}e^{-t/2} \sin \frac{\sqrt{3}}{2}t \quad \text{for } t > 0$$

Figure 18. Amplitude response of the ideal lowpass filter with cutoff frequency at 1 rad/s, together with the amplitude responses of the normalized Butterworth filters of orders $n=2, 3, 4, 5$. Note that the approximation more closely matches the ideal as the order of the filter increases.

Figure 19 plots the step response of the normalised Butterworth filters of orders 2,3,4,5, as obtained by application of the Laplace transform. It can be seen that as the order increases (and the amplitude response more closely approximates the ideal) the overshoot, settling time and delay time of the filters all increase, but the risetime is approximately constant.

The procedure outlined above can be used to find the exact step response of a filter, allowing a designer to compare the suitability of various filters in pulse transmission applications. Designers should also have an intuitive understanding of the relationship between amplitude response and transient response of a filter. A lowpass filter allows low frequencies to pass to the output, but blocks high frequencies. Thus when the input is a step

function, the output will preserve the steady-state constant behavior of the input, but will act to block the high frequencies involved in the transition from 0 to 1. This can be seen in Fig. 19, where the high-order filters that are most effective at blocking high frequencies are least effective in capturing the discontinuity in the input. We now recognize the RC circuit of Fig. 4, with the output voltage taken across the capacitor, as a lowpass filter. If the output voltage were taken across the resistor, we would have a highpass filter whose step response captures the initial discontinuity in the step but then falls away to zero due to its inability to pass DC. Readers interested in a more detailed discussion of the relationship between frequency response and transient response of filters are referred to Refs. 1 and 7.

Figure 19. Step response of the normalized Butterworth filters of orders $n=2, 3, 4, 5$.

TRANSMISSION LINE MATRIX (TLM) METHOD

CHRISTOS CHRISTOPOULOS
 Director, George Green Institute
 for Electromagnetics Research
 University of Nottingham,
 Nottingham, United Kingdom

1. HISTORICAL BACKGROUND

The transmission-line modeling or matrix method, commonly referred by the acronym TLM, belongs to the class of differential equation methods and it is best known in its implementation in the time domain (TD-TLM). Implementations in the frequency domain are also available, but the method is known primarily as a time-domain method. It models electromagnetic field phenomena by analogy to pulse propagation in networks of transmission lines—hence its name. The idea of using circuits to model fields is not a new one. The foundation work in this area was done some time ago [1–3], but the difficulty at the time of solving such large networks precluded any useful implementation. This had to wait the advent of modern digital computers and the work of John and Beurle in 1971 [4], which set the scene for the rapid development of TLM into a versatile and general tool for EM simulation. The first developments were for models in two dimensions where an intuitive derivation of suitable network topologies is straightforward. The first three-dimensional structure appeared in 1975 [5]. There followed a period of development to obtain a circuit structure with good accuracy, efficiency, and versatility as described by Hofer [6]. The circuit structure (TLM node), which is the workhorse of TLM today, is described as the symmetric condensed node (SCN) and was developed in 1985 [7]. This marks the year when TLM entered its period of maturity. Many developments followed thereafter both improving the basic SCN and introducing complementary techniques that enhanced the power

of TLM. These are described in more detail in the following sections. More details of the TLM technique may be found in a large number of journal papers and in a number of texts that may be consulted for a fuller explanation of TLM and its applications [8–10]. The next section introduces the basics of TLM in a manner that should be accessible to all before more complex issues are addressed.

2. BASIC CONCEPTS

A basic introduction to the idea of TLM can proceed from an example of propagation in a transmission line and of one-dimensional field propagation. For a typical transmission line, as shown by two segments in Fig. 1, the differential equation describing the evolution of the current in space and in time is

$$\frac{\partial^2 i}{\partial x^2} = \frac{LC}{(\Delta x)^2} \frac{\partial^2 i}{\partial t^2} + \frac{GL}{(\Delta x)^2} \frac{\partial i}{\partial t} \quad (1)$$

where L and C are the inductance and capacitance, respectively, for a segment of the line of length Δx and G represents line losses.

In a similar way one can derive an equation for the current density j in one-dimensional field propagation

$$\frac{\partial^2 j}{\partial x^2} = \mu\epsilon \frac{\partial^2 j}{\partial t^2} + \mu\sigma \frac{\partial j}{\partial t} \quad (2)$$

where μ , ϵ , and σ respectively are the magnetic permeability, electric permittivity, and electrical conductivity of the medium.

One can see that Eq. (1) for the circuit and (2) for the field have the same structure. This isomorphism between the two equations means that field behavior may be understood by reference to circuit behavior. All that needs to be done is to establish appropriate circuit topologies in two and three dimensions and a formal equivalence between field and circuit quantities. This is possible to do. For the case of the one-dimensional example shown here, the equivalence is shown in Table 1.

Inspection of Eq. (2) shows that the two terms on the right-hand side represent wavelike behavior and diffusionlike behavior, respectively. By minimizing the wave term relative to the diffusion term, the models described

Figure 1. A simple one-dimensional transmission-line network to illustrate circuit-field analogies.

Table 1. Equivalence between Circuit and Field Quantities

Circuit	EM Field
I	j
$L/\Delta x$	μ
$C/\Delta x$	ϵ
$1/R \Delta x$	σ

thus may be used to study diffusion phenomena such as thermal conduction [9].

The lumped circuit shown in Fig. 1 can be replaced by transmission-line (TL) segments. Hence, in essence, in TLM models the field problem is reduced to lumped circuit models (space discretization), which in turn are reduced to TL models (time discretization). The art in TLM modeling is to devise TL interconnect topologies, in what are referred to as “nodes,” with each node describing a small block of space of dimensions $\Delta x \Delta y \Delta z$, such as there is an exact equivalence between the voltages and currents in each node and electric and magnetic fields. The TLM node is the equivalent of the computational element or molecule in other methods much like the Yee cell in FDTD.

A schematic arrangement in two dimensions is shown in Fig. 2a. Here, a mesh of transmission lines is shown, each line in the diagram representing a TL, namely, a line and its return conductor (not shown). One node is shown highlighted by a broken line. If a voltage pulse

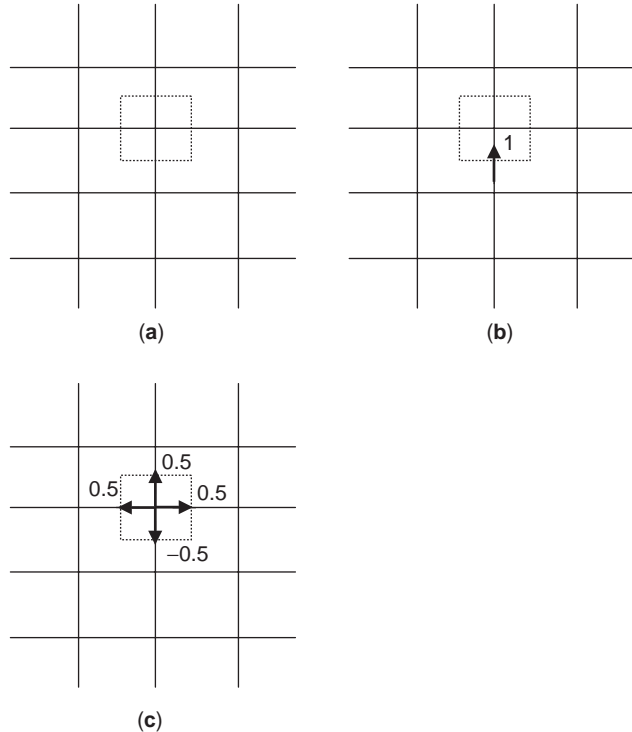

Figure 2. Schematic of a 2D TLM mesh: (a) 2D mesh with one node marked out; (b) impulse excitation at one port; (c) output after the first scattering event.

of magnitude 1 V is incident as shown in Fig. 2b, then this pulse will scatter at the node. If the TL characteristic impedance is Z , then at the node the pulse encounters three TLs in parallel (characteristic impedance $Z/3$) and scatters at this discontinuity with a reflection coefficient -0.5 and a transmission coefficient 0.5 . The scattered pulses are as shown in Fig. 2c. The reflected pulse of -0.5 V combines with the incident pulse of 1 V so that in total the pulse on this TL has a magnitude of 0.5 V. As a result of the scattering, a secondary isotropic wavefront is formed at the node in accordance with Huygens’ principle [11]. TLM can thus be viewed as a discrete implementation of the Huygens principle [12]. After the initial scattering, pulses propagate to adjacent nodes and the process repeats. The TLM algorithm consists of the process of “scattering” at each node; “connection,” that is, the exchange of pulses between nearest neighbors; followed by another “scattering”; and so on. Figure 3 illustrates the results of scattering and connection at the first two timesteps following the isotropic excitation of one node.

For TM modes the basic TLM node in two dimensions (2D) is described as a “shunt” node and is shown in Fig. 4. The dual of this node for TE modes is described as a “series” node. As an illustration, the scattering process in a shunt node is described below:

In order to proceed for the node shown in Fig. 4, we assume that four incident pulses travel toward the node at timestep k . These are labeled as

$${}_k V_j^i \quad j = 1, 2, 3, 4$$

where the superscript “i” stands for incident pulse (traveling toward the center of the node). We also assume that the characteristic impedance of each line segment is Z_{TL} . For each of the four line segments, a Thevenin equivalent circuit is derived and therefore each node is now represented as in Fig. 5. The total voltage at the center of the node can then be obtained directly:

$${}_k V_z = 0.5({}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i) \quad (3)$$

The electric field component E_z and magnetic field components H_x, H_y are then directly obtained:

$${}_k E_z = -0.5 \frac{({}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i)}{\Delta z} \quad (4)$$

$${}_k H_x = \frac{{}_k V_3^i - {}_k V_1^i}{Z_{TL} \Delta x}, \quad {}_k H_y = \frac{{}_k V_2^i - {}_k V_4^i}{Z_{TL} \Delta x} \quad (5)$$

Scattering is directly implemented as follows

$${}_k V_1^r = {}_k V_z - {}_k V_1^i = 0.5(-{}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i) \quad (6)$$

and similarly for the other reflected components. These expressions can be put into a matrix form

$${}_k \mathbf{V}^r = \mathbf{S}_k \mathbf{V}^i \quad (7)$$

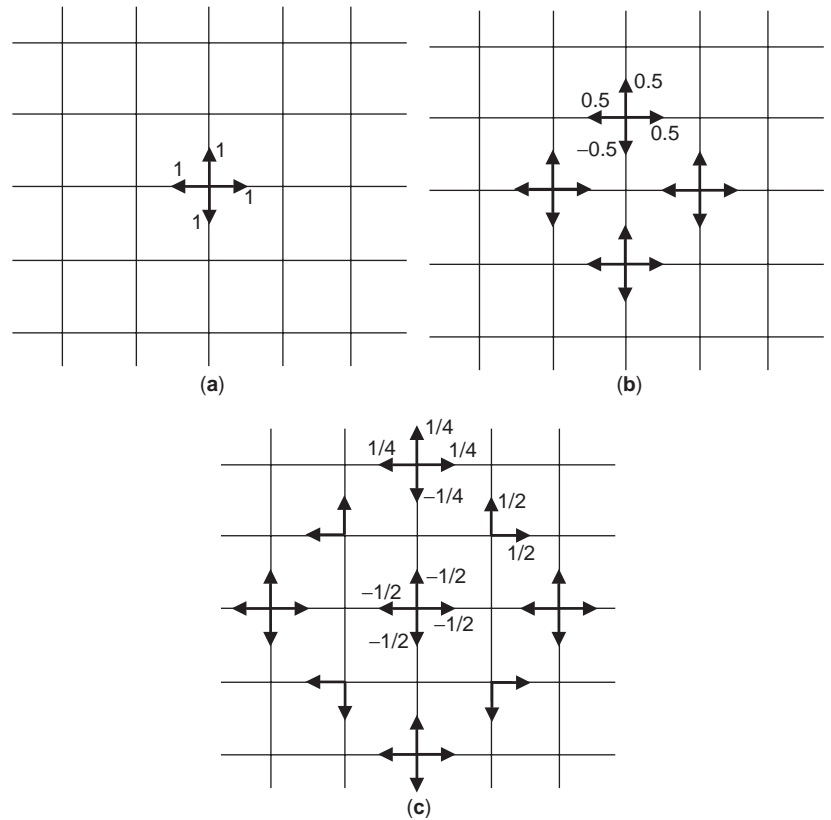

Figure 3. Scattering in a 2D TLM mesh: (a) symmetric excitation at one node; (b) output after the first timestep; (c) output after the second timestep.

where S is the scattering matrix, which for the case of the shunt node shown here is given by

$$S = 0.5 \begin{bmatrix} -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \end{bmatrix} \quad (8)$$

Equations (7) and (8) show the process of scattering at each node. Scattered pulses are passed on to the adjacent ports of neighboring nodes to form the new incident voltages at timestep $k + 1$ in a process described as “connection.” This is expressed schematically as

$${}_{k+1}V^i = C_k V^r \quad (9)$$

where C is described as the “connection” matrix. The TLM algorithm consists of the repetition at each timestep of the processes of scattering and connection at each node with appropriate modifications to account for initial and boundary conditions. The same procedure applies to all TLM schemes, including those in three dimensions, but the form of the scattering matrix in (8) is different. It will be seen from this basic description of TLM that it is a

Figure 4. The shunt 2D TLM node for TM modes.

Figure 5. The Thevenin equivalent circuit of the shunt node.

scattering algorithm—energy goes in at each node (incident pulses) and comes out (reflected pulses). The scattering process is lossless (S is unitary). Because we have an exact solution of a passive network, unconditional stability is ensured. Accuracy is good as long as at least 10 segments per wavelength are used.

Several modifications can be made to this basic scheme to extend the applicability of the model in Fig. 4. Foremost among them is the inclusion of stubs to allow for the modeling of inhomogeneous lossy materials. A suitable node is shown in Fig. 6, where two stubs are included: an infinitely long stub (conductance G_s) and an open-circuit stub (admittance Y_s). This node can model TM propagation in a medium of relative dielectric constant ϵ_r and electrical conductivity σ . The choice of parameters is as follows:

$$u_{\text{TL}} = \frac{\Delta x}{\Delta t} = \sqrt{2} \frac{1}{\sqrt{\mu_0 \epsilon_0}}, \quad Z_{\text{TL}} = \sqrt{2} \sqrt{\frac{\mu_0}{\epsilon_0}} \quad (10)$$

$$Y_s = 4 \frac{(\epsilon_r - 1)}{Z_{\text{TL}}}, \quad G_s = \sigma \Delta x \quad (11)$$

In this case the scattering matrix is given by

$$S = \frac{1}{\hat{Y}} \begin{bmatrix} 2 - \hat{Y} & 2 & 2 & 2 & 2\hat{Y}_s \\ 2 & 2 - \hat{Y} & 2 & 2 & 2\hat{Y}_s \\ 2 & 2 & 2 - \hat{Y} & 2 & 2\hat{Y}_s \\ 2 & 2 & 2 & 2 - \hat{Y} & 2\hat{Y}_s \\ 2 & 2 & 2 & 2 & 2\hat{Y}_s - \hat{Y} \end{bmatrix} \quad (12)$$

where

$$\hat{Y} = 4 + \hat{Y}_s + \hat{G}_s, \quad \hat{Y}_s = Y_s Z_{\text{TL}}, \quad \hat{G}_s = G_s Z_{\text{TL}} \quad (13)$$

Figure 6. The shunt node with capacitive and lossy stubs added.

The inclusion of stubs permits the development of a model where all linklines have the same (free-space) parameters, hence ensuring the same timestep (synchronism) in the entire mesh. Stubs add capacitance to account for the presence of dielectric materials other than free space. Similar procedures apply to the dual node (series node). More detailed information may be found in the references already cited.

3. TLM IN THREE DIMENSIONS

In the previous section the rudiments of TLM were presented with reference to simple two-dimensional structures so that the basic modeling philosophy could be explained in simple physical terms. In this section the model is extended to three dimensions (3Ds) by presenting the *symmetric condensed node* (SCN), which is extensively used in 3D TLM models.

The structure best suited to general 3D models is the SCN described by Johns [7] and shown in Fig. 7. In this figure the traditional labeling of each port is shown (numbers 1–12) alongside an alternative labeling scheme introduced latter. This node describes the properties of EM propagation in a cuboidal block of space $\Delta x \Delta y \Delta z$. In a regular SCN, $\Delta x = \Delta y = \Delta z$. But with the addition of stubs, this restriction can be removed to form a more flexible structure for general modeling. For simplicity, the regular SCN is discussed first, which results in a uniform mesh.

At each of the six faces of the cube there are two ports polarized at 90° to each other to account for all possible wave polarizations. In total, therefore, there are 12 ports and the scattering matrix is a 12×12 . It is a sparse matrix, and its elements, which are nonzero, can be identified by physical intuition or by formal methods. The value of each element can be readily obtained by enforcing circuitual laws, charge, and energy conservation

Figure 7. The three-dimensional symmetric condensed node (SCN).

(the scattering matrix must be unitary). A detailed discussion may be found in Refs. 7 and 9. For the stubless SCN, S is given by

$$S = 0.5 \begin{bmatrix} 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & -1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & -1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \end{bmatrix} \quad (14)$$

It will be seen from (this matrix) that the scattering process is particularly simple, amounting to a simple averaging of four incident voltage pulses to obtain each scattered (reflected) pulse. There is no need for matrix inversion or matrix manipulation of any kind. The 3D TLM algorithm is then an implementation of the scheme described for 2D format in connection with Eqs. (7) and (9), where the scattering matrix is as given by (14). The connection matrix C is again very simple, codifying information for each node and its nearest ports in each coordinate direction. The correspondence between field and circuit quantities is again, as in the case of the 2D node, straightforward.

Fields may be calculated at the center of the node or at the boundaries between nodes. As an illustration the electric field component E_x at the center of the node is associated with port generating voltages in the x direction and is obtained as follows:

$$E_x = -\frac{V_x}{tax} = -\frac{V_1^i + V_2^i + V_9^i + V_{12}^i}{2tax} \quad (15)$$

Similarly, for the magnetic field component in the same direction, we obtain

$$H_x = \frac{I_x}{tax} = \frac{V_4^i + V_7^i - V_5^i - V_8^i}{2Ztax} \quad (16)$$

Fields at the boundary between nodes are also easily obtained as shown below for two field components at the boundary between nodes (x,y,z) and $(x+1,y,z)$:

$$E_y = -\frac{V_{11}^i(x,y,z) + V_3^i(x+1,y,z)}{tay} \quad (17)$$

$$H_z = \frac{V_3^i(x+1,y,z) - V_{11}^i(x,y,z)}{Ztaz}$$

Current and charge density may be obtained directly from the fields using Ampere and Gauss laws or with reference to the analogies between field and circuit quantities.

Excitation of the mesh is achieved by launching appropriate voltage pulses on the TL of particular nodes. As an illustration, to launch an electric field component $E_x = E_0$ at a particular node, the following voltage pulses must be applied:

$$V_1^i = V_2^i = V_9^i = V_{12}^i = -\frac{E_0 tax}{2} \quad (18)$$

Perfectly conducting boundaries are easily imposed on the mesh at the connection stage, at the boundaries between nodes, by specifying that the reflection coefficient there is equal to -1 . More complex boundaries (e.g., with frequency-dependent properties) can also be specified as explained in the following sections.

A variable mesh ($\Delta x \neq \Delta y \neq \Delta z$), or a mesh describing an inhomogeneous material, is established by adding stubs to the standard SCN described above, to maintain synchronism and account for values of permittivity and permeability larger than one. In the most general case, open-circuit, short-circuit, and infinitely long stubs are used to account for ϵ, μ, σ of the medium [7,9]. The structure thus obtained is referred to as the *stuffed SCN*. However, this is not the most efficient structure, and in most practical implementations of TLM the *hybrid SCN* is employed. In this node, synchronism is maintained, but the condition that all link lines have the same characteristic impedance is relaxed. This allows all the required inductance (μ in field terms) to be modeled by the linklines, and stubs are needed only to account for ϵ [13]. This results in a reduction of the storage required and in operating the mesh at a larger timestep compared with a stuffed SCN. Alternatively, all the required capacitance may be described by the linklines, and stubs then account for extra inductance. A general discussion of the properties of the hybrid SCN may be found in a paper by Trenkic et al. [14]. For problems with

cylindrical symmetry, non-Cartesian nodes are available to facilitate modeling [15].

Developments to increase the efficiency of TLM computation are described in the literature. A particular technique to speed up scattering is described in another paper by Trenkic et al. [16]. For each coordinate direction, total voltage and current are first calculated and the reflected voltages are then obtained from

$$V_{y\text{mx}}^r = V_x - ZI_z - V_{y\text{px}}^i \quad (19)$$

Similar equations apply for the y and z directions. The notation used to designate voltage pulses in (19) is as follows: superscripts “i” or “r” indicate incident or reflected voltages, the first subscript indicates direction of propagation (x , y , or z), the second subscript (“ n ” or “ p ”) indicates line segment along the negative or positive axis, and the third subscript indicates the polarization direction of the pulse (x , y , or z).

4. THEORETICAL FOUNDATIONS OF TLM

In this section some of the general concepts that underpin the foundation of TLM are discussed together with important features of the method such as dispersion and accuracy.

4.1. The General SCN TLM Node

A number of TLM nodes are available, many of them derivatives of the basic SCN, which appeared in the literature over the years. These may be unified under a general formulation described in Ref. 17. It accounts for a general anisotropic materials represented by ϵ_{ri} , μ_{ri} , $i = 1, 2, 3$ where the indices 1, 2, 3 refer to the coordinate directions x, y, z . In this node, for the i -directed, j -polarized link line, the capacitances and inductances per unit length are C_{ij}, L_{ij} . The i -directed stubs represent capacitance and inductance:

$$C_0^i, L_s^i$$

The TLM constitutive equations are (Δi is the node size in i direction)

$$\begin{aligned} C_{kitak} + C_{jitaj} + C_0^i &= \epsilon_{r0} \epsilon_{ri} \frac{t_j t_k}{t_i} \\ L_{jktaj} + L_{kjtak} + L_s^i &= \mu_0 \mu_{ri} \frac{t_j t_k}{t_i} \end{aligned} \quad (20)$$

Synchronism requires that the same timestep prevail throughout; therefore

$$t_j t_k = t_i \sqrt{C_{ij} L_{ij}} \quad (21)$$

Using all possible permutations of $i, j, k \in \{x, y, z\}$, we obtain six equations from (20) and another six from (21). There

are 18 unknown parameters

$$C_{ij}, L_{ij}, C_0^i, L_s^i$$

and therefore there remain 6 degrees of freedom. By imposing additional restrictions on the linkline and stub parameters, several TLM nodes may be derived. According to Trenkic et al. [17], a classification of 3D TLM condensed nodes in the time domain is as follows:

- *Stub-loaded nodes*, which have the same characteristic impedance for all linklines (constant L/C ratio for all six lines giving the additional constraints).
- *Hybrid nodes*, which have either open- or short-circuit stubs (thus supplying three additional conditions), the other three conditions obtained by demanding that all the line impedances modeling the same magnetic or electric field components are the same.
- *Supercondensed nodes*, which have no stubs at all; therefore six conditions are imposed by demanding that all stub capacitances and inductances be equal to zero. The supercondensed node is described in Ref. 18.
- *General nodes*, which have a combination of linklines and stubs.

According to the constitutive equations above, a *general symmetric condensed node* (GSCN) may be derived where material properties may be shared between linklines and stubs. The advantage of this option is that an optimization is possible to achieve, for example, particular dispersion characteristics. This in general results in a node with six different characteristic impedances, six stubs, and six lossy elements. The general theory of the GSCN and its scattering properties may be found in Ref. 17.

4.2. Field-Theoretic Derivation of TLM

An elegant derivation of TLM SCN method is by applying the method of moments (MoM) to Maxwell's equations [19, 20]. The field components are expanded in a set of subdomain basis functions, as shown below for the x components,

$$\begin{aligned} E_x(\vec{x}, t) &= \sum \lim its_{k,l,m,n} k + (1/2) E_{l,m}^x H_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ &\quad + \sum \lim its_{k,l,m,n} k + (1/2) E_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ H_x(\vec{x}, t) &= \sum \lim its_{k,l,m,n} k + (1/2) H_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \\ &\quad + \sum \lim its_{k,l,m,n} k + (1/2) H_{l,m,n}^x F_{l,m,n}^x(\vec{x}) T_{k+(1/2)}(t) \end{aligned} \quad (22)$$

where

$$k + (1/2) E_{l,m,n}^\mu, \quad k + (1/2) H_{l,m,n}^\mu, \quad \mu = x, y, z$$

are the expansion coefficients. The other components are obtained by permutation of x, y, z and the corresponding

discrete coordinates l, m, n . The basis functions in time are defined as

$$T_{k\pm(1/2)}(t) = g\left(\frac{t}{\Delta t} - k \mp \frac{1}{2}\right)$$

where

$$g(x) = \begin{cases} \text{trix}1 - |x|, & |x| < 10, \\ |x| \geq 1 \end{cases}$$

The spatial basis functions are defined as

$$F_{l,m,n}^{\mu}(\vec{x}) = H_l(x)F_{m\pm(1/2),n}(pa, \mu, v)$$

where H is a rectangular pulse function and F is a two-dimensional triangular basis function. This spatial basis functions provides a step approximation in the μ direction and a piecewise linear approximation in the diagonal directions of the plane perpendicular to the μ direction. Substituting these expansions into Maxwell's equations, sampling with delta functions and the derivatives of delta functions, and combining the 12 resulting equations gives the following form:

$$(M_1 + TM_2)\mathbf{b} = (M_3 + TM_4)\mathbf{a} \quad (23)$$

In this expression \mathbf{a} and \mathbf{b} are the incident and reflected wave amplitudes, respectively. Introducing the normal TLM choices for the timestep, one obtains, after some manipulation [19]

$$\mathbf{b} = TS\mathbf{a} \quad (24)$$

where S is the normal scattering matrix for the TLM SCN node, thus demonstrating that the TLM scattering scheme may be derived directly from MoM procedures. An interesting development, which stems from the theoretical foundation of TLM described above, is the derivation of the alternating TLM (ATLM) scheme, which reduces computational effort and removes spurious solutions at the expense of more complicated boundary conditions [20].

4.3. Dispersion Properties of TLM

A mesh consisting of a lattice of SCN TLM nodes is essentially a lowpass network, and therefore propagation properties are dependent on both frequency and propagation angle. At the interface between areas of the mesh with different spatial resolutions, waves encounter, effectively, a numerical discontinuity. These features are generally described as "dispersion" and are common to all numerical schemes such as FDTD. However, each particular scheme has its own unique dispersion characteristics, and a basic understanding is useful in applications where control of errors is important. A simple analysis of the 3D SCN based on circuit concepts may be done in certain cases [21], and results may be obtained using numerical means [22]. For propagation along the diagonal, the regular SCN exhibits no dispersion, but in other directions there is dispersion that increases with frequency. The best advice, which is common to all similar

numerical schemes, is to use a resolution of at least 10 segments per wavelength at the highest frequency of interest. If this is done, dispersion errors of a few percent under the worst circumstances should be expected. Studying dispersion properties by deriving dispersion relations in a closed analytical form is a much more demanding task, but some significant progress has been reported [23,24].

The problem of propagation behavior at the interface between different meshes is a difficult one, and no general analytical expressions are available that allow a rapid assessment of prevailing errors. Most studies are based on numerical work and the general advice is that abrupt changes in resolution should be avoided. A study that compares the behavior of TLM and FDTD for the same grading ratios across interfaces may be found in Ref. 25.

4.4. A Modal View of TLM

Another interesting insight into TLM is to examine its structure in terms of modal components.

At the surface of each mode there are 12 electric and 12 magnetic field components, which are related by an admittance operator Y :

$$\mathbf{H} = Y\mathbf{E} \quad (25)$$

Expressing field components in terms of incident and reflected voltages at the node gives

$$\mathbf{E} = \mathbf{V}^i + \mathbf{V}^r, \quad \mathbf{H} = y_0(\mathbf{V}^i - \mathbf{V}^r) \quad (26)$$

where y_0 is a scalar quantity. Combining these expressions, one obtains the scattering equation for the TLM node

$$\{y_0 I + Y\}\mathbf{V}^r = \{y_0 I - Y\}\mathbf{V}^i \quad (27)$$

where I is the identity matrix. The best way to solve Eq. (27) is to solve an eigenvalue problem

$$Y\mathbf{U}_n = \gamma_n \mathbf{U}_n \quad (28)$$

where \mathbf{U}_n and γ_n are the eigenvectors and eigenvalues of Y , respectively. Defining a matrix U with columns that are the eigenvector of Y , the voltage components incident and reflected at each node may be expressed in terms of modal components:

$$\mathbf{V}^i = U\mathbf{X}^i, \quad \mathbf{V}^r = U\mathbf{X}^r \quad (29)$$

Combining these expressions with (27) gives the following equation, after some manipulation:

$$X_n^r = \frac{y_0 - \gamma_n}{y_0 + \gamma_n} X_n^i \quad (30)$$

This expression shows that, effectively, the admittance seen into the node by each mode is the eigenvalue, as shown schematically in Fig. 8.

Figure 8. Admittance seen by each mode incident on a TLM node.

The structure of Y and its eigenvalues can be formally derived or obtained from physical intuition in terms of 12 cylindrical harmonics (two TE and two TM modes per coordinate direction). As an example for TM modes the field components are

$$\begin{aligned} E_{z,n} &= \frac{J_n(k_0 r)}{J_n(k_0 \Delta)} \cos(n\varphi) \\ H_{\varphi,n} &= \frac{1}{j\omega\mu} \frac{dJ_n(k_0 r)/dr}{J_n(k_0 \Delta)} \cos(n\varphi) \end{aligned} \quad (31)$$

where k_0 is the wavenumber and the fields were normalized at the edge of the node $r = \Delta$. The eigenvalues for this mode are

$$\gamma_n = \frac{H_{\varphi,n}}{E_{z,n}} = \frac{1}{j\omega\mu} \left. \frac{dJ_n(k_0 r)/dr}{J_n(k_0 r)} \right|_{r=\Delta} \quad (32)$$

Using a small argument expansion for the Bessel functions, the eigenvalue for the $n = 0$ TM_{z0} mode is obtained:

$$\gamma_0 = j \frac{\omega\epsilon\Delta}{2} \quad (33)$$

Hence the reflection coefficient for the TM_{z0} mode is

$$\Gamma = \frac{Y_0 - \gamma_0}{Y_0 + \gamma_0} \simeq e^{-jk\Delta} \quad (34)$$

This represents a simple phase shift on a lossless line segment. Similar expressions are obtained for the other modes. TLM therefore may be interpreted as a procedure for implementing in the time domain the process of analysis of total voltages into modes, the proper reflection of each mode at the node, and the recombination of modes to obtain total voltages for transmission to adjacent nodes. These ideas are useful in implementing schemes for embedding thin wires into TLM nodes. More details may be found in Ref. 26.

5. FURTHER DEVELOPMENTS AND SELECTED APPLICATIONS

5.1. Absorbing Boundary Conditions

All differential equation numerical techniques that are based on a volumetric discretization require special boundary conditions to deal with open-boundary problems.

Typically, at the extremities of the numerical mesh, where an open boundary exists, a termination must be

placed that mimics, as far as possible, the open boundary of the real physical problem. The simplest approach in TLM has been to use the “matched boundary condition,” which effectively terminates the line segments at the open boundary with the medium’s characteristic impedance. This is an inexpensive absorbing boundary condition to use and should be employed whenever possible. The resulting small reflections are acceptable in all except the most demanding problems.

In cases where a better absorbing boundary condition is required, two approaches have emerged for use in a TLM mesh. The first approach is based on the Johns matrix concept and is particularly suitable for terminating waveguide problems [27]. In time-domain diakoptics the impulse response of the TLM mesh at selected input points is in effect a discrete Green function, which is referred to as the “Johns matrix”. If this response is known, then the response to any excitation is obtained by convolving the excitation with its Johns matrix. At an interface marking an open boundary, the Johns matrix is in effect a reflection coefficient matrix such as impulses reflected at the interface are dependent on the impulses not only at a given time but also at previous times. This approach works well and efficiently on simple open boundaries such as those found in waveguide problems.

For terminating open boundaries in more general configurations, the computational cost of the Johns matrix approach is unacceptable and schemes based on the “perfectly absorbing layer” [also known as “perfectly matched layer” (PML)] are generally preferred. This effectively introduces a fictitious material as an absorber and is used extensively in FDTD schemes. An implementation of the PML boundary condition in TLM is described in Ref. 28. It should be noted that the PML schemes exhibit instabilities under certain conditions, notably when terminating waveguides contain irises, and hence in such cases the Johns matrix approach should be preferred.

5.2. Multigrid Schemes

Mesh refinement is necessary whenever fine features such as wires, wire looms, edges, and thin walls with perforations need to be described in the mesh. It would appear that the simplest way and the one resulting in the best accuracy is to use a finer mesh so that the finest feature can be accommodated by the resolution of the mesh. This would imply typically four sampling points per fine feature. The resulting size of the computation, however, would be excessively large. An alternative is to use a finer mesh only where it is required, thus resulting in a multigrid mesh.

Substantial effort has been expended in this area over many years as reviewed in Ref. 29. There are many difficulties to overcome, and it appears that an entirely satisfactory scheme is not available. Two schemes, that allow for a multigrid mesh in TLM are described in Refs. 30,31. Multigrid schemes are available mainly as research tools and should be used with caution and only for small resolution ratios between fine and coarse meshes.

5.3. The ADI TLM

Another development in TLM, which results in an implicit algorithm, is the alternate-direction-implicit TLM (ADI-TLM) or split-step TLM (SS-TLM) [32–34] scheme. These algorithms split sampling in time into two steps. As an example, for the x component of the electric field, two sub-equations are obtained:

$$\begin{aligned} \frac{1}{2} \left[\epsilon \frac{\partial E_x}{\partial t} + \sigma E_x \right] &= \frac{\partial H_z}{\partial y} \\ \frac{1}{2} \left[\epsilon \frac{\partial E_x}{\partial t} + \sigma E_x \right] &= -\frac{\partial H_y}{\partial z} \end{aligned} \tag{35}$$

The first step is implemented by approximating the first equation in (35) between times $(n - \frac{1}{2})\Delta t$ and $n \Delta t$ and the second equation between $n \Delta t$ and $(n + \frac{1}{2})\Delta t$. The second step is similarly obtained by approximating the second equation between $(n + \frac{1}{2})\Delta t$ and $(n + 1)\Delta t$, and the first between $(n + 1)\Delta t$ and $(n + \frac{3}{2})\Delta t$. This results in an implicit algorithm, but a larger timestep can be employed compared to nonsplit explicit TLM algorithms. The overall result is that in some circumstances a computational saving is achieved. It is not clear at present whether these benefits persist when dealing with general EM problems with inhomogeneous materials, embedded wires, or similar.

5.4. Modeling of General Materials with Frequency-Dependent Properties in the Time Domain

Simple materials with frequency independent properties are easily modeled in TLM by adjusting node parameters (dielectrics, losses) or reflection coefficients (perfect conductors). For more general materials, which may involve dependence on frequency, anisotropy, chirality, nonlinearity, and other properties, special techniques need to be developed for time-domain models. The simplest way to visualize the procedures to be followed in the development of such models, is to consider that in the frequency-domain material properties represent in effect the transfer function of an analog filter. By deriving an equivalent digital filter, which has the same frequency response as the analog filter, a time-domain procedure is readily obtained that can be directly embedded into the time-domain TLM model.

A simple yet important example is of propagation in a Debye material where

$$\epsilon(\omega) = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + j\omega\tau} \tag{36}$$

where $\epsilon_s, \epsilon_\infty, \tau$, are the static permittivity, permittivity at infinite frequencies, and relaxation time, respectively. Limiting, for simplicity, the discussion to 1D propagation in a Debye medium the calculation proceeds as follows.

The basic circuit equivalent for the problem is shown in Fig. 9. The TLM equivalent of this circuit is shown in

Figure 9. A segment of a model to describe 1D propagation in a Debye medium.

Fig. 10, where all impedances are normalized to

$$Z_0 = \frac{1}{Y_0} = \sqrt{\frac{\mu_0}{\epsilon_0}} \tag{37}$$

The timestep and the following parameters are calculated from

$$\begin{aligned} \Delta t &= \frac{\Delta x}{c} \\ \beta &= \exp\left(\frac{-\Delta t}{\tau}\right) \\ \alpha &= (\epsilon_s - \epsilon_\infty)(1 - \beta) \\ g &= \sigma \Delta x Z_0 \\ t &= \frac{2}{2\epsilon_\infty + g + 2\alpha} \\ t_s &= 2t(\epsilon_\infty + \alpha - 1) \\ t_f &= t\beta \end{aligned} \tag{38}$$

Figure 10. The normalized equivalent circuit of the circuit in Fig. 9, where lumped components were replaced by link and stub lines.

The total voltage is obtained from

$${}_k V = t({}_k V_0^i + {}_k V_1^i) + t_s {}_k V_s^i + t_f {}_{k-1} u \quad (39)$$

The quantity u is obtained by the procedure shown in Fig. 11. The reflected voltages are then calculated as follows:

$$\begin{aligned} {}_k V_0^r &= {}_k V - {}_k V_0^i \\ {}_k V_1^r &= {}_k V - {}_k V_1^i \\ {}_k V_s^r &= {}_k V - {}_k V_s^i \end{aligned} \quad (40)$$

The algorithm requires one backstore variable. Similar procedures are available to deal with material modeling in three dimensions and with a range of material parameters [35–39].

5.5. Multiscale Schemes

The problem of fine features in large computations and the need to deal effectively and efficiently with multiscale problems were already discussed [29]. Two examples are given here for two important practical problems: the simulation of coupling to wires and the simulation of the shielding effectiveness of cabinets.

For describing thin wires, the approach first described by Holland and Simpson [40] has been used for some time. It is based on the principle of calculating an in-cell capacitance to represent the wire and thus building an interface between the wire and the rest of the TLM mesh. Calculation of the parameters of this interface is based on the quasistatic assumption regarding the field around the wire. Several papers discuss in detail the nature of this interface for a wire placed between nodes [41], a wire placed at the node center [42], and multiconductor looms [43]. All these developments suffer from a number of assumptions and limitations.

An alternative technique is based on taking into account more than one modes for the field around the wire [modal expansion technique (MET)]. Because MET takes more modes into account (some of which are asymmetric), it is suited to placing the wire arbitrarily anywhere in the node. It is also accurate and removes several other restrictions inherent in the conventional approach. MET is based on the approach described in Section 4.4 for a node without a wire, with the important modification that more modes need now be taken into account, and, the imped-

ance seen by incoming pulses takes account of the presence of the wire. The complete field solution for a long wire is

$$\begin{aligned} E_z(r, \varphi) &= \sum_{n=-\infty}^{\infty} B_n e^{jn\varphi} \left[J_n(k_0 r) - \frac{J(k_0 a)}{N_n(k_0 a)} N_n(k_0 r) \right] \\ H_\varphi(r, \varphi) &= \frac{1}{j\omega\mu_0} \frac{\partial E_z}{\partial r} \end{aligned} \quad (41)$$

From this it can be seen that the static solution used in the conventional approach based on Holland and Simpson is only the first term in this expansion. Depending on the degrees of freedom available, several modes may be used. In two dimensions, where TLM nodes have four ports, four modes are employed. In three dimensions, for a z -directed wire, four modes (TE, TM, TEM odd, TEM even) and four angular instances are selected, making a total of 16 modes. Wires that are offset from the center of the node may also be described by exploiting as an example the addition theorems for Bessel functions. The approach of working out the eigenvalues, the impedance seen by each mode and for constructing suitable algorithms, may be found in Ref. 26.

Another problem of importance in many applications is the description of a thin wall with numerous perforations that is part of a resonant box (e.g., equipment cabinet). It is simply computationally far too expensive to generate a mesh with the necessary resolution to describe all relevant features. The simplest approach to this type of problem is to place the thin wall with perforations between nodes and to account for its properties by a frequency-dependent scattering matrix $S(\omega)$ implemented during the connection process in TLM. This technique is referred to as a *digital filter interface* (DFI) since it reduces to a time-domain algorithm as part of the connection process. Each coefficient of the scattering matrix is put into standard Padé form and then the frequency-domain Prony method is used to find its poles and zeros. The resulting expression is converted into the discrete time domain by application of the bilinear transformation. The resulting equations in state form relating incident and reflected voltages are of the form

$$\begin{aligned} V^i &= B_0 V^r + \mathbf{B}' X \\ X &= z^{-1} A' X + z^{-1} \mathbf{1}' V^r \end{aligned} \quad (42)$$

Figure 11. Signal flow diagram representing the algorithm for implementing the model for Debye materials.

In (42) the first equation is the output equation and the second is the state equation, and the computational procedure is shown in Fig. 12. Details may be found in Ref. 44. Using this approach, very substantial computational savings can be made. Moreover, the frequency-dependent scattering matrix may be obtained by numerical simulation, analytically or experimentally. The calculation of the poles and zeros is a preprocessing task and therefore is not an overhead on the main timestepping simulation.

Figure 12. Signal flow diagram of the “connection” process to account for fine features using the DFI algorithm.

5.6. Frequency-Domain TLM (FD-TLM)

TLM is mainly used as a time-domain method but can also be implemented in the frequency domain. In FD-TLM time-harmonic variations are used and therefore discretization in space only is required. This considerably simplifies the modeling of materials and other features. However, the algorithm requires the inversion of a large matrix.

Several schemes are available in which either the characteristic impedance of each line is kept the same or phase constants are kept the same. Details may be found in the literature [45–48].

TRANSMISSION LINE THEORY

RAGHU K. SETTALURI
Oregon State University
Corvallis, OR

A transmission line is a network that connects a generator circuit to a load for the purpose of transmitting electric energy or information from one point to another. Examples of transmission lines include cable connection between a service provider and your television set, telephone wires, interconnection between a transmitter and an antenna, and optic nerves and neural networks in human brain. The list can go on and on with the same essential purpose of transporting energy or information between

two points. In these examples, we can notice one important difference for each scenario. The choice of transmission line is different and depends on the purpose and application. For example, high-power transmission lines that are used to transport megawatts of electric energy need to be thicker and bulkier to accommodate the large power-handling capability and minimize power losses. On the other hand, a microminiaturized interconnect in the 4 GHz central processor of your desktop or laptop needs to be precisely designed to transfer the information in a densely packed circuit environment! In electrical engineering applications, the choice of a suitable transmission medium depends on a variety of factors including the frequency of operation, power handling, and the topology.

Many readers might be familiar with basic circuit analysis techniques for low-frequency electric circuits, which have been well developed over decades. At low frequencies, the physical size of the circuit is much smaller compared with the wavelength. This condition implies that when a load is connected to a voltage source via a length of transmission line, the voltage appears instantaneously at the load end without any time delay, which also implies that lumped elements such as inductors, capacitors, and resistors will have much smaller sizes compared with wavelength, and we can conveniently assume that the voltage across an element on one side of the circuit was exactly in phase with the voltage on the other side. Thus size or separation between elements was never an issue in the low-frequency circuit design!

When the size of an element is a considerable fraction of a wavelength or many wavelengths, the network becomes *distributed* in nature. In this case, aside from time variation, voltages and currents can vary in magnitude and phase as a function of distance. A transmission line may no longer be considered as a simple interconnecting mechanism between two points. It behaves like a distributed-parameter network, for which the transmission properties need to be considered as a part of the design process, which leads to electromagnetic wave propagation on transmission lines with possible standing wave formations.

1. PROPAGATION MODES

The orientation of electric and magnetic fields and their interaction along a transmission line is essentially decided by the geometry of the transmission line structure, which is generally characterized by the *mode* supported by the transmission line structure for the electromagnetic wave propagation. Figure 1 shows several commonly used transmission lines, which are broadly classified into three main categories. The two-wire line, coaxial line, and strip-line, shown Figs. 1a–1c, support transverse electromagnetic (TEM) mode, where the electric and magnetic fields are entirely transverse to the direction of propagation. Many of the characteristics of wave propagation in TEM supporting structures are the same as those for a uniform plane wave propagating in an unbounded dielectric medium.

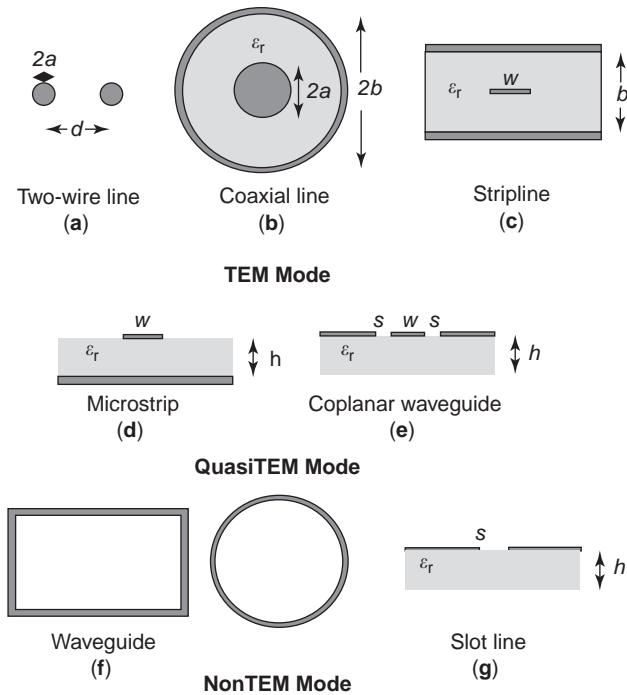

Figure 1. Commonly used transmission lines supporting different propagation modes.

A microstrip line and a coplanar waveguide (Figs. 1d and 1e) are two commonly used planar transmission lines at microwave frequencies. As a result of the presence of the air-dielectric interface, these structures are considered as inhomogeneous transmission lines. Here, the field lines between the conducting strip and the ground lines are not contained entirely in the substrate, and these structures support quasiTEM mode of propagation. However, because the nontransverse field components are considerably smaller compared with the transverse field components, for most practical applications, they can be included in the TEM class of transmission lines. A common feature among TEM and quasiTEM transmission line structures is that they require at least two conductors to support TEM mode and frequencies as low as DC can propagate along these lines.

Several other transmission lines exist that do not support TEM or quasiTEM mode of propagation. These include the rectangular and circular waveguides (Fig. 1f) and slotlines (Fig. 1g). Depending on the configuration, these structures support several higher order modes, such as transverse electric (TE) and transverse magnetic (TM), where the presence of a longitudinal field component cannot be ignored. The minimum frequency (also called the *cutoff* frequency) of the electromagnetic wave that can be supported in these structures depends on factors such as mode number and physical dimensions. Further, the transmission properties will have a strong frequency dependence. As transmission lines supporting TEM/quasiTEM wave propagation are more commonly used in practice, this article focuses on understanding

the wave propagation in the case of TEM supporting structures.

2. TRANSMISSION LINE EQUATIONS

As we have noticed in our earlier discussion, incorporating the spatial dependence of fields is important while addressing the characteristics of the transmission lines at high frequencies. For a given structural geometry, the transmission line characteristics can be determined by solving the Maxwell's equations [1] in various regions. This approach can provide a complete description of electric and magnetic fields at every point in the region. However, many times we are interested in terminal quantities such as voltage, current, impedance, and power, for which a discretized circuit representation of a distributed transmission line may offer simpler, yet adequately accurate solution.

Let us consider a transmission line connected to a source at one end and a load at the other end, as shown in Fig. 2a. If we choose a small section of the line with differential length Δz , it can be modeled as a discrete circuit, as shown in Fig. 2b and described by the following four basic parameters:

- R , resistance per unit length for both conductors, in Ω/m
- L , inductance per unit length for both conductors, in H/m
- G , conductance per unit length in S/m
- C , capacitance per unit length in F/m

The inductance L , represents the total series self inductance in both the conductors and the capacitance C , represents the capacitive coupling between the two conductors, which depends on the proximity between the conductors. R and G develop because of the conductor losses of both conductors and dielectric losses that exist in the medium between the conductors respectively. Thus R and G are essentially the *attenuation* or *loss* parameters of the transmission line. A finite length of transmission line can be considered as a cascade of several sections of infinitesimal length Δz , representing the distributed nature of the line.

The quantities $v(z, t)$ and $i(z, t)$ represent the instantaneous voltage and current at the input of the differential length section at node N . Similarly, $v(z + \Delta z, t)$ and $i(z + \Delta z, t)$ represent the same quantities on the output side at node $N + 1$. Applying Kirchhoff's voltage law, we obtain

$$v(z, t) - R\Delta z i(z, t) - L\Delta z \frac{\partial i(z, t)}{\partial t} - v(z + \Delta z, t) = 0 \quad (1a)$$

Rearranging the terms in Eq. (1a) leads to

$$-\frac{v(z + \Delta z, t) - v(z, t)}{\Delta z} = Ri(z, t) + L \frac{\partial i(z, t)}{\partial t} \quad (1b)$$

Figure 2. Transmission line and lumped-element representation for the purpose of deriving the Telegrapher's equations. (a) Definition of voltages and currents on a transmission line connected between a source and a load. (b) Lumped-element equivalent circuit for an elemental length of transmission line.

Similarly, applying Kirchhoff's current law to node $N+1$ in Fig. 2b leads to

$$i(z, t) - G\Delta z v(z + \Delta z, t) - C\Delta z \frac{\partial v(z + \Delta z, t)}{\partial t} - i(z + \Delta z, t) = 0 \quad (2a)$$

Again, rearranging the terms in Eq. (2a), we have

$$-\frac{i(z + \Delta z, t) - i(z, t)}{\Delta z} = Gv(z, t) + C \frac{\partial v(z, t)}{\partial t} \quad (2b)$$

In the limit, $\Delta z \rightarrow 0$, Eqs. (1b) and (2b) become

$$-\frac{\partial v(z, t)}{\partial z} = Ri(z, t) + L \frac{\partial i(z, t)}{\partial t} \quad (3a)$$

$$-\frac{\partial i(z, t)}{\partial z} = Gv(z, t) + C \frac{\partial v(z, t)}{\partial t} \quad (3b)$$

The first-order partial differential equations given in Eqs. (3) are the time-domain form of the transmission line equations, which are also called the *Telegrapher's* equations.

As we are primarily interested in sinusoidal steady-state conditions, we can apply the phasor notation with cosine reference to represent the time-domain equations given in Eqs. (3) in frequency-domain. For this, we define

$$v(z, t) = \text{Re}[V(z)e^{j\omega t}] \quad (4a)$$

$$i(z, t) = \text{Re}[I(z)e^{j\omega t}] \quad (4b)$$

where, $V(z)$ and $I(z)$ are phasor quantities dependent on space coordinate z only, and each of them could be real or

complex, and Re represents the real part of a complex quantity. Substituting Eqs. (4a) and (4b) in Eqs. (3) yields the following first-order ordinary differential equations in frequency-domain:

$$-\frac{dV(z)}{dz} = (R + j\omega L)I(z) \quad (5a)$$

$$-\frac{dI(z)}{dz} = (G + j\omega C)V(z) \quad (5b)$$

Eqs. (5) are called the *time-harmonic transmission line equations*.

3. WAVE PROPAGATION ON AN INFINITE TRANSMISSION LINE

The two coupled first-order time-harmonic transmission line equations given in Eqs. (5) can be combined to give two second-order uncoupled differential equations in $V(z)$ and $I(z)$ as

$$\frac{d^2V(z)}{dz^2} - \gamma^2 V(z) = 0 \quad (6a)$$

$$\frac{d^2I(z)}{dz^2} - \gamma^2 I(z) = 0 \quad (6b)$$

where

$$\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)} \quad (m^{-1}) \quad (7)$$

is the *complex propagation constant* of the transmission line, whose real and imaginary parts, α and β , represent

the *attenuation constant* (Np/m) and *phase constant* (rad/m) of the line, respectively. For all passive transmission lines, α will be either zero or a positive quantity.

The wave equations given in Eqs. (6) have solutions of the form

$$V(z) = V_0^+ e^{-\gamma z} + V_0^- e^{\gamma z} \tag{8a}$$

$$I(z) = I_0^+ e^{-\gamma z} + I_0^- e^{\gamma z} \tag{8b}$$

The terms $e^{-\gamma z}$ and $e^{\gamma z}$ represent the wave propagation in $+z$ and $-z$ directions, respectively. V_0^+ and I_0^+ are the wave amplitudes in the $+z$ direction, and V_0^- and I_0^- are the wave amplitudes in the $-z$ direction. These amplitudes are related via the expression

$$\frac{V_0^+}{I_0^+} = -\frac{V_0^-}{I_0^-} = \frac{R + j\omega L}{\gamma} \tag{9}$$

The ratio of the forward wave amplitudes or the negative of the backward wave amplitudes is also defined as *characteristic impedance*, Z_o , of the transmission line, where

$$Z_o = \frac{R + j\omega L}{\gamma} = \frac{\gamma}{G + j\omega C} = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \tag{10}$$

Note that the parameters γ and Z_o can be complex and are independent of the length of the transmission line. As seen in Eqs. (7) and (10), these characteristic properties of the line are directly related to the line parameters $R, L, G,$ and C , which are real in nature. These parameters are dependent on the geometry of the transmission line and material properties of the conductors and the dielectric medium. For example, the line parameters for coaxial line and a two-wire transmission line are given in Table 1.

3.1. Special Cases

3.1.1. Lossless transmission line. The transmission line equations derived in Section 3 are for a general transmission line taking the effect of finite conductivity of the conductors and dielectric losses into account. However, in many practical situations, transmission lines at radiofrequencies are designed to have conductors with high

conductivities and dielectric materials with small values of loss tangent, $\tan\delta$, which would result in values of $R \ll \omega L$ and $G \ll \omega C$. Therefore, if we approximate $R = 0 = G$ in Eqs. (7) and (10), we get

$$\gamma = \alpha + j\beta = j\omega\sqrt{LC} \tag{11a}$$

$$\alpha = 0 \tag{11b}$$

$$\beta = \omega\sqrt{LC} \tag{11c}$$

$$Z_o = \sqrt{\frac{L}{C}} \tag{11d}$$

Thus, the propagation constant, γ , for a lossless transmission line becomes purely imaginary, reasserting the fact that attenuation will be zero for ideal lines with no dielectric and conductor losses. From Eq. (11d), it can be seen that the characteristic impedance, Z_o , becomes real for a lossless line. Phase velocity v_p , which is defined as the velocity of propagation of an equiphase front on the transmission line, is given as

$$v_p = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \tag{12}$$

From Eq. (12), it can be seen that the phase velocity is independent of the frequency of the propagating wave. As any arbitrary signal can be composed of a combination of sinusoidal waves of different frequencies and amplitudes, a constant phase velocity for all frequencies will ensure that all these waves will travel with the same velocity along a lossless line without suffering any attenuation, thus preserving the shape of the signal. On the other hand, for a general lossy transmission line, from Eq. (7), it can be seen that the phase velocity, β , and attenuation, α , are functions of frequency. As different frequency components propagate with different velocities and attenuation factors, the signal suffers *dispersion* and gets *distorted* as it propagates along the line.

3.1.2. Distortionless line. The theory for distortionless line was first proposed by Oliver Heaviside, whose contributions to the electromagnetism were well described in [2]. Consider a general lossy transmission line, which

Table 1.

Structure	Transmission line parameters			
	R (Ω/m)	L (H/m)	G (S/m)	C (F/m)
Two-wire Line (Fig. 1a)	$\frac{R_s}{\pi a}$	$\frac{\mu}{\pi} \ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)$	$\frac{\pi\sigma}{\ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)}$	$\frac{\pi\epsilon}{\ln\left(\frac{d}{2a} + \sqrt{\left(\frac{d}{2a}\right)^2 - 1}\right)}$
Coaxial Line (Fig. 1b)	$\frac{R_s}{2\pi} \left[\frac{1}{a} + \frac{1}{b}\right]$	$\frac{\mu}{2\pi} \ln\left(\frac{b}{a}\right)$	$\frac{2\pi\sigma}{\ln\left(\frac{b}{a}\right)}$	$\frac{2\pi\epsilon}{\ln\left(\frac{b}{a}\right)}$

Notes:

a. $\mu, \epsilon,$ and σ are the material properties of the dielectric medium.

b. R_s is the surface resistance of the conductors, which is related to the frequency and material properties of the conductor.

satisfies the condition

$$\frac{R}{L} = \frac{G}{C} \quad (13)$$

Substituting Eq. (13) in Eqs. (7) and (10), we get

$$\gamma = \alpha + j\beta = R\sqrt{\frac{C}{L}} + j\omega\sqrt{LC} \quad (14)$$

$$Z_o = \sqrt{\frac{L}{C}} \quad (15)$$

Phase velocity, v_p , is given by,

$$v_p = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} \quad (16)$$

Comparing Eqs. (14)–(16) with Eqs. (11) and (12), it can be seen that, except for a nonzero value of attenuation constant, the distortionless line has same characteristics as that of a lossless line. Although the signal suffers attenuation as it propagates along the line, because of the constant phase velocity, waves of different frequency components will travel with the same velocity, thus preserving the shape of the signal, which is why it is called the *distortionless line*.

4. WAVE CHARACTERISTICS ON TERMINATED TRANSMISSION LINE

As you may recall, the general solution for transmission line wave equations given in Eqs. (8) consists of two types of wave propagation—the wave traveling in forward (+z) direction and the wave traveling in the backward (−z) direction. When a wave is incident at one end on an infinitely long transmission line, it continues to propagate in +z or −z direction depending on the direction of the incident wave. Thus, only one of the two terms consisting of either $e^{-\gamma z}$ or $e^{+\gamma z}$ exists. Let us now consider a transmission line of finite length l , terminated by an arbitrary load impedance Z_L , as shown in Fig. 3. It is assumed that the load is at $z=0$ and the source is connected at $z=-l$.

Using Eqs. (9) and (10), Eqs. (8a) and (8b) can be modified to contain only two unknown voltage amplitudes V_o^+ and V_o^- as

$$V(z) = V_o^+ e^{-\gamma z} + V_o^- e^{\gamma z} \quad (17a)$$

$$I(z) = \frac{V_o^+}{Z_o} e^{-\gamma z} - \frac{V_o^-}{Z_o} e^{\gamma z} \quad (17b)$$

At $z=0$, Eqs. (17a) and (17b) become

$$V_L = V(z=0) = V_o^+ + V_o^- \quad (18a)$$

$$I_L = I(z=0) = \frac{V_o^+}{Z_o} - \frac{V_o^-}{Z_o} \quad (18b)$$

Also, V_L and I_L are related via the load impedance, Z_L , as

$$Z_L = \frac{V_L}{I_L} \quad (19)$$

Using Eqs. (18a) and (18b) in Eq. (19) and rearranging terms, we get

$$V_o^- = \Gamma V_o^+ \quad (20a)$$

where

$$\Gamma = |\Gamma| e^{j\theta_r} = \left(\frac{Z_L - Z_o}{Z_L + Z_o} \right) \quad (20b)$$

Γ , which is the ratio of the reflected wave amplitude and the incident wave amplitude, is called the *voltage reflection coefficient*. As both Z_o and Z_L could be complex quantities, Γ can also be complex in general. It may be seen that, for all transmission lines, $|\Gamma| \leq 1$.

Using Eq. (20a) in Eqs. (17a) and (17b), we get

$$V(z) = V_o^+ (e^{-\gamma z} + \Gamma e^{\gamma z}) \quad (21a)$$

$$I(z) = \frac{V_o^+}{Z_o} (e^{-\gamma z} - \Gamma e^{\gamma z}) \quad (21b)$$

The ratio of $V(z)$ and $I(z)$ is called the *input impedance*, Z_{in} , and is given by

$$Z_{in}(z) = \frac{V(z)}{I(z)} = Z_o \left[\frac{1 + \Gamma e^{2\gamma z}}{1 - \Gamma e^{2\gamma z}} \right] \quad (\Omega) \quad (22)$$

At the input of the transmission line, the input impedance can be written as

$$Z_{in}(-l) = Z_o \left[\frac{1 + \Gamma e^{-2\gamma l}}{1 - \Gamma e^{-2\gamma l}} \right] \quad (\Omega) \quad (23)$$

Substituting Eq. (20b) in Eq. (23) and rearranging the terms, we get

$$Z_{in}(-l) = Z_o \left[\frac{Z_L + Z_o \tanh \gamma l}{Z_o + Z_L \tanh \gamma l} \right] \quad (\Omega) \quad (24)$$

Thus, Z_{in} is the impedance seen at the input of the transmission line, when the line is terminated with a load impedance Z_L . From the generator standpoint, the transmission line-load impedance combination can be replaced by a simple impedance Z_{in} , without disturbing the input voltage and current amplitudes, as shown in Fig. 3b. If the line is lossless, we can substitute for $\gamma = j\beta$ in Eq. (24) and get a modified expression for Z_{in} , as

$$Z_{in}(-l) = Z_o \left[\frac{Z_L + jZ_o \tan \beta l}{Z_o + jZ_L \tan \beta l} \right] \quad (\Omega) \quad (25)$$

4.1. Standing Wave Ratio

Consider a lossless transmission line of characteristic impedance Z_o , which is terminated by an arbitrary load impedance Z_L . From Eqs. (21a) and (21b), the expressions for

Figure 3. (a) A finite length transmission line terminated with a load impedance, Z_L . (b) Equivalent representation in terms of the input impedance, Z_{in} .

$V(z)$ and $I(z)$ for the lossy transmission line can be written as

$$V(z) = V_0^+ (e^{-j\beta z} + \Gamma e^{j\beta z}) \tag{26a}$$

$$I(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} - \Gamma e^{j\beta z}) \tag{26b}$$

The magnitude of the voltage, $|V(z)|$, will be

$$|V(z)| = |V_0^+| \cdot |1 + |\Gamma| e^{j(\theta_r + 2\beta z)}| \tag{27}$$

where, $\Gamma = |\Gamma| e^{j\theta_r}$ has been substituted.

Equation (27) shows that the voltage magnitude oscillates as a function of z , as shown in Fig. 4, indicating the standing wave formation. We can see that the voltage will be maximum when $e^{j(\theta_r + 2\beta z)} = 1$, and is given by

$$V_{\max} = |V_0^+| (1 + |\Gamma|) \tag{28a}$$

Similarly, voltage will be minimum when $e^{j(\theta_r + 2\beta z)} = -1$, and is given by

$$V_{\min} = |V_0^+| (1 - |\Gamma|) \tag{28b}$$

It may be noticed that when the load impedance is the same as the characteristic impedance of the line, the reflection coefficient $\Gamma = 0$, from Eq. (27), and we can see that $|V(z)| = |V_0^+|$, a constant value independent of z . As $|\Gamma|$ increases, the ratio of V_{\max} to V_{\min} increases, which leads us to define *voltage standing wave ratio (VSWR)*, or simply *standing wave ratio (SWR)*, as

$$SWR = \frac{V_{\max}}{V_{\min}} = \frac{1 + |\Gamma|}{1 - |\Gamma|} \tag{29}$$

SWR is always a real number such that $1 \leq SWR \leq \infty$. For a matched transmission line (when $Z_o = Z_L$), $SWR = 1$. It may also be noted that the distance between two successive voltage maxima (or minima) is $\lambda/2$, where λ is the wavelength on the transmission line.

4.2. Special Cases of Terminated Lossless Transmission Lines

Often, we use lossless transmission lines with special terminations to give interesting characteristics. For example, in impedance tuning networks and microwave filter design we commonly use *stubs* (open- or short-circuited transmission lines) in series or shunt configuration as part of the design. Also, at microwave frequencies, the

Figure 4. Standing wave formation on a lossless transmission line.

open- and short-circuited stubs can be used to replace lumped capacitors and inductors, which are otherwise impractical to realize. Similarly, we use lines with quarter wavelength for impedance transformation. Section 4.2.1 briefly describes the special properties of some of the lossless lines.

4.2.1. Open-Circuited Line. When a transmission line is open-circuited at one end, as shown in Fig. 5a, it sees an infinite load impedance ($Z_L = \infty$). From Eq. (20b), we can see that the voltage reflection coefficient $\Gamma = 1$, which means that the SWR becomes ∞ . From Eqs. (26a) and (26b), the voltage and current on an open-circuited loss-

Figure 5. A lossless transmission line terminated with an (a) open circuit, (b) voltage distribution, (c) current distribution, and (d) input reactance as a function of the distance from the termination.

less transmission line are given by

$$V_{oc}(z) = V_0^+ (e^{-j\beta z} + e^{j\beta z}) = 2V_0^+ \cos \beta z \quad (30a)$$

$$I_{oc}(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} - e^{j\beta z}) = \frac{-2jV_0^+}{Z_0} \sin \beta z \quad (30b)$$

Both voltage and current are plotted as a function of the distance from the load location in Figs. 5b and 5c, respectively. As a result of the sinusoidal nature, both the quantities are periodic and repeat for multiples of λ .

Substituting $Z_L = \infty$ in Eq. (25) for the expression for input impedance, we get

$$Z_{oc} = Z_{in} = -jZ_0 \cot \beta z \quad (\Omega) \quad (31)$$

We can see from Eq. (30) that the input impedance Z_{oc} for the open-circuited line is always purely imaginary irrespective of length z . The variation of open-circuit reactance (imaginary part of Z_{oc}) is plotted as a function of z in Fig. 5d. The plot is again periodic and repeats for multiples of $\lambda/2$. The behavior varies between being inductive and capacitive as the length z is varied.

4.2.2. Short-circuited line. A lossless transmission line short circuited at the load end ($Z_L = 0$) is shown in Fig. 6a. Here, $\Gamma = -1$ and $SWR = \infty$. The voltage and current along the line can be given by

$$V_{sc}(z) = V_0^+ (e^{-j\beta z} - e^{j\beta z}) = -2jV_0^+ \sin \beta z \quad (32a)$$

$$I_{sc}(z) = \frac{V_0^+}{Z_0} (e^{-j\beta z} + e^{j\beta z}) = \frac{2V_0^+}{Z_0} \cos \beta z \quad (32b)$$

From Eq. (25), the input impedance for a short-circuited line can be given as

$$Z_{sc} = jZ_0 \tan \beta z \quad (\Omega) \quad (33)$$

The voltage, current, and the input reactance are plotted in Figs. 6b–6d as a function of the distance, z . As it can be seen, the input reactance for a shorted transmission line is also purely imaginary irrespective of the value of z . Comparing Figs. 5 and 6, we can see that in the range where X_{oc} is inductive, X_{sc} is capacitive, and vice versa. The input reactances of the short-circuited and open-circuited lossless transmission lines are essentially the same if their lengths differ by an odd multiple of $\lambda/4$.

Consider an open-circuited transmission line of length much smaller compared with a wavelength. As the electrical length of the line $\beta l \ll 1$, we can make the approximation that $\tan \beta l \cong \beta l$. From Eq. (31), at the input of the line, we have

$$Z_{oc} \cong \frac{Z_0}{j\beta l} = \frac{\sqrt{L/C}}{\omega \sqrt{LC}l} = \frac{1}{j\omega Cl} \quad (34)$$

This equation implies that an open-circuited lossless transmission line with a very short length will behave as a capacitance of Cl farads as shown in Fig. 7a. Similarly,

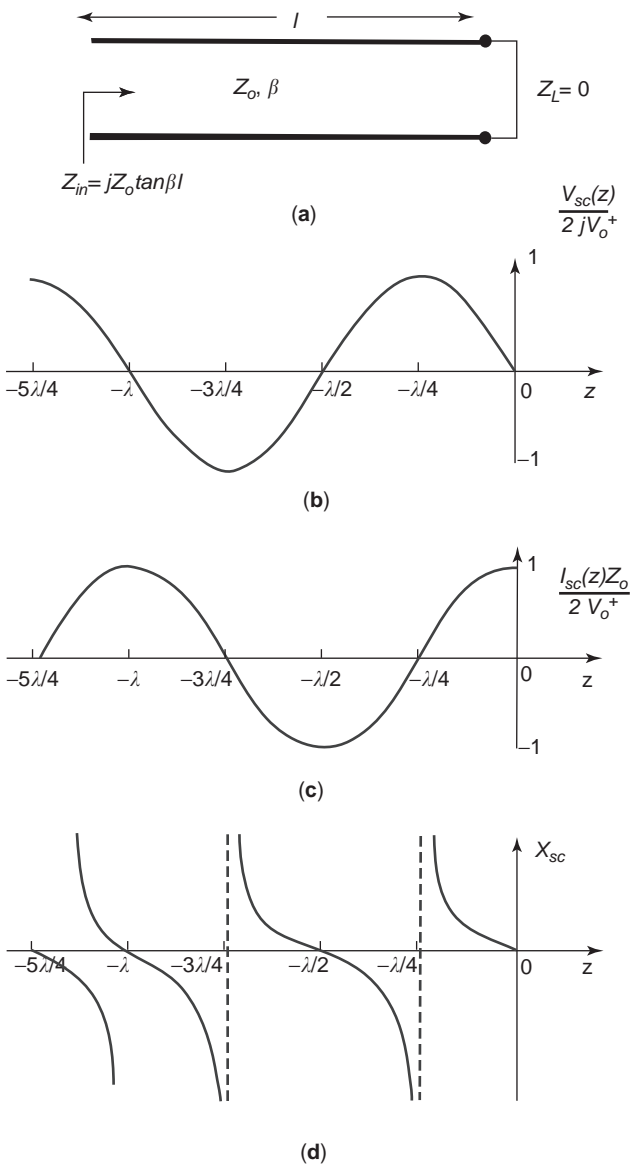

Figure 6. A lossless transmission line terminated with a (a) short circuit, (b) voltage distribution, (c) current distribution, and (d) input reactance as a function of the distance from the termination.

consider a short-circuited transmission line of small length. From Eq. (33), we get

$$Z_{sc} \approx Z_0 \cdot j\beta l = \sqrt{L/C} \cdot j\omega \sqrt{LC}l = j\omega Ll \quad (35)$$

Thus a short-circuited lossless transmission line with a short length can behave as an inductance of Ll henries, as shown in Fig. 7b.

This property of open- or short-circuited transmission lines behaving as lumped inductors or capacitors will be a useful feature at microwave frequencies, where discrete capacitor or inductor realization will be very difficult because of the parasitics associated with the structure. By proper choice, an open-circuited or short-circuited

Figure 7. Transmission lines as circuit elements.

line can replace the lumped elements during circuit design.

4.2.3. Quarter-wave line. When the length of a transmission line is an odd multiple of $\lambda/4$, ($l = (2n - 1)\lambda/4$, n is a nonzero positive integer),

$$\beta l = \frac{2\pi}{\lambda} (2n - 1) \frac{\lambda}{4} = (2n - 1) \frac{\pi}{2} \Rightarrow \tan \beta l \rightarrow \pm\infty$$

and Eq. (25) becomes

$$Z_{in} = \frac{Z_0^2}{Z_L} \quad (36)$$

Hence, the load impedance connected at one end of a quarter-wave transmission line appears to be inverted at the other end. Thus, an open-circuited quarter-wave line appears to be short circuited at the input terminals and vice versa. This *impedance inverting* feature is used in many circuit design applications such as filters and impedance transformers.

4.2.4. Half-wave line. When the length of a lossless line is an integral multiple of $\lambda/2$ ($l = n\lambda/2$, n is a nonzero positive integer),

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{n\lambda}{2} = n\pi, \Rightarrow \tan \beta l \rightarrow 0$$

and Eq. (25) reduces to

$$Z_{in} = Z_L \quad (37)$$

which implies that a load impedance connected to a half-wave lossless transmission line appears to be the same without any change at the input terminals.

4.3. Transmission Line Characterization from Open- and Short-Circuit Measurements

A microwave network analyzer is an instrument, which can be used to measure the input impedance of any device connected to its input terminal. We can determine the characteristics of an unknown lossy transmission line of length less than or equal to $\lambda/2$, by measuring the input impedance under open-circuit and short-circuit conditions.

From Eq. (24), when $Z_L = \infty$,

$$Z_{oc} = Z_o \coth \gamma l \quad (\text{open-circuited line}) \quad (38)$$

when $Z_L = 0$,

$$Z_{sc} = Z_o \tanh \gamma l \quad (\text{short-circuited line}) \quad (39)$$

From Eqs. (38) and (39), we have

$$Z_o = \sqrt{Z_{oc} Z_{sc}} \quad (\Omega) \quad (40)$$

and

$$\gamma = \frac{1}{l} \tanh^{-1} \sqrt{\frac{Z_{sc}}{Z_{oc}}} \quad (\text{m}^{-1}) \quad (41)$$

where Z_o and γ are the characteristic impedance and propagation constant of the lossy line, respectively.

Example 1. A lossless transmission line of characteristic impedance of 50 ohms is connected to a load impedance of $60 \angle 60^\circ \Omega$. What is the load reflection coefficient? Find the input impedance and voltage reflection coefficient at $l = \lambda/8$ and $3\lambda/8$. Also, calculate the standing wave ratio of the line.

Solution: A simple schematic indicating input impedances at different locations is shown in Fig. 8a.

Load reflection coefficient,

$$\begin{aligned} \Gamma_L &= \frac{(Z_L - Z_o)}{(Z_L + Z_o)} = \frac{(30 + j51.96 - 50)}{(30 + j51.96 + 50)} \\ &= 0.1279 + j0.571 = 0.5837 \angle 78^\circ \end{aligned}$$

From Eq. (25), we have,

$$Z_{in} = Z_o \left[\frac{Z_L + jZ_o \tan \beta l}{Z_o + jZ_L \tan \beta l} \right]$$

Case (i) $l = \lambda/8$

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{\lambda}{8} = \frac{\pi}{4} \Rightarrow \tan \beta l = 1$$

$$(Z_{in})_{\lambda/8} = 50 \left[\frac{30 + j51.96 + j50}{50 + j(30 + j51.96)} \right]$$

$$= 165.96 - j60.85 \quad \Omega$$

$$\Gamma_{\lambda/8} = \left(\frac{165.96 - j60.85 - 50}{165.96 + j60.85 + 50} \right)$$

$$= 0.571 - j0.121 = 0.5837 \angle -12^\circ$$

Case (ii) $l = 3\lambda/8$

$$\beta l = \frac{2\pi}{\lambda} \cdot \frac{3\lambda}{8} = \frac{3\pi}{4} \Rightarrow \tan \beta l = -1$$

$$(Z_{in})_{3\lambda/8} = 50 \left[\frac{30 + j51.96 - j50}{50 - j(30 + j51.96)} \right]$$

$$= 13.28 + j4.87 \quad \Omega$$

The input impedance Z_{in} at $3\lambda/8$ can also be determined using a different procedure. Once we have calculated the input impedance at $\lambda/8$, that length of line terminated with the load can be replaced by the calculated input impedance at $\lambda/8$, as shown in Fig. 8b, which leaves with a line with length $3\lambda/8 - \lambda/8 = \lambda/4$. Thus, we have a quarter-

Figure 8. Transmission line problem in Example 1.

wave line of characteristic impedance $50\ \Omega$, terminated with a new load $(Z_{in})_{\lambda/8} = 165.96 - j60.85\ \Omega$. From Eq. (36), we can calculate $(Z_{in})_{3\lambda/8}$ as

$$\begin{aligned} (Z_{in})_{3\lambda/8} &= \frac{Z_o^2}{(Z_{in})_{\lambda/8}} = \frac{50^2}{165.96 - j60.85} \\ &= 13.28 + j4.87\ \Omega \end{aligned}$$

The reflection coefficient at $3\lambda/8$ can be calculated as

$$\begin{aligned} \Gamma_{3\lambda/8} &= \left(\frac{13.28 + j4.87 - 50}{13.28 + j4.87 + 50} \right) = -0.571 + j0.121 \\ &= 0.5837 \angle 168^\circ \end{aligned}$$

We can see that the magnitude of reflection coefficient at different locations is the same, and only the angle changes depending on the distance from the load.

The SWR for the line is

$$SWR = \frac{1 + |\Gamma|}{1 - |\Gamma|} = \frac{1 + 0.5837}{1 - 0.5837} = 3.804$$

5. SMITH CHART

Transmission line calculations, such as determination of input impedance and reflection coefficient, often involve manipulations with complex quantities making it tedious compared with dealing with real numbers. The *Smith chart*, which was developed by P.H. Smith [3,4], is considered to be the most widely used graphical technique for the analysis and design of transmission line circuits. Some readers may feel that in today’s world of powerful computers and modern scientific calculators, graphical ways of solving engineering problems may seem out of the ordinary. More than just being a graphical tool, the Smith chart provides a powerful way of visualizing the transmission line phenomenon, which is why many commercially available popular CAD software used for RF and microwave circuit design have integrated Smith chart calculations into the design stream.

The most common form of the Smith chart is shown in Fig. 9. First, it is important to understand that a Smith chart is essentially a polar plot of the voltage reflection coefficient, Γ . Therefore, we begin with expressing Γ as a complex quantity

$$\Gamma = |\Gamma|e^{j\theta_\Gamma} = \Gamma_r + j\Gamma_i \tag{42}$$

The right-hand side of the horizontal diameter in the chart represents the Γ_r axis, and the top side of the vertical diameter represents the Γ_i axis. $|\Gamma|$ is plotted as a radius ($|\Gamma| \leq 1$) from the center of the chart. The angle, θ_Γ ($-180^\circ \leq \theta_\Gamma \leq 180^\circ$) is measured from the Γ_r axis. We can also relate Γ to the load impedance as

$$\Gamma = \left(\frac{Z_L - Z_o}{Z_L + Z_o} \right) = \left(\frac{Z_L/Z_o - 1}{Z_L/Z_o + 1} \right) = \left(\frac{z_L - 1}{z_L + 1} \right) \tag{43}$$

where

$$z_L = r + jx = \frac{Z_L}{Z_o}$$

z_L is the *normalized* load impedance. In fact, all impedances we plot on the chart are normalized with respect to the characteristic impedance, Z_o .

From Eq. (43), we can write z_L in terms of Γ as

$$z_L = \left(\frac{1 + \Gamma}{1 - \Gamma} \right) \tag{44}$$

Thus, we can write

$$z_L = r + jx = \left(\frac{1 + \Gamma_r + j\Gamma_i}{1 - \Gamma_r - j\Gamma_i} \right) \tag{45}$$

The real and imaginary parts of this equation are

$$r = \frac{1 - \Gamma_r^2 - \Gamma_i^2}{(1 - \Gamma_r)^2 + \Gamma_i^2} \tag{46a}$$

$$x = \frac{2\Gamma_i}{(1 - \Gamma_r)^2 + \Gamma_i^2} \tag{46b}$$

Eqs. (46a) and (46b) can be rearranged as

$$\left(\Gamma_r - \frac{r}{1+r} \right)^2 + \Gamma_i^2 = \left(\frac{1}{1+r} \right)^2 \tag{47}$$

$$(\Gamma_r - 1)^2 + \left(\Gamma_i - \frac{1}{x} \right)^2 = \left(\frac{1}{x} \right)^2 \tag{48}$$

Equation (47) describes a family of circles called the *resistance circles*, where each circle is associated with a specific value of resistance, r . The resistance circles for different values of r are shown on the chart. We can notice that the centers of all r -circles lie on the horizontal axis. All circles pass through the $(\Gamma_r = 1, \Gamma_i = 0)$ point. The largest r -circle is the $r = 0$ circle with a unity radius.

Equation (48) represents the other family of circles called the *reactance circles*, which are also shown on the chart. Different values of x lead to circles of different radii with centers at different positions on the $\Gamma_r = 1$ line. These circles are always orthogonal to the resistance circles. Reactance circles with positive reactance ($x > 0$) lie in the upper half of the chart and those with $x < 0$ lie in the lower half. Intersection of a resistance and reactance circle represents the normalized load impedance, z_L .

One of the main advantages of the Smith chart is that it can be used directly to read the reflection coefficient for a given normalized load impedance and vice versa without having to calculate them. Another useful feature is that the value of the resistance passing through the intersection of the $|\Gamma|$ circle and the Γ_r axis (positive real axis) directly equals the standing wave ratio, SWR. Perhaps the most important feature of the Smith chart is that the angular motion on a constant $|\Gamma|$ circle in a clockwise or counterclockwise direction represents a corresponding movement on a terminated transmission line toward the generator or the load, respectively. Thus, a movement of half a wavelength in the line length on the transmission line corresponds to a complete 360° revolution on the $|\Gamma|$

Figure 9. The Smith chart.

circle reaching the same normalized impedance (or reflection coefficient) point, which reasserts the fact we have seen earlier in the case of a half-wave line, where the input impedance is same as the load impedance. Thus the Smith chart takes into account the periodic behavior of the transmission line.

Example 2. Calculate the input impedance and reflection coefficient for the problem given in Example 1 at $\lambda/8$ and $3\lambda/8$ using the Smith chart. Also, find the SWR of the line.

Solution: The procedure for calculating the above parameters using the Smith chart is described in steps as shown below:

1. Calculate normalized $z_L = Z_L/Z_o = 0.6 + j1.039$ and mark the same on the Smith chart as point A in Fig. 10.
2. With OA as the radius, draw a circle. Measure the radius and normalize it with respect to the radius of the largest r circle ($r = 0$ circle). Read $|\Gamma| = 0.58$.
3. Extend OA to intersect the angular scale given on the Smith chart for reflection coefficient. Mark the reading. This gives the angle of Γ in degrees. $\theta_r = 78^\circ$.
4. Mark the reading where the $|\Gamma|$ circle intersects the positive real axis. This gives $SWR = 3.8$.
5. From point A, move 0.125λ toward the generator to reach point B. Mark the reading on the angular scale of reflection coefficient. This gives angle of Γ at

Figure 10. The Smith chart solution for Example 2.

$l = \lambda/8$. The magnitude of Γ remains the same. Measure $(\theta_\Gamma)_{\lambda/8}$ as -12° .

6. Mark the normalized impedance value by observing r and x values at B, where $\Gamma = 0.58 \angle -12^\circ$. We get

$$r = 3.3 \text{ and } x = -1.21$$

$$\begin{aligned} \therefore (Z_{in})_{\lambda/8} &= 50.(z_{in})_{\lambda/8} = 50.(3.3 - j1.21) \\ &= 165 - j60.5 \Omega \end{aligned}$$

7. From B, move $\lambda/4$ toward the generator to reach point C. Join OC and extend it to intersect the

angular scale for Γ at 168° . This gives $(\Gamma)_{3\lambda/8} = 0.58 \angle 168^\circ$.

$$\begin{aligned} (z_{in})_{3\lambda/8} &= r + jx = 0.265 + j0.1 \\ (Z_{in})_{3\lambda/8} &= 50.(z_{in})_{\lambda/8} = 50.(0.265 + j0.1) \\ &= 13.25 + j5 \Omega \end{aligned}$$

6. NETWORK PARAMETERS OF A GENERAL LOSSY TRANSMISSION LINE

Transmission lines are used in every microwave network system design. When we look at various blocks of a

Table 2.

Type	Two-port Parameters	
ABCD	$A = \cosh(\gamma l)$ $C = Y_C \sinh(\gamma l)$	$B = Z_C \sinh(\gamma l)$ $D = \cosh(\gamma l)$
Z	$Z_{11} = Z_C \coth(\gamma l)$ $Z_{12} = Z_{21}$	$Z_{21} = Z_C \operatorname{cosech}(\gamma l)$ $Z_{22} = Z_{11}$
Y	$Y_{11} = Y_C \coth(\gamma l)$ $Y_{12} = Y_{21}$	$Y_{21} = -Y_C \operatorname{cosech}(\gamma l)$ $Y_{22} = Y_{11}$
S	$S_{11} = \frac{Z_C^2 - Z_o^2}{2Z_C Z_o \coth \gamma l + Z_C^2 + Z_o^2}$ $S_{12} = S_{21}$	$S_{21} = \frac{2Z_C Z_o}{2Z_C Z_o \cosh \gamma l + (Z_C^2 + Z_o^2) \sinh \gamma l}$ $S_{22} = S_{11}$

microwave system, such as a transceiver, we see components such as amplifiers, mixers, oscillators, and filters interconnected using transmission lines of different characteristic impedances, propagation constants, and lengths. Depending on the overall system requirement, these transmission lines could be realized in different configurations such as a microstrip line, coplanar waveguide, stripline, or waveguide among several variations. For a given physical geometry, the electrical characteristics, Z_o and γ for these transmission lines, can be obtained based on the available analytical/numerical approaches from the literature. Interested readers are encouraged to refer to [5–7].

A common approach in microwave network analysis is to represent each component as a two-port or multiport network and use the network analysis principles to calculate the overall characteristics of the larger network formed by interconnecting various components. In this procedure, each component is associated with a set of network parameters, such as impedance (Z), admittance (Y), transmission (ABCD) or scattering (S) parameters, and the voltage/current or wave amplitudes are interrelated at various junctions/interconnections to obtain the overall characteristics of the system. As with other components, transmission lines can also be treated as microwave networks, and the knowledge of network parameters will often be useful when they are used in a system.

Table 2 presents various commonly used network parameters of a general lossy transmission line. The line is assumed to have a characteristic impedance of Z_C , propagation constant, γ , and length l . The expressions for the scattering (S) parameters assume that the reference port impedance is considered to be Z_o , which is different from the characteristic impedance Z_C . The expressions for a lossless transmission line can be directly obtained from Table 2 by replacing γ with $j\beta$. In the case of scattering

parameters, when $Z_C = Z_o$, the line becomes a matched lossy transmission line of length l and the scattering matrix reduces to

$$S = \begin{bmatrix} 0 & e^{-\gamma l} \\ e^{-\gamma l} & 0 \end{bmatrix} \quad (49)$$

frequencies. The incoming signal from the channel passes through the preselector filter, RF amplifier, and image filter, where it is applied to the mixer. The mixer combines the incoming signal with the local oscillator (LO) waveform to generate output at the sum and difference of the signal and LO frequencies. The LO frequency can be above or below the signal frequency. If the LO frequency is above the signal frequency, the receiver uses high-side injection. If the LO frequency is below the signal frequency, the receiver uses low-side injection. The intermediate frequency (IF) filter selects either the sum or the difference and rejects the other. The selected frequency is termed the intermediate frequency (IF), and the IF amplifier provides additional gain at this frequency. The detector/demodulator extracts the transmitted information from the IF waveform. Some superhet architectures use two or more intermediate frequencies in succession to simplify the requirements placed on the filters. The mixing process is sometimes called *conversion*. A receiver with one intermediate frequency is a single-conversion receiver, and a receiver with two intermediate frequencies is a dual-conversion receiver. Unless explicitly stated otherwise, examples in this article refer to single-conversion receivers.

Although other receiver architectures exist, the superheterodyne has many advantages. Distributing the amplifier gain between the RF and IF frequencies makes it less difficult to prevent unwanted oscillation. The receiver is tuned to a wanted input frequency by selecting the frequency of the LO. The IF filter can have a fixed center frequency, so its characteristics like bandwidth and delay can be optimized. It does not have to be retuned when the receiver is tuned to a new channel.

1.3.1. Weak Signal Performance. At UHF, internally generated noise limits the weakest signal that can be detected. The noise generated by the RF amplifier is amplified by all the stages in the receiver so that it determines the receiver sensitivity. Low-noise, high-gain RF amplifiers produce the greatest sensitivity. There is often a trade-off between sensitivity and strong signal performance, because a high-gain RF amplifier can overload the mixer with a strong signal.

1.4. Images

The mixing or frequency conversion process introduces unwanted and spurious responses. The most important unwanted response is called an image. The image frequency and the wanted frequency are symmetrical about the LO frequency. Any unwanted signal at the image frequency that gets into the mixer will be amplified and demodulated essentially as if it came in at the wanted frequency. Consider a simple example. A TV broadcast receiver is tuned to 561.25 MHz, the video carrier frequency for television channel 29. The receiver has an IF of 45 MHz, so the LO runs at 516.25 MHz. A difference frequency of 45 MHz is generated by mixing 561.25 MHz and 516.25 MHz. Suppose there is a nearby transmitter on channel 14. When the 471.25 MHz channel 14 video mixes with the 516.25 MHz LO output, the difference is also

45 MHz. The receiver is tuned to channel 29, but it will also pick up channel 14 if the channel 14 signal reaches the mixer. The preselector and image filters must pass the desired signal but reject the image. Figure 3 shows the frequency relationship among the desired signal, the image, and the LO for a single-conversion receiver. Note that the image and the wanted response are separated by twice the IF frequency. A dual-conversion superhet would have three images.

Images are the key drawback to the superheterodyne architecture. Their elimination requires filters, and image rejection is easier with high IF frequencies. The higher the IF frequency, the more difficult it is to make narrowband filters. Filters are the major impediment to fully integrated UHF receivers. They are usually separate discrete components.

1.5. Spurious Responses

The image is only one of many possible unwanted mixer outputs. The mixer is an inherently nonlinear device that generates and combines harmonics of the LO and signal frequencies. Continuing with the numbers from the previous example, the second harmonic of the 516.25 MHz LO appears at 1032.5 MHz. If a 538.75 MHz signal reaches the mixer, the mixer generates a second harmonic at 1077.5 MHz. The mixer also generates the sum and the difference of the harmonics. One of these products is at the 45 MHz IF frequency, and the receiver has a spurious response at 538.75 MHz. This response is sometimes called the half IF spur because it appears 22.5 MHz or one-half the IF frequency from the desired response. Two times the IF, in this case 90 MHz, separates the image from the wanted signal. It is much easier to design the image and the preselector filters to remove the image than the half IF spur.

Other spurious products are a serious problem in superhet receivers. Mixers generate not only the second harmonic but higher order harmonics as well. Balanced mixers, which suppress the even-order harmonics, are widely used to eliminate some of the spurious mixing products. UHF receivers may have multiple mixers and intermediate frequencies, and predicting all the spurious mixing products can be difficult. Software for this purpose is commercially available to help the designer select mixers.

Figure 3. The frequency relationship between the desired signal, the local oscillator signal, and the image signal for a TV receiver with a 45 MHz intermediate frequency. Note that the image and the desired signal frequencies are symmetric about the local oscillator frequency.

1.5.1. Strong Signal Behavior. At UHF frequencies, it is difficult to build a preselector filter narrow enough to pass a single channel of information. It may not be desirable to build very narrowband filters if the receiver is to be tuned over a range of frequencies. If the range of desired signal frequencies cannot pass through the preselector filters, then these filters must be retuned when the LO is tuned to the new frequency. This process, called tracking, increases the complexity of the receiver. For these reasons the receiver's ultimate bandwidth is usually set at IF, and a number of unwanted signals can reach the mixer.

All of the unwanted signals that reach the mixer will produce sum and difference frequency products with the LO. The RF amplifier may generate some of the unwanted signals. RF amplifiers are not perfectly linear; strong signals can cause them to saturate. This nonlinearity generates harmonics, which combine either in the amplifier itself or in the mixer.

The nonlinear behavior of amplifiers and mixers is specified in terms of third-order mixing products. Figure 4 shows a test setup for measuring these products. The output for an ideal amplifier would be only at the input frequencies f_1 and f_2 . Amplifier nonlinearities generate harmonics of f_1 and f_2 plus the mixing products of these harmonics. These mixing products are specified in terms of the harmonic number of the signals that generate them. Particularly important are the third-order products $2f_1 - f_2$ and $2f_2 - f_1$. Figure 5 shows the output of a nonideal amplifier. The third-order products are the most problematic because their frequencies fall close to the desired signal and are difficult to filter.

As an example, consider a handheld analog cellular telephone receiver. Channel 1 is 870.030 MHz, channel 2 is 870.060 MHz, channel 3 is 870.090 MHz, and channel 4 is 870.120 MHz. The second harmonic of channel 2 is 1740.12 MHz. If this mixes with channel 3, the difference is 870.030 MHz, which is channel 1. Similarly, the second harmonic of channel 3 mixes with channel 2 to produce a signal at 870.12 MHz, which is channel 4. Figure 5 shows that third-order mixing of channels 2 and 3 creates signals on channels 1 and 4. If the receiver is tuned to channel 1 or 4 and strong channel 2 and 3 signals are present, then nonlinear RF amplifier or mixer products will interfere with channel 1 or 4, limiting the receiver's ability to detect a weak signal on these channels.

The nonlinear products increase with increasing signal levels. The power in the third-order products increases three times faster than the power of the desired signals. The point where the power in the third-order products

Figure 4. A test setup for measuring third-order products. The frequencies shown are for the example presented in the text.

Figure 5. Sketch of a spectrum analyzer display showing the output of a nonideal amplifier with strong input signals at 870.06 and 870.09 MHz. The amplifier generates unwanted third-order products at 870.03 and 870.12 MHz.

would be equal to the power in the desired signal is called the third-order intercept point.

1.5.2. Spurious Free Dynamic Range. The weakest signal the receiver can detect is limited by the internally generated noise. The equivalent power of this noise is the noise floor. The strongest signals the receiver can tolerate without internally generated interference are those that create a third-order mixing product that equals the noise floor. The ratio of the strongest signal power to the noise floor power is the spurious free dynamic range (SFDR).

High-gain, low-noise RF amplifiers maximize sensitivity. Maximizing SFDR requires a careful tradeoff among the gain, noise performance, and third-order intercept of all the stages prior to the narrowest filter in the system. Building a sensitive receiver is relatively easy; building a sensitive receiver that can handle strong signals can be a challenge.

1.6. Other Receiver Topologies

1.6.1. Direct Conversion Receivers. The superhet receiver converts the incoming signal to an intermediate frequency, but it is possible to convert the radio signal directly to the original baseband of the transmitted information. This requires the LO to be tuned to the frequency of the incoming signal. If the signal and LO frequencies are equal, their difference is zero. The mixer output is the original information, which was contained in modulation sidebands, about the carrier frequency. A receiver that works this way is called a direct conversion (DC), homodyne, or zero IF receiver (see Fig. 6).

Direct conversion receivers offer a simpler design and fewer components than superhets. High-gain amplifiers are easier to build at baseband than at the signal or IF frequency, so a DC receiver can be as sensitive as a superhet. This topology minimizes the number of components at the RF and IF frequencies. On the other hand, mixer imbalance and LO leakage (LO feedthrough) into the antenna can cause large DC offsets. Local oscillator phase noise is highest close to the LO frequency, and the mixer translates this noise directly to baseband. Low-frequency noise in mixers and high-gain baseband amplifiers can limit sensitivity. Depending on the choice of mixer, DC receivers have spurious responses at integer multiples of the input frequency, so a preselector filter is

Figure 6. The homodyne or direct conversion receiver. The incoming signal is converted directly to baseband without intermediate processing at an intermediate frequency.

still required. As all the signal processing occurs at baseband, it is possible to integrate the entire receiver, including the mixer. This is attractive for small low-power receivers like those found in pagers. DC receivers cannot be used for narrowband FM without extra signal processing.

1.6.2. Tuned Radiofrequency Receivers. The tuned radiofrequency (TRF) receiver of Fig. 7 is an old design that offers great simplicity. The signal passes through a preselector filter and is amplified by an RF amplifier at the signal frequency. The classic TRF receiver consists of a cascade of tuned amplifiers. The filtering and amplifying functions are combined. The amplified signal goes directly to the detector, which is typically a simple diode amplitude demodulator. TRF receivers work well with amplitude modulation or on-off keyed digital signals. They are not used for narrowband phase or frequency modulation, because these waveforms are difficult to demodulate at UHF. The simplicity of the TRF is attractive for low-current, low-cost applications. As the TRF receiver has no oscillators, there is no oscillator radiation. TRF receivers escape the government regulations that limit RF emissions. They have none of the spurious mixing responses that are a problem in superhet receivers. As TRF receivers contain no mixers, they have no images and can reproduce exactly the frequency or phase information in the original signal.

TRF receivers have several disadvantages. They are not frequency agile and thus are useful only for single-frequency systems. TRF receivers cannot use standard low-cost filters like those available at common IFs for superhets. Narrowband filters, which match modulation bandwidths, are difficult to build at UHF, and tuning a TRF receiver to a new frequency requires retuning or replacing the filters. TRF receiver sensitivity is limited because of the difficulty of building stable high-gain amplifiers at UHF. For these reasons, the UHF applications for TRF receivers tend to be limited to low-cost, short-range devices.

1.6.3. Regenerative and Superregenerative Receivers. Regenerative receivers come from the earliest days of radio and are capable of very high sensitivity with only a

Figure 7. The tuned radiofrequency receiver. The incoming signal is amplified and detected without frequency conversion.

single active device. A regenerative receiver is an amplifier to which frequency selective positive feedback has been applied. If the feedback is adjusted below the point of oscillation, the receiver acts as a square law detector. It is suitable for amplitude-modulated signals. The feedback can be advanced to the point where oscillation occurs. The regenerative receiver then acts as a self-oscillating direct conversion receiver. In this mode, it will demodulate single sideband (SSB) or continuous wave signals.

The superregenerative receiver is a variation on the regenerative theme. The positive feedback is advanced beyond the point where oscillations begin. This increases the gain. It takes a finite amount of time for the oscillation amplitude to buildup because of energy storage in the oscillator-tuned circuit. Before the oscillation amplitude reaches a significant level, the oscillating amplifier is shut off or “quenched.” The process of oscillation buildup and quenching is repeated. Injecting a signal close to the oscillation frequency speeds the buildup of oscillations. The envelope of any amplitude modulation on the injected signal can be extracted from the amplitude of the oscillations in the superregenerative detector.

Superregenerative receivers find application in short-range, low-cost devices such as radio-controlled toys and garage door openers. They work well at UHF, and their high sensitivity and extreme simplicity make them attractive for such applications.

The major drawbacks of a superregenerative receiver are poor selectivity and the potential to create interference. They can be easily overloaded by strong adjacent channel signals, and, if not properly designed, they can radiate a potent signal of their own. The use of positive feedback results in very high gain, but it accentuates any variations in amplifier gain because of temperature, voltage, aging, or other effects. Stable performance is difficult to obtain, and receiver bandwidth will vary inversely with gain. It is very difficult to meet emission specifications with regenerative and superregenerative receivers.

2. DESIGNING SUPERHETERODYNE RECEIVERS FOR UHF

2.1. Weak Signal Behavior

2.1.1. Noise Temperature and Receiver Sensitivity. Sensitivity is a measure of a receiver’s weak signal performance. Depending on the particular application, sensitivity may be expressed in terms of [1] the receiver’s noise floor, [2] the minimum detectable signal, or [3] the minimum input signal level necessary to achieve a useful output. However defined, sensitivity is closely related to the irreducible noise level at the receiver’s output.

Noise is generated within all electronic components, active or passive. The noise power that a resistor at physical temperature T would deliver to an ideal power meter whose response is frequency independent over a measurement bandwidth B is given by

$$P_N = kTB \quad (1)$$

where k is Boltzmann's constant (1.38×10^{-23} J/K).

Any other one-port noise source can be described by an equivalent noise temperature T_N such that the noise delivered to an ideal power meter with measurement bandwidth B is

$$P_N = kT_N B \quad (2)$$

Now imagine a two-port device with gain g connected between an antenna or other noise source with noise temperature T_A and a load. The noise power delivered to the load will consist of amplified input noise plus additional noise that is generated inside the two-port device:

$$p_N = gkT_A B + \Delta p \quad (3)$$

where Δp is the internally generated noise (see Fig. 8).

For analysis, it is convenient to represent the internally generated noise as if it came from a fictitious noise source at the input of a noiseless equivalent circuit of the two-port device. This noise temperature T_e of this fictitious noise source is the effective input noise temperature of the device (see Fig. 9):

$$p_N = gkT_A B + \Delta p = gkT_A B + gkT_e B = gk(T_A + T_e)B \quad (4)$$

If a receiver with effective input noise temperature T_e is connected to an antenna with equivalent noise temperature T_A , the resulting system noise temperature T_S is given by

$$T_S = T_A + T_e \quad (5)$$

The receiver noise floor is $kT_S B$, where B is the overall receiver bandwidth (usually set by the IF filter). The minimum detectable signal (MDS) is usually specified as the noise floor. Depending on the application, the receiver sensitivity may be defined as the noise floor or as the

Figure 8. Representation of a real receiver. It amplifies thermal noise from the antenna and adds its own internally generated noise.

Figure 9. The noiseless equivalent receiver. Internally generated noise is represented as if it came from a fictitious input at temperature T_e .

minimum signal necessary to produce a specified output signal-to-noise ratio (SNR). The noise floor is sometimes specified with a bandwidth B of 1 Hz. At room temperature, this corresponds to -174 dBm.

2.1.2. Noise Figure. Although noise temperature is perhaps a more immediately useful quantity, the noise figure of a UHF receiver is more commonly specified. The noise figure of a two-port device was originally defined as the ratio of the input SNR to the output SNR. This definition is quite useful for “back of the envelope” calculations for point-to-point microwave systems, but it suffers from a lack of uniqueness (because it depends on the antenna noise temperature) and universal applicability. Officially, noise figure is “the ratio of (A) the total noise power per unit bandwidth (at a corresponding output frequency) delivered by the system into an output termination to (B) the portion thereof engendered at the input frequency by the input termination, whose noise temperature is standard (290 K at all frequencies)” [1].

Mathematically, the noise figure is given as a ratio by nf and in decibels by NF :

$$nf = 1 + \frac{T_e}{290} \quad (6)$$

$$NF = 10 \log_{10}(nf) \quad (7)$$

Although some authors argue rather vehemently that noise figure is not a meaningful concept, it is well established as a specification for UHF receivers and their components. Overall values of 2 dB are achievable. Most calculations ultimately require the noise temperature, conveniently obtained from the noise figure by

$$T_e = 290(nf - 1) \quad (8)$$

The noise figure as defined in Eq. (6) is the standard noise figure, based on an assumed standard source noise temperature of 290 K. This is the one that manufacturers measure and quote. An actual noise figure, based on the true source temperature, is often used to calculate the minimum detectable signal or SNR degradation. See Ref. 2 for an excellent discussion of noise figure issues.

2.1.3. Determining Receiver Noise Temperature and Noise Figure. Most analyses of receiver performance assume that bandwidth narrows as one moves from the

RF input to the IF output. The last stage has the narrowest bandwidth, and it effectively determines the overall bandwidth. Thus, if the preselector, RF amplifier, mixer, and so on, have bandwidths $B_1, B_2, B_3 \dots B_N$, and if B_N is much less than any of the others, then the overall bandwidth B is given by

$$B \approx \min\{B_1, B_2, B_3 \dots B_N\} = B_N \quad (9)$$

Under these conditions, the overall noise temperature and noise figure are given by

$$T_e = T_1 + \frac{T_2}{g_1} + \frac{T_3}{g_1 g_2} + \dots + T_N \prod_{m=1}^{N-1} \frac{1}{g_m} \quad (10)$$

$$\text{nf}_o = \text{nf}_1 + \frac{\text{nf}_2 - 1}{g_1} + \frac{\text{nf}_3 - 1}{g_1 g_2} + \dots + (\text{nf}_N - 1) \prod_{m=1}^{N-1} \frac{1}{g_m} \quad (11)$$

where T_i, g_i , and B_i , are the noise temperature, gain, and bandwidth of the i th stage. It is important to note that the gains and noise figures in the preceding equations are ratios, not decibel values.

If one bandwidth dominates but is not the bandwidth of the last block in the chain, it is still possible to calculate T_e and NF_o . This situation occurs in some modern receiver designs that put most of their gain in a wideband amplifier at the end of the IF chain. A narrowband low-gain amplifier precedes the mixer. This architecture leads to better dynamic range performance. Under these conditions, let B_1 and g_1 be the bandwidth and gain of the low gain and narrowband part of the receiver, and let B_2 and g_2 be the bandwidth and gain of the subsequent high gain and wideband part of the receiver. The corresponding noise temperatures and noise figures are T_1 and nf_1 and T_2 and nf_2 . Under these conditions, the output noise power is given by Eq. (12) and the overall noise temperature and noise figure by Eqs. (13) and (14).

$$p_o = g_1 g_2 k T_A B_1 + g_1 g_2 k T_1 B_1 + g_2 k T_2 B_2 \quad (12)$$

$$= g_1 g_2 k T_A B_1 + g_1 g_2 k T_e B_1$$

$$T_e = T_1 + T_2 \frac{B_2}{g_1 B_1} \quad (13)$$

$$\text{nf}_o = 1 + \frac{T_e}{T_o} = \text{nf}_1 + (\text{nf}_2 - 1) \frac{B_2}{g_1 B_1} \quad (14)$$

It is possible for the wideband IF stage to dominate the receiver's noise performance in this topology. Additional filters are sometimes added just prior to the detector, or as part of the detector, effectively narrowing B_2 .

2.1.4. Mixer Noise Performance. Like all two-port devices, mixers both process incoming noise and add to it their own internally generated noise. The situation is more complicated in mixers because the input noise is translated in frequency from two places in the spectrum. Noise coming in at the wanted signal frequency and at the unwanted image frequency appears at the IF frequency.

Depending on how the total output noise power is interpreted, a mixer can be described by both a double sideband (DSB) noise figure and a single sideband (SSB) noise figure. A single sideband noise temperature corresponds to the single sideband noise figure, and a double sideband noise temperature corresponds to the double sideband noise figure. The SSB quantities are twice as large (or 3 dB larger if expressed in decibels) as the DSB quantities, which seems backward.

This confusion develops largely because SSB and DSB apply to the NF measurement technique rather than to the way in which the mixer is used. In an NF measurement, the input to the mixer is connected to a broad-band noise source, and the noise power at the mixer output is compared with the noise power at the mixer input. The noise figure so measured is called the DSB NF because noise got into the mixer through both the wanted signal frequency and the unwanted image frequency. Noise at the two frequencies is analogous to the two sidebands that surround a carrier in some modulation schemes. For the given output power, there is twice as much input noise power as there would be in an SSB noise measurement. Thus, the signal-to-noise ratio is 3 dB better than it would be in an SSB noise measurement, and the DSB noise figure is 3 dB better than the SSB noise figure. See Refs. 3 and 4 for a detailed discussion of the measurement issues.

A double set of parameters with the SSB quantities larger than the DSB quantities leads to a great deal of confusion about which noise figure should be used for a particular application. See Ref. 2 for a detailed discussion of this point. The rule of thumb is if, for a particular application, the mixer input sees equal incoming noise powers at the signal and image frequencies, the mixer is described by the SSB noise temperature and noise figure. If the input noise level at the signal frequency is much greater than the input noise level at the image frequency, then the frequency-translated image noise has little effect on the output noise power, and the mixer is described by the DSB noise temperature and noise figure.

The last situation is attractive because it allows the lower noise figure to be used. The reader should note that its application does require that the mixer see insignificant input noise in the image band. If the stage immediately ahead of the mixer is an image rejection filter, its noise output in the image band should be checked. The filter could look like a noise source at the ambient temperature.

2.1.5. LO Phase Noise. Local oscillator noise can be a significant contributor to the overall receiver noise level. Oscillator noise takes two forms: amplitude and phase noise. In well-designed oscillators, the effect of amplitude noise can be neglected [5], but phase noise effectively phase-modulates the oscillator frequency. Oscillator performance is measured in terms of the power spectral density of the resulting modulation sidebands. The spectral density can be predicted from the Q of the oscillator resonator and from the noise power generated by the active device in the oscillator [6]. Figure 10 shows the phase noise in a typical oscillator output spectrum.

Phase noise degrades receiver dynamic range through what is called "reciprocal mixing." Figure 11 shows the

Figure 10. The phase noise spectrum of a typical local oscillator.

effect of reciprocal mixing in a receiver containing a noisy LO and a strong adjacent channel signal that is outside the IF bandwidth. Without the LO noise, this signal would be rejected by the IF filter. With LO noise the strong adjacent channel signal acts as a “local oscillator” for the oscillator noise. The oscillator noise appears as signals adjacent to the LO, and those noise frequencies separated by the IF from the interfering signal will be mixed into the IF. The noise floor is increased by the oscillator phase noise, and it obscures the desired weak signal.

Phase noise produces an additional receiver impairment in systems where information is carried in signal frequency (frequency modulation, FM) or phase (phase modulation, PM). In digital phase shift keyed (PSK) systems, it is necessary to regenerate the phase of the carrier signal as a demodulation reference. Mixing transfers the phase noise of the receiver’s LO to the incoming signal. This increases the phase uncertainty of the demodulation reference and leads to bit errors.

2.2. Strong Signal Behavior

2.2.1. Nonlinear Operation and Intermodulation Products.

In ideal linear components, superposition holds, and the output waveform is linearly proportional to the input waveform. No frequencies appear in the output waveform that were not present in the input waveform. Any real two-port device will, when driven hard enough, become nonlinear. Nonlinear operation in receivers creates unwanted signals called intermodulation products that interfere with the

Figure 11. An illustration of reciprocal mixing, the process by which local oscillator phase noise combines with an adjacent channel signal to raise the receiver noise floor.

wanted signals. It also can cause a loss of sensitivity when an unwanted strong signal is close in frequency to a wanted weak signal.

To illustrate nonlinearity, consider an RF amplifier with a sinusoidal input at frequency f_1 . A typical plot of input power versus the output power delivered at frequency f_1 would appear as shown in Fig. 12.

At low power levels, the relationship between output and input powers is linear. At high levels of input power, the slope decreases and the input-output relationship becomes nonlinear. This onset of nonlinearity is called gain compression (or just compression). A common measure of large-signal handling ability is the input 1 dB compression point, the input power level at which the output power falls 1 dB below the extrapolation of the linear relationship. Gain compression in a receiver results in an effect called desensitizing. If a receiver is tuned to a weak signal and a strong signal appears in the RF amplifier’s pass-band, the strong signal can reduce the RF amplifier gain. The gain reduction can make the weak signal disappear even though the strong signal is not translated into the IF passband and never reaches the demodulator. Desensitizing is a problem in large-signal handling that is distinct from intermodulation products.

Increasing the input power beyond the 1 dB compression point causes the plot to fall farther below a linear relationship. This part of the curve is called the compression region. The output power reaches a peak and then decreases. The peak is called saturation, and the region beyond the peak is the overdrive region.

Output power falls below the linear value after compression begins because output is developed at frequencies other than the input frequency. As long as the input is a sinusoid at frequency f_1 , these frequencies are harmonics of f_1 (i.e., $2f_1, 3f_1 \dots$) and easy to filter. If the input contains two or more frequencies, then the resulting intermodulation products can interfere with and distort the wanted output signal.

Intermodulation products are usually described in terms of a two-tone test, where the input signal is two equal-amplitude sinusoids at closely spaced frequencies f_1 and f_2 . These represent a wanted signal and an equal-amplitude adjacent-channel interferer. Nonlinearities cause

Figure 12. Nonlinear behavior of an amplifier. As the input power level increases, the gain decreases below its linear value.

outputs to appear at all the sums and positive differences of integer combinations of f_1 and f_2 . The most important are the third-order products at frequencies $2f_1 - f_2$ and $2f_2 - f_1$, described earlier (see Fig. 13).

To quantify the process, one should plot the output power P_{o3} at one of the third-order frequencies ($2f_1 - f_2$ or $2f_2 - f_1$) versus the input power P_{o1} at f_1 or f_2 . On a dBm or dBW scale, the curve will be a straight line with a slope of 3, at least for reasonable values of input power [7]. On the same graph, we can also plot output power at one of the input frequencies. Below the compression region, this will be the straight line. If we extrapolate the straight line far enough, it will cross the third-order curve at the third-order intercept point. The corresponding input power is called the third-order input intercept point IIP3, and the corresponding output power is called the third-order output intercept point OIP3 (see Fig. 14). IIP3 and OIP3 measure the strong-signal handling capabilities of an amplifier, mixer, or other two-port device. Note that the third-order intercept point is a graphical construction. No real device operates at that point.

To measure the intercept points, one can drive the device at a level where the third-order products are measurable and view the output on a spectrum analyzer. Figure 13 sketches the resulting display. If P_{o1} and P_{o3} are the output powers in dBm at one of the wanted frequencies and one of the third-order frequencies, then the rejection R is given by

$$R = P_{o1} - P_{o3} \text{ dB} \tag{15}$$

P_{o1} is related to the input power P_i at one of the wanted frequencies (f_1 or f_2) by the gain, G , of the device.

$$P_{o1} = P_i + G \text{ dBm} \tag{16}$$

The input and output intercept points can be calculated from

$$IIP_3 = \frac{R}{2} + P_i \text{ dBm} \tag{17}$$

$$OIP_3 = \frac{R}{2} + P_{o1} \text{ dBm} \tag{18}$$

$$OIP_3 = IIP_3 + G \text{ dBm} \tag{19}$$

2.2.2. Determining Receiver Third-Order Intercept Point. Consider a receiver that consists of a cascaded system of M stages with dB gains G_i and dBm input intercept points IIP_i . The corresponding linear values are g_i and iip_i .

Following Ref. 8, we assume that (1) the interfaces between stages are all at 50Ω and (2) the third-order products add in-phase. Assumption (1) is realistic, and assumption (2) leads to a worst-case analysis. Under these conditions, we can project the output intercept points of the individual stages through to the output of the last stage and add the projected values reciprocally. For 1, 2, 3, and M stages, the overall output intercept point in milli-

Figure 13. The spectrum of the output of a nonlinear amplifier with inputs at frequencies f_1 and f_2 . The amplifier creates unwanted third-order products at frequencies $2f_1 - f_2$ and $2f_2 - f_1$. The wanted output signals are at power level P_{o1} and the unwanted products are at power level P_{o3} .

watts is given by

$$oip_o = \frac{1}{\frac{1}{oip_1}} \text{ for 1 stage} \tag{20}$$

$$oip_o = \frac{1}{\frac{1}{oip_2} + \frac{1}{g_2 \times oip_1}} \text{ for 2 stages} \tag{21}$$

$$oip_o = \frac{1}{\frac{1}{oip_3} + \frac{1}{g_3 \times oip_2} + \frac{1}{g_3 \times g_2 \times oip_1}} \text{ for 3 stages} \tag{22}$$

$$oip_o = \frac{1}{\frac{1}{oip_M} + \sum_{i=1}^{M-1} \frac{1}{oip_i \times \prod_{k=i+1}^M g_k}} \text{ for } M \text{ stages} \tag{23}$$

This formula can be written in a simpler form to yield OIP_o directly in dBm:

$$OIP_o = -10 \log_{10} \left[\sum_{i=1}^M \frac{1}{oip_i g_i + 1 g_{i+2} \dots g_M} \right] \tag{24}$$

Figure 14. An illustration of how first-order (P_{o1}) and third-order (P_{o3}) output power increase with increasing input power in a nonlinear device. The straight-line extrapolations of the two curves cross at the third-order intercept point.

The overall input intercept point is the overall output intercept point divided by the total gain.

$$iip_o = \frac{oip_o}{\prod_{i=1}^M g_i} \tag{25}$$

Expressed in dBm,

$$IIP_o = OIP_o - \sum_{i=1}^M G_i \tag{26}$$

2.3. Dynamic Range

The dynamic range of a receiver is the decibel difference between the strongest signal and the weakest signal that the receiver can handle. There are multiple definitions of dynamic range, depending on how the strongest signal and the weakest signal are defined.

2.3.1. Spurious Free Dynamic Range. Spurious free dynamic range makes the weakest signal the MDS (receiver noise floor $kT_S B$), where T_S is the system noise temperature and B is the bandwidth. T_S is the sum of the antenna noise temperature T_A and the effective input noise temperature of the receiver T_e :

$$T_S = T_A + T_e \tag{27}$$

so this definition describes the receiver when it is used with an antenna having a specified noise temperature.

The strongest signal used in the SFDR definition is the input power that, in a two-tone intermodulation test, makes the power in either of the third-order products at the receiver output equal to the noise power (see Fig. 15). Mathematically,

$$SFDR = \frac{2}{3}(IIP_3 - MDS) \text{ dB} \tag{28}$$

Figure 15. The spurious free dynamic range of a receiver is the decibel difference between the noise floor and the input signal level that would bring third-order products to the noise floor.

2.3.2. Other Definitions of Dynamic Range. In practice, third-order products may be tolerated at levels somewhat higher than the noise floor. The maximum permissible signal may be the input power for which the rejection R in Eq. (17) reaches a specified level.

2.4. UHF Receiver Design

2.4.1. LO and IF Frequency Selection. There are several standard IF frequencies (10.7 MHz and 45 MHz are two examples commonly used in UHF radios), and the selected IF frequency should be one for which appropriately priced components are available. The higher the IF frequency, the farther images will lie from the wanted frequency and the easier it will be to filter them out. Beyond these general guidelines, the IF and LO frequencies should be selected so that no high-level inter-modulation products fall within the IF passband.

To illustrate the process, consider a mixer with input signal f_S , local oscillator signal f_L , and wanted IF output signal f_I . Depending on whether the LO frequency is above (high-side injection) or below (low-side injection) the signal frequency, the mixer will produce a wanted output at either

$$f_i = f_L - f_R \tag{29}$$

or

$$f_i = f_R - f_L \tag{30}$$

The mixer will also produce unwanted outputs at all positive values of

$$f_o(m, n) = \pm(mf_L \mp nf_R) \tag{31}$$

where m and n are positive integers. If any of these spurious responses (“spurs”) fall within the IF passband—that is, if

$$f_o(m, n) = f_i \pm \frac{B}{2} \tag{32}$$

where B is the IF bandwidth—they can interfere with wanted signals. The frequencies f_i , f_R , and f_L , must be chosen so that this either does not occur or any spurs within the IF passband are at negligible power levels. The process, described later, is outlined in Ref. 9. The amplitudes of the spurs depend on the nature of the mixer’s nonlinearity. Typical values are found in Ref. 10 and in most mixer manufacturer’s catalogs.

We began by treating the frequencies as parameters and m and n as positive real variables. The relationship between m and n is

$$n = \pm \frac{f_i}{f_R} \pm m \frac{f_L}{f_R} \tag{33}$$

All solutions to Eq. (33) that yield integer values of m and n correspond to spurious responses that may fall within the IF passband of the receiver.

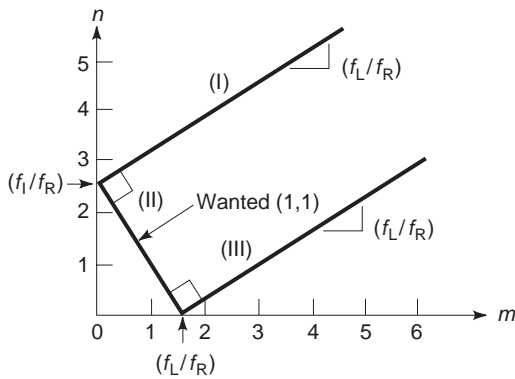

Figure 16. A graphical technique to check for mixer spurious responses in a receiver. The three straight lines are plotted from Eq. (34). In an ideal receiver design, the lines would not cross any points corresponding to integer values of both m and n except (1, 1).

Plotting these equations on a set of n versus m axes (Fig. 16) yields three straight lines whose equations are

$$\begin{aligned} n &= \frac{f_I}{f_R} + m \frac{f_L}{f_R} \text{ (curve I)} \\ n &= \frac{f_I}{f_R} - m \frac{f_L}{f_R} \text{ (curve II)} \\ n &= -\frac{f_I}{f_R} + m \frac{f_L}{f_R} \text{ (curve III)} \end{aligned} \quad (34)$$

We plot these for f_R and f_L corresponding to the upper and lower limits of the receiver's tuning range. The needed lines are easy to draw from the known intercepts (f_I/f_R) and (f_I/f_L) and the slope (f_L/f_R). Ideally, only the line representing the wanted response should pass through a point corresponding to integer values of m and n . That should be the (1, 1) point.

If one of the plotted curves comes close to an integer-valued point, we can determine if the corresponding spur lies within the passband by plotting the appropriate line with f_I replaced by $f_I \pm B/2$.

With properly chosen IF and LO frequencies, no high-level spurs will fall within the IF passband. Usually, a high LO frequency gives better performance.

2.4.2. Mixer Selection [11]. Almost any nonlinear device can serve as a mixer. Mixers can be active or passive, and they can rely on filters or cancellation or on some combination of both to provide needed isolation between their RF, IF, and LO ports. Figures-of-merit for mixers include conversion gain, noise figure, third-order intercept point, required LO drive, and relative levels of intermodulation products. Some mixer types are more sensitive to impedance mismatches than others.

Active mixers require dc power, less amplifier gain, and less LO drive than passive mixers. Passive mixers do not need dc, but they require more LO drive and more amplifier gain than active mixers. Which type of mixer requires less total dc power for the whole receiver depends on the overall design. Manufacturing factors (cost, ease of auto-

mated assembly, etc.) may be more important in mixer selection than small differences in RF characteristics or power consumption.

Mixers may be unbalanced, single balanced, or double balanced. An unbalanced mixer usually has a single active component (a diode or a transistor) and relies on filters to provide LO-RF and LO-IF isolation. Single-balanced mixers use cancellation to achieve LO-RF isolation and filters for LO-IF isolation. Double-balanced mixers use cancellation to achieve both LO-RF and LO-IF isolation. Usually (but not always), whether a mixer is unbalanced, single balanced, or double balanced can be determined by counting the balun transformers. An unbalanced mixer has none, a single-balanced mixer usually has one, and a double-balanced mixer usually has two.

Diode mixers operate as switches and chop the RF waveform at the LO frequency. As proper operation depends on the LO rather than the RF signal turning the diodes on and off, the maximum RF power that a diode mixer can handle without unacceptable distortion is somewhere between 10 and 6 dB below the LO level. Switching-diode mixers usually offer a larger dynamic range but higher conversion loss and noise figure than mixers whose operation is based on device nonlinearity.

Low-cost double-balanced diode mixers are widely available. They are inherently broad-band and offer conversion gains typically between -6 and -8 dB. Required RF drive levels are fairly high— $+5$ dBm is typical.

Passive field-effect transistor (FET) mixers apply the LO directly to the gate of an unbiased FET. The LO drive modulates the channel resistance at the LO frequency, and the RF signal applied to the drain sees this modulation. As their operation is based on this resistance modulation, passive FET mixers are often called FET resistive mixers. Their primary advantage over diode mixers is that they offer very good intermodulation distortion performance; third-order input intercept points of $+30$ dBm or better are possible. FET resistive mixers can be made with single devices or in single-balanced and double-balanced configurations.

Active FET mixers can consist of single devices. In the past, dual-gate active FET mixers were common, but these have largely disappeared. Gilbert cell multipliers offer uniformly good performance.

An image-canceling mixer contains two internal mixers whose LO drives are 90° out of phase. The RF amplifier output is divided and fed to both mixers in phase. The output of one internal mixer is phase shifted by an additional 90° . The resulting waveforms may be added or subtracted to cancel the unwanted (image) response. (See Ref. 2.) Successful operation of an image-canceling mixer depends on maintaining the required power levels and phase shifts over the IF bandwidth for the expected signal amplitudes and operating temperature ranges. Typical image suppression is in the 28 to 45 dB range.

2.4.3. RF and IF Amplifiers. RF amplifiers for UHF receivers are selected to give the desired overall noise figure and dynamic range. IF amplifiers are selected to present a particular desired signal level at the demodulator. To keep the demodulator from being overdriven at high-input

signal levels, IF amplifiers may incorporate limiting or automatic gain control (AGC), depending on whether signal amplitude information is important. Both RF and IF amplifiers are available as separate components for all standard frequency bands, chips combining IF and mixing or RF and mixing functions are widely available. These typically incorporate Gilbert cell multipliers. One current example is the Motorola MC13156 wideband IF system that may be used as the basis for a complete radio or IF system for frequencies up to 500 MHz. Another is the RF Micro-Devices RF2411, covering 500 MHz to 1900 MHz.

2.4.4. RF and IF Filters. The first stage of most receivers is a band-pass filter (often called a preselector) that rejects noise and unwanted signals (particularly unwanted signals at image frequencies) outside of the desired tuning range. Bandpass filters at IF keep unwanted mixer products out of the demodulator, select the desired channel, and determine the overall noise bandwidth of the receiver. The IF filter usually determines the selectivity of a super-het receiver.

Selecting RF and IF filters is similar to selecting mixers. There are many competing types and usually no immediately obvious best choice for a given application. RF filter design and manufacturing are so specialized that receiver designers usually select filters from catalogs and data sheets instead of building their own. Selection is based on technical characteristics, price, and manufacturing considerations.

Filters for IF include crystal, ceramic, and SAW (surface acoustic wave). RF filters can be made with SAW, dielectric, helical resonator, and transmission line technologies. *LC* filters tend to be too lossy for these applications. Active filters are usually not available or not cost effective at RF and IF frequencies.

Filter specifications are based on treating the filter as a two-port device driven by a source with a specified resistance R_i and feeding a load resistance R_o . The values of R_i and R_o depend on the filter type and frequency range. For example, ceramic filters for 10.7 MHz IF applications expect to see 330 Ω , whereas values between 1 and 2.5 k Ω are common for 455 kHz ceramic filters.

Let V_o and V_i be the phasor output and input voltages for a filter operating at frequency f . The complex transfer function $H(f)$ of the filter is given by

$$H(f) = \frac{V_o(f)}{V_i(f)} = |H(f)|e^{-j\phi(f)} \quad (35)$$

The filter attenuation A in dB is given by

$$A(f) = -20 \log_{10}|H(f)| \quad (36)$$

Insertion loss (IL) is the value of A at the filter's center frequency f_0 .

$$\text{IL} = A(f_0) \quad (37)$$

Manufacturers normally provide plots of A versus f . A variety of bandwidths are often specified in addition to the

expected 3 dB value. The shape factor of a filter is the ratio of one of these larger bandwidths (for example, the 60 dB bandwidth) to the 3 dB bandwidth. An ideal "brick wall" filter would have a shape factor of 1.

The phase response $\phi(f)$ of a filter is also important, but it is plotted far less frequently. Ideally, $\phi(f)$ should be a linear function of frequency. In that case, the spectral components of a complex waveform would pass through the filter without changing their relative phases. Phase distortion is particularly important in analog FM and in digital applications.

Phase distortion is measured by group delay, T , which has units of time and is given by

$$T = \frac{\partial\phi}{\partial\omega} = \frac{1}{2\pi} \frac{\partial\phi}{\partial f} \quad (38)$$

Relating receiver performance to filter group delays usually requires computer simulation. No simple formulas are available.

Some mixers (diode mixers in particular) are sensitive to the impedance presented at the IF port at frequencies outside of the passband. Some crystal filters are particularly troubling in this regard. Diplexer circuits are available to isolate the mixer from the filter's impedance variations. See Ref. 2 for a further discussion of this issue.

2.4.5. Demodulators. The choice of demodulator for a given receiver design depends on the modulation that is to be received. For a given application, demodulators differ in fidelity, dynamic range, and input and output signal levels.

2.4.6. RF Integrated Circuits for UHF Receivers. The level of integration available in receivers and receiver subsystems is increasing rapidly, particularly for consumer applications. For further information, see Refs. 12–14.

ULTRA-WIDEBAND RADIO

KAZIMIERZ SIWIAK
TimeDerivative, Inc.
Coral Springs, Florida

1. INTRODUCTION

Ultra-wideband signaling is essentially the art of generating, modulating, emitting, and detecting impulse wavelet signals that inherently occupy large bandwidths. Impulse transmissions date back to the infancy of wireless technology. They include the experiments of Heinrich Hertz in the 1880s, and the 100-year-old sparkgap “impulse” transmissions of Guglielmo Marconi, who in 1901 sent the first ever over-the-horizon wireless transmission from the Isle of Wight to Cornwall on the British mainland. Early radio circuits consisted solely of passive electrical components, without tubes or transistors, and hence lacked the means to efficiently receive the short transient impulse energy. Therefore radio subsequently developed along narrowband frequency-selective analog techniques. This led to voice broadcasting and telephony—and more recently to digital telephony and wireless data. Through the years, a small cadre of scientists have worked to develop and refine impulse technologies. The origin of modern UWB technology stems from work in time-domain electromagnetics begun in the early 1960s to fully describe the transient behavior of certain classes of microwave networks. By 1970 the primary focus in impulse radio research was on impulse radar techniques and government-sponsored projects. Through the late 1980s, the technology was alternately referred to as “baseband,” “carrier-free,” or “impulse”—the term “ultrawideband” was not applied until approximately 1989 by the U.S. Department of Defense. By that time UWB theory, techniques, and many hardware approaches had experienced nearly 30 years of extensive development [1] culminating in today’s UWB technology [2]. In the late 1980s digital techniques began to mature to the point where the commercial practicality of modern low-power impulse radiocommunications and precision radar could be demonstrated using

an impulse time coding–time modulation approach. Digital impulse radio [3–12], the modern echo of Hertz’s century-old transmissions, now emerges under the banner “ultrawideband” radio.

An FCC Report and Order legalized unlicensed UWB emission in the United States on February 14, 2002, with a full report issued on April 22, 2002 [13] and the subsequent publication of U.S. 47 *Code of Federal Regulations* (CFR) Part 15(f) spelling out the rules for UWB emissions in the United States. Five categories of UWB devices are summarized in Table 1. The rules do not spell out either the signaling or the waveforms. To access the UWB spectra, the intentionally radiated EIRP levels must be below –41.3 dBm/MHz. The measurement method specifies the use of a metal ground plane, or else EIRP must be below –46 dBm/MHz if measured in an anechoic chamber. A *UWB transmitter* is defined as one that emits a UWB signal with bandwidth of the lesser of 500 MHz or 20% bandwidth, as measured at the –10-dB point.

UWB wavelets or pulses are bursts of electromagnetic energy. Normally, the wavelet duration in time is inversely related to its occupied bandwidth. For example, a 1-ns wavelet occupies 1 GHz of spectrum, a 2-ns pulse occupies 500 MHz, while a 133-ps pulse instantaneously occupies 7.5 GHz of spectrum. The “zero crossing” rate of a wavelet determines where in the spectrum that wavelet bandwidth will appear. Finally the envelope shape of the wavelet (and to some extent the zero-crossing structure) determine the detail of the distribution of the energy in the spectrum. Conventional technologies like OFDM (orthogonal frequency division multiplexing) can be configured so that the signal meets the UWB spectrum access rules, and hence might also appear in the UWB bands. OFDM in the UWB spectrum does not employ short pulses, but rather constitutes a symbol wavelet that is an ensemble of modulated sinusoidal carriers spanning at least 500 MHz. The OFDM wavelet is a long burst equal to the OFDM symbol duration, where the symbol duration defines the OFDM carrier spacing, while the total OFDM bandwidth results from the aggregation of those carriers. For example, 122 carriers spaced every 4.125 MHz span at total of 504 MHz, and the OFDM symbol wavelet duration is approximately 0.25 ms.

2. UWB RADIO TECHNOLOGIES

A UWB radio physical layer standard is under development within the IEEE 802 LAN/MAN Standards Committee. The IEEE 802.15.3a, *Wireless Personal Area Networks* (W-PAN)¹ task group are tackling the definition of an alternative UWB radio physical layer for the 802.15.3 W-PAN standard [14]. The IEEE 802.15.4 project in a new group 4a are considering a new physical layer that is to include positioning and distancing capabilities. UWB proposals within 4a are inevitable because of the demonstrated positioning capabilities of UWB systems [5].

¹W-PAN is a trademark of IEEE, Piscataway, NJ; generic acronym is WPAN (wireless personal-area network).

Table 1. Classes of UWB Devices Authorized under U.S. FCC Rules

Class/Application	UWB Spectra for Operation at Part 15 Limits	User Limitations
Communications and measurement systems	3.1–10.6 GHz (different out-of-band emission limits for indoor and handheld devices)	No
Imaging: ground-penetrating radar, wall, medical imaging	<960 MHz <i>or</i> 3.1–10.6 GHz	Yes
Imaging: through-wall	<960 MHz <i>or</i> 1.99–10.6 GHz	Yes
Imaging: surveillance	1.99–10.6 GHz	Yes
Vehicular	22–29 GHz	No

The IEEE Project 802.15.3a task group provides us with examples of three very different UWB radio systems. All three systems described here evolved from the Project 802.15a UWB PHY (physical layer) proposal. As of this writing, the approach to a standard has not been chosen, and perhaps this reflects the abundance of good choices! The three implementations show how differently a physical description of a radio can become while conforming to the same broad regulatory requirements. One method is based on orthogonal frequency-division multiplexing (OFDM), and another is based on direct-sequence code-division multiple access (DSUWB). A third method is a time-division/frequency division multiple access (TD/FDMA) pulse approach. Of these, the TD/FDMA is closest to an impulse radio. Additionally time-modulated (TM-UWB²) and transmitted delayed reference (TDR-UWB) examples are shown in Table 2.

The 802.15.3a process has exposed several viable techniques to access the UWB spectrum, as summarized in Table 2. All three systems access a minimum of about 1.5 GHz in the simplest mode of operation. OFDM and TD/FDMA systems hop among at least three channels of about 500 MHz width within the 3.1–5 GHz range. DSUWB uses one channel of 1.4 GHz bandwidth. All three have a way of utilizing the segment of spectrum between 3.1 and approximately 5 GHz with similar performance. Each, additionally, has ways of increasing performance, again essentially by similar amounts, by utilizing the rest of the UWB band up to 10.6 GHz. Table 2 shows that each method delivers more than 100 Mbps (megabits per second) at 10 m distance and well over 400 Mbps at shorter distances. All of the methods were crafted to meet the regulatory criteria for access to the UWB spectrum. Time-modulated ultrawideband (TM-UWB) and transmitted delay reference (TDR-UWB) are also represented in Table 2.

Modulation efficiency is the needed energy per bit : noise density ratio for achieving a bit error rate (BER) no greater than a specified value. A BER less than 10^{-3} is used for comparison in the table. Table 3 lists various modulations that have been applied to UWB systems. System designers wishing to estimate performance in realistic environments should consider the additional propagation losses usually encountered in practical environments. Performance in multipath and shadowing conditions should also be considered.

²The proprietary (capitalized) term Time Modulated UWB and acronym TM-UWB are trademarks of Time Domain Corporation, Huntsville, AL.

2.1. An OFDM Approach to UWB

The OFDM approach to UWB meets the “500 MHz bandwidth” requirement by using 122 carriers that are modulated with a quadrature phase shift keying (QPSK) constellation. The composite signal occupies a 504-MHz-wide channel and persists on a channel for the information length of 242.42 ns plus the 60.61 ns cyclic prefix time, and then switches to another channel within a 9.5 ns guard time. The long symbol interval, approximately 242 ns, means that multipath fading is effectively viewed through a narrow band (approximately 4 MHz) filter. This OFDM system will encounter full Rayleigh fading in multipath channels. Because the UWB emission regulations limit power per megahertz, a larger utilized bandwidth will result in a larger total emitted average power. The three time-frequency hopping OFDM signals occupy 1.5 GHz. Frequency hopping is used in this OFDM approach as a way of having this system occupy a large total bandwidth for the purpose of increasing the total radiated power.

The system parameters for an OFDM system are shown in Table 4. At least three data rates are supported: 110, 200, and 480 Mbps, with additional data rates possible. QPSK modulation is used on the OFDM tones, and a 128-point Fourier transform generates the OFDM tones. Different data rates are supported by different combinations of error correction coding rates, numbers of tones carrying data, and the spreading rate on each tone. Additional channels spaced 528 MHz all the way up to the bandlimit at 10.6 GHz provide additional system capacity, more available power, and combinations of power and capacity to further improve performance. This OFDM approach uses conventional radio techniques to access the 7500 MHz of unlicensed spectrum under the UWB rules. The performance of this OFDM will resemble that of 122 narrowband radios, each occupying about 4 MHz of spectrum. Multipath manifests itself as full Rayleigh fading and is dealt with by spreading the forward error correction code across the frequency bands.

2.2. A DS-UWB Approach to UWB

Direct-sequence spread spectrum (DSSS) has roots in secure and military communications systems. It also appears in the IEEE 802.11b wireless local area network standard. In this UWB implementation, summarized in the DS-UWB column of Table 2, we see a direct sequence approach designed to occupy at least 1.5 GHz bandwidth in the 3.1–5.15 GHz range and 3.7 GHz bandwidth in the

Table 2. Three UWB Systems Crafted to Meet U.S. Regulatory Requirements

	OFDM	DS-UWB	TD/FDMA Pulses	TM-UWB	TDR-UWB
Bands	3–13	2	3–13	1	1
Bandwidths	3–13 × 504 MHz	1.5 and 3.6 GHz	3 × 550–13 × 528 MHz	2 GHz	2 GHz
Frequency ranges (GHz)	3.1–4.8 4.8–10.6	3.1–5.15 5.825–10.6	3.1–5.0 4.9–10.6	3.1–5.2	3.1–5.2

Coding rate	0.44	0.44	1
Code length (chips/s)	32	32	1
Channel chip rate (Gchips/s)	1.368	1.368	1.368

5.8–10.6 GHz range. The DS-UWB parameters are listed in Table 5. Unlike a traditional carrier based DSSS system, this UWB approach uses nonsinusoidal wavelets tailored to occupy the desired spectrum in an efficient manner. Figure 1 shows a sample wavelet along with its spectral content in the 3.1–5.1 GHz band. Figure 2 shows another sample wavelet that occupies the 5.8–10.6 GHz band. The lowest-cost systems are envisioned to use the lower frequency band. The two bands can be used independently, or together to provide a range of options for system deployment. This system uses a multilevel biorthogonal keying (*M*-BOK) modulation or *M*-BOK in combination with QPSK depending on the required data rate.

The UWB bandwidth spreading is accomplished by sending the wavelets shown in Figs. 1 and 2 at the 1.368 Gchip/s chip rate. Modulation of the sequence of wavelets “whitens” the spectrum, which means that it disrupts regularities that would otherwise result in spectral lines. *M*-BOK modulation comprises 24/32-length ternary orthogonal sequences (−1, 0, +1) of wavelets. The ternary codes simultaneously provide the DS spreading as well as the *M*-BOK modulation symbol set. Either 1, 2, 3,

Figure 1. UWB wavelet and its spectrum in the 3.1–5 GHz range.

Figure 2. UWB wavelet and its spectrum in the 6–10.6 GHz range.

or 6 bits are sent with each code symbol. For example, 64-BOK modulation takes 6 chips at a time ($2^6 = 64$ BOK combinations) to form a symbol. The 24-length ternary codes are used with 2-BOK, 4-BOK, and 8-BOK, while 32-length codes are used with 64-BOK. *M*-BOK modulation has the property that as *M* increases without bound the modulation efficiency approaches the Shannon-limited value of -1.59 dB.

Symbols are sent at 42.75 Msym/s, resulting in a channel bit rate of 256.5 Mbps. The data are encoded with a rate 0.44 error correction code resulting in the 112 Mbps information data rate seen in Tables 1 and 4. A second set of wavelets that have orthogonal properties to the wavelets depicted in Figs. 1 and 2 are sent on top of the original wavelets in a manner analogous to quadrature phase shift keying (QPSK) in carrier-based radio systems. With QPSK there are up to 12 bits per symbol. This doubles the data information rate to 224 Mbps. Finally, moving from a 0.87 rate to a 0.44 rate error correcting code, and using QPSK, a 448 Mbps data information rate is achieved. Many other combinations of modulation depths (*M*-BOK) and coding rates are possible including a 1.368 Gbps mode at 1 bit per chip with error correction omitted. The *M*-BOK codes along with forward error correction are especially effective in multipath propagation. This example of a UWB system uses wavelets that are approximately 1.5 and 3.6 GHz, respectively, when measured at the points 10 dB down from the peak level. They resemble an impulse approach where the impulses are sent with minimal spacing between them. The design and characteristics of wavelet impulses are given in Ref. 2.

2.3. A TD/FDMA Approach to UWB

The time-division/frequency-division multiple-access approach (TD/FDMA) uses impulses that are centered at frequencies spaced by 550 MHz. Here the impulses are 3 ns long and occupy a 700 MHz bandwidth when measured at points 10 dB below the peak value. The

Figure 3. Impulse wavelets for a TD/FDMA UWB system.

impulse wavelets for the lower four bands are shown in Fig. 3. The corresponding spectral occupancy is portrayed in Fig. 4.

Multipath is mitigated by the time interval between pulses that appear on the same channel. The TD/FDMA system used impulses that are separated in time.

2.4. TM-UWB Technology

A TM-UWB system is introduced in Table 2. TM-UWB transmitters emit ultrashort pulses with tightly controlled pulse-to-pulse intervals. The waveform pulsewidths are typically less than 1 ns in duration, and are centered near 4 GHz, with pulse-to-pulse intervals of 25–1000 ns. The pulse-to-pulse interval is varied on a pulse-by-pulse basis

Figure 4. Spectrum occupancy of the TD/FDMA UWB system.

in accordance with two components: an information signal and a channel code. The TM-UWB receiver directly converts the received RF signal into a baseband digital or analog output signal. A receiver correlator coherently converts the electromagnetic pulsetrain to a baseband signal in one stage. A single bit of information may be spread over multiple wavelets, providing a way of scaling the energy content of a data bit with the data rate. The receiver coherently sums the proper number of pulses to recover the transmitted information.

TM-UWB systems use a fine pulse shift modulation by positioning the pulse one quarter-cycle early or late relative to the nominal PN-coded location (Fig. 5), or by pulse polarity. Furthermore, multilevel pulse position modulation may be used to provide enhanced bit-energy:noise ratio performance. The error probability for fine-shift modulation in additive white Gaussian noise (AWGN) follows the same behavior as conventional orthogonal or ON/OFF keying (OOK), while the error probability of pulse polarity modulation in AWGN follows the same behavior as that of conventional BPSK or antipodal signaling. Because TM-UWB modulation is based on accurate timing, the method is especially suitable for accurate distance determination. FCC-certified TM-UWB devices demonstrating communications, distancing, and 2D radar are commercially available [5].

2.5. TRD-UWB Technology

A method of transmitting and receiving impulses that can implement an efficient rake receiver is exemplified by TRD-UWB, [15]. The method employs differentially encoded impulse pairs sent at a precise spacing D . The system is shown in the simplified block diagram of Fig. 6. The transmitter sends a pair of pulses separated by a delay D , and differentially encoded by pulse polarity. The pulses, including propagation induced multipath replicas, are received and detected using a correlator with one input fed directly and another input delayed by D . The receiver resembles a conventional DPSK receiver that in AWGN exhibits an error probability P_D [16] of

$$P_D = \frac{1}{2} \exp\left(-\gamma_b \frac{N-1}{N}\right) \tag{1}$$

where $N > 1$ is the number of differentially encoded pulses in a sequence and γ_b is the SNR per bit. The integration interval is sufficiently long to rake in some multipath

Figure 5. PN-coded UWB waveform sequence in time.

energy. TRD-UWB modulation performance is compared with other modulations in Table 3.

One channelization method employing TRD-UWB, [15], has $N = 2$ and employs a family of delays D_i . Impulse pair sequences of these delay combinations constitute the channels. Table 3 compares the error probability P_D of TRD-UWB with N arbitrarily large to the performance of other modulations.

3. UWB SHORT PULSE RADIATION AND RECEPTION

Solving for the radiated fields of pulses applied to antennas involves finding solutions to Maxwell’s equations in space and time. We begin by defining the geometry of a dipole antenna that supports surface currents $\mathbf{J}(\mathbf{r}', \tau)$ at points described by a vector \mathbf{r}' pointing from the coordinate origin to the current density point, and by a retarded time variable $\tau = t - R/c$. The solution to the dipole current density on an arbitrarily shaped antenna is well beyond the scope of this work, and approximations will be given on the basis of Ref. 2. Numerical solutions for specific antenna shapes can be found using the FDTD numerical method, as described in Ref. 18. The solutions given below are general, that is, they apply to narrowband signals as well as UWB wavelets. Narrowband solutions are always approximated by sinusoids; hence narrowband solutions are always sine waves.

3.1. UWB Wavelet Fields

The vector \mathbf{r}' in Fig. 7 points to the antenna current vector \mathbf{J} , and the radiated field point is \mathbf{r}_a . An additional vector \mathbf{R} with magnitude R points from the current point to the field point. A general expression for the magnetic far-zone field for the geometry in Fig. 7 using the space-time

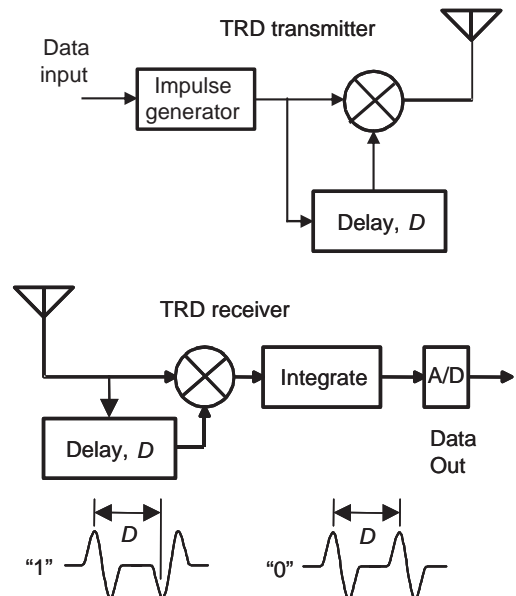

Figure 6. A TRD-UWB transmitter and receiver.

Figure 7. A wideband dipole.

integral equation (STIE) formulation [17] is

$$\mathbf{H}(\mathbf{r}, t) = \frac{1}{4\pi rc} \int_V \frac{\partial}{\partial \tau} \mathbf{J}(\mathbf{r}', \tau) \times \mathbf{a}_r dV' \quad (2)$$

The integral over volume V reduces to an integration over the surface current density \mathbf{J} , the *retarded time variable* is $\tau = t - R/c$, where c is the speed of propagation and \mathbf{a}_r is a unit vector pointing in the direction of radiation. A key factor in Eq. (2) is the appearance of the partial derivative in τ , which includes both time *and* delay. The radiated magnetic field \mathbf{H} and hence the electric field \mathbf{E} are related to a time and delay derivative of the antenna current density; that is, to the acceleration of charges on the antenna. Thus, the radiated field signal shapes will be different from the signal shape supplied to the feedpoint of the antenna. *This is a key difference from narrowband solutions where the signal shape everywhere is sinusoidal.* We note that this time-delay derivative is not always present, as for example in some traveling-wave antennas, which are not consider here.

An approximate solution for the magnetic fields radiated from the dipole aligned with the z axis and having effective length $2h_a$ is given in Ref. 2.

$$H_\phi(r, t) = \frac{\sin(\theta) h_a}{4\pi rc} \frac{\partial}{\partial t} \{ I_z(t) + I_z(t - [1 - \cos(\theta)]h_a/c) + I_z(t - [1 + \cos(\theta)]h_a/c) \} \quad (3)$$

where $I_z(t)$ is the dipole feedpoint current. The usual spherical (r, θ, ϕ) coordinates are employed, and the $\sin(\theta)$ term is the projection of the z -directed current density on the θ direction at the observation point. The electric far field is

$$\mathbf{E}_\theta(r, t) = -\eta_0 \mathbf{H}_\phi(r, t) \quad (4)$$

The fields in Eq. (3) appear to emanate from three sources (see Fig. 7): one at the feedpoint and one at each dipole end. The total magnetic field comprises time derivative compo-

nents that are delayed by t as well as by $\cos(\theta)h_a/c$. Thus two processes contribute to the field signal shape, a time and distance delay. *Both processes tend to lengthen the signal in time; hence both processes will contribute to a narrowing of the radiated bandwidth compared to the bandwidth of the signal supplied to the antenna.* Furthermore, and more generally, the delay term $[1 \pm \cos(\theta)]h_a/c$ in Eq. (3) means that the radiated signal shape as a function of time will vary depending on where the observation point is, measured by the observation angle θ relative to the antenna axis.

3.2. Receiving UWB Wavelets

Antennas, for example dipoles, receive signals by a process of impressing incident fields onto the receiving antenna surface. These fields are weighted and summed up to appear as a voltage across the feedpoint terminals of the receiving antenna. The receiving process can be derived from the *principle of reciprocity in electromagnetic theory* applied to the receiver antenna problem as shown in Ref. 2. Alternatively, and perhaps in a clearer fashion, the Lorentz force law can be used to relate the force \mathbf{F} exerted on a charge q by the incident electric \mathbf{E} and magnetic \mathbf{H} fields on an antenna having length Δh . For the infinitesimal antenna

$$\mathbf{F} = \mathbf{E}q + q\mu_0 \mathbf{v} \times \mathbf{H} \quad (5)$$

The antenna velocity \mathbf{v} here is zero acting over the incremental antenna length here, so the magnetic field term drops out. The force per charge, has the units of voltage, so

$$V_R(t) = - \int_{-\Delta h/2}^{\Delta h/2} \frac{1}{q} \mathbf{F} \cdot d\mathbf{l} = - \int_{-\Delta h/2}^{\Delta h/2} \mathbf{E}^{\text{inc}} \cdot d\mathbf{l} = - \mathbf{E}^{\text{inc}}(t) \Delta h \quad (6)$$

giving the result that the open circuit received voltage on a point antenna is proportional to the electric field incident on it. For finite-size wideband dipole antennas, the received voltage signal V_R is related to the transmitted current signal I_T through several processes that can alter the shape of the signal. First, I_T gives rise to a current density distribution \mathbf{J} on the transmitting antenna. This current density has time delays associated with it depending on the transmitter antenna dimensions. The current densities produce the electric field \mathbf{E}^{inc} at the field point on the receiving antenna that is proportional to the time-delay derivative of the transmitting antenna current density. Finally, the received open circuit voltage V_R is a summation of weighted electric field points, and another set of signal time delays is encountered in this summation due to the physical dimensions of the receiving antenna. A reasonable approximation for the voltage received by a wideband dipole is

$$V_R(t) = -h_a(E_z(t) + E_z(t - [1 - \cos(\theta)]h_a/c) + E_z(t - [1 + \cos(\theta)]h_a/c)) \quad (7)$$

Thus, the received signal V_R comprises weighted sum of and time-delayed derivatives of the transmitted current I_T . If the antenna is small, then there are no time-delay components in the received-signal shape.

4. PROPAGATION OF UWB SIGNALS

Wavelets, both UWB and narrowband, propagate in free space as expanding spherical waves. Thus, the inverse square law applies. In buildings and in cluttered environments the wavelets additionally shed energy to multipath dispersion. Thus we expect a propagation phenomenon that has a free-space term multiplied by a dispersion term. It is easy to show theoretically and from measurements [19] that the dispersion term gives rise to a term that increases the propagation law (to approximately inverse third power inside buildings). The dispersion term is also related to the maximum energy available for rake receiver gain.

4.1. The SBY Median Multipath Propagation Model

A propagation model in multipath, the SBY model [2], for the strongest impulse is based on theory and measurements given in Ref. 19. The path gain P_G between 0 dBi antennas is weighted by receiver antenna aperture ($c^2/4\pi f_m^2$), where f_m is the geometric mean of the low- and high-frequency band edges of the UWB pulse and c is the velocity of propagation. The SBY path gain model is

$$P_G = 10 \log\{[c/4\pi df_m]^2 [1 - \exp(-(d_t/d)^{n-2})]\} \quad (8)$$

where n is the propagation law beyond a breakpoint distance d_t . Nominally, based on measurements, $n = 3$. The term in brackets represents wavelet (including sinusoidal waves) attenuation due to the time dispersion of multipath occurring beyond the breakpoint distance d_t . Using a small argument approximation to the terms in the brackets, the resulting $(d_t/d)^{n-2}$ term, with $n = 3$, gives rise to an overall inverse third-power propagation law inside buildings. Equation (8) is especially useful for modeling propagation in short range indoor personal area networks as exemplified by the IEEE 802.15.3 standard.

4.2. Relation to Maximum Rake Gain

The maximum average rake gain is defined by the ratio of "total energy density" to "single-impulse energy density," which is the term in brackets in Eq. (8), and on average is

$$G_{\max} = 10 \log[1 - \exp(-(d_t/d)^{n-2})] \quad (9)$$

Based on some indoor measurements, $d_t = 1$ and $n = 3$, so $G_{\max} = 10 \log(d/d_t)$, so that G_{\max} increases with d as $10 \log(d)$. This means that on average, the maximum rake gain possible results from the total collection of all the multipath dispersed energy, and is given by Eq. (9).

5. RECOVERING UWB IMPULSE ENERGY

UWB signals are detected in a correlation-type receiver. A filter with impulse response $h(t)$ is optionally placed between signal $s(t)$ at the receiver antenna load and the correlator input. The locally generated correlation template pulse $p(t)$ multiplies the received data pulse and is integrated and sampled at the correlator output. The receiver implementation efficiency e_c is

$$e_c = 10 \log \left[\frac{\left| \iint s(\tau) h(\tau - t) d\tau p(t) dt \right|^2}{\int s(t)^2 dt \int \left| \int p(\tau) h(\tau - t) d\tau \right|^2 dt} \right] \quad (10)$$

and is maximized when

$$C \int p(\tau) h(\tau - t) d\tau = s(t) \quad (11)$$

provided $h(t)$ is causal and where C is the RMS value of $s(t)$. Solutions to Eq. (11) range from the matched template, $h(t) = \delta(t)$ (the Dirac delta function) with $p(t) = s(t)$, to the matched filter, $h(t) = s(-t)$ with $p(t) = \delta(t)$. The correlator efficiency depends strongly on the shape of the signal $s(t)$ and its relationship to $h(t)$ and $p(t)$. The efficiency e_c can typically range from -6 to -2 dB for simple rectangular templates, to a fraction of a decibel in some receiver implementations.

6. A UWB LINK PERFORMANCE

The UWB link specifies a transmitter and antenna providing an EIRP of P_{TX} , a receiver with sensitivity S_{RX} , and a propagation factor P_L determined at a convenient distance. A transmitter operating over an equivalent bandwidth of about 1.3 GHz emits $P_{TX} = -10$ dBm. A companion UWB receiver operating in AWGN (-174 dBm/Hz), referenced to a data bandwidth W Hz, with noise figure, implementation loss and margin totaling L dB, and operating at an SNR dB signal-to-noise ratio per bit, has a sensitivity

$$S_{RX} = -174 + 10 \log(W) + L + \text{SNR dBm} \quad (12)$$

The propagation term P_L is evaluated at a distance $d = 1$ m using Eq. (8), and the resulting system gain SG, including a receiver antenna gain of G_{RX} dBi, is

$$\text{SG} = P_{TX} - S_{RX} + P_L + G_{RX} \quad \text{dB} \quad (13)$$

When $f_c = 4$ GHz, then $P_L = -45$ dB, and using a data bandwidth of $W = 40$ MHz, losses $L = 10$ dB, SNR = 7 dB, and $G_{RX} = 5$ dBi, the receiver sensitivity is $S_{RX} = -81$ dBm, and the system gain at one meter is SG = 31 dB.

Using Eq. (8), a 31 dB system gain at 1 m permits a median range of approximately 11 m without rake gain. A "perfect rake" receiver would permit a median range of more than 31 meters. Practical implementations would result in a median-range performance between 10 and 30 m at a 40 Mbps throughput data rate.

7. APPLICATIONS AND MARKETS OF UWB SYSTEMS

UWB technology uniquely harnesses an ultra wideband of spectrum to provide high-bandwidth communications, but in certain implementations also enables indoor precision tracking and radar sensing on top of communications.

7.1. UWB Applications

The unique capabilities of UWB driving it into application space markets include

- Communications and sensors
- Position location and tracking
- Radar

UWB has characteristic attributes that make it especially attractive in those three categories. These include

- *Stealth*—in many varieties of UWB the signal appears to be very-low-level background noise to an unintended narrow band receiver
- *Local-area networks*—the exceptionally large available bandwidth can be used as the basis for a short-range wireless local-area network with data rates approaching 1 Gbps
- *Position location*—some UWB systems are capable of determining the 3D location of any of its transponders to within a few centimeters
- *Radar imaging*—UWB systems can be used as an open-air, through-wall, or ground-penetrating radar imager
- *Security bubble*—some UWB systems can be configured to create a security “bubble” in the fashion of a bistatic radar to detect penetration of the bubble walls
- *Vehicular radar systems*—UWB has an available vehicular radar band in the frequency range 22–29 GHz for use in collision avoidance and parking aids.

7.2. The Role of UWB in Wireless Markets

Advancements in UWB radio technology promise the opportunity of creating unique solutions meeting emerging market needs. There are essentially three basic market spaces in which UWB plays a role.

7.2.1. Wireless Communications. As available bandwidth to users increases, applications will continue to evolve to fill the available bandwidth and demand further increases. On top of this increasing demand for bandwidth, the increase in mobile telephony and travel has spurred demand for bandwidth mobility, implying wireless technology. Initial applications of UWB will evolve from the existing market needs for higher-speed data transmission, but demand for multimedia-capable wireless is already driving multiple initiatives in the wireless standards bodies. UWB solutions will emerge that are tailored for these applications because of the available high bandwidth. In particular, high-density multimedia applications, such as multimedia streaming in “hotspots” such as airports or shopping centers or even in multidwelling

units, will require bandwidths not currently enabled by continuous-wave “narrowband” technologies. The ability to tightly pack high-bandwidth UWB “cells” into these areas without degrading performance will further drive the development of UWB solutions. UWB radio systems using microwatts of power have already been demonstrated with data rates up to hundreds of Mbps at useful ranges in home and office environments.

7.2.2. Precision Tracking. As the mobility of people and objects increases, up-to-date and precise information about their location becomes a relevant market need. While GPS and some E911 technologies promise to deliver some level of accuracy outdoors, current indoor tracking technologies remain relatively scarce and have accuracies on the order of 3–10 m. UWB implementations are an adjunct to GPS and E911 that allow the precise determination of location and the tracking of moving objects within an indoor space to an accuracy of a few centimeters or less. This, in turn, enables the delivery of location-specific content and information to individuals on the move, and the tracking of high-value assets for security and efficient utilization. While this is an emerging market segment, the accuracy provided by UWB will accelerate market growth and the development of new applications in this area. UWB technology is uniquely positioned to provide distancing and location capabilities to wireless sensor networks. The popularity of wireless sensor networks is expected to grow dramatically in the near future because they provide practical machine-to-machine communication at a very low cost. The growth is expected to duplicate the recent explosion of wireless LANs [20]. Accurate distance measuring using UWB has been demonstrated adequately in recent years, and several corporations have developed chip sets as early as 1993 demonstrating distance measuring capabilities [5,21]. Aether Wire & Location, Inc., chose a direct-sequence spread-spectrum (DSSS) approach to measure distance using UWB. Time Domain Corporation pioneered a time-modulated impulse approach, which not only measured position but also fused data communications within the same protocol. In the IEEE 802 organization, a new group, 4a, has begun work to propose a new radio physical layer for the 802.15.4 standard. Because of the unique capabilities of UWB to satisfy the need for positioning, low data rates at longer distances, and high system capacities, UWB proposal are inevitable.

7.2.3. Radar. Finally, UWB signals enable inexpensive high-definition radar. With the new radar capability created by the addition of UWB, the radar market will grow dramatically and radar will be used in areas currently unthinkable. Some of the key new radar applications where UWB is likely to have a strong impact include automotive sensors, collision avoidance sensors, smart airbags, intelligent highway initiatives, personal security sensors, precision surveying, and through-wall public safety applications. Through-wall radar is already being tested to assist law enforcement and public safety personnel in clearing and securing buildings more quickly and with less risk by providing the capability to detect human presence and movement through walls. Radar enhanced security

domes based on precision radar have already demonstrated the capability to detect motion near protected areas, such as high-value assets, personnel, or restricted areas. The dome is software configurable to detect movement passing through the edge of the dome, but can disregard movement within or beyond the dome edge. Operation of vehicular radar in the 22–29 GHz band is permitted under the UWB rules using directional antennas on automobiles. These devices are able to detect the location and movement of objects near a vehicle, enabling features such as near collision avoidance, improved airbag activation, and suspension systems that better respond to road conditions.

7.3. UWB over Wires

UWB technology can be delivered over wirelines and cables. This could effectively double the bandwidth available to cable television (CATV) systems without modification to the existing infrastructure [22]. Over-wire technology for coax cable can provide up to 1.2 Gbps downstream and up to 480 Mbps upstream of additional bandwidth, at low cost, on differing CATV architectures. The UWB signals can be introduced at the cable headend and extracted at the customer premises. The wireline UWB technology does not interfere with or degrade television, high-speed internet, voice, or other services already provided by the CATV infrastructure. This will give operators the ability to leverage existing infrastructure to deliver greater functionality in the pursuit of additional revenues. As shown in Fig. 8, the system uses innovative techniques to seamlessly integrate the UWB-wireless and UWB-wired communications.

This integrated wireline and wireless technology provides tremendous wireless networking bandwidth but that also extends content security all the way from the cable provider's headend offices out to a variety of wirelessly networked devices. The concept turns the home entertainment center into a wireless hub and networking gateway.

8. ADDRESSING THE WIRELESS SPECTRUM SQUEEZE WITH UWB

UWB operates at ultralow power, transmitting impulses over multiple gigahertz of bandwidth. Each pulse, or pulse

sequence, is randomized by modulation, thus appears as incremental “white noise” to other narrowband radiofrequency devices. UWB operates with emission levels commensurate with levels of unintentional emissions from common digital devices such as laptop computers and pocket calculators. Today we have a “spectrum drought” in which there is a finite amount of available spectrum, yet there is a rapidly increasing demand for spectrum to accommodate new commercial wireless services. Even the defense community continues to find itself defending its spectrum allocations from the competing demands of commercial users and other government users. UWB exhibits incredible spectral efficiency that takes advantage of underutilized spectrum, effectively creating “new” spectrum for existing and future services by making productive use of what appears as the “noise floor” in conventional receiver bandwidths. The best applications for UWB are for indoor use in high-clutter environments. UWB technology enables not only communication devices but also positioning capabilities of exceptional performance. The fusion of positioning and data capabilities in a single technology opens the door to exciting and new technological developments.

ULTRA-WIDEBAND WIRELESS SYSTEMS

BRIAN M. DONLAN
 R. MICHAEL BUEHRER
 JEFFERY H. REED

 Blacksburg, Virginia

1. INTRODUCTION

The concept of ultra-wideband (UWB) has been in existence since the early 1960s when short subnanosecond pulses were applied to the characterization of microwave networks. Impulses were used to probe the network, which allowed the system's impulse response to be determined. In the late 1960s, this impulse excitation technique was eventually applied to the design of wideband antennas and, as a natural consequence, led to the beginnings of pulse-based radar and communications systems [1]. Soon after, the first UWB communications patent was awarded in 1973 to Sperry [1], whose system focused on the transmission and reception of short subnanosecond pulses. However, until 1994, the majority of the research in the United States was conducted under the umbrella of classified U.S. government projects [1]. Research continued into what is now referred to as Impulse Radio and was primarily propelled in the academic realm by the work of Scholtz and Win [2–6] during the 1990s. Since the Federal Communications Commission (FCC) approved a First Report and Order in February 2002, allowing for the development, production, and operation of unlicensed commercial UWB devices, research efforts have increased dramatically and interest in UWB remains strong.

This article focuses on the different aspects of UWB as they relate to the research and development of future UWB applications and places emphasis on pulse-based UWB. First, a brief discussion of the FCC's First Report and Order is provided because it will directly impact the

development and production of UWB devices. A general introduction into UWB follows, and the remainder of the article focuses on possible UWB applications, including the current IEEE standardization efforts for wireless personal area networks (WPANs).

2. FCC GUIDELINES AND REGULATIONS

On February 14, 2002, the FCC approved a First Report and Order allowing the development and operation of unlicensed UWB devices in the United States, a milestone for the commercial development of UWB technology. (At the time this article was being written, regulation efforts were underway in both Europe and Asia.) Much effort was expended to characterize UWB and to determine the operating limitations that should be imposed on these devices. The result was a description of several target applications along with their allowable operating frequency ranges and power emission limits. The specific applications of interest to the FCC fall into three categories: imaging systems, vehicular radar systems, and communications and measurement systems. The imaging systems are subcategorized into ground-penetrating radar (GPR), wall imaging, through-wall imaging, medical, and surveillance systems. (Surveillance systems are not imaging systems but are regulated as such [7].)

Currently, all communications and imaging systems are allowed to operate in the 3.1–10.6 GHz range (high-frequency range). However, some additional spectrum has been allocated for certain imaging applications. GPR, wall imaging, and through-wall imaging can currently also operate below 960 MHz (low-frequency range). From 1.99–3.1 GHz (mid-frequency range), through-wall imaging and surveillance systems are permitted as well. The final application area, vehicular radar, must operate in the 24 GHz band with the stipulation that the center frequency is 24.075 GHz. Figures 1–3 provide the imposed limits on the spectral emissions allowed for each type of device. Furthermore, the regulations restrict the physical operation of

Figure 1. FCC spectral mask for communications and measurement systems. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

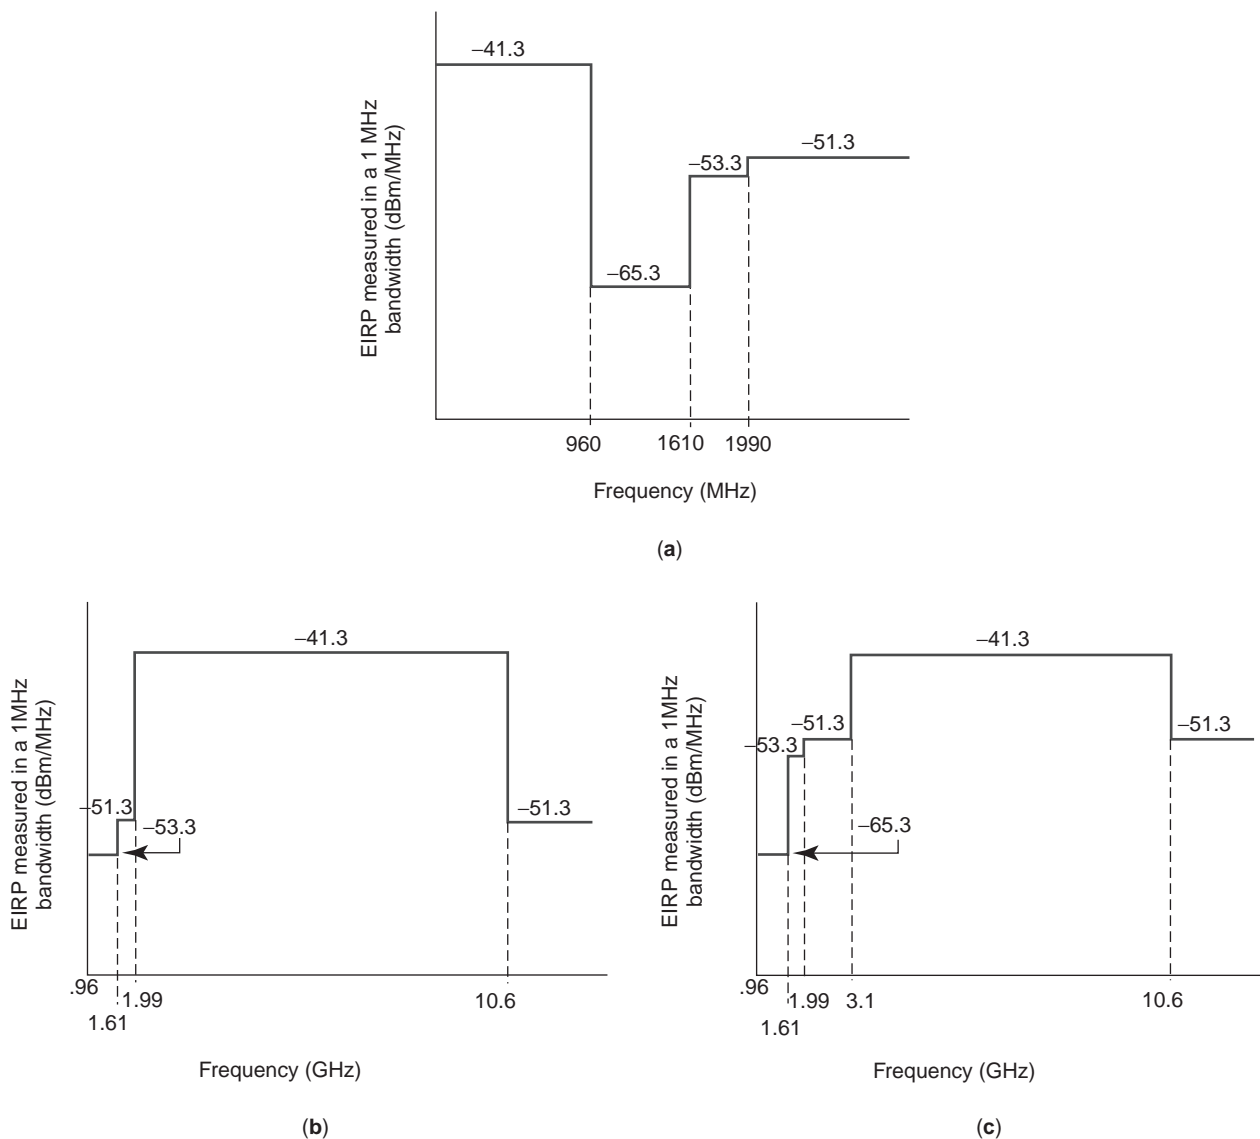

Figure 2. FCC mask for imaging systems for (a) low (b) mid and (c) high frequency.

Figure 3. FCC spectral mask for vehicular radar systems.

the devices and the individuals who may operate them. For instance, GPR must be operated only within close proximity to the ground. Use of GPR and wall imaging systems is limited to law enforcement, fire and rescue, scientific research organizations, commercial mining companies, and construction companies. Through-wall imaging systems may be operated by only law enforcement and fire and rescue entities. Medical systems are restricted to medical professionals, and surveillance systems may be used by law enforcement, fire and rescue, public entities, and industrial entities [7]. The imaging devices, therefore, will target only specific markets and are unavailable to the general public. The largest and most recognizable application in the general consumer market will be communications devices. Specifically, UWB is being targeted for high-speed home and business networking, and the first devices will most likely be for wireless personal area networks (WPANs). Vehicular

radar may also appear in the consumer automobile market for applications such as collision avoidance.

For any device designed for the previously mentioned applications to be considered UWB, it must also adhere to the guidelines set forth by the FCC. The commission defines a UWB signal as one that has a fractional bandwidth of 0.20 or greater when operating below 2.5 GHz or a bandwidth exceeding 500 MHz when operating above 2.5 GHz (both measured at the -10 dB emission point). The fractional bandwidth is defined as $2(f_H - f_L)/(f_H + f_L)$, where f_H is the upper frequency and f_L is the lower frequency, each measured at the -10 dB emission point [7]. As a point of reference, narrowband systems typically have a fractional bandwidth of less than 0.01.

3. PROPERTIES OF UWB

For the United States, the FCC currently defines UWB for commercial regulation. This definition allows for the possible use of many different waveform types as long as they can adhere to the regulatory restrictions. Historically, however, UWB refers to the use of pulses with ultra-short time durations, typically subnanosecond, which consequently have extremely large bandwidths, which is sometimes referred to as carrier-free or impulse radio/radar. The ensuing discussion will focus on the properties of UWB as they relate to impulse radio.

3.1. Pulses

Many researchers typically consider a Gaussian pulse or a derivative of the Gaussian pulse as the pulse used in UWB systems. Several pulse generation techniques use transistors or diodes to create Gaussian pulses [8], but these are not discussed here. A Gaussian pulse can be simply described by the waveform

$$p(t) = e^{-\frac{1}{2}(t/t_p)^2} \quad -\infty < t < \infty \quad (1)$$

where t_p is approximately the width of the pulse in seconds. Figure 4 provides an example of a Gaussian pulse with $t_p = 1$ ns and its corresponding magnitude spectrum. The -10 dB bandwidth of this signal is approximately 2 GHz. Note that all -10 dB bandwidth measurements are with respect to power.

Considering the derivatives of the Gaussian pulse is also of interest. Producing these pulses by filtering the original Gaussian pulse is possible, but more importantly, the antennas employed in a UWB system can largely impact the shape of the pulse, and many times the antenna results in the differentiation of the generated pulse on transmission. Antennas are an extremely important component of a UWB system and deserve a great deal of consideration when designing a UWB system. (Schantz [9] offers a detailed introduction.) Here we simply provide the first and second derivatives of the Gaussian pulse, which are given by

$$\frac{d}{dt} p(t) = \frac{t}{t_p} e^{-\frac{1}{2}(t/t_p)^2} \quad (2)$$

and

$$\frac{d^2}{dt^2} p(t) = \frac{1}{t_p^2} e^{-\frac{1}{2}(t/t_p)^2} - \frac{t^2}{t_p^3} e^{-\frac{1}{2}(t/t_p)^2} \quad (3)$$

Figures 5 and 6 provide example plots of the first and second derivatives with their corresponding spectra, again for $t_p = 1$ ns. Here, the -10 dB bandwidths are approximately 2.5 GHz and 2.7 GHz, respectively.

As mentioned earlier and shown in Figs. 1–3, the FCC specifies both the frequency range and the power limitations for UWB emissions. Therefore, the baseband pulses previously mentioned could not be used for the mid- and high-frequency imaging, vehicular radar, or communications applications. Thus, it may be desirable to modulate a sinusoid using the Gaussian pulse in order to shift the pulse into the proper frequency range. Such an RF pulse could be described by

$$p(t) = e^{-\frac{1}{2}(t/t_p)^2} \cdot \sin(2\pi f_{c,UWB} t) \quad (4)$$

where $f_{c,UWB}$ is the center frequency of the RF pulse. Figure 7 provides an example of such an RF pulse, along with its corresponding spectrum, for $t_p = 1$ ns and $f_{c,UWB} = 6$ GHz. The -10 dB bandwidth for this pulse is approximately 4 GHz with the signal centered at 6 GHz.

These RF pulses, however, use the allotted spectrum inefficiently. Examining Figs 1 and 7 shows that the amplitude must be reduced for the sides of the spectrum to fit

Figure 4. (a) Gaussian pulse and (b) spectrum.

Figure 5. (a) First derivative of a Gaussian pulse and (b) spectrum.

under the spectral mask, which leaves portions of the spectrum significantly underutilized. Recent works have approached this as a filter design problem, designing a pulse's spectrum to more closely match the spectral mask [10,11].

These impulse-like signals provide some inherent advantages that make them appealing for use in communications and radar systems (including imaging systems). First, because of the short duration and quick “rise” and “fall” times of these signals, the energy contained within the pulse is spread over a large bandwidth, resulting in a low-power spectral density, which makes UWB appealing as an overlay technology, making coexistence with regulated narrowband devices possible. This possibility could partially ease the spectrum shortage in the United States and is likely largely responsible for the FCC's consideration of UWB. The “spreading” of energy could also present the possibility for low-probability-of-detection/interception (LPD/I) communications and could be extremely beneficial in a military setting. Several advantages in the time-domain exist as well. In terms of radar, the pulses can be used in a low-duty cycle system to provide precise timing information and can, therefore, improve a radar's ranging precision. For communications, the narrow pulses provide multipath immunity because paths arriving at the receiver are much less likely to interfere with one another. Consequently, a UWB system would experience much less fading than a traditional narrowband system. However, it is difficult to exploit this diversity. A large number of resolvable

paths arrive at the receiver, and searching for these paths and performing channel estimation is very computationally intensive, which remains a significant research challenge.

3.2. Channel

The characterization of the wireless UWB channel is extremely important and will help ensure the success of future UWB systems. Much of the recent UWB research has focused on this characterization by trying to determine the large- and small-scale effects of the indoor UWB channel, ultimately creating a representative channel model that would be applicable to system design. Channel measurement campaigns have been conducted using both time-domain and frequency-domain measurement systems [12–19]. Frequency-domain measurements are typically conducted using a vector network analyzer (VNA). Time-domain measurement systems probe the channel using pulses like those previously described and using a digital sampling oscilloscope. The following describes both the large- and small-scale modeling aspects of the channel.

The large-scale effects of the channel refer to the expected received power (i.e., path loss) seen at a receiver. The power is expressed as a function of distance, obstacles, and the channel properties in general. The modeling aspects do not differ in principle from traditional narrowband path loss, but some differences should be noted. The

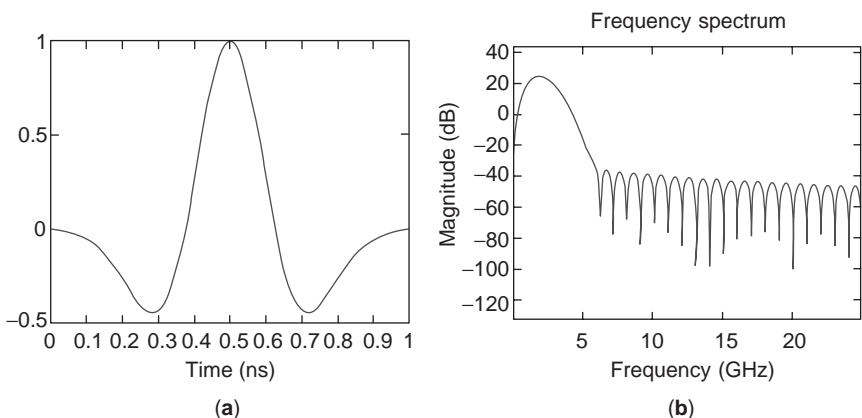

Figure 6. (a) Second derivative of a Gaussian pulse and (b) spectrum.

Figure 7. (a) Gaussian modulated RF pulse and (b) spectrum.

calculation of path loss is still performed relative to a reference measurement, and the standard narrowband path loss equation still applies, which is given by

$$P_r(d)_{dBm} = \bar{P}_r(d_0)_{dBm} - 10n \log_{10}\left(\frac{d}{d_0}\right) + X_\sigma \quad (5)$$

where $P_r(d)_{dBm}$ represents the received power at a distance d computed relative to a reference distance d_0 . X_σ is the shadowing term and is a log-normal random variable with a standard deviation σ . However, the Friis transmission formula, which traditionally provides a means for predicting received power in free space, is no longer applicable. The Friis transmission formula is given by

$$P_r = \frac{P_t G_t G_r \lambda^2}{(4\pi d)^2} \quad (6)$$

where P_t is the transmit power, G_t is the transmit antenna gain, G_r is the receive antenna gain, λ is the wavelength of interest, and d is the separation in meters between the transmitter and receiver [19,20]. Several issues develop when applying Eq. (6) to a UWB signal. First, the formulation of the equation assumes constant gain antennas, which is sufficient for calculating values for narrowband signals. However, for UWB signals, the antennas used will not likely be constant gain over the entire bandwidth of the UWB signal. Second, even if the antennas were constant gain, no single wavelength could be associated with the UWB signal. In general, the impact of the antennas on the UWB pulses makes the theoretical calculations of the received power extremely problematic. Such calculations could be performed using an integral equation that takes into account the antenna gains, but more practically, the calculations would most likely have to be facilitated through the use of a reference measurement. Note that Eq. (6) can be restated similar to Eq. (5) as

$$P_r(d) = P_r(d_0) \left(\frac{d_0}{d}\right)^2$$

where $P_r(d_0)$ contains all the antennas effects.

The small-scale effects of the channel refer to the arrival of multipath components at the receiver. These

effects are typically modeled as a time-invariant linear filter with the channel impulse response, $h(t)$, given by

$$h(t) = \sum_{k=0}^{N-1} a_k \delta(t - t_k) \quad (7)$$

where a_k is a random amplitude whose polarity is determined by a binary random variable [2]. This equation can be recognized as the classic narrowband model with the phase replaced by polarity. Therefore, the traditional definitions for the small-scale statistics still apply. The mean excess delay, $\bar{\tau}$, is given by

$$\bar{\tau} = \frac{\sum a_k^2 \tau_k}{\sum a_k^2} \quad (8)$$

where a_k^2 represents the power in the path at a time delay, τ_k [20]. The RMS delay spread, σ_τ , is given by

$$\sigma_\tau = \sqrt{\bar{\tau}^2 - (\bar{\tau})^2}, \quad \text{where } \bar{\tau}^2 = \frac{\sum a_k^2 \tau_k^2}{\sum a_k^2} \quad (9)$$

using the same notation [20]. The goal is to then create a statistical tap delay model matching the statistics of the measured environment [18,21]. In practice, matching additional statistics, such as the number of paths and the max excess delay, is also helpful. Note that Eqs. (8) and (9) refer to the average statistics of the data. To make the best match possible, comparing the statistics cumulative distribution functions (CDFs) is also a good idea [22,23].

Creating such models can be facilitated through the use of a time-domain measurement system, which probes the environment using very short time duration pulses, which results in the channel “impulse” response being received at the receiver. Obviously, this is an approximation, and the narrower the pulse, the better the resolution of the system. However, techniques exist, most notably the CLEAN algorithm, that allow one to extract an approximate tapped delay line channel model, like the one described in Eq. (7) [24].

Much research has focused on the small-scale characterization of the indoor UWB channel for both residential and office environments. Foerster and Li propose that the

UWB channel can be modeled using a modified Saleh–Valenzuela model for both the line-of-sight (LOS) and non-line-of-sight (NLOS) channels [25,26], and this modified Saleh–Valenzuela model has been adopted by the 802.15.3 standards body. This modified model and the Saleh–Valenzuela model both assume that multipath arrives in clusters, with a cluster and the paths within a cluster both arriving according to a Poisson distribution. The energy decay of the cluster and paths are both considered to occur exponentially. According to this model, the channel impulse response can be given as

$$h(t) = \sum_{l=0}^L \sum_{k=0}^K \alpha_{k,l} \delta(t - T_l - \tau_{k,l}) \quad (10)$$

where $\alpha_{k,l}$ is the path amplitude, T_l is the arrival time of the l th cluster, and $\tau_{k,l}$ is the delay of the k th multipath component relative to the l th cluster arrival time. Note that unlike the Saleh–Valenzuela model, the magnitude of the path amplitudes, $\alpha_{k,l}$, are considered to vary according to a log-normal distribution instead of a Rayleigh distribution. Also, a path is modeled as being real instead of complex, with its polarity being determined by an equally likely binary random variable. The cluster and path distributions can then be given by

$$p(T_l | T_{l-1}) = \Lambda \exp[-\Lambda(T_l - T_{l-1})], \quad l > 0$$

$$p(\tau_{k,l} | \tau_{(k-1),l}) = \lambda \exp[-\lambda(\tau_{k,l} - \tau_{(k-1),l})], \quad k > 0 \quad (11)$$

where Λ is the cluster arrival rate, and λ is the ray arrival rate.

McKinstry found that, for his particular set of measurement data, the indoor LOS channel was best modeled using a modified single Poisson model [24]. The channel model, which uses a single cluster with paths arriving according to a Poisson distribution, was modified to include a few dominant early paths. This model was found to match nicely in terms of BER performance and average statistics.

Using McKinstry’s measurement set, Venkatesh et al. suggest a two-cluster NLOS channel model. This channel model is very similar to the Saleh–Valenzuela model, but rather than having a random number of arriving multipath clusters, this model defines only two clusters because of the characteristics of the measurement set. The model was found to match the data quite well in terms of BER performance, average statistics, and cumulative distribution of those statistics. A good discussion of UWB channel measurements and modeling can be found in [21].

It should be noted that how well a channel model fits a particular environment will certainly vary from environment to environment. However, in general, the UWB channel may be statistically modeled as having paths that arrive according to a Poisson distribution, with the path amplitudes decaying exponentially.

A strong advantage of UWB signals for communication applications is that, because of the resolvability of the multipath components in Eq. (10), the total received energy shows very little fluctuation. However, the receiver must capture the entire available signal. Simple struc-

tures may be unable to capture all of the multipath components, leading to increased fading and lower average energy [4,5].

3.3. Communications

As wireless devices continue to proliferate and we head more and more toward a completely wireless world, UWB may make its largest immediate impact in communications. The following discussion describes the digital modulation techniques typically considered for UWB, which mirror those for sinusoidal carrier modulation [27].

Any of the pulses described previously could be incorporated into several different M -ary or binary modulation schemes. Of the several modulation techniques, two are predominately considered in research and industry: pulse position modulation (PPM) and biphase modulation. (Note that biphase is an antipodal modulation scheme, and “biphase” is somewhat of a misnomer because a baseband pulse has no phase parameter associated with it. However, the technique is still commonly referred to as biphase modulation.)

PPM is an M -ary modulation format that conveys information by placing pulses at specified time delays. This modulation scheme is typically orthogonal in time, and, in the binary case, its performance in Additive White Gaussian Noise (AWGN) is identical to binary frequency shift keying (BFSK). Consider Fig. 8, which illustrates 4-ary PPM modulation. Here, T_c is associated with the amount time used to transmit one UWB pulse. T_c is then accordingly divided into M (in this case, 4) different timeslots of width δ . The bit or symbol being transmitted then determines within which timeslot the pulse is placed. Demodulation is performed at the receiver by correlating a template with each of the four timeslots to determine the most likely transmitted symbol. Note that the demodulation requires precise synchronization, making the issue of delay spread extremely important. Depending on the pulse width and the delay spread of the channel (i.e., pulse interaction), synchronization could be difficult, rendering the system ineffective.

Biphase modulation is strictly a binary scheme by which information is encoded into the polarity of the pulse. Biphase is therefore antipodal and has identical performance in AWGN to binary phase shift keying (BPSK). Figure 9 provides an illustration of biphase modulation where a negative pulse represents a 0 and a positive pulse represents a 1.

Figure 8. 4-ary pulse position modulation.

Figure 9. Biphase modulation.

Other modulation techniques are also possible with UWB. These techniques include pulse amplitude modulation (PAM) and on-off keying (OOK). PAM is an M -ary modulation format that encodes the information in the amplitude of the pulse. Figure 10 gives an example of a 4-ary PAM scenario. PAM, however, is not a particularly attractive modulation scheme because UWB systems are typically power limited and PAM is increasingly energy inefficient with increasing M . With every doubling of M , approximately 6 dB/bit of additional signal-to-noise ratio (SNR) is required to achieve equivalent performance. (Proakis provides the relevant derivations [27].) OOK is a binary scheme. In this case, the presence or absence of a pulse determines whether a 1 or a 0 was transmitted. This technique is also energy inefficient but may be attractive for a low-cost, low-complexity system. Figure 11 provides an example of OOK.

Some UWB system designs also include the use of time hopping for the purpose of multiple access. (Time hopping also provides some other advantages discussed later.) As UWB is a target technology for WPANs, multiple access will be a very important issue. Any of the previously discussed modulation types could be used in conjunction with time hopping, but PPM is typically considered in the literature and will be the basis of the following discussion. Scholtz first presented time hopping PPM (TH-PPM) for UWB [28], and it has been discussed in many other works [24,29]. Such a system can be described by

$$s^{(k)}(t) = \sum_j A p(t - jT_f - c_j^{(k)}T_c - \delta d_{\lfloor j/N_s \rfloor}^{(k)}) \quad (12)$$

where

- $s^{(k)}(t)$ is the transmitted signal for the k th user
- A is the amplitude of the pulse, equal to $\sqrt{E_p}$, where E_p is the energy per pulse

Figure 10. 4-ary pulse amplitude modulation.

Figure 11. On-Off keying modulation.

- N_s is the number of pulses used to represent one data symbol, i.e., the pulse repetition number
- $p()$ is the transmitted pulse shape with normalized energy
- T_f is the frame repetition time (a UWB frame is defined as the time interval in which one pulse is transmitted)
- $c_j^{(k)}$ is the time hopping sequence, often pseudorandom and/or repetitive
- T_c is the granularity of the time hop delay (together $c_j^{(k)}$ and T_c determine the “coarse” time dithering)
- δ is the PPM time delay parameter
- $d_{\lfloor \cdot \rfloor}^{(k)}$ is a function of the data sequence (the notation $\lfloor \cdot \rfloor$ represents the integer portion of the argument)

The total received signal is given by

$$r(t) = \sum_k s^{(k)}(t) * h^{(k)}(t) \quad (13)$$

where $h^{(k)}(t)$ is the channel impulse response between the k th user and the receiver and $*$ denotes the convolution operation [28].

Figure 12 provides a depiction of an unmodulated pulse train without time hopping. The frame, T_f , represents the time between pulses, and T_p represents the pulse width.

In contrast, Fig. 13 provides an example of a time hopped signal where a frame, T_f , is considered to be the time in which one pulse is sent. The frame is divided into several timeslots of period T_c . Referring to the discussion on PPM, T_c represents the same timeslot given in Fig. 8. A pulse is then transmitted in any one of the timeslots. In a multiple access scenario, the k th user would have a unique code, $c_j^{(k)}$, which is usually pseudorandom, and it would specify the time hopping location of the pulse from frame to frame. Modulation then occurs independently within the timeslot. In regards to modulation, the variable N_s specifies the number of pulses used to transmit one symbol or bit. Using $N_s > 1$ introduces time diversity over the period of one symbol, which provides the system with a processing or spreading gain proportional to N_s , in turn improving the ability to properly detect a symbol (for a constant transmit power) at the cost of reducing the data rate.

Several research issues must be addressed for UWB to reach its full potential as a communications technology. For example, the successful exploitation of the favorable qualities of UWB signals is highly dependent on the receiver structure. However, detector and channel estimation approaches that can provide both high energy capture

Figure 12. UWB pulse train (no modulation and no time hopping).

[4,5] and low complexity are nontrivial. The problem is further complicated by the difficulty of predicting the pulse shape because of the channel or even the antenna itself. This item highlights the need for a different approach for UWB than for traditional communication system design. Second, the low-power spectral density and dense multipath structure of the received signal make synchronization particularly difficult. Third, data networks have traditionally relied on carrier sense mechanisms for medium access control (MAC), which will be particularly difficult with UWB signals in dense multipath. Finally, because UWB signals are to be overlaid on existing systems, narrowband interference will exacerbate an already difficult detection and synchronization problem. Many interference mitigation algorithms assume acquisition has occurred, which ignores the difficulty in achieving acquisition in the presence of strong interference. Research is currently ongoing to address each of these concerns.

3.4. Radar

All radar, whether it is imaging or target recognition, can benefit from the use of UWB pulses. From a spectral standpoint, the bandwidth of the signal directly relates to the resolution of the radar, and, from a temporal standpoint, the ability to periodically send very short pulses allows for accurate timing and therefore improved ranging precision. These characteristics make UWB an ideal candidate for radar.

Consider again the Gaussian pulses mentioned in Eqs. (1)–(3). These pulses could be transmitted singularly, but a method using a group of pulses offers some advantages, which is sometimes referred to as pulse compression. It involves sending a series of successive pulses that are modulated by a pseudorandom (PN) binary sequence, b_n . Note that this technique could also be used in communications and is sometimes referred to as direct sequence UWB (DS-UWB). The transmitted signal $s(t)$ could then be given by

$$s(t) = \sum_{n=0}^{N-1} b_n p(t - nt_p) \quad (14)$$

where $p(t)$ is a single pulse, N is the length of the PN sequence, and b_n takes on the values -1 and $+1$ [30]. The advantages for radar are two-fold. First, by sending a series of pulses, the average power of the radar “pulse” is increased. This increase is beneficial because the ability to detect a target directly relates to the available signal energy. Second, the accurate range resolution may still be attained by using a code matched filter for the pulse sequence. Doing so produces a spike when the sequence is properly aligned in the matched filter, compressing the sequence into one pulse, and like DS-SS, it also offers some interference suppression. The performance of the radar is then directly related to the autocorrelation of the group of UWB pulses [30]. Also, although UWB does not suffer from the effects of Doppler, like traditional sinusoidal radar, motion-induced effects still exist. Motion can contribute to pulse distortion causing individual pulse shapes to vary as pulses interact with each other and different materials. This distortion can cause the compressed pulse to broaden, degrading the resolution of the system.

Another important aspect for radar is target recognition, which directly relates to the interaction of the signal with an object. One of the differences between UWB and sinusoidal signals is that the interaction of UWB pulses with certain objects and materials will result in a change in the parameters of the pulse, causing a transformation in the pulse’s shape. On the other hand, a sinusoidal signal’s interactions, such as subtractions, additions, differentiations, and integrations, all result in a change in signal parameters, specifically the magnitude and the phase, but the shape of the signal remains the same. The association of a specific pulse shape with a target provides UWB with a distinct advantage in this area [31].

The interaction of a Gaussian pulse with a complex target can be considered a linear time invariant system (similar to the UWB channel) [30]. Thus each target will have a unique impulse response that is a function of the target’s material make-up, shape, size, and the signal’s angle of arrival. The impulse response, $h_s(t)$, is given by

$$h_s(t) = \sum_{i=0}^{N-1} E_i e^{-a_i^2(t-t_i)^2} \quad (15)$$

Figure 13. Example frame for time hopping UWB.

Figure 14. UWB versus narrowband signals.

and is a series of time-shifted Gaussian pulses representing a complex target with N scattering centers, where E_i weights the Gaussian pulse and a_i controls the shape of the Gaussian impulse [30]. The response of a Gaussian pulse to a target is then given as

$$s(t) = p(t) * h_s(t) \tag{16}$$

where $*$ denotes the convolution operation.

The received signal, $s(t)$, then contains specific information regarding the target’s location and structure and is often referred to as the “target image.” It should be noted that this profile is sensitive to the location of the radar with respect to the target; more specifically, the relative angle between the two is of importance because the target’s response will change with different angles of arrival [30].

3.5. Interference

As a result of the extremely wide bandwidth of a UWB signal, the interference a UWB system both inflicts and observes is a concern. The spectral limits proposed by the FCC are, by their own consent, conservative estimates of the acceptable emission levels for UWB devices. This provision is mainly to protect the legacy narrowband government systems from interference caused by UWB devices. One major concern is the impact of UWB on the operation of GPS systems, especially because of air traffic’s depen-

dence on this technology. Therefore, UWB transmissions are not allowed in the spectrum allocated for GPS. The following provides some comments on interference from both perspectives.

The intent of the FCC is to eventually amend the imposed limits once the interference that UWB systems inflict can be sufficiently characterized. The initial thinking is that UWB will cause little interference to in-band narrowband systems. Consider the illustration given in Fig. 14. Even if the two signals are received with equal power, a UWB signal should add little noise to the narrowband signal because a very small fraction of the UWB signal’s power is in the narrowband signal’s bandwidth. Several research efforts have investigated the impact of a UWB signal on existing systems. Light presents test results examining the effects of UWB signals on many different legacy military systems [32]. Light found that UWB transmissions did interfere with some devices more than others and that many factors impact the level of interference, including pulse shape and pulse repetition frequency. This work also reports that some devices were susceptible to interference at transmit powers even below the FCC spectral mask. Giuliano et al. analyzes the effects of UWB on UMTS [33]. Using simulation, they conclude that UWB poses no threat to the operation of UMTS. The effects of aggregation are also a concern because, especially for communications applications, many colocated devices may be operating simultaneously. This issue requires much more investigation.

In the context of UWB-based interference, it is important to consider the effect of a stream of pulses. Consider again the pulse train represented in Fig. 12. As a result of the periodic nature of the pulse train, transmitting a signal of this nature would produce spectral lines in the pulse’s spectrum. Figure 15 provides an example of such a signal’s spectrum. As previously stated, time hopping actually serves a dual purpose: besides multiple access, it can also be used to smooth the spectrum of the UWB signal. In contrast, Fig. 16 shows the spectrum with time hopping using a random hopping sequence with sixteen different time-slots. Comparing Fig. 15(a) and Fig. 16, a noticeable difference exists between the magnitudes of the two signals’ spectra. By employing time hopping, the periodicities are greatly reduced, which smoothes the spectrum by reducing the spectral lines. Note that it is also possible to combat spectral lines by using biphas modulation.

Figure 15. (a) Spectrum of unmodulated pulse train and (b) a magnified portion. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 16. Spectrum of time hopped pulse train. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Regardless of any future changes in the FCC's spectral mask, UWB will most likely continue to suffer from interference caused by in-band narrowband systems, which will limit a system's range. Firoozbakhsh et al. analyzed the performance of a UWB system in the presence of an 802.11a network [34]. Through simulation, they found that 802.11a could cause significant interference and greatly degrades the UWB system's performance, which will likely be true of many narrowband systems. It will therefore be necessary to apply advanced signal processing techniques to perform interference cancellation. As the problem is similar to that of spread spectrum, ideally some crossover will occur from previous spread spectrum front-end interference cancellation techniques. Unfortunately, techniques such as linear prediction filters, which are purely digital, are not yet viable solutions because the current state-of-the-art does not allow for an entirely digital cost-effective UWB system. Some possible solutions include the use of transform domain processing, a combination analog-digital cancellation circuit, and the use of a Rake receiver to exploit the temporal diversity of the UWB channel. Such research is beginning to emerge and will probably garner considerable attention in the near future.

4. UWB APPLICATIONS

The extremely large bandwidth of UWB provides the potential for high-data rate communications, and accurate ranging devices (e.g., radar). These characteristics make UWB attractive for a variety of interesting applications, from digital communication to imaging. These applications include ground-penetrating radar, through-wall imaging, medical imaging, WPANs, and vehicular radar. The following provides introductions and examples for these UWB wireless applications. Please see [35] for additional information.

4.1. Ground-Penetrating Radar Systems

Ground-penetrating radar (GPR) systems will provide the ability to locate objects that are beneath the ground,

beneath rubble, and so forth. The capabilities of GPR are affected by the range of frequencies used in the system. The characteristics of the object, its location, and the medium in which it is buried in part determine which frequency band is most suited for detection. For instance, higher frequencies allow for more accurate depth resolution. However, the soil will introduce greater attenuation at higher frequencies, and therefore deep objects may not be detected. In this case, lower frequencies would be more beneficial. The use of large bandwidth, baseband pulses are therefore very attractive for this application as they incorporate a wide range of frequencies [36,37].

Park et al. demonstrate the viability of such a device by demonstrating its ability to find metal objects buried in the ground at varied depths [37]. The GPR system employed used separate transmit and receive antennas and a 2.5 ns pulse. A 5 G/s digital sampling scope was used to digitize the signal and a 2-D image signal processing algorithm was used to interpret the results. An additional study also investigated the use of GPR for the detection of plastic landmines, another extremely important application [37].

4.2. Through-Wall Imaging Systems

Through-wall imaging systems use UWB radar to monitor the movements of people through a wall. Time Domain Corporation (www.timedomain.com) has a working through-wall imaging system called RadarVision. The device transmits pulses at ten million pulses per second and has a range of thirty feet. It has been demonstrated to penetrate reinforced concrete, concrete block, sheetrock, brick, wood and wood composites, plaster, tile, and fiberglass. Many situations can be envisioned where a device of this nature would be extremely beneficial. Consider a hostage situation where it would be extremely advantageous to know the locations and movements of the people within the room. Also, consider a burning building where a fire fighter could determine if anyone was still trapped within a room. Many other scenarios can be envisioned, and this could be an extremely useful device in the near future.

4.3. Medical Systems

Medical imaging radar systems present much promise for the ability to provide noninvasive medical monitoring. For instance, UWB radar has been demonstrated to provide the ability to monitor the movements of the heart wall. Much like what was described in the radar section, the pulses will respond differently to different materials (in this case, the heart tissue and blood). Specifically, an impedance difference exists between the blood and heart muscle, which provides different reflection magnitudes and allows the heart to be monitored [38]. Using this idea, a UWB radar prototype was developed at La Sapienza University in Rome. The device operates at 800 MHz and has the ability to detect heart and body movements [38]. This concept could be extended to applications involving other parts of the body because the pulse will react uniquely to different fluids, organs, and tissues in the body. Besides heart monitoring, the applications could possibly extend to respiratory monitoring and fetal monitoring (an ultrasound replacement). At some point, it

could even extend to actual imaging of the brain, heart, chest, and so forth. Nevertheless, many challenges still lay ahead, most notably characterizing the response of certain pulses to bodily tissues and organs.

4.4. Communications Systems

UWB communications systems have recently received the most attention of any UWB area, with visions of low-power, high-data rate wireless devices being available in the near future. Multispectral Solutions, Inc., (www.multispectral.com) has long been involved with the development of UWB radios and has many working UWB communications products [1]. These devices include transceivers for both voice and data and even a tactical ad hoc wireless network. However, most of these devices were developed for the U.S. military rather than as part of the current FCC regulations.

The current push for wireless UWB communications devices among industry, however, is in WPANs, groups of interconnected wireless devices within one's own personal operating space. These devices can communicate among each other and with an already existing network, a wireless local area network (WLAN) for instance. The devices include laptop computers, mobile phones, PDAs, digital cameras, and other handheld devices. The IEEE 802.15.3 working group is responsible for developing a standard for high-data rate WPANs that would provide low-cost, low-power solutions for wireless digital and multimedia applications. Within this working group, a task group, 802.15.3a, was formed to investigate UWB as an alternative physical layer technology for the standard. There has been much debate within the task group over which technology to use, and they have yet to reach a conclusion. Two possibilities are being considered: a MultiBand OFDM approach and a direct sequence approach using pulses (DS-UWB). (DS-UWB was mentioned in the Section 3.4.)

The MultiBand OFDM supporters formed the MultiBand OFDM Alliance (MBOA, www.multibandofdm.org), which is comprised of many industry leaders, and has created its own specifications and standards for UWB wireless devices. Staccato Communications (www.staccato.com), a member of MBOA, has developed a MultiBand OFDM Transceiver and MAC PCI card, which they have integrated into an MBOA UWB Development Platform based on the MBOA specifications. Many more MultiBand OFDM (MB-OFDM) devices will likely begin to emerge in the near future.

MB-OFDM divides the available spectrum into subbands, with each subband having a bandwidth of 528 MHz. Using OFDM symbols, the information is transmitted by interleaving these symbols across the specified subbands. A time-frequency code is then used to determine which particular frequency and timeslot will be used for a given symbol [39]. These subbands provide the capability to avoid interferers, simply by avoiding a particular band, and also facilitate more effective use of spectrum. Compared with pulse-based systems, MB-OFDM requires less precise timing and can easily be designed to meet the FCC spectral mask.

Even so, some commercially available communications products are based on the traditional pulse-based UWB. Specifically, XtremeSpectrum, recently acquired by Motorola, offers its Trinity Chipset (www.xtremespectrum.com), which includes a medium access controller, a baseband processor, an RF transceiver, an RF front end, and an antenna. The MAC protocol adheres to the 802.15.3 standard. Trinity includes selected data rates of 25, 50, 75, and 100 Mbps and uses biphase modulation. In a demonstration for the FCC, the chipset was used to simultaneously stream multiple high-definition television (HDTV) feeds.

The IEEE is also considering creating another standard, 802.15.4, where UWB is also a potential technology. In general, 802.15.4 would be a standard for low-data rate, low-complexity devices that have an extended battery life. These devices could possibly be used for sensors, interactive toys, smart badges, remote controls, and home automation. (Please visit www.ieee.org for the latest news concerning 802.15.4.)

The Time Domain Corporation provides evaluation and analysis kits based on their PulsON 200 chipset, which includes timing, correlator, and digital baseband chips. These devices are not intended for wireless multimedia or WPAN devices but as investigative tools. The systems are capable of data rates from 75 kbps to 9.6 Mbps. The devices are FCC compliant and have a center frequency of 4.7 GHz with a bandwidth of 3.2 GHz.

Aether Wire & Location, Inc., (www.aetherwire.com/) is developing devices called localizers. These localizers are approximately pager-sized units that transmit a unique pulse waveform as a result of the antennas used in their systems. A single pulse is actually represented by a series of two pulses, in which case the transmission of a 1 is represented by a positive pulse followed by a negative pulse, and the transmission of a 0 is the inverse of this. These devices can provide centimeter accuracy over large distances and are targeted for a variety of applications generally centered around position location. Unlike GPS, which uses triangulation and fixed satellites to locate objects, these localizers are capable of defining their position relative to other localizers. Some of the possible applications for these devices include the location of persons, possibly for military, law enforcement, fire and rescue, or even personal situations, sensor networks, smart homes, smart highways, and inventory control [40].

4.5. Vehicular Radar Systems

Vehicular radar is a promising application for improving driver safety. Sensors can be placed throughout a vehicle, creating a network for collecting valuable information. This information could be used to sense driving conditions, aid in parking, avoid collisions, detect objects in blind spots, aid cruise control, and aid airbag deployment. However, the current frequency range and spectral emissions limits will place constraints on the sensors' operation. As always, a tradeoff will occur between the bandwidth and the range resolution. The closer ranging applications will need a much larger bandwidth (narrower pulses) than the longer ranging applications. For close-range systems, it

would be possible to use PN-coded waveforms for improved ranging [41] (like that described in the radar section). However, in this instance, the ability to isolate the transmit and receive antennas is a concern because it will impact the dynamic range of the system. However, for longer ranging applications, a pulsed-based system with a low duty cycle could be used, which would help with the isolation of the transmit and receive antennas.

As a note, Multispectral Solutions, Inc., has developed a UWB backup sensor that can detect objects from one foot to thirty feet. It has a 500 MHz bandwidth and operates in the 5.4–5.9 GHz band [1], but unfortunately this falls outside of the frequency range specified by the FCC.

5. CONCLUSION

This article provided an introduction into the basic principles of UWB, mainly in the context of impulse radio. Modulation formats, pulse types, the channel, and interference considerations were all discussed in terms of radar and communications systems. The final section of the chapter introduced possible UWB applications as defined by the FCC. UWB presents many exciting possibilities and many technical challenges must still be overcome.

UNDERGROUND PROPAGATION

Y. P. ZHANG
Nanyang Technological
University
Singapore

Underground structures such as subway networks and subterranean cities play important roles in our daily life. Everyday millions of passengers travel through subway networks or thousands of people go shopping in subterranean cities worldwide. Obviously, radio systems are needed in underground structures for normal and emergency operations. Underground structures are either constructed in tunnels or linked with tunnels. To design radio systems for underground structures, the understanding of the propagation of radiowaves in tunnels is essential. Substantial research efforts have been made on this topic and a good knowledge of the involved propagation mechanisms is now available [1]. In the following sections, we introduce underground propagation by considering a straight circular tunnel with axial conductors. We assume that only one axial conductor such as the high-voltage cable is suspended in the tunnel and other axial conductors such as rails and pipes are on the tunnel wall. Despite the mediocre conductivity of the tunnel wall, we can already obtain a good picture of the propagation phenomena by comparing the

tunnel with a coaxial cable, the inner and outer conductors of which are the axial conductor and the tunnel wall. The structure supports the propagation of the coaxial mode that has current flowing along the axial conductor and returning along the tunnel wall. Figure 1 shows the attenuation constant of the coaxial mode as a function of frequency and distance from the axial conductor to the tunnel wall [2]. Note that the attenuation constant of the coaxial mode generally increases with frequency and decreases with the distance from the axial conductor to the tunnel wall. As the attenuation constant of the coaxial mode takes on relatively low values at lower frequencies, radio systems using the coaxial mode propagation at frequencies lower than a few hundred kilohertz have been exploited successfully in various underground mines across the world.

In addition to the coaxial mode, the structure also supports the propagation of waveguide modes when the frequency exceeds the cutoff frequency determined by the tunnel shape and size. The cutoff frequency occurs approximately at tens of MHz for most tunnels. Figure 2 shows the attenuation constant of the fundamental waveguide mode in the tunnel as a function of frequency [3]. As shown, the attenuation constant of the fundamental waveguide mode generally decreases with frequency. It should be mentioned that the axial conductor has no effect whatsoever on the propagation of the fundamental waveguide mode because the electric field has only a circular component. As the attenuation constant of the fundamental waveguide mode takes on relatively low values above the cutoff, it is possible to communicate in the tunnel using the fundamental waveguide mode propagation in the ultra-high frequency (UHF) range. In this process, the antennas of radio systems are mainly coupled to the electromagnetic field of the fundamental waveguide mode. A problem with the propagation of waveguide modes is the disastrous additional attenuation caused by tunnel bends, corners, and crossings, and of vehicles obstructing a large part of the tunnel cross section.

An important but fortuitous discovery in underground propagation was that a coaxial cable with an imperfect

Figure 1. Attenuation constant of the coaxial mode for a single conductor of diameter 1 cm and conductivity 10^9 S/m in the circular tunnel of radius 2 m, $\epsilon_{r1} = 10$, $\sigma = 10^{-2}$ S/m.

Figure 2. Attenuation constant of the fundamental TE_{01} waveguide mode in the circular tunnel of radius 2 m, $\epsilon_{r1} = 10$, $\sigma = 10^{-2}$ S/m.

shield seemed to guide radiowaves continuously in the tunnel [4]. This was the origin of leaky feeder techniques. The leaky feeder supports two coaxial modes in the tunnel. One is between the inner and outer conductors of the leaky feeder and the other between the outer conductor of the leaky feeder and the tunnel wall. Figure 3 shows the attenuation constant of the leaky feeder as a function of frequency. The leaky feeder techniques take advantage of the relatively low attenuation of the coaxial mode of the coaxial leaky feeder itself. Furthermore, the leaky feeder techniques are not sensitive to tunnel bends, corners, and crossings as well as to the presence of local obstacles. As a result, the leaky feeder techniques are widely used to construct radio systems in underground structures.

The propagation of waveguide modes in underground structures is called natural propagation, whereas the propagation of coaxial modes in underground structures is called guided propagation. We focus on natural propagation in

Figure 3. Attenuation constant of the leaky feeder RLC 4.4/11.1.

Section 1 and guided propagation in Section 2. Finally, we summarize the conclusions in Section 3.

1. NATURAL PROPAGATION

By natural propagation we mean that no special-purpose cables are strung in the tunnel to guide radiowaves. Propagation is then that of waveguide modes. Unintentional axial conductors in the tunnel may influence these modes, but this effect is considered as of second order at the frequencies considered here at UHF or above [1].

1.1. Imperfect Waveguide Model

The ambient media of a tunnel at UHF or above behaves as dielectrics with the relative permittivity in the range 5–10. Under these conditions, the tunnel can reasonably be treated as an oversized imperfect waveguide. Therefore, natural propagation will be possible only above a cutoff frequency determined by the tunnel size and shape. As the frequencies of UHF radio signals are higher than the cutoff frequency of the tunnel oversized imperfect waveguide model, the natural propagation of UHF radiowaves is realized through a fundamental and infinite number of higher order waveguide modes. All of these waveguide modes are hybrid and lossy modes because of the tunnel electromagnetic imperfectness. An exact analytical solution to the problem of natural propagation in the rectangular or arched tunnel would lead to extreme complexity. The difficulty lies in the matching of the tangential components of electromagnetic fields on the tunnel walls. Approximate methods are obviously required. Emslie et al. studied natural propagation in the rectangular tunnel and Yamaguchi et al. in the arched tunnel [4,5]. Common to these studies is the fact that the boundary conditions are satisfied approximately because the fields in the corner regions do not enter the derivation of the solutions. We adopt the approach similar to Emslie et al. However, we start with the construction of more general expressions for two scalar components of Hertz electric and magnetic vectors.

The imperfect waveguide model of a straight empty rectangular tunnel is shown in Fig. 4, with its rectangular cross section of sides a and b . The ambient media, assumed to be lossy nonmagnetic homogeneous, have complex wavenumbers

$$K_1 = \omega \sqrt{\mu_1 \epsilon_0 \epsilon_{r1}^*} = \omega \sqrt{\mu_1 \epsilon_0 \left(\epsilon_{r1} - j \frac{\sigma_1}{\omega \epsilon_0} \right)} \quad (1)$$

for the top and bottom walls and

$$K_2 = \omega \sqrt{\mu_2 \epsilon_0 \epsilon_{r2}^*} = \omega \sqrt{\mu_2 \epsilon_0 \left(\epsilon_{r2} - j \frac{\sigma_2}{\omega \epsilon_0} \right)} \quad (2)$$

for the left and right walls. The enclosed space of the imperfect waveguide model of the straight empty rectangular tunnel is filled with air of constitutive parameters μ_0 and ϵ_0 . The rigorous analytical solution to the natural propagation of UHF radiowaves in this imperfect

Figure 4. The imperfect waveguide model of a straight empty rectangular tunnel.

waveguide model of the straight empty rectangular tunnel would be extremely complex. However, the approximate analytical solution can be obtained if the transverse dimensions are much larger than the free space wavelength. This condition is usually satisfied in actual tunnels for UHF radiowaves. Thus, most of the power travels in the model interior region, a small part travels in regions K_1 and K_2 , and even less travels in the four-corner regions. Consequently, only a tolerable error will be introduced into the solution of the propagation when we neglect the fields in the corner regions.

For the present problem, it is convenient to describe the fields in terms of y components of electric Π_y^e and magnetic Π_y^m Hertz vectors. Except the source, the Hertz vectors satisfy the Helmholtz equation.

$$\nabla^2 \Pi_y^e + K_i^2 \Pi_y^e = 0 \quad (3)$$

$$\nabla^2 \Pi_y^m + K_i^2 \Pi_y^m = 0 \quad (4)$$

where K_i is complex wavenumber.

Once the Π_y^e and Π_y^m are determined, the related electromagnetic fields can be described as follows [1]:

$$E_x = \frac{\partial^2 \Pi_y^e}{\partial y \partial x} + j\omega\mu_i \frac{\partial \Pi_y^m}{\partial z} \quad (5)$$

$$E_y = \left(K_i^2 + \frac{\partial^2}{\partial y^2} \right) \Pi_y^e \quad (6)$$

$$E_z = \frac{\partial^2 \Pi_y^e}{\partial y \partial z} - j\omega\mu_i \frac{\partial \Pi_y^m}{\partial x} \quad (7)$$

$$H_x = \frac{\partial^2 \Pi_y^m}{\partial x \partial y} - j\omega\epsilon_i \frac{\partial \Pi_y^e}{\partial z} \quad (8)$$

$$H_y = \left(K_i^2 + \frac{\partial^2}{\partial y^2} \right) \Pi_y^m \quad (9)$$

$$H_z = \frac{\partial^2 \Pi_y^m}{\partial y \partial z} + j\omega\epsilon_i \frac{\partial \Pi_y^e}{\partial x} \quad (10)$$

We will first deal with the interior region of the imperfect waveguide model of the straight empty rectangular tunnel. The required forms for the y components of Hertz vectors are

$$\Pi_y^e = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} A_{mn} \text{Sin}(k_{xm}x) \text{Sin}(k_{yn}y) \exp(-\Gamma_{mn}z) \quad (11)$$

$$\Pi_y^m = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} A_{mn}^* \text{Cos}(k_{xm}x) \text{Cos}(k_{yn}y) \exp(-\Gamma_{mn}z) \quad (12)$$

For the region ($x \geq \frac{a}{2}$), expressions for the y components of Hertz vectors are thus

$$\Pi_y^e = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} B_{mn} \exp(\gamma_{xm}x) \text{Sin}(k_{yn}y) \exp(-\Gamma_{mn}z) \quad (13)$$

$$\Pi_y^m = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} B_{mn}^* \exp(\gamma_{xm}x) \text{Cos}(k_{yn}y) \exp(-\Gamma_{mn}z) \quad (14)$$

whereas for the region ($y \geq \frac{b}{2}$),

$$\Pi_y^e = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} C_{mn} \text{Sin}(k_{xm}x) \exp(\gamma_{yn}y) \exp(-\Gamma_{mn}z) \quad (15)$$

$$\Pi_y^m = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} C_{mn}^* \text{Cos}(k_{xm}x) \exp(\gamma_{yn}y) \exp(-\Gamma_{mn}z) \quad (16)$$

where the above y components of Hertz vectors are functions of Γ_{mn} , which appears in the following equations:

$$k_{xm}^2 + k_{yn}^2 - \Gamma_{mn}^2 = K_0^2 \quad (17)$$

$$k_{xm}^2 + \gamma_{yn}^2 - \Gamma_{mn}^2 = K_1^2 \quad (18)$$

$$\gamma_{xm}^2 + k_{yn}^2 - \Gamma_{mn}^2 = K_2^2 \quad (19)$$

where $K_0 = \omega\sqrt{\mu_0\epsilon_0}$. Matching the tangential field components on the walls of the imperfect waveguide model of the straight empty rectangular tunnel, we can derive

$$\begin{aligned} k_{xm} \text{tg} \left(\frac{k_{xm}a}{2} \right) &= -\frac{\gamma_{xm}(\Gamma_{mn}^2 - k_{xm}^2)\mu_1}{(\Gamma_{mn}^2 + k_{xm}^2)\mu_0} \\ &\approx -\frac{jK_0\mu_1\sqrt{\epsilon_{r1}^* - 1}}{\epsilon_{r1}^*\mu_0} \end{aligned} \quad (20)$$

$$\begin{aligned} k_{xm} \text{Ctg} \left(\frac{k_{xm}a}{2} \right) &= -\frac{\gamma_{xm}(\Gamma_{mn}^2 - k_{xm}^2)\epsilon_1}{(\Gamma_{mn}^2 + k_{xm}^2)\epsilon_0} \\ &\approx -\frac{jK_0\epsilon_1\sqrt{\epsilon_{r1}^* - 1}}{\epsilon_{r1}^*\epsilon_0} \end{aligned} \quad (21)$$

$$k_{yn} \text{tg} \left(\frac{k_{yn}b}{2} \right) = -\frac{\gamma_{yn}\mu_0}{\mu_2} \approx -\frac{jK_0\mu_0\sqrt{\epsilon_{r2}^* - 1}}{\mu_2} \quad (22)$$

$$k_{yn} \text{Ctg} \left(\frac{k_{yn}b}{2} \right) = -\frac{\gamma_{yn}\epsilon_0}{\epsilon_2} \approx -\frac{jK_0\epsilon_0\sqrt{\epsilon_{r2}^* - 1}}{\epsilon_2} \quad (23)$$

Equations (20) and (22) are the propagation modal equations for E_{mn}^h modes. For these types of modes, the main electric field component is the horizontal E_x , whereas the vertical electric field component E_y is zero. Similarly, Equations (21) and (23) are the propagation modal equations for E_{mn}^v modes. For these types of modes, the main electric field component is the vertical E_y , whereas the horizontal electric field component E_x is zero.

Both analytical and numerical solutions can be obtained for the propagation modal Equations (20)–(22), and (23). Using the procedures given in [6], we get

$$k_{xm} \approx \frac{m\pi}{a} + j \frac{2\pi m \epsilon_{r1}^*}{K_0 a^2 \sqrt{\epsilon_{r1}^* - 1}} \tag{24}$$

$$k_{yn} \approx \frac{n\pi}{b} + j \frac{2\pi n}{K_0 b^2 \sqrt{\epsilon_{r2}^* - 1}} \tag{25}$$

for E_{mn}^h modes, and

$$k_{xm} \approx \frac{m\pi}{a} + j \frac{2\pi m}{K_0 a^2 \sqrt{\epsilon_{r1}^* - 1}} \tag{26}$$

$$k_{yn} \approx \frac{n\pi}{b} + j \frac{2\pi n \epsilon_{r2}^*}{K_0 b^2 \sqrt{\epsilon_{r2}^* - 1}} \tag{27}$$

for E_{mn}^v modes. These results show that k_{xm} and k_{yn} are complex. The first terms are the same as for a waveguide with perfect electric walls. The small second terms account for the energy loss absorbed by the walls of the imperfect waveguide model of the straight empty rectangular tunnel.

Substituting Eqs. (24) and (25) into Eq. (17), we obtain the propagation constants for E_{mn}^h modes as

$$\begin{aligned} \Gamma_{mn}^h &= \alpha_{mn}^h + j\beta_{mn}^h \\ &\approx \sqrt{m^2 \left[\frac{\pi}{a} + j \frac{2\pi \epsilon_{r1}^*}{K_0 a^2 \sqrt{\epsilon_{r1}^* - 1}} \right]^2 + n^2 \left[\frac{\pi}{b} + j \frac{2\pi}{K_0 b^2 \sqrt{\epsilon_{r2}^* - 1}} \right]^2} - K_0^2 \end{aligned} \tag{28}$$

$$\begin{aligned} \alpha_{mn}^h &\approx \frac{2(m\pi)^2}{K_0^2 a^3} \operatorname{Re} \left(\frac{\epsilon_{r1}^*}{\sqrt{\epsilon_{r1}^* - 1}} \right) \\ &\quad + \frac{2(n\pi)^2}{K_0^2 b^3} \operatorname{Re} \left(\frac{1}{\sqrt{\epsilon_{r2}^* - 1}} \right) \text{ Np/m} \end{aligned} \tag{29}$$

$$\beta_{mn}^h \approx \sqrt{K_0^2 - \left(\frac{m\pi}{a} \right)^2 - \left(\frac{n\pi}{b} \right)^2} \tag{30}$$

Similarly, substituting Eqs. (26) and (27) into Eq. (17) gives the propagation constants for E_{mn}^v modes as

$$\begin{aligned} \Gamma_{mn}^v &= \alpha_{mn}^v + j\beta_{mn}^h \\ &\approx \sqrt{m^2 \left[\frac{\pi}{a} + j \frac{2\pi}{K_0 a^2 \sqrt{\epsilon_{r1}^* - 1}} \right]^2 + n^2 \left[\frac{\pi}{b} + j \frac{2\pi \epsilon_{r2}^*}{K_0 b^2 \sqrt{\epsilon_{r2}^* - 1}} \right]^2} - K_0^2 \end{aligned} \tag{31}$$

$$\begin{aligned} \alpha_{mn}^v &\approx \frac{2(m\pi)^2}{K_0^2 a^3} \operatorname{Re} \left(\frac{1}{\sqrt{\epsilon_{r1}^* - 1}} \right) \\ &\quad + \frac{2(n\pi)^2}{K_0^2 b^3} \operatorname{Re} \left(\frac{\epsilon_{r2}^*}{\sqrt{\epsilon_{r2}^* - 1}} \right) \text{ Np/m} \end{aligned} \tag{32}$$

$$\beta_{mn}^v \approx \sqrt{K_0^2 - \left(\frac{m\pi}{a} \right)^2 - \left(\frac{n\pi}{b} \right)^2} \tag{33}$$

These analytical results show that the attenuation constants of both E_{mn}^h and E_{mn}^v modes are directly proportional to the square of the mode order and are inversely proportional to the square of frequency and to the cube of the imperfect waveguide model size of the straight empty rectangular tunnel, and the phase constants are almost identical to those of the perfect conducting waveguide. Now assuming that the complex wavenumbers of the ambient media of the imperfect waveguide model of the straight empty rectangular tunnel are the same $K_1 = K_2$, we note from Eqs. (29) and (32) that E_{11}^h and E_{11}^v modes have the minimum attenuation for the case of $a > b$ and $b > a$, respectively. Thus, let an electric type transmit antenna oriented in the X direction excite the natural propagation of the imperfect waveguide model of the straight empty rectangular tunnel, the E_{11}^h mode will represent the field distribution in the far region of the imperfect waveguide model of the straight empty rectangular tunnel as a is larger than b for most tunnels. The E_{11}^h wave is the fundamental mode of the imperfect waveguide model of the straight empty rectangular tunnel.

Knowing the propagation of waveguide modes does not allow a calculation of the strength of radio signals in the imperfect waveguide model of the straight empty rectangular tunnel. We also need to know the excitation of the transmit antenna and the reception of the receive antenna to these modes. The excitation or reception of an antenna to these modes can be calculated as follows. Consider the antenna located at point (x, y) in the cross section of the imperfect waveguide model of the straight empty rectangular tunnel. The power that the antenna receives or transmits is given by

$$P_{mn} = A_e S_{mn}(x, y) \tag{34}$$

where A_e is the effective area of the antenna and $S_{mn}(x, y)$ is Poynting's vector. One can express A_e as

$$A_e = \frac{G\lambda^2}{4\pi} \tag{35}$$

and $S(x,y)$ as

$$S_{mn}(x,y) = \frac{1}{2} \eta_0 \text{Cos}^2\left(\frac{m\pi x}{a}\right) \text{Cos}^2\left(\frac{n\pi y}{b}\right) \quad (36)$$

where G is the antenna gain, λ is the wavelength, and η_0 is the free space characteristic impedance. The power, calculated as the flux of this vector through the cross section of the imperfect waveguide model of the straight empty rectangular tunnel, is given by

$$P_{mn} = \frac{\eta_0 ab}{4} \quad (37)$$

The excitation or reception loss of the antenna is defined as

$$\frac{P_{mn}}{P} = \frac{2\pi ab}{\lambda^2 G} \text{Cos}^{-2}\left(\frac{m\pi x}{a}\right) \text{Cos}^{-2}\left(\frac{n\pi y}{b}\right) \quad (38)$$

It should be mentioned that Eq. (38) does not remain accurate when the antenna is located close to the tunnel wall. Figure 5 shows the measured natural propagation together with the calculated one from the imperfect waveguide model. The measurement was made at 900 MHz in a tunnel of 4 m wide and 3.5 m high. As shown, the imperfect waveguide model predicts the general trend of the strength of the radio signal.

It is thus, in principle, easy to design radio systems for unobstructed straight tunnels. A safety margin should be included to account for standing waves. These cannot be avoided in practice: they are because of the existence of several modes traveling with different phase velocities [1]. It is far more difficult to predict the undesirable mode conversion caused by discontinuities such as bends, corners, and vehicles in tunnels and changes in cross sections. It is found that they increase the propagation loss of waveguide modes. The calculation of this additional propagation loss is extremely difficult by the imperfect waveguide theory.

Figure 5. Measured natural propagation together with the calculated from the imperfect waveguide model.

1.2. Geometrical Optical Model

The problem of the natural propagation of radiowaves at UHF or above can also be solved with the geometrical optics. The geometrical optical model has been developed by Mahmoud and Wait for a straight empty rectangular tunnel [7]. Hwang et al. and Zhang et al. extended the geometrical optical approach to branched tunnels [8,9] and Didascalou et al. to arbitrarily shaped tunnels [10]. Chen and Jeng considered the effects of traffic vehicles in tunnels [11] and Pallares et al. the transition from land propagation to tunnel propagation [12]. By assuming that the radiowaves are locally plane waves, the Fresnel reflection coefficients of vertically and horizontally polarized plane waves incident on the tunnel walls can be used. Thus, the natural propagation is achieved via a direct ray and many reflected rays caused by the tunnel walls. The tunnel wall reflection points of the rays can be easily determined by adopting the image principle of geometrical optics. As the contribution of a reflected ray to the propagation is weighted by its reflection coefficient, it will become weaker as the reflected ray undergoes multiple reflections. In other words, only those images in the vicinity of the tunnel walls are significant for the propagation in the far-field region. The fields are obtainable from any two suitable scalar potentials. Based on the problem to be solved, we choose Π_x^e , Π_y^e as two scalar functions, where Π_x^e and Π_y^e are x and y components of Hertz electric vectors, respectively [7]. They are given by

$$\begin{aligned} & \begin{bmatrix} \Pi_x^e(x,y,z) \\ \Pi_y^e(x,y,z) \end{bmatrix} \\ &= \left(\frac{1}{4\pi j \omega \epsilon_0} \right) \sum_l \cdot \sum_i \left[\frac{\exp(-jK_0 r_{li})}{r_{li}} \right] [M_{li}] \begin{bmatrix} S_x \\ S_y \end{bmatrix} \end{aligned} \quad (39)$$

where S_x and S_y are the horizontal and vertical dipole moments of the source located at $(x_s, y_s, 0)$, l and i are integers representing the multiple images of the source in any arbitrary manner, and M_{li} is the product of the reflection coefficients of the images taking into account the coupling between the horizontally and vertically polarized rays. Equation (39) is an exact equation provided that the geometrical ray approximation is valid.

$$r_{li} = [z^2 + (x - x_l)^2 + (y - y_i)^2]^{1/2} \quad (40)$$

(x_l, y_i) are the coordinates of the $l - i$ image, where

$$x_l = 2ma \pm x_0, \quad m = -\infty \text{ to } \infty \quad (41)$$

$$y_i = 2nb \pm y_0, \quad m = -\infty \text{ to } \infty \quad (42)$$

and $[M_{li}]$ is the product of all the reflection coefficient matrices involved in producing the $l - i$ image. If only the field components of major polarization are of interest, the coupling between the horizontally and vertically polarized rays can be neglected, as a result, Equation (39) is

approximated as

$$\begin{aligned} \begin{bmatrix} \Pi_x^e(x, y, z) \\ \Pi_y^e(x, y, z) \end{bmatrix} &\cong \left(\frac{1}{4\pi j\omega\epsilon_0} \right) \sum_l \cdot \sum_i \frac{\exp(-jK_0 r_{li})}{r_{li}} \\ &\times \begin{bmatrix} R_H^{n_l} & R_V^{n_l} \\ R_V^{n_l} & R_H^{n_l} \end{bmatrix} \begin{bmatrix} S_x \\ S_y \end{bmatrix} \end{aligned} \quad (43)$$

where R_H and R_V are the Fresnel reflection coefficients for horizontal and vertical polarizations, respectively, n_l and n_i are the numbers of reflection on the vertical and horizontal tunnel walls, respectively, involved in forming the $(l - i)$ image of the antenna. The respective horizontal and vertical electric field components are then obtained by

$$E_x(x, y, z) = \left(K_0^2 + \frac{\partial^2}{\partial x^2} \right) \Pi_x^e + \frac{\partial^2 \Pi_y^e}{\partial x \partial y} \quad (44)$$

$$E_y(x, y, z) = \left(K_0^2 + \frac{\partial^2}{\partial x^2} \right) \Pi_y^e + \frac{\partial^2 \Pi_x^e}{\partial x \partial y} \quad (45)$$

Modern radio systems measure the strength of radio signals in power. Knowing that the antenna radiates P_t power in the tunnel space, the dipole moments of the antenna are given by

$$\begin{aligned} \begin{bmatrix} S_x \\ S_y \end{bmatrix} &= I \frac{\cos(\omega t + \phi)}{\omega} L \begin{bmatrix} \hat{x} \\ \hat{y} \end{bmatrix} \\ &= \sqrt{\frac{P_t}{60\pi}} \frac{\cos(\omega t + \phi)}{\omega} \begin{bmatrix} \hat{x} \\ \hat{y} \end{bmatrix} \end{aligned} \quad (46)$$

where L is the length of the antenna. For half-wavelength dipoles used as both the distributed and received antennas, the received power for horizontal and vertical polarization can be expressed as

$$\begin{aligned} \begin{bmatrix} P_{rH}(x, y, z) \\ P_{rV}(x, y, z) \end{bmatrix} \\ = \left(\frac{\lambda}{4\pi} \right)^2 \left| \sum_l \cdot \sum_i \left[\frac{\exp(-jK_0 r_{li})}{r_{li}} \right] \begin{bmatrix} R_H^{n_l} & R_V^{n_l} \\ R_V^{n_l} & R_H^{n_l} \end{bmatrix} \right|^2 \sqrt{P_t} \end{aligned} \quad (47)$$

If directional antennas are used, antenna gain must be taken into consideration. Generally, the geometrical optical approach will give the propagation attenuation constant in a numerical form. Figure 6 shows the measured natural propagation together with the calculated one from the geometrical optical model. The measurement was made at 900 MHz in a tunnel of 9 m wide and 5 m high. As shown, the geometrical optical model predicts not only

Figure 6. Measured natural propagation together with the calculated from the geometrical optical model.

the general trend but also the rapid variation of the strength of the radio signal.

1.3. Statistical Model

Natural propagation of multiple waveguide modes in underground structures produces the random signal fluctuations [13]. The signal fluctuations can be decomposed into the slow fading engendered by the global mode variations and the fast fading caused by the interference of local modes. The slow fading in many propagation environments has been found to follow theoretical lognormal distribution. The lognormal probability density on dB terms is given in function of the mean η and of the standard deviation δ as

$$P(r) = \frac{1}{\delta\sqrt{2\pi}} \exp\left(-\frac{(r - \eta)^2}{2\delta^2}\right) \quad (48)$$

The fast fading has been found to follow Rician or Rayleigh. The Rice probability density on dB terms is given by

$$\begin{aligned} P(r) &= \frac{1}{8.68\alpha^2} \exp\left(\frac{r}{4.34} - \frac{(d^2 + \exp(r/4.34))}{2\alpha^2}\right) \\ &\times I_0\left(\frac{d}{\alpha^2} \exp\left(\frac{r}{4.34}\right)\right) \end{aligned} \quad (49)$$

where $I_0(x)$ is a modified Bessel function of order zero and d is the fundamental mode signal. This fundamental mode signal can decrease the standard deviation of the received signal envelope if it increases relative to higher order mode signals. When $d=0$, Equation (49) becomes the Rayleigh probability density. The mean of the Rice probability density is expressed as

$$\eta = \exp(-y)\alpha\sqrt{\frac{\pi}{2}}[(1+2y)I_0(y) + 2yI_1(y)] \quad (50)$$

where $I_1(y)$ is a modified Bessel function of order 1 and $y = d^2/4x^2$. The standard deviation is expressed as

$$\delta = \sqrt{d^2 + 2x^2 - 1} \quad (51)$$

In Equations (50) and (51), η and δ are known after we have statistically analyzed the experimental data files. Hence, simultaneous solution to Equations (50) and (51) will find the parameters α and d of the theoretical Rice probability density. The impact of conversion of higher order modes to the fundamental mode signal can be described by the ratio of the fundamental mode signal to higher order mode signals as

$$K = 10 \log(d^2/2\delta^2) \quad (52)$$

In addition, another key parameter to describe the slow fading is power loss that generally is represented by z^n . z is the separation between the transmit and receive antennas, and n is the loss exponent to be determined experimentally. The analysis of natural propagation measurements shows $n < 2$ for line-of-sight paths and $n > 2$ for non-line-of-sight paths in underground structures.

The slow fading statistics deals with the remaining slow variation after removal of the power distance dependence. It is a useful indicator of estimate of the coverage and cochannel interference. Many radio propagation environments predicted that the slow fading would follow the lognormal probability distribution as expressed in Equation (48). However, our measurements conducted in various underground structures show a consistent deviation from the lognormal probability distribution as presented in Fig. 7. The standard deviation is 4.7 dB. This deviation becomes worse when the signal level is moved further away from its median value. It indicates that the fundamental mode and the higher order modes are closely associated in an enclosed space of underground structures

Figure 7. Cumulative distribution of natural propagation slow fading.

and are not randomly independent as in other radio propagation environments.

The fast fading statistics deals with the remaining rapid variation after removal of the slow fading. It is useful to determine the safety margin for link budget calculation. Our measurements indicate that the fast fading occurs in all regions. However, within the short-distance region where the receive antenna is near the transmit antenna, the received signal consistently shows more rapid and deeper fluctuations. The fast fading is strongly related to the structure dimensions and the frequency. The fast and deep fading cover a longer distance for either the case of larger dimensional underground structure or higher frequency. These results can be explained as follows. In the short-distance region, there are more significant higher order modes that cause large fluctuations. In the long-distance region, as the higher order modes become less significant, only the fundamental mode, the direct incident signal, contributes the most to the received signal. Therefore, the fast fading diminishes as the receiver is moving farther away from the transmitter. Higher frequencies and larger dimensions will generate more significant higher order modes. As a result, the fading region will extend farther. Figure 8 shows that the fast fading in the straight empty sections of a tunnel is correlated well to Rician distribution. Figure 9 shows that the fast fading in the curved empty sections does not closely fit Rayleigh distribution. Further analysis also revealed that there was some correlation between Tx-Rx separation and the fast fading distribution in the straight empty sections of tunnels.

2. GUIDED PROPAGATION

By guided propagation we mean that special-purpose cables such as leaky feeders are strung in the tunnel to guide radiowaves. Leaky feeders can be classified into coupled and radiated types. A coupled-type coaxial leaky

Figure 8. Cumulative distribution of natural propagation fast fading in straight sections of a tunnel.

Figure 9. Cumulative distribution of natural propagation fast fading in curved sections of a tunnel.

feeder has either a longitudinal slot or small apertures in the outer conductor with spacing much smaller than the operating wavelength, whereas a radiated-type coaxial leaky feeder has periodic apertures in the outer conductor with spacing comparable with the operating wavelength.

2.1. Diffuse Model

A coupled-type leaky feeder is shown in Fig. 10, in which there are small apertures situated in the leaky feeder outer conductor. The interval distance d between two adjacent apertures is much smaller than the operational wavelength λ . For the coupled-type leaky feeder, radiation depends on scattering of the local fields by nearby random objects. To look for a detailed model of scattering from the leakage fields of the coupled-type leaky feeder is not promising because underground structures are so varied. Instead, we can assume heuristically that each small aperture radiates diffusely through a cylindrical surface of some radius larger than the physical radius of the coupled-type leaky feeder, but small compared with the distance to the receiver [14]. The mean power flow per unit solid angle in a given direction from a surface element is proportional to $\text{Cos } \gamma$, where γ is the angle of emission with respect to the normal. In photometry, this assumption is called *Lambert's cosine law*, and it is satisfied approximately by many diffusely emitting surfaces. We use it here with no further justification than analytic convenience. The diffuse model undertakes to calculate the median power level over a region whose dimensions are comparable with a wavelength. Local fluctuations in the field amplitude are expected to be Rayleigh distributed, as would

Figure 10. A coupled-type leaky feeder.

result from scattering of leakage fields by nearby inhomogeneities located randomly along the couple-type leaky feeder.

The diffuse model follows that the power flow per unit solid angle from a thin, Lambert's law coupled-type leaky feeder element is proportional to

$$\Phi_1(\theta) = \text{Sin}(\theta) \tag{53}$$

where θ is the angle between the viewing direction and the coupled-type leaky feeder axis. The equivalent electric field generated at distance r by a thin coupled-type leaky feeder element is proportional to

$$E = \frac{\sqrt{\text{Sin}\theta}}{r} \tag{54}$$

The standard coupling loss C of a leaky feeder is defined as

$$C = 10 \log_{10}(P_{\text{feeder}}/P_{\text{dipole}}) \tag{55}$$

where P_{dipole} is the median power received by a half-wave dipole moved along a path parallel to and at a distance D from a long straight leaky feeder carrying power P_{feeder} . The distance D is conventionally 2 m. It is easy to relate the standard coupling loss to the power radiated per unit length of the diffuse model. Let P_{dipole} be the power received by a half-wave dipole parallel to and at a distance D from the axis of a long diffuse radiator having negligible attenuation over distances comparable with D . Let H be the power radiated per unit length in the polarization to which the dipole responds (typically a diffuse source radiates equal power in both polarizations). The power-transmitting pattern $\Phi_1(\theta)$ of an element of the coupled-type leaky feeder is given by Equation (65), and the power-receiving pattern of the half-wave dipole is

$$\Phi_2(\theta) = \frac{\text{Cos}^2[(\pi/2)\text{Sin}\theta]}{\text{Sin}^2\theta} \tag{56}$$

The power received by the dipole is

$$P_{\text{dipole}} = \frac{\Pi\lambda^2}{N_1N_2} \int_{-\infty}^{\infty} \frac{\Phi_1\Phi_2}{r^2} dx \tag{57}$$

where $x = DCot\theta$, $r = DCsc\theta$, and the normalized constants are

$$N_{1,2} = 2\pi \int_0^\pi \Phi_{1,2}(\theta)\text{Sin}\theta d\theta \tag{58}$$

A straight calculation gives

$$P_{\text{dipole}} = (8\Pi/\pi D)(\lambda/4\pi)^2 \tag{59}$$

Equations (55) and (59) relate the feeder power, the standard coupling loss, and the effective radiated power per unit length. If the input power to the leaky feeder is P_{input} and the leaky feeder has a matched termination, then the

radiated power per unit length is

$$\Pi = (\pi D/8)(4\pi/\lambda)^2 10^{-C/10} \exp(-2\alpha z) P_{input} \quad (60)$$

at a distance z from the feed point, where α is the attenuation constant in Np/m. Note that in the diffuse model, the coupling loss depends on the orientation of the receiving dipole. If “axial” denotes the orientation in which the dipole parallels to the leaky feeder axis, “radial” denotes the orientation in which the dipole points directly toward the leaky feeder axis, and “transverse” denotes the orientation perpendicular to both of these, it turns out that

$$\frac{P_{radial}}{P_{axial}} = \frac{\int_0^{2\pi} \text{Cos}^2[(\pi/2)\text{Sin}\theta](\text{Sin}\theta/\text{Cos}^2\theta) d\theta}{\int_0^{2\pi} \text{Cos}^2[(\pi/2)\text{Cos}\theta](\text{Sin}\theta/\text{Sin}^2\theta) d\theta} \quad (61)$$

$$= 0.456 \text{ or } -3.41 \text{ dB}$$

and

$$\frac{P_{transversel}}{P_{axial}} = \frac{\int_0^{2\pi} \text{Sin}\theta d\theta}{\int_0^{2\pi} \text{Cos}^2[(\pi/2)\text{Cos}\theta](\text{Sin}\theta/\text{Sin}^2\theta) d\theta} \quad (62)$$

$$= 1.64 \text{ or } 2.15 \text{ dB}$$

We shall use the axial dipole as a reference and assume that the dependence on orientation is less than the other uncertainties of the diffuse model.

2.2. Geometrical Optical Model

A radiated-type leaky feeder is shown in Fig. 11. It is seen that periodic slots situated in the leaky feeder outer conductor exist. The interval distance d between two adjacent slots is comparable with the operational wavelength λ . The frequency band, where the radiated mode exists, is given by the inequality

$$(\sqrt{\epsilon_r} - 1)d \leq \lambda \leq (\sqrt{\epsilon_r} + 1)d \quad (63)$$

where ϵ_r is the relative permittivity of the dielectric material inside the leaky feeder. Within this band, the radiation mechanism is comparable with the radiation of an array of magnetic dipoles oriented along the leaky feeder axis [15]. The azimuthal component of the electric field radiated by the leaky feeder in free space is given by

$$E_\phi = \sum_{i=1}^N E_i \text{Sin}(\theta_i) \frac{\exp(-jK_0 r_i - jK_0 \sqrt{\epsilon_r}(i-1)d)}{r_i} \quad (64)$$

Figure 11. A radiated-type leaky feeder.

where E_i is the field amplitude of the i th slot and r_i is the distance from the i th slot to the observation point. As for the leaky feeder installed in an underground structure, the electric field produced by the leaky feeder will be modified by the existence of the structure walls. The effects of the structure walls on the electric field are calculated according to the image principle.

2.3. Statistical Model

Guided propagation of leaky feeders in underground structures involves the random mechanism. We have to resort to a statistical model for measurements. Guided propagation from a leaky feeder in underground structures can be expressed by the equation

$$P_r = P_t - \alpha z - L_c - L_v - L_b - 10n \log_{10}(D) \quad (65)$$

where P_r is the received power, P_t is the transmitted power, z is the distance along the leaky feeder to the point nearest the receiver, α is the attenuation constant of the leaky feeder, L_c is the coupling loss referenced to 1 m radial distance from the cable, L_v is the variability in coupling loss, L_b is the loss factor because of blockage, D is the distance between the cable and the receiver, and n is the loss exponent. The aim of the measurements has been to quantify the unknown parameters in this equation.

Typical plots of guided propagation by the coupled-type leaky feeder 512RC8R at 2 GHz are shown in Figs. 12 and 13 for the measurements in the corridor and room of a basement, respectively. In both cases, the received signal levels fluctuate over the whole routes. Also, the received signal levels are stronger in the corridor than those in the room, which is because the received signal traveled a shorter radial distance in the corridor, whereas the received signal not only propagated a longer radial distance but also underwent the wall penetration loss into the room. For the corridor case, it is noted that the received signal levels appear stronger along the middle route than those along the side routes. The route-dependent difference in the received signal levels is mainly attributed to the coupling pattern of the leaky feeder. As the slot of the

Figure 12. Guided propagation by the coupled-type leaky feeder 512RC8R at 2 GHz in the corridor of a basement.

Figure 13. Guided propagation by the coupled-type leaky feeder 512RC8R at 2 GHz in the room of a basement.

leaky feeder was installed facing downward, it resulted in the occurrence of the downward maximum coupling; therefore, the received signal levels were observed stronger along the middle route. For the room case, it is evident that a slight decrease exists in the received signal levels along a route parallel to the axis of the leaky feeder; however, a considerable decay exists in the received signal levels along a route radial to the axis of the leaky feeder. The quantified parameters for Equation (65) from the measurements are listed in Table 1.

The fading statistics are examined. Analysis of the slow fading components of the measurements shows that they basically fit the lognormal distribution in both directions, parallel and radial, to the leaky feeder, which can be seen from Fig. 14. The solid and dot curves represent the lognormal and experimental distributions with the mean of 0.0 dB and the standard deviation of 1.8 dB for the direction parallel to the leaky feeder. The dash-dot and asterisk curves stand for the lognormal and experimental distributions with the mean of -0.06 dB and the standard deviation of 2.5 dB for the direction radial to the leaky feeder. Analysis of the fast fading components of the measurements shows that they follow the Rayleigh distribution in the direction parallel to the cable and the Rician distribution in the direction radial to the leaky feeder, which can be seen from Fig. 15. The solid and dot curves express the Rayleigh and experimental distributions with the mean value of -0.02 dB and the standard deviation of 6.0 dB for the direction parallel to the leaky feeder. The dash-dot and asterisk curves depict the Rician and experimental distributions with a K value of 4.0 dB for the room case.

Table 1. The Parameters Obtained from the Measurement

L_c (dB)	L_v (dB)	L_b (dB)	α (dB/100m)	n
89.2	Min. -6.10	8.6	16	Min. 0.51
	Max. 6.80 (brick wall)			Max. 1.15
	Mean -0.06			Mean 0.90
	Std. 2.52			Std. 0.24

3. CONCLUSIONS

Both natural and guided propagation in underground structures have been covered in this article. Natural propagation is that of waveguide modes or multiple rays. The fundamental mode is important for long-distance propagation as it suffers the least attenuation, whereas higher order modes are problematic as they cause fluctuation because of addition or subtraction of these modes. As the contribution of a reflected ray to the propagation is weighted by its reflection coefficient, and will become weaker as the reflected ray undergoes multiple reflections. Thus, only the direct ray and those rays with fewer reflections are significant for long-distance propagation. Natural propagation suffers from the disastrous additional attenuation caused by bends, corners, and crossings, and vehicles in underground structures. Guided propagation is that of

Figure 15. Cumulative distribution of guided propagation fast fading.

coaxial modes, and mode conversion plays an important role. Guided propagation takes advantage of the relatively low attenuation of the coaxial mode of the leaky feeder itself. Furthermore, guided propagation is not sensitive to bends, corners, and crossings as well as to the presence of local obstacles. As a result, guided propagation finds wide application in underground structures to construct radio systems.

1. INTRODUCTION

Keller's geometrical theory of diffraction (GTD) [1,2] constitutes a major breakthrough for solving problems of electromagnetic (EM) radiation and scattering at high frequencies. The GTD can also be applied to solving acoustic and elastic wave problems; however, only the EM case is discussed here. At high frequencies (or short wavelengths), the radiating/scattering object becomes large in terms of the wavelength, and as a result, conventional numerical solution methods, as well as convergent eigenfunction expansion-based solutions, respectively, which are best suited for low to moderately high frequencies, become highly inefficient and even intractable for treating electrically large problems. The reason for the latter difficulties stems from the fact that such convergent expansions and numerical methods are generally based on exact formulations that must satisfy EM field conditions of self-consistency in a global sense, i.e., over the entire radiating/scattering object at once, rather than in a highly local sense as done in the high-frequency approximation. It is noted that the property of localization of EM radiation, propagation, scattering, and diffraction phenomena at high frequencies will become more apparent later in Section 2.

Recently, the development of fast solvers for significantly increasing the efficiency of numerical methods in solving large problems has met with some success. However, for truly large problems, asymptotic high-frequency methods in general, and especially ray methods such as the GTD and its uniform version, still remain the most useful analysis tools. More importantly, asymptotic high-frequency methods, and in particular the GTD, are probably the only methods that can directly provide a valuable physical insight into the radiation and scattering mechanisms. The latter property of the GTD is extremely important not only for gaining a clear physical understanding of the wave radiation and scattering phenomena, but it, in turn, is important for providing useful design information in dealing with problems of radiation and scattering in engineering applications. The latter physical insight is provided by the GTD because it describes the phenomena of wave radiation/scattering locally in terms of rays that arrive at the observer after originating from certain localized or critical points (or flash points) on a radiating/scattering object. In most practical applications, such objects can be quite complex. These GTD rays are associated firstly with the incident, reflected and transmitted rays of classic geometrical optics (GO), and secondly with an additional new class of diffracted rays that have been introduced by Keller [1] into the GTD via a generalization of Fermat's principle.

The GTD [1,3] explained, for the first time, the phenomena of high-frequency diffraction systematically in terms of rays. Prior to Keller's GTD, which he introduced in the 1950s, it was Thomas Young [4] who in 1802 attempted to explain light diffraction by a slit in terms of rays that actually originated at the edges of the slit. However, the early ideas of Young on the use of rays to explain diffraction by a slit were eventually superseded in 1816 by Fresnel's approach [5] in which he employed a wave theory (or Huygen-Fresnel principle) that explained slit diffraction more accurately. Thus, Keller's GTD revives Young's ideas, and it provides a very systematic and modern treatment of diffraction by including diffracted rays that exist in addition to the rays of classic GO.

The above GTD rays may be visualized through a simple example in Fig. 1 as follows. The primary source at Q' in Fig. 1 launches rays radially from Q' in all directions. Only for simplicity, this source is assumed to be a point source; however, the ideas presented below can be directly extended to a source of finite extent. When such a point source radiates in the presence of an impenetrable object as shown in Fig. 1, then the GO rays incident from Q' , which directly impinge on the smooth part of the objects, but which do not graze the object, are transformed into a set of GO reflected rays. For an observer at $P=P_1$ or $P=P_2$ in the lit region, where the source is directly visible, the field radiated by the source arrives at P_1 via the direct (or incident) and reflected GO ray paths, respectively. The reflected ray at P_1 is generated by an incident ray path, which is transformed into a reflected path at an appropriate point of reflection Q_R on the lit (or directly illuminated) portion of the surface. The point Q_R is such that the incident and reflected ray directions at this point satisfy Snell's law of reflection (which is a consequence of Fermat's principle for reflected rays). This law of reflection simply implies that the incident ray, the reflected ray, and the surface normal at Q_R all lie in the same plane, which is usually defined as the incidence plane; furthermore, the angles that the incident and reflected rays make with the surface normal at Q_R must be the same ($\theta^i = \theta^r$ in Fig. 2). It is noted that the EM point source at Q' , which launches rays radially outward from Q' , generates a

Figure 2. Unit vectors fixed in the incident and reflected rays.

spherical wave, i.e., it generates a spherical wavefront at a sufficient distance from Q' . The family of rays is always perpendicular to their associated wavefront surface in an isotropic medium, and the rays are straight lines in a homogeneous medium, as shown in Fig. 3. The following development is restricted to rays in a homogeneous isotropic medium. The wavefront is defined as an equiphase surface, and the phase here refers to the phase delay along a ray path; this delay, which increases linearly with increase in distance along the ray, results from the finite speed of propagation of the wave field associated with any ray. This wave speed, or phase velocity, is given by ω/k for a single frequency, time harmonic (or continuous wave) field. In this development, the source and the fields are assumed to satisfy an $e^{i\omega t'}$ time harmonic variation, where ω is $2\pi f$ with f being the wave frequency and t' denotes the time.

The source at Q' excites GO incident and reflected rays that exist only in a limited region of space surrounding the radiating/scattering object. In particular, the incident rays do not exist beyond the edge induced geometrical shadow boundary, because the edge geometry serves as a screen to block or shadow a portion of the incident GO rays. This incident shadow boundary (ISB) is shown in Fig. 1, and it is an extension of the incident ray past the edge at Q_E . Likewise, the incident ray, which grazes a smooth part of the object, defines a surface shadow boundary (SSB), as also shown in Fig. 1. The SSB is formed by an extension of the incident ray past the point of grazing incidence on the smooth portion of the object; here, again, the smooth portion of the object blocks or shadows the incident rays past grazing. Furthermore, the reflected rays cannot exist past the edge induced reflection shadow boundary (RSB) as at a point P_3 in Fig. 1, because a surface does not exist past the edge to produce reflection. In the case of the reflection of the incident ray, which grazes a smooth convex surface, one may visualize the coalescing of ISB and RSB into a

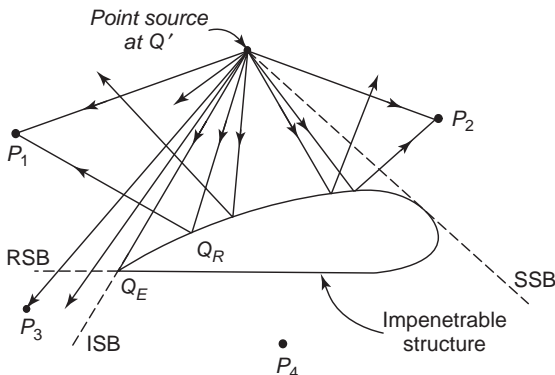

Figure 1. Geometrical optics (GO) incident and reflected rays produced by an electromagnetic point source radiating in the presence of an impenetrable structure.

Figure 3. Wavefront surface and associated family of rays.

single SSB. It is clear from the above discussion that the classic GO incident and reflected rays do not penetrate into the shadow region; hence, the GO field vanishes completely in the geometrical shadow cast by the object illuminated from the source at Q' . The latter is seen clearly in Fig. 1, where no GO rays exist at any point P_4 in the shadow region where the source at Q' is not directly visible. This failure of the GO field in the shadow zone behind an object, where the source and its image are not directly visible, was overcome by Keller's GTD [1]. In contrast to the situation in Fig. 1, the diffracted rays of the GTD now develop at Q_E and Q_S , as shown in Fig. 4, to reach an observer at P_4 in the shadow zone. The existence of these diffracted rays can be verified via the asymptotic high-frequency solutions to appropriate canonical problems, which also indicate that the asymptotic solutions to problems of radiation, scattering, and diffraction exhibit highly local properties. Moreover, such asymptotic analysis serves to identify the so-called large parameters relevant to various diffraction mechanisms. Asymptotic high-frequency (HF) solutions become increasingly accurate with increase in the size of their large parameters. Typically, a large parameter in an asymptotic HF analysis involves a product of the wavenumber k and some characteristic distance L pertaining to any diffraction mechanism. For example, for a point source excited impenetrable half screen, the large parameter kL is given by $k \frac{s's}{s'+s} \sin^2 \beta_0$, where β_0 is the angle between the incident ray and the edge tangent at the point of edge diffraction Q_E . Also, s and s' are the distances from Q_E to the observer at P and from Q_E to the source at Q' , respectively. Although asymptotic HF solutions become increasingly accurate with increasing wave frequency, they remain surprisingly accurate even for moderately high frequencies for which the radiating/scattering object is only a few wavelengths in extent (rather than tens or hundreds of wavelengths in extent).

Some of the diffracted rays that develop from Keller's generalization of Fermat's principle are illustrated below in Fig. 5. The diffracted rays shown in Fig. 5(a) and 5(e) are present in Fig. 4. In general, diffracted rays develop whenever an incident ray field impinges on a surface

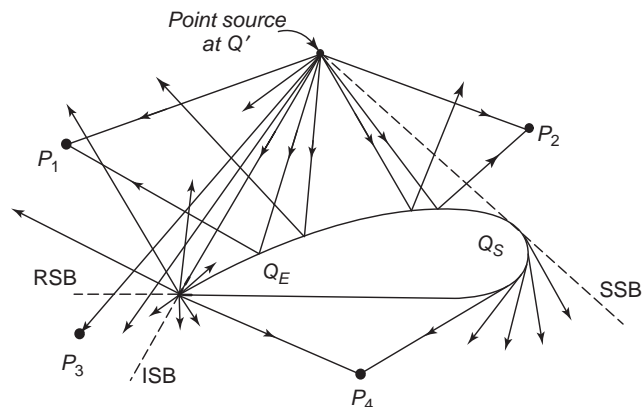

Figure 4. Edge diffracted rays originating from the edge Q_E and rays diffracted tangentially from the surface ray excited at the point of grazing Q_S .

discontinuity on a radiating/scattering object, or on a discontinuity in surface boundary conditions, or both. Diffracted rays are also initiated at grazing incidence on a smooth convex surface.

The initial values of the diffracted field are given in terms of a diffraction coefficient, exactly analogous to a reflection or transmission coefficient, which provides the initial values of the reflected and transmitted fields of classic GO. These diffraction coefficients indicate how the diffracted fields are launched into space surrounding a diffracting object. As mentioned previously, the local nature of the high-frequency diffraction phenomena allows one to find the diffraction coefficients, once and for all, from the asymptotic high-frequency solution to appropriate simpler canonical problems. The latter model the local geometrical and electrical properties in the neighborhood of the point of diffraction as in the original problem. As such, the GTD provides an efficient analytical high-frequency solution to large complex problems for which exact analytical solutions are not possible. Consequently, a GTD analysis of the radiation/scattering from complex structures (e.g., aircraft, spacecraft, ships, etc.) can be developed by simulating such objects with simpler shapes that only locally need to provide a sufficiently accurate description of all the dominant reflection and diffraction effects. It is for this reason that the GTD can provide information on ways to control the radiation/scattering as indicated previously. Although the GTD is not a rigorous method, it generally yields the leading terms in the asymptotic high-frequency solutions of diffraction problems.

It is noted that because GTD is a purely ray optical method, it fails at and near the ray shadow boundaries, i.e., the GTD fails within the so-called "transition regions" adjacent to ISB, RSB, and SSB. Transition regions are those through which the high-frequency fields must undergo a rapid change from one ray optical form to another across the shadow boundaries. Typically, the GTD field predicts an erroneous infinite field value for the diffracted fields at these shadow boundaries. The failure of the GTD at shadow boundaries can be overcome via the use of a uniform version of the GTD, such as the UTD [6–8] or the UAT [9–11], respectively. The uniform version basically patches up the GTD where it fails in the shadow boundary transition regions, because the high-frequency fields depart from a strictly ray optical behavior in these regions, and it automatically recovers the purely ray optical GTD behavior, which is valid outside these transition regions. In particular, the UTD contains Fresnel-type functions for describing the proper behavior within the ISB and RSB transition regions produced by edges [6]. On the other hand, one requires the Fock-type transition function for describing the behavior of the fields within the SSB transition regions associated with diffraction by smooth convex objects. For the sake of simplicity, the discussion in this work is restricted to impenetrable or perfectly conducting diffracting structures. Actually, only a limited amount of work has been done to date for describing HF diffraction by penetrable structures; the latter is a more complex problem [12,13]. Also, not much work has been done to describe high-frequency diffraction by objects in lossy media, or in anisotropic media, or the high-frequency diffraction by

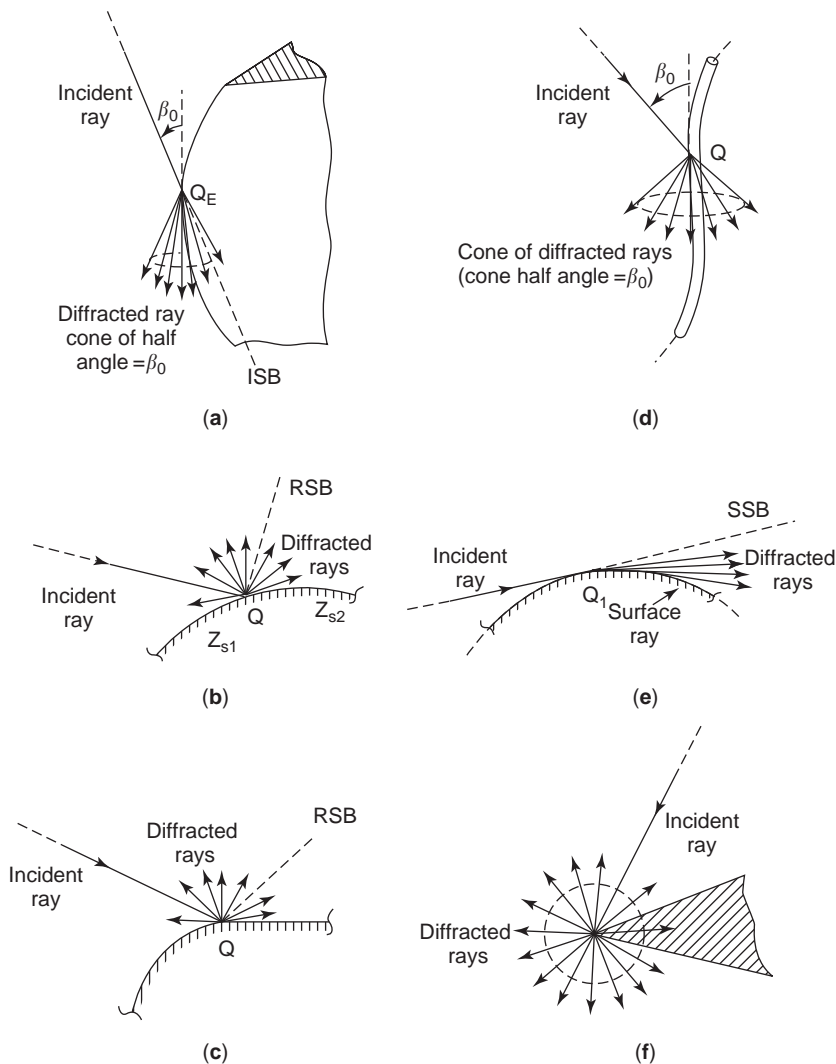

Figure 5. Examples of diffracted rays: (a) diffraction by a curved wedge, (b) diffraction at a discontinuity in surface impedance (Z_{s1} and Z_{s2}), (c) diffraction at a discontinuity in surface curvature, (d) diffraction by a thin curved wedge, (e) diffraction by a smooth convex surface, (f) diffraction by a corner in a plane screen.

anisotropic structures; nevertheless, some references to such work are available in the literature [12,14].

The GTD and its uniform versions, UTD and UAT, fail within regions of GO and diffracted ray caustics. Ray caustics are present whenever a family of rays merge or intersect to form a focal point, line, or surface, respectively. In some of these cases, the solutions can be patched up by Airy integral-type caustic transition functions [15,16], or in other cases by the equivalent current method (ECM) [17–24], or by methods of Physical Optics (PO) and its modifications such as the Physical Theory of Diffraction (PTD) [20,25,26]. The PTD may be regarded as an integral version of the GTD; it was developed by Ufimtsev at about the same time as Keller’s GTD. The PTD corrects PO, whereas GTD corrects GO; likewise, PO is a part of PTD analogous to the fact that GO is a part of the GTD. As such, the PO/PTD requires an integration of the known asymptotic currents over the radiating/scattering object. Therefore, the PO/PTD does not scale with frequency, i.e., the number of samples for integration increases rapidly with frequency making it more cumbersome even though it is more robust for applications. The GTD or UTD, on the other hand, does not require any integration on the

radiating/scattering object, and the ray paths generally remain independent of frequency making it more efficient. However, it may be less robust in some cases than the PO/PTD because one needs to find the ray paths; this fact may become somewhat complicated for arbitrary, smooth convex surfaces on which rays follow the surface geodesics, or for calculating rays associated with multiple wave interactions if they are important. Progress is being made to find such ray paths very efficiently, and work continues in this area of GTD/UTD applications. An alternative to PTD is the relatively more recent incremental theory of diffraction (ITD), which offers some advantages and is presented in [24]. It is noted, however, that the PO/PTD and ITD methods, unlike UTD, are not sufficiently developed as yet to adequately account for diffraction around smooth convex objects. It is noted that, in practical applications, it is the UTD and not GTD that must be used to obtain nonsingular and continuous fields across ray shadow boundaries. Only for far-zone calculations, the UTD may reduce to GTD in most cases if the illumination is uniform.

In Section 2, explicit UTD expressions are given for the two main mechanisms of diffraction, namely for the problems of diffraction by perfectly conducting wedges and

smooth convex surfaces, respectively. Some other commonly encountered diffraction problems are also listed. Additionally, some future research directions in the GTD/UTD area are mentioned briefly. In Section 3, several applications of UTD are provided to illustrate the utility and accuracy of this method for solving electrically large EM problems of practical interest.

Before proceeding further, to provide some expressions for the GTD/UTD field that propagate along GTD/UTD rays, it is useful to introduce the notation that will be used for dealing with time harmonic (or single frequency) fields. As EM waves exhibit polarization properties, it is essential to describe EM fields and sources as vector quantities. The vector field or source can be denoted here, in general, by $\overline{\mathcal{F}}(\bar{r}, t'')$, where \bar{r} is a vector to some observation point. For a time harmonic field,

$$\overline{\mathcal{F}}(\bar{r}, t'') = \text{Re} \overline{F}(\bar{r}, \omega) e^{j\omega t''} \quad (1)$$

where $\overline{F}(\bar{r}, \omega)$ is a phasor field that has direction (polarization) \hat{u} , and a magnitude $|\overline{F}(\bar{r}, \omega)| = \sqrt{\overline{F} \cdot \overline{F}^*}$. The preceding relations for $|\overline{F}|$ contains a scalar or dot product between \overline{F} and its complex conjugate \overline{F}^* (with asterisk denoting the conjugate operator). In the development to follow, the time harmonic factor $e^{j\omega t''}$ will be suppressed and the field/source expressions will be given in the phasor domain, i.e., in terms of the \overline{F} type quantity. Once \overline{F} is known, the time-dependent field/source quantity $\overline{\mathcal{F}}$ can be found trivially from it. The wavenumber k , in the expression for the wave speed (ω/k), is given by $\omega/\sqrt{\mu\epsilon}$, where μ and ϵ are the electrical permeability and permittivity of the isotropic, homogeneous medium in which the rays propagate.

2. GTD/UTD FIELDS

In this section, expressions for the UTD fields are presented in some detail for describing the diffraction by perfectly conducting wedges and smooth convex surfaces. As the UTD reduces to the ray optical GTD fields outside the shadow boundary transition regions, a separate discussion of GTD fields is not given. Also, only the uniform version of GTD corresponding to UTD is presented rather than discussing both UTD and UAT, which is primarily because of space limitations. A very brief discussion is also provided for other diffraction problems. As the leading terms in the GTD/UTD high-frequency asymptotic approximation are in the GO fields, the present discussion will begin with a description of the GO fields that are ray optical fields.

2.1. GO Fields

The classic GO field description can be obtained in several ways. A solution to Maxwell's equations in terms of an asymptotic expansion in inverse powers of the wavenumber, k , referred to as the Luneberg Kline expansion, yields the GO field as the leading term [3]. One can also evaluate the GO field by asymptotically evaluating the radiation integral in terms of known equivalent source distributions

(in the representation based on the equivalence theorem or the corresponding Green's theorem) over a wavefront (or equiphase surface) patch. The latter asymptotic evaluation of the radiation integral is done via the double stationary phase method in which the large parameter is ks , where s is the distance along the ray measured to the observation point from a stationary point O on the wavefront; it is noted that \bar{s} is normal to the wavefront/phasefront at O . Alternatively, the GO fields emerge from asymptotic solutions to appropriate canonical scattering and diffraction problems, and they again constitute the leading terms in the resulting asymptotic expansion. It is noted that asymptotic expansions are, in general, semi-convergent; hence, the convergence is based on retaining only a fixed number of terms in the expansion (usually only a few dominant terms) and allowing the large parameter of the asymptotic solution to increase until the resulting field converges to within some prescribed error bounds. In contrast, convergent expansions are evaluated for a fixed value of the parameter and by allowing the number of terms to increase until the result converges to within some prescribed error criterion; a tight control on the error bound is possible for convergent expansions. Nevertheless asymptotic high-frequency solutions generally remain very accurate within their domain of validity (determined primarily by the minimum value that the largeness parameter must assume in the asymptotic development in which a fixed number of dominant terms are retained). The accuracy of the asymptotic solutions can be established by comparison with known exact solutions where possible, or corresponding measured results, respectively. In the following development, the classic GO field expressions are obtained via simple, heuristic arguments based on geometrical considerations.

In GO, the field propagates along ray paths determined by Fermat's principle. As energy is transported along rays within the ray optical framework for GO fields, it follows that power must be conserved in a narrow tube of rays, i.e., in an astigmatic ray tube or a ray pencil as in Fig. 6. Consider an axial (central) ray in that tube denoted by the path \overline{OP} , where P is the observation point on the ray and O is some previous point along this ray path. Let $|\overline{OP}| = s$, which is the distance from O to P . It is then of interest to find the GO field at P if its field value is known at an earlier point O .

In order to find the continuation of the electric field $\overline{E}(O)$ at O to its value $\overline{E}(P)$ at P , one makes the usual assumption that power is conserved in a ray tube, i.e., the power $\Delta P(O)$ crossing the surface dA_o of the ray tube at O must be the same as the power $\Delta P(P)$ crossing the surface dA of that same tube at P . From Fig. 6, one observes that

$$dA_o \approx |(\rho_1 d\psi_1)(\rho_2 d\psi_2)| \quad (1a)$$

and

$$dA \approx |[(\rho_1 + s)d\psi_1][(\rho_2 + s)d\psi_2]| \quad (2)$$

where ρ_1 and ρ_2 are the principle of wavefront radii of curvature at O . Consequently, the power $\Delta P(O)$ and $\Delta P(P)$,

Figure 6. Astigmatic GO ray tube corresponding to Eq. (4).

which is transferred across the ray tube surfaces at O and P , are given by $\frac{|\bar{E}(O)|^2}{2Z_o} dA_o$ and $\frac{|\bar{E}(P)|^2}{2Z_o} dA$, respectively, where Z_o is the wave impedance for the homogeneous isotropic medium in which the rays propagate. Conservation of power in a ray tube therefore requires $\Delta P(O) = \Delta P(P)$ or

$$|\bar{E}(P)| = |\bar{E}(O)| \sqrt{\frac{\rho_1 \rho_2}{(\rho_1 + s)(\rho_2 + s)}} \quad (3)$$

via Eqs. (1a) and (2). One next heuristically incorporates the local plane wave polarization and phase into the expression in Eq. (2) to arrive at the GO expression for the electric field intensity at P

$$\bar{E}(P) = \bar{E}(O) \sqrt{\frac{\rho_1 \rho_2}{(\rho_1 + s)(\rho_2 + s)}} e^{-jks} \quad (4)$$

The polarization is unchanged from O to P because the medium is homogeneous and isotropic. Rays can bend in an inhomogeneous medium and, in that case, the polarization can change from O to P . The local plane wave phase and polarization in Eq. (4) is associated with the central ray from O to P in Eq. (4). The GO field in Eq. (4) is referred to as an arbitrary ray optical field. The ray tube in Fig. 6 is referred to as an astigmatic ray tube, or a quadratic ray tube, because ρ_1 and ρ_2 , the principle wavefront radii of curvature at O , are assumed to be different in general. If $\rho_1 = \rho_2 = \rho$, then the ray optical field becomes a simple spherical wave. If $\rho_1 = \rho_2 = \rho \rightarrow \infty$, then the ray optical field is everywhere a plane wave. If $\rho_1 = \rho$, where ρ is bounded and $\rho_2 \rightarrow \infty$, then one gets a cylindrical wave. Thus, it can be observed that plane, cylindrical, conical, and spherical waves are all special cases of the general GO astigmatic wavefield in Eq. (4). The ray congruencies or intersections at 1-2 and 3-4 for the ray pencil (or tube) in Fig. 6 form a ray caustic corresponding to the centers of the wavefront radii of curvatures ρ_1 and ρ_2 . The accepted sign convention is that the distances, ρ_1 and ρ_2 , are respectively positive if the ray caustics, or ray foci, at 1-2 and 3-4 occur along the ray path (in the direction \hat{s}) before reaching the reference point O , as is seen to be the case in Fig. 6; otherwise they are negative. The distance s is positive in the ray propagation direction. Also, the positive branch of the square root is chosen in Eq. (4). Indeed, if

one crosses a caustic along a ray path, then

$$\sqrt{\frac{\rho_i}{\rho_i + s}} = \left| \sqrt{\frac{\rho_i}{\rho_i + s}} \right| e^{j\frac{\pi}{2}}, \text{ if } \rho_i = -|\rho_i| \text{ and } s > -|\rho_i|, \text{ for } i = 1 \text{ or } 2 \quad (5)$$

It is noted that Eq. (4) becomes singular at the caustic locations 1-2 and 3-4 of Fig. 5. Hence, the GO field in Eq. (4) is not valid at and near these caustics. As the astigmatic ray field is locally plane with phase being tracked locally as a plane wave along the ray path direction \hat{s} , the magnetic field intensity, \bar{H} , is given via the plane wave condition

$$\bar{H} = Z_o^{-1} \hat{s} \times \bar{E}$$

along the ray, i.e., at O or P or any other point on that ray. Note that $Z_o = (Y_o)^{-1}$ is the plane wave impedance in the medium.

The general GO field expression in Eq. (4) can be associated with the incident, reflected, or transmitted GO fields, respectively. As the discussion is restricted to impenetrable objects for simplicity, no transmitted waves will be discussed explicitly. Outside the shadow boundary transition regions, the GTD field, as postulated by Keller, is also a ray optical field of the type in Eq. (4). Hence,

$$\bar{E}^p(P) = \bar{E}^p(O) \sqrt{\frac{\rho_1^p}{\rho_1^p + s^p}} \sqrt{\frac{\rho_2^p}{\rho_2^p + s^p}} e^{-jks^p} \quad (6a)$$

with

$$p = i, r, \text{ or } d \quad (6b)$$

to represent the incident ($p = i$), reflected ($p = r$) or diffracted ($p = d$) fields, respectively.

2.2. Incident GO Ray Field Expression

Incident GO ray field is given by (6a) with $p = i$ in (6b), namely

$$\bar{E}^i(P) = \bar{E}^i(O) \sqrt{\frac{\rho_1^i}{\rho_1^i + s^i}} \cdot \frac{\rho_2^i}{\rho_2^i + s^i} e^{-jks^i} U_i \quad (7)$$

in which U_i is a step function that has a value of unity within the lit region where the incident field is directly visible, and $U_i = 0$ in the shadow region behind an obstacle that blocks the incident ray system (see Fig. 1).

2.3. Reflected GO Ray Field Expression

It is shown in Fig. 6 how an incident ray tube is transformed into a reflected ray tube at the point of reflection Q_R on a smooth, perfectly conducting surface. The incident ray direction \hat{s}^i and the unit normal vector to the surface at the point of reflection Q_R define the plane of incidence. From Fermat's principle, the reflected ray (along \hat{s}^r) must also lie in this plane of incidence, namely, $\hat{n} \cdot (\hat{s}^i \times \hat{s}^r) = 0$. Also, Fermat's principle implies Snell's law, which simply states that the angles of incidence and reflection are the

same with respect to the surface normal at Q_R , as in Fig. 2. The field $\overline{E}^r(P)$ at P , which is reflected from a smooth surface when an astigmatic ray field $\overline{E}^i(Q_R)$ is incident at any point of reflection Q_R has the ray optical form

$$\overline{E}^r(P) = \overline{E}^i(Q_R) \sqrt{\frac{\rho_1^r}{\rho_1^r + s^r} \cdot \frac{\rho_2^r}{\rho_2^r + s^r}} e^{-jks^r} \quad (8)$$

The above results directly from (6a) with $p = r$ as in (6b). It is clear from Fig. 6 that the geometry of the reflected astigmatic ray tube depicts Q_R as the reference point on that tube, and the principle wavefront radii of curvatures ρ_1^r and ρ_2^r of reflected field are measured from this reference at Q_R ; the reflected ray distance s^r is also measured from Q_R . A reflection coefficient $\overline{R}(Q_R)$ at Q_R is introduced, which indicates how much of the field incident at any point of reflection Q_R is transformed into a reflected field at that point and in the direction \hat{s}^r of the reflected ray. Thus, $\overline{R}(Q_R)$ is simply defined by

$$\overline{E}^r(Q_R) = \overline{E}^i(Q_R) \cdot \overline{R}(Q_R) \quad (9)$$

Hence, $\overline{E}^r(P)$ in Eq. (8) becomes via Eq. (9) the following:

$$\overline{E}^r(Q_R) = \overline{E}^i(Q_R) \cdot \overline{R}(Q_R) \sqrt{\frac{\rho_1^r \rho_2^r}{(\rho_1^r + s^r)(\rho_2^r + s^r)}} e^{-jks^r} U_r \quad (10)$$

where U_r is a step function whose value is unity in the region only where the reflected GO field exists and is zero elsewhere. It is useful to express $\overline{E}^i(Q_R)$ and $\overline{E}^r(P)$ in terms of unit vectors $(\hat{e}_{||}^i, \hat{e}_{\perp}^i)$ and $(\hat{e}_{||}^r, \hat{e}_{\perp}^r)$ that are fixed in the incident and reflected rays, respectively, as shown in Fig. 2. The set of unit vectors $(\hat{s}^i, \hat{e}_{||}^i, \hat{e}_{\perp}^i)$ and $(\hat{s}^r, \hat{e}_{||}^r, \hat{e}_{\perp}^r)$ form an orthogonal triad, namely

$$\hat{e}_{\perp}^i = \hat{s}^i \times \hat{e}_{||}^i \quad \text{and} \quad \hat{e}_{\perp}^r = \hat{s}^r \times \hat{e}_{||}^r \quad (11)$$

The $\hat{e}_{||}^i$ and $\hat{e}_{||}^r$ are unit vectors that lie in the plane of incidence [defined by \hat{s}^i and $\hat{n}(Q_R)$]. On the other hand, \hat{e}_{\perp}^i is perpendicular to the plane of incidence (and hence of reflection). In the ray coordinates $(\hat{s}^i, \hat{e}_{||}^i, \hat{e}_{\perp}^i)$ and $(\hat{s}^r, \hat{e}_{||}^r, \hat{e}_{\perp}^r)$, the $\overline{R}(Q_R)$ may be expressed as

$$\overline{R}(Q_R) = \hat{e}_{||}^i R_h(Q_R) \hat{e}_{||}^r + \hat{e}_{\perp}^i R_s(Q_R) \hat{e}_{\perp}^r \quad (12)$$

For a perfectly conducting surface, the boundary condition that the total tangential electric field vanishes on such a surface leads to

$$\hat{n}(Q_R) \times [\overline{E}^i(Q_R) + \overline{E}^r(Q_R)] = 0 \quad (13)$$

It follows for a perfect electric conductor (PEC) that R_h and R_s in Eq. (12) are given by

$$R_h = \mp 1 \quad (14)$$

For a nonperfectly conducting surface with radii of curvature large in terms of the wavelength, the R_h and R_s can

be found from the canonical problem of electromagnetic plane wave reflection from a plane surface with the same local electrical properties as those of the original surface at Q_R . The original surface at Q_R is assumed to be ‘‘locally’’ flat for the purpose of calculating \overline{R} from an appropriate canonical problem. The incident astigmatic GO ray field at Q_R is also assumed to satisfy ‘‘local’’ plane wave conditions in this high-frequency approximation. The subscripts h and s in Eq. (12) denote the commonly used nomenclature assigned to the ‘‘vertical’’ and ‘‘horizontal’’ field polarizations. However, the subscripts s and h actually correspond to the acoustic soft and hard cases indicating the strong connection between \overline{EM} and acoustics for high-frequency reflection. Clearly, \overline{R} is polarization-dependent. The effect of surface curvature at Q_R on the field reflected to P is contained in ρ_1^r and ρ_2^r of Eq. (10). These $\rho_{1,2}^r$ may be found as discussed in [6,27]. The phase of the reflected field along the reflected ray path $\overline{Q_R P} = |\overline{Q_R P}| \hat{s}^r$ is contained in e^{-jks^r} of Eq. (10).

A convenient matrix notation for Eq. (10) is given by

$$\begin{pmatrix} E_{||}^r(P) \\ E_{\perp}^r(P) \end{pmatrix} = \begin{pmatrix} R_h & 0 \\ 0 & R_s \end{pmatrix} \begin{pmatrix} E_{||}^i(Q_R) \\ E_{\perp}^i(Q_R) \end{pmatrix} \sqrt{\frac{\rho_1^r \rho_2^r}{(\rho_1^r + s^r)(\rho_2^r + s^r)}} e^{-jks^r} \quad (15)$$

It is noted that Eq. (10) [and Eq. (15)] fails at caustics, i.e., when P moves to the paraxial ray tube intersections where $(\rho_1^r + s^r) = 0$ or $(\rho_2^r + s^r) = 0$ at 1'-2' or 3'-4', respectively, in Fig. 7. If $\rho_{1,2}^r > 0$, then $s^r = -|\rho_{1,2}^r|$ in virtual space inside the reflecting surface. On the other hand, if the caustics ρ_1^r or ρ_2^r are in physical space, then ρ_1^r or ρ_2^r are negative, i.e., $s^r = -|\rho_1^r|$ or $s^r = -|\rho_2^r|$, respectively, at the caustic. Whenever a ray crosses a caustic, then $\frac{\rho_{1,2}^r}{\rho_{1,2}^r + s^r}$ changes sign, and $\sqrt{\frac{\rho_{1,2}^r}{\rho_{1,2}^r + s^r}} = \left| \frac{\rho_{1,2}^r}{\rho_{1,2}^r + s^r} \right| e^{j\pi/2}$ for an $e^{+j\omega t}$ time harmonic dependence.

A uniform asymptotic solution is required to patch up fields near caustics, see, for example [15,16,28]. Also, the

Figure 7. Reflected ray tube geometry.

simple GO ray representation fails for reflection from a smooth surface near grazing incidence; this failure can be overcome using the uniform GTD (or UTD) solution for the lit zone pertaining to the problem of EM of an incident GO ray field by a smooth PEC convex surface, as discussed later in Section 2.4.2. It is important to note that near the SSB (i.e., as $\theta^i \rightarrow \pi/2$), the ρ_1^r and ρ_2^r approach the following limiting values:

$$\rho_2^r \rightarrow \frac{\rho_g(Q_R) \cos \theta^i}{2} \rightarrow 0 \text{ for } \theta^i \rightarrow \pi/2 \quad (16a)$$

$$\rho_2^r \rightarrow \rho_b^i \quad (16b)$$

where $\rho_g(Q_R)$ is the surface radius of curvature in the plane of incidence at Q_R and ρ_b^i is the radius of curvature of the incident wavefront in the plane tangent to the surface at Q_R for $\theta^i \rightarrow \pi/2$. The total GO electric field E^{GO} at a point P_L in the lit region is the sum of the fields of the incident and reflected rays; hence,

$$\begin{aligned} \bar{E}^{GO}(P_L) = & \bar{E}^i(P_L)U_i + \bar{E}^r(Q_R) \\ & \cdot \bar{R} \sqrt{\frac{\rho_1^r \rho_2^r}{(\rho_1^r + s^r)(\rho_2^r + s^r)}} e^{-jks^r} U_r \end{aligned} \quad (17)$$

In summary, it is noted that the GO incident and reflected fields are discontinuous across their associated shadow boundaries such as ISB, RSB, and SSB in Figs. 1 and 4. The failure of GO to account for a proper nonzero field within the shadow zone behind an impenetrable obstacle can be overcome through the GTD/UTD. Nevertheless, GO generally yields the dominant contribution to the total high-frequency fields, and it constitutes the leading term in the GTD/UTD solution.

The reflected GO field $\bar{E}^r(P_L)$ for the two-dimensional (2-D) case can be deduced directly from the 3-D case by allowing ρ_1^r or ρ_2^r to approach infinity. Thus, one may let $\rho_1^r \equiv \rho^r$ and $\rho_2^r \rightarrow \infty$ in Eq. (17) to arrive at the 2-D reflected GO field $\bar{E}^r(P_L)$ as

$$\bar{E}^r(P_L) = \bar{E}^i(Q_R) \cdot \bar{R} \sqrt{\frac{\rho^r}{\rho^r + s^r}} e^{-jks^r} U_r \quad (18)$$

in which the incident ray optical field $\bar{E}^i(Q_R)$ is now a cylindrical wave at Q_R and the caustic distance ρ^r in Eq. (18) for the 2-D case is given by

$$\frac{1}{\rho^r} = \frac{1}{s^i} + \frac{2}{\rho_g(Q_R) \cos \theta^i} \quad (19)$$

where θ^i has the same meaning as before and s^i is the radius of curvature of the incident cylindrical wavefront at Q_R . If the cylindrical wave is produced by a 2-D line source, then s^i can be chosen to be the distance from that line source to the point of reflection Q_R on the 2-D boundary. The quantity $\rho_g(Q_R)$ denotes the radius of curvature of the 2-D boundary at the point of reflection Q_R .

2.4. Diffracted Ray Fields

As mentioned previously, diffracted rays are introduced in the GTD via a generalization of Fermat’s principle. The initial value of the diffracted ray field is given in terms of a diffraction coefficient. Away from the point of diffraction, the diffracted rays behave according to the laws of GO. The phenomenon of edge diffraction will be discussed first, and it will be followed by a discussion on the phenomenon of diffraction at a smooth convex surface. The latter phenomenon is more complicated to describe mathematically than edge diffraction.

2.4.1. Edge Diffraction. When a ray is incident on an edge in an otherwise smooth surface, it produces diffracted rays that lie on a cone about the tangent to the edge at the point of diffraction such that the angle β_0 between the incident ray and the edge tangent equals the half angle of the diffracted ray cone, as shown in Fig. 5(a). This cone of diffracted rays is referred to as the “Keller cone,” and it results from the generalization of Fermat’s principle to describe rays diffracted by an edge.

Let an arbitrarily plane polarized astigmatic ray optical field be incident on a perfectly conducting curved wedge, as shown in Fig. 8. The point O , and the edge tangent at the point of diffraction Q_E , define a plane; then ρ_e^i is the radius of curvature of the incident astigmatic wavefront in that plane. The resultant total HF electric field $\bar{E}(P)$ at any point P exterior to the wedge is given by

$$\bar{E}(P) \sim \bar{E}^{GO}(P) + \bar{E}^d(P) \quad (20)$$

where the symbol \sim denotes “asymptotically equals to.” As before, the GO field component $\bar{E}^{GO}(P)$ is given as

$$\bar{E}^{GO}(P) = \bar{E}^i(P)U_i + \bar{E}^r(P)U_r \quad (21)$$

Figure 8. Edge-diffracted ray tube.

The domains of existence of the incident and reflected ray fields $\overline{E}^i(P)$ and $\overline{E}^r(P)$ are indicated by the step functions U_i and U_r , respectively, which are defined for a wedge as

$$U_i = \begin{cases} 1, & \text{if } 0 < \phi < \pi + \phi' \\ 0, & \text{if } \pi + \phi' < \phi < n\pi \end{cases} \quad (22)$$

and

$$U_r = \begin{cases} 1, & \text{if } 0 < \phi < \pi - \phi' \\ 0, & \text{if } \pi - \phi' < \phi < n\pi \end{cases} \quad (23)$$

The wedge faces make the angles 0 and $n\pi$, respectively, so that the wedge angle is $(2-n)\pi$, as in Fig. 9(b). The azimuthal angles ϕ and ϕ' are made by the projections

Figure 9. Edge fixed planes of incidence and diffraction.

of the directions of incidence and observation on a plane perpendicular to the edge at the point of diffraction Q_E . These angles are measured from a plane tangent to the “0” face of the wedge at Q_E , as shown in Fig. 9(b).

The expressions for the GO incident and reflected fields have been discussed previously. The diffracted field \overline{E}^d exists exterior to the wedge (i.e., for $0 < \phi < n\pi$). From (6a) and (6b), one may write the general field expression for the ray diffracted in the direction \hat{s}^d from Q_E as

$$\overline{E}^d(P) \sim \overline{E}^d(P_o) \sqrt{\frac{\rho_1^d \rho_2^d}{(\rho_1^d + s_o^d)(\rho_2^d + s_o^d)}} e^{-jks_o^d} \quad (24)$$

The diffracted ray tube corresponding to Eq. (24) is shown in Fig. 8. The superscript “d” on $\rho_{1,2}^d$ and s_o^d denotes that these quantities are associated with the diffracted ray field component. In order to relate $\overline{E}^d(P)$ to the incident field at the point of edge diffraction Q_E , one moves the reference P_o in Fig. 8 to the point of edge diffraction Q_E by letting $\rho_1^d \rightarrow 0$, so that

$$\overline{E}^d(P) = \lim_{\rho_1^d \rightarrow 0} [\sqrt{\rho_1^d} \overline{E}^d(P_o)] \sqrt{\frac{\rho_2^d}{(\rho_1^d + s_o^d)(\rho_2^d + s_o^d)}} e^{-jks_o^d} \quad (25)$$

As $\overline{E}^d(P)$ is independent of the reference point P_o , the above limit exists, and it is defined as

$$\lim_{\rho_1^d \rightarrow 0} \sqrt{\rho_1^d} \overline{E}^d(P_o) \equiv \overline{E}^i(Q_E) \cdot \overline{D}_e^k \quad (26)$$

where $\overline{D}_e^k = \overline{D}_e^k(\phi, \phi', \beta_0; k)$ is Keller’s “dyadic edge diffraction coefficient” at Q_E , which indicates how the energy is distributed in the diffracted field as a function of the angles ϕ , ϕ' , and β_0 ; \overline{D}_e^k also depends on n and the wave-number k . From Eqs. (25) and (26), it is clear that

$$\overline{E}^d(P) \sim \overline{E}^i(Q_E) \cdot \overline{D}_e^k(\phi, \phi', \beta_0; k) \sqrt{\frac{\rho_e}{s^d(\rho_e + s^d)}} e^{-jks^d} \quad (27)$$

where $\lim_{\rho_1^d \rightarrow 0} \rho_2^d \equiv \rho_e$ (edge diffracted ray caustic distance), and likewise $\lim_{\rho_1^d \rightarrow 0} s_o^d \equiv s^d$, as shown in Fig. 8. $\overline{E}^d(P)$ is polarized transverse to the diffracted ray direction \hat{s}^d because the field $\overline{E}^d(P)$ is ray optical; hence, the associated magnetic field can be expressed via local plane wave conditions at P as

$$\overline{H}^d(P) \sim Y_0 \hat{s}^d \times \overline{E}^d(P) \quad (28)$$

If the incident field $\overline{E}^i(Q_E)$ exhibits a rapid spatial variation at the point of edge diffraction Q_E , then an additional term referred to as a slope diffracted field must be added to Eq. (27) to describe the diffraction effects accurately; however, that slope diffracted field will not be described here. An expression for finding the diffracted ray caustic distance ρ_e is given later in Eq. (47).

It is convenient to express the dyadic edge diffraction coefficient \overline{D}_e^k in terms of unit vectors fixed in the incident and diffracted ray as follows. Let \hat{s}^i and \hat{e} define an edge

fixed plane of incidence where \hat{e} is the edge tangent at Q_E . Likewise, let \hat{s}^d and \hat{e} define the edge fixed plane of diffraction. The law of diffraction that defines the Keller cone is $\hat{s}^i \cdot \hat{e} = \hat{s}^d \cdot \hat{e}$. Thus, $\beta'_0 = \beta_0$. Let $\hat{\beta}'_0$ and $\hat{\beta}_0$ be parallel to the edge fixed planes of incidence and diffraction, respectively, as in Fig. 9(a), and let

$$\hat{\beta}'_0 = \hat{s}^i \times \hat{\phi}' \quad \hat{\beta}_0 = \hat{s}^d \times \hat{\phi} \quad (29)$$

Here, $\hat{\phi}$ and $\hat{\phi}'$ point in the direction of increasing ϕ and ϕ' angles, respectively. The incident field $\vec{E}^i(Q_E)$ can be expressed in terms of the triad of unit vectors $(\hat{s}^i, \hat{\beta}'_0, \hat{\phi}')$ fixed in the incident ray; likewise, the edge diffracted field $\vec{E}^d(P)$ can be expressed in terms of $(\hat{s}^d, \hat{\beta}_0, \hat{\phi})$ fixed in the diffracted ray. Then in the ray coordinates, one writes

$$\vec{E}^i(Q_E) = \hat{\beta}'_0 E_{\beta'_0}^i + \hat{\phi}' E_{\phi'}^i \quad (30)$$

and

$$\vec{E}^d(P) = \hat{\beta}_0 E_{\beta_0}^d + \hat{\phi} E_{\phi}^d \quad (31)$$

One can relate \vec{E}^d to \vec{E}^i through the previously introduced dyadic diffraction coefficient \overline{D}_e in Eq. (26), where

$$\overline{D}_e^k = -\hat{\beta}'_0 \hat{\beta}_0 D_{es}^k - \hat{\phi}' \hat{\phi} D_{eh}^k \quad (32)$$

The scalar components of the dyadic diffraction coefficient, namely, D_{es}^k and D_{eh}^k , can be found from the asymptotic solutions of appropriate canonical wedge diffraction problems; they are given by

$$D_{es}^k(\phi, \phi'; \beta_0) = \frac{-e^{-j\frac{\pi}{4}} \sin \frac{\pi}{n}}{n\sqrt{2\pi k} \sin \beta_0} \left[\frac{1}{\cos \frac{\pi}{n} - \cos\left(\frac{\phi - \phi'}{n}\right)} \mp \frac{1}{\cos \frac{\pi}{n} - \cos\left(\frac{\phi + \phi'}{n}\right)} \right] \quad (33)$$

The subscripts s and h in Eqs. (32) and (33) refer again to acoustic soft and hard boundary conditions indicating the intimate connection between EM and acoustics for explaining high-frequency diffraction. It is clear that the Keller edge diffraction coefficient in Eq. (33) becomes singular at the incident shadow boundary (ISB) and the reflection shadow boundary (RSB), which occur when $\phi = \pi + \phi'$ and $\phi = \pi - \phi'$, respectively. Thus, the result in Eq. (27) together with Eqs. (32) and (33) is not valid at and near the GO incident and reflection shadow boundaries. This deficiency of GTD can be overcome via the use of uniform geometrical theory of diffraction (UTD). According to the UTD [6,8], the total HF field exterior to the wedge is still given by Eq. (27) as in Keller's original GTD; however, the \vec{E}^d in Eqs. (27), (32), and (33) is modified such that \overline{D}_e of Eq. (32) is now replaced by the UTD edge

diffraction coefficient \overline{D}_e , so that

$$\vec{E}^d(P) = \vec{E}^i(Q_E) \cdot \overline{D}_e(\phi, \phi'; \beta_0; k) \sqrt{\frac{\rho_e}{s^d(\rho_e + s^d)}} e^{-jks^d} \quad (34)$$

The \overline{D}_e in Eq. (34) can also be expressed as

$$\overline{D}_e = -\hat{\beta}'_0 \hat{\beta}_0 D_{es} - \hat{\phi}' \hat{\phi} D_{eh} \quad (35)$$

In matrix notation, Eq. (34) becomes

$$\begin{bmatrix} E_{\beta_0}^d \\ E_{\phi}^d \end{bmatrix} = \begin{bmatrix} -D_{es} & 0 \\ 0 & -D_{eh} \end{bmatrix} \begin{bmatrix} E_{\beta'_0}^i \\ E_{\phi'}^i \end{bmatrix} \sqrt{\frac{\rho_e}{s^d(\rho_e + s^d)}} e^{-jks^d} \quad (36)$$

in which the D_{es} and D_{eh} are [6,8]

$$D_{eh}(\phi, \phi'; \beta_0) = \frac{-e^{-j\frac{\pi}{4}}}{2n\sqrt{2\pi k} \sin \beta_0} \left[\cot\left(\frac{\pi + (\phi - \phi')}{2n}\right) \cdot F[kL^i a^+(\phi - \phi')] + \cot\left(\frac{\pi - (\phi - \phi')}{2n}\right) \cdot F[kL^i a^-(\phi - \phi')] \mp \left[\cot\left(\frac{\pi + (\phi + \phi')}{2n}\right) \cdot F[kL^{rn} a^+(\phi + \phi')] + \cot\left(\frac{\pi - (\phi + \phi')}{2n}\right) \cdot F[kL^{ro} a^-(\phi + \phi')] \right] \right] \quad (37)$$

where the asymptotic large parameter kL (with the superscripts i, rn, ro , on L omitted for convenience) is required to be sufficiently large (generally greater than 3) and

$$a^\pm(\beta) = 2 \cos^2\left(\frac{2n\pi N^\pm - \beta}{2n}\right) \quad (38)$$

The N^\pm are the integers that most nearly satisfy the equation

$$2\pi n N^\pm - \beta = \pm \pi \quad (39)$$

with

$$\beta = \phi \pm \phi' \quad (40)$$

Note that $n=2$ for a half plane or a semiinfinite curved screen. Also, $n=3/2$ for an exterior right angled wedge, etc. For a point source (or spherical wave) type illumination, the distance parameter L^i is

$$L^i = \frac{s^i s^d}{s^i + s^d} \sin^2 \beta_0 \quad (41)$$

in which s^i and s^d are the distances from the point of edge diffraction at Q_E to the source and observation points, respectively. Only for a straight wedge with planar faces

that is illuminated by a point source does

$$L^{r0} = L^{rn} = L^i = \frac{s^i s^d}{s^i + s^d} \sin^2 \beta_0 \quad (42)$$

as in Eq. (41). For a general astigmatic ray optical illumination that is characterized by two distinct principal wavefront radii of curvature, ρ_1^i and ρ_2^i , the above L^i must be modified as shown below in the general expressions for L^{r0} and L^{rn} pertaining to a curved wedge; thus,

$$L^i = \left[\frac{s^d(\rho_e^i + s^d)\rho_1^i\rho_2^i \sin^2 \beta_0}{\rho_e^i(\rho_1^i + s^d)(\rho_2^i + s^d)} \right]_{\text{at ISB}} \quad (43)$$

$$L^r = \left[\frac{s^d(\rho_e^r + s^d)\rho_1^r\rho_2^r \sin^2 \beta_0}{\rho_e^r(\rho_1^r + s^d)(\rho_2^r + s^d)} \right]_{\text{at RSB}} \quad (44)$$

Here, L^{r0} and L^{rn} are the values of L^r associated with the “0” and “n” faces of the wedge, respectively. Furthermore, ρ_e^r is given by

$$\frac{1}{\rho_e^r} = \frac{1}{\rho_e^i} - \frac{2(\hat{n} \cdot \hat{n}_e)(\hat{s}^i \cdot \hat{n})}{a \sin^2 \beta_0} \quad (45)$$

Also, ρ_e is given by

$$\frac{1}{\rho_e} = \frac{1}{\rho_e^i} - \frac{\hat{n}_e \cdot (\hat{s}^i - \hat{s}^d)}{a \sin^2 \beta_0} \quad (46)$$

The unit vector \hat{n} is defined in Fig. 9(b), whereas \hat{n}_e is a unit vector normal to the edge that is directed away from the center of edge curvature at Q_E . The radius of edge curvature is denoted locally by “ a ” in Eqs. (45) and (46). ρ_e^i is the radius of curvature of the incident wavefront at Q_E that lies in the edge fixed plane of incidence. In the far zone, when $s^d \gg \rho_{1,2}^i$, $s^d \gg \rho_{1,2}^r$, and $s^d \gg \rho_e$, then the L^i and L^r in Eqs. (43) and (44) simplify to $L \approx \frac{\rho_1 \rho_2 \sin^2 \beta_0}{\rho_e}$, in which the superscripts on L , ρ_1 , and ρ_2 are omitted for convenience. It is noted that L^i and L^r in Eqs. (43) and (44) are calculated on the appropriate shadow boundaries. The transition function, F , which appears in Eq. (37), contains a

Figure 10. Plot of $F(\sigma)$ versus σ .

Fresnel integral; it is defined by

$$F(x) = 2j\sqrt{x}e^{jx} \int_{\sqrt{x}}^{\infty} d\tau e^{-j\tau^2} \quad (47)$$

A plot of the above UTD transition function $F(x)$ is illustrated in Fig. 10. In Eq. (47), $\sqrt{x} = |\sqrt{x}|$ if $x > 0$ and $\sqrt{x} = -j|\sqrt{x}|$ if $x < 0$. If $x < 0$, then $F(x)|_{x < 0} = F^*(|x|)$, where * denotes the complex conjugate. Exterior to the (ISB/RSB) transition regions, x becomes large and $F(x) \rightarrow 1$, so that the uniform D_{es}^{eh} in Eq. (37) then reduces to Keller’s form as it should; namely,

$$\bar{D}_e \rightarrow \bar{D}_e^h \text{ outside the transition region} \quad (48)$$

Near the (ISB and RSB) boundaries, the small argument approximation for $F(x)$ may be employed (because $x = 0$ on ISB and RSB); namely,

$$F(x) \xrightarrow{x \rightarrow 0} \sqrt{\pi x} e^{j(\frac{\pi}{4} + x)} \quad (49)$$

Using the above limit into Eq. (37) yields the following result for the diffracted field \bar{E}^d at ISB or RSB:

$$\bar{E}^d|_{\text{ISB;RSB}} = \left[\mp \frac{1}{2} \bar{E}^{i;r} + \begin{pmatrix} \text{continuous} \\ \text{higher order} \\ \text{terms} \end{pmatrix} \right]; \quad (50)$$

$$\text{if } \left\{ \begin{array}{l} \text{on lit side of ISB; RSB} \\ \text{on shadow side of ISB; RSB} \end{array} \right\}$$

The result in Eq. (50) ensures the continuity of the total HF field in Eq. (20) across ISB and RSB. The field contribution developing from the edge excited “surface diffracted rays” is not included in Eq. (37); it may be important for observation points close to the surface shadow boundaries (SSB) associated with the tangent to the “0” and “n” faces of a curved wedge at Q_E if the “0” and “n” faces are convex boundaries. The result in Eqs. (34) and (36) along with Eq. (37) is valid away from any diffracted ray caustics and away from the edge caustic at Q_E .

For grazing angles of incidence on a perfectly conducting wedge with planar faces, $D_{es} = 0$, and D_{eh} must be replaced by $D_{eh}/2$. The reason for the one-half factor in the latter case is explained as follows. The incident and reflected GO fields tend to combine into a single “total incident field” as one approaches grazing angles of incidence; consequently, only half of this “total field” is the incident field. The illumination at grazing angles of incidence at an edge in a curved surface cannot be handled as easily as the case of a wedge with planar faces. Presently, one can only treat angles of incidence that are greater than $\left[\frac{2}{k\rho_g(Q_E)} \right]^{1/3}$, where $\rho_g(Q_E)$ is the radius of curvature of the surface in the direction of

the incident ray at the point of edge diffraction Q_E . Under the above restrictions, the result in Eq. (37) for D_{eh}^{es} simplifies in the case of a plane or curved screen ($n = 2$ case) to

$$D_{eh}^{es}(\phi, \phi', \beta_0) = \frac{-e^{-j\frac{\pi}{4}}}{2\sqrt{2\pi k} \sin \beta_0} \left[\sec\left(\frac{\phi - \phi'}{2}\right) F[kL^i a(\phi - \phi')] \mp \sec\left(\frac{\phi + \phi'}{2}\right) F[kL^r a(\phi + \phi')] \right] \quad (51)$$

where $a(\beta) = 2 \cos^2(\beta/2)$ and $L^{i,r}$ are as in Eqs. (43) and (44) with the understanding that L^r is evaluated at the RSB corresponding to the face that is illuminated; hence the superscripts “o” and “n” in L^r are dropped for this $n = 2$ case.

The UTD edge diffracted field $\bar{E}^d(P)$ for the 2-D situation can be obtained from Eq. (34) by allowing ρ_e to approach infinity and by requiring $\beta_0 = \pi/2$; thus, for the 2-D case,

$$\bar{E}^d(P) = \bar{E}^i(Q_E) \bullet \bar{D}_e(\phi, \phi', \pi/2; k) \frac{e^{-jks^d}}{\sqrt{s^d}} \quad (52)$$

The \bar{D}_e in Eq. (52) for the 2-D case is available from Eqs. (36) and (51) with $\beta_0 = \pi/2$ (or $\sin \beta_0 = 1$). Also, L^i for the 2-D case is given by Eq. (44) with $\beta_0 = \pi/2$; in particular,

$$L^i = \frac{s^i s^d}{s^i + s^d} \quad (53)$$

Likewise, L^r is obtained from Eq. (44) with $\beta_0 = \pi/2$, $\rho_1^r \rightarrow \infty$, $\rho_2^r \equiv \rho^r$ [as in Eq. (19)], and $\rho_e^r \rightarrow \infty$; therefore, in the 2-D case,

$$L^r = \frac{\rho^r s^d}{\rho^r + s^d} \quad (54)$$

Note that ρ^r in Eq. (54) is the same as the one in Eq. (19), as indicated above; however, ρ^r is, in general, different for the “o” and “n” faces of the wedge, with L^{ro} and L^{rn} denoting the values of L^r for these two different faces. Although the expression for L^r in Eq. (44) is fixed to its value on the RSB for convenience, the one in Eq. (54) can be evaluated as a function of the observation point with almost the same ease as if one had approximated the value of L^r by its value at the RSB. The values of L^i and L^r for the 3-D case involve various caustic distances, as is evident from Eqs. (43) and (44). These distances are generally slowly varying within the ISB and RSB transition regions, and it is therefore convenient to approximate L^i and L^r throughout the transition regions by their values fixed at the ISB and RSB, as done in Eqs. (43) and (44). Outside the respective transition regions, the F functions containing L^i and L^r approach unity and are thus unaffected by the above approximation.

It is noted that the comment below Eq. (50) in regard to grazing incidence is also valid for the 2-D case. It is important to note that the difference between \bar{D}_e and \bar{D}_e^k is that the former is range dependent whereas the latter is not. As a

result, Eq. (37) is not strictly ray optical within the ISB and RSB transition regions; exterior to these regions, $\bar{D}_e \rightarrow \bar{D}_e^k$, as indicated before. Figure 11 illustrates the diffraction of a plane wave by a perfectly conducting half-plane. It is noted that the geometrical optics field is discontinuous; however, the UTD diffracted field compensates the GO discontinuity to yield a total UTD field that is continuous.

2.4.2. Diffraction at a Smooth Convex Surface. The geometry associated with the problem of the diffraction by a smooth convex surface is shown in Fig. 12 (and also Fig. 1(e)). The total high-frequency field $\bar{E}(P)$ for the situation in Fig. 12 can be expressed as [8,29,30]

$$\bar{E}(P) = \begin{cases} \bar{E}^i(P_L)U + \bar{E}^r(P_L)U + \bar{E}^d(P_L), & \text{if } P = P_L \text{ in the lit zone} \\ \bar{E}^d(P_S)[1 - U], & \text{if } P = P_S \text{ in the shadow zone} \end{cases} \quad (55)$$

Figure 11. Continuity of the total UTD field surrounding a perfectly conducting half-plane excited by a plane wave.

Figure 12. Diffraction at a convex surface.

The incident and reflected fields, \vec{E}^i and \vec{E}^r , are associated with the incident (direct) and reflected GO rays shown in Fig. 12. The step function U in Eq. (55) is defined below with respect to the surface shadow boundary (SSB) as

$$U = \begin{cases} 1, & \text{in the lit region which lies above} \\ & \text{the SSB where source is visible} \\ 0, & \text{in the shadow region which lies} \\ & \text{below the SSB where source is invisible} \end{cases} \quad (56)$$

The surface diffracted field $\vec{E}^d(P_S)$ follows the surface diffracted ray path into the shadow region, as in Figure 12; whereas, the field $\vec{E}^d(P_L)$, which is diffracted into the lit region, follows the reflected ray path (of \vec{E}^r) in this solution. Therefore, it is convenient here to combine the GO reflected field $\vec{E}^r(P_L)U$ and the diffracted field $\vec{E}^d(P_L)$ into a single ‘‘generalized reflected field,’’ $\vec{E}^{gr}(P_L)U$ in the lit region, so that Eq. (55) becomes

$$\vec{E}(P) = \begin{cases} \vec{E}^i(P_L)U + \vec{E}^{gr}(P_L)U, & \text{if } P = P_L \text{ in the lit zone} \\ \vec{E}^d(P_S)[1 - U], & \text{if } P = P_S \text{ in the shadow zone} \end{cases} \quad (57)$$

The fields $\vec{E}^{gr}(P_L)$ and $\vec{E}^d(P_S)$ are given symbolically by

$$\vec{E}^{gr}(P_L) \sim \vec{E}^i(Q_R) [\hat{R}_s \hat{e}_\perp \hat{e}_\perp + \hat{R}_h \hat{e}_\parallel^i \hat{e}_\parallel^r] \cdot \sqrt{\frac{\rho_1^r \rho_2^r}{(\rho_1^r + s^r)(\rho_2^r + s^r)}} e^{-jks^r} \quad (58)$$

$$\vec{E}^d(P_S) \sim \vec{E}^i(Q_1) [\hat{D}_s \hat{b}_1 \hat{b}_2 + \hat{D}_h \hat{n}_1 \hat{n}_2] \cdot \sqrt{\frac{\rho_S}{s^d(\rho_S + s^d)}} e^{-jks^d} \quad (59)$$

where the points Q_R and Q_1 and the distances s^r and s^d are indicated in Fig. 12. The surface diffracted ray caustic distance ρ_S is shown in Fig. 13. The quantities within brackets involving \hat{R}_s and \hat{D}_h in Eqs. (58) and (59) may be viewed as the generalized dyadic coefficients for surface

Figure 13. Surface-diffracted ray path.

reflection and diffraction, respectively. The subscripts s and h in Eq. (59) once again denote the acoustic soft and hard contributions to diffraction, respectively, as in Eqs. (34) and (37). It is noted that Eqs. (58) and (59) are expressed invariantly in terms of the unit vectors fixed in the reflected and surface diffracted ray coordinates. The unit vectors \hat{e}_\parallel^i , \hat{e}_\parallel^r , and \hat{e}_\perp in Eq. (58) have been defined earlier in connection with the reflected field. It can be shown that cross terms actually exist in the above generalized dyadic reflection coefficient; but, in general, their effect is seen to be weak within the SSB transition region. Also, these cross terms vanish in the deep lit region and on the SSB, hence, they have been ignored in Eq. (58).

At Q_1 , let \hat{t}_1 be the unit vector in the direction of incidence, \hat{n}_1 be the unit outward normal vector to the surface, and $\hat{b}_1 = \hat{t}_1 \times \hat{n}_1$; likewise, at Q_2 , let a similar set of unit vectors ($\hat{t}_2, \hat{n}_2, \hat{b}_2$) be defined with \hat{t}_2 in the direction of the diffracted ray as in Fig. 14. In the case of surface rays with zero torsion, $\hat{b}_1 = \hat{b}_2$. It is clear from Fig. 13 that ρ_S in Eq. (59) is the wavefront radius of curvature of the surface diffracted ray evaluated in the \hat{b}_2 direction at Q_2 . First, the UTD expressions for \hat{R}_s and \hat{D}_h in Eqs. (58) and (59) will be given below; it will be shown that these expressions are valid within the transition region adjacent to the SSB. Subsequently, it will be shown how these expressions automatically simplify outside the SSB transition region to

Figure 14. Unit vectors fixed in the surface ray.

reduce to those obtained by Keller in his GTD representation. The R_h and D_h in Eqs. (58) and (59) are

$$\tilde{R}_h = - \left[\sqrt{\frac{-4}{\zeta^L}} e^{-j(\zeta^L)^3/12} \left[\frac{e^{-j\pi/4}}{2\sqrt{\pi}\zeta^L} [1 - F(x^L)] + \tilde{P}_h(\zeta^L) \right] \right] \quad (60)$$

for the lit region

and

$$\begin{aligned} \tilde{D}_h = & - \left[\sqrt{m(Q_1)m(Q_2)} \sqrt{\frac{2}{k}} \frac{e^{-j\pi/4}}{2\sqrt{\pi}\zeta} [1 - F(x^d)] + \tilde{P}_h(\zeta) \right] \\ & \cdot \sqrt{\frac{d\eta(Q_1)}{d\eta(Q_2)}} e^{-jkt} \text{ for the shadow region} \end{aligned} \quad (61)$$

The function F appearing above has been defined earlier in Eq. (47). The Fock-type surface reflection function \tilde{P}_h is related to the (soft) Pekeris function (p^*) by

$$\tilde{P}_h(\delta) = \left\{ \begin{matrix} p^*(\delta) \\ q^*(\delta) \end{matrix} \right\} e^{-j\frac{\pi}{4}} - \frac{e^{-j\frac{\pi}{4}}}{2\sqrt{\pi}\delta} \quad (62)$$

(Note that $\delta = 0$ at SSB)

where p^* and q^* are finite and well behaved even when $\delta = 0$; these universal functions are plotted in Figs 15 and 16. Also,

$$\begin{aligned} \tilde{P}_h(\delta) &= \frac{e^{-j\frac{\pi}{4}}}{\sqrt{\pi}} \int_{-\infty}^{\infty} d\tau \frac{\tilde{Q}V(\tau)}{\tilde{Q}W_2(\tau)} e^{-j\delta\tau} \\ \tilde{Q} &= \left\{ \begin{matrix} 1, & \text{soft case (h)} \\ \frac{\partial}{\partial\tau}, & \text{hard case (v)} \end{matrix} \right\} \end{aligned} \quad (63)$$

Figure 15. Plot of $e^{-j\pi/4}p^*(\zeta)$ versus ζ .

Figure 16. Plot of $e^{-j\pi/4}q^*(\zeta)$ versus ζ .

in which the Fock-type Airy functions are

$$\begin{aligned} 2jV(\tau) &= W_1(\tau) - W_2(\tau); \\ W_1(\tau) &= \frac{1}{\sqrt{\pi}} \int_{\infty e^{-j2\pi/3}}^{\infty} e^{t\tau - t^3/3} dt \end{aligned} \quad (64)$$

$$W_2(\tau) = \frac{1}{\sqrt{\pi}} \int_{\infty e^{j2\pi/3}}^{\infty} e^{t\tau - t^3/3} dt \quad (65)$$

The rest of the quantities occurring in Eqs. (60) and (61) are

$$\zeta^L = -2m(Q_R) \cos \theta^i; \quad \zeta = \int_{Q_1}^{Q_2} dt' \frac{m(t')}{\rho_g(t')} \quad (66)$$

$$m(\bullet) = \left[\frac{k\rho_g(\bullet)}{2} \right]^{1/3}$$

$$t = \int_{Q_1}^{Q_2} dt'; \quad X^L = 2kL \cos^2 \theta^i; \quad X^d = \frac{kL\zeta^2}{2m(Q_1)m(Q_2)} \quad (67)$$

The quantity $\rho_g(Q_R)$ in $m(Q_R)$ denotes the surface radius of curvature at Q_R in the plane of incidence; whereas, $\rho_g(Q_{1,2})$ is the surface radius of curvature at $Q_{1,2}$ in the $\hat{t}_{1,2}$ direction. The dt' in Eqs. (66) and (67) is an incremental arc length along the surface ray path that must be a surface geodesic in accordance with Keller's generalization of Fermat's principle for diffracted rays. The angle of incidence θ^i is shown in Fig. 12. Also, the $d\eta(Q_1)$ and $d\eta(Q_2)$ in Eq. (61) denote the widths of the surface ray tube at Q_1 and Q_2 , respectively; the surface ray tube is formed by considering a pair of rays adjacent to the central ray, as in Fig. 13. The geodesic surface ray paths are easy to find on cylinders, spheres, and cones. For example, they are helical paths on cylinders and great circles on spheres. For arbitrary convex surfaces, the geodesic surface ray paths must be found numerically. The distance

parameter L in Eq. (67) is given by

$$L = \frac{\rho_1^i(Q_1)\rho_2^i(Q_1)}{(\rho_1^i(Q_1) + s)(\rho_2^i(Q_1) + s)} \cdot \frac{s(\rho_b^i(Q_1) + s)}{\rho_b^i(Q_1)} \quad (68)$$

where

$$s \equiv (s^r|_{SSB} = s^d|_{SSB});$$

$$\rho_b^i(Q_1) = \left\{ \begin{array}{l} \text{incident wavefront radius of curvature} \\ \text{in the } \hat{b}_1 \text{ direction at } Q_1 \end{array} \right\} \quad (69)$$

The distance s in Eq. (69) may be obtained by projecting $(s^r|_{SSB})$ on the SSB if the observation point within the ($\text{lit}_{\text{shadow}}$) side of the SSB transition region does not move in a predetermined manner. If the observation point moves across the SSB in a predetermined fashion, then it is clear that s in Eq. (69) can be found unambiguously. The $\rho_1^i(Q_1)$ and $\rho_2^i(Q_1)$ in Eq. (68) denote the principal radii of curvature of the incident wavefront at Q_1 , and ρ_b^i , which is defined in Eq. (69), has been mentioned previously in Eq. (16b). For the special case of point source or spherical wave illumination, the L in Eq. (67) simplifies to

$$L = \frac{s's}{s' + s} \text{ for spherical wave illumination} \quad (70)$$

where

$$s' \equiv (\rho_1^i(Q_1) = \rho_2^i(Q_1) = \rho_b^i(Q_1))$$

$$= \left\{ \begin{array}{l} \text{distance from the point source to} \\ \text{the point of grazing incidence at } Q_1 \end{array} \right\} \quad (71)$$

For the case of plane wave illumination, $s' \rightarrow \infty$, and hence Eq. (70) simplifies to

$$L = s \text{ for plane wave illumination} \quad (72)$$

If the incident wavefront is of the converging type ($\rho_{1,2}^i < 0$), or converging-diverging type ($\rho_1^i \geq 0; \rho_2^i \leq 0$), then the parameter L in Eq. (67) can become negative. It has not been fully investigated how the general solution can be completed if L becomes negative. On the other hand, if one of the principle directions of the incident wavefront coincides with one of the principal planes of surface at grazing, then one can treat a converging, or converging-diverging (saddle) type wavefront for which $L < 0$ by replacing $F(X^{L,d})$ with $F^*(|X^{L,d}|)$. Note that the asterisk in F^* denotes the complex conjugate operator. The use of $F^*(|X^{L,d}|)$ when $L < 0$ leads to a continuous total field at SSB in this case.

The above UTD result is valid outside the paraxial (i.e., near axial) regions of quasicylindrical or elongated convex

surfaces; a different solution is required in the paraxial region, and it has not yet been completed. It is assumed that the source and observation points are not too close to the surface. Also, it is assumed that any caustics of the incident ray system are not too close to the surface. Furthermore, the amplitude of the incident field is assumed to be slowly varying at Q_R and Q_1 ; otherwise, it is necessary to add a slope diffraction contribution. The UTD solution described above remains accurate if kL and m are sufficiently large. Typically, kL should be larger than 3, although, in some cases, kL can be made smaller. Also, m should be such that $2m^3 > 5$ or so; however, the results generally lose their accuracy slowly as $2m^3$ becomes smaller. It is noted that the angular extent of the SSB transition region is of order m^{-1} radians.

A surface diffracted field of the type $\bar{E}^d(P_S)$ can also be present in the lit zone if the surface is closed; this may be seen noting that the field of the type \bar{E}^d can propagate around the closed surface. Also, additional contributions to $\bar{E}^d(P_S)$ can be present in the shadow zone for a closed surface because surface diffracted rays can be initiated at all points of grazing incidence on that closed surface; furthermore, these surface rays can undergo multiple encirclements around a closed body. However, these additional surface diffracted ray contributions are generally quite weak in comparison with the \bar{E}^{gr} contribution within the lit zone for surfaces that are quite large in terms of the wavelength; hence their contribution may be neglected in such cases.

The parameters ζ^L , ξ , X^L , and X^d become small as one approaches the surface shadow boundary, SSB, from both the lit and shadow regions. As one approaches the SSB, the small argument limiting form of the transition function $F(x)$, which has been introduced previously in Eq. (49), becomes helpful for verifying the continuity of the total high-frequency field at the SSB. On the other hand, the above parameters become large as one moves outside the SSB transition region; in this case, \hat{R}_s reduces to $R_s = \mp 1$ outside the SSB transition region, so that $\bar{E}^{gr}(\hat{P}_L) \rightarrow \bar{E}^r(P_L)$ of GO, and likewise $\bar{E}^d(P_S) \rightarrow \bar{E}_k^d(P_S)$ therein, respectively, in which the Keller surfaced diffracted ray field $\bar{E}_k^d(P_S)$ is given by [1,3,31]

$$\bar{E}_k^d(s) \sim \bar{E}^i(Q_1) \cdot \bar{T}^k(Q_1, Q_2) e^{-jkt}$$

$$\cdot \sqrt{\frac{d\eta(Q_1)}{d\eta(Q_2)}} \sqrt{\frac{\rho_s}{s^d(\rho_s + s^d)}} e^{-jks^d} \quad (73)$$

$$\bar{T}^k(Q_1, Q_2) = [\hat{b}_1 \hat{b}_2 T_s + \hat{n}_1 \hat{n}_2 T_h] \quad (74)$$

where

$$T_{s,h} = \sum_{n=1}^N D_n^{s,h}(Q_1) e^{-\int_{Q_1}^{Q_2} \alpha_n^{s,h}(t') dt'} D_n^{s,h}(Q_2) \quad (75)$$

The D_n^s and α_n^s are the Keller's GTD diffraction coefficients and attenuation constants for the n th soft (s) or hard (h)

surface ray mode. Thus, in the GTD, the surface ray field consists of surface ray modes that propagate independently of one another. Also, this surface ray field is not the true field on the surface; it is a boundary layer field. The GTD result of Eq. (73) in terms of Eqs. (74) and (75) is not valid within the SSB transition region. On the other hand, the UTD result of Eqs. (58) and (59) in terms of Eqs. (60) and (61) is indeed valid and continuous across the SSB.

The UTD result for the 3-D configuration can be simply modified to recover the corresponding UTD result for the 2-D case by allowing the caustic distances ρ_1^r and ρ_s in Eqs. (58) and (59) to recede to infinity. Then, let

$$\rho_2^r \equiv \rho^r \text{ if } \rho_1^r \rightarrow \infty \text{ and } \rho_s \rightarrow \infty \quad (76)$$

so that

$$\vec{E}^{gr}(P_L) \approx \vec{E}^i(Q_R) \cdot [\vec{R}_s \hat{e}_\perp \hat{e}_\perp + \vec{R}_h \hat{e}_\parallel^i \hat{e}_\parallel^r] \sqrt{\frac{\rho^r}{\rho^r + s^r}} e^{-jks^r} \quad (77)$$

in which ρ^r is as in Eq. (19), and

$$\vec{E}^d(P_s) \approx \vec{E}^i(Q_1) \cdot [\vec{D}_s \hat{b} \hat{b} + \vec{D}_h \hat{n}_1 \hat{n}_2] \frac{e^{-jks^d}}{\sqrt{s^d}} \quad (78)$$

because $[\hat{b}_1 = \hat{b}_2 \equiv \hat{b}$ for the 2-D case (note: $\hat{b} = \hat{e}_\perp$)]. The \vec{R}_s and \vec{D}_s in Eqs. (77) and (78) are as defined earlier, respectively; only the L appearing in Eq. (67) is given by

$$L = \frac{s' s^d}{s' + s^d} \text{ for the 2-D case} \quad (79)$$

where s' is the distance from the 2-D line source to the point of grazing incidence at Q_1 and $s \equiv s^d|_{SSB}$ as before. A comparison of the UTD and GTD solutions for a 2-D circular cylinder illuminated by a nearby line source is

illustrated in Figs. 17(a) and 17(b); those UTD solutions are then compared with the corresponding exact (Eigenfunction) solutions in Figs. 18(a) and 18(b).

2.4.3. Some Additional Diffraction Problems. Sections 2.4.1 and 2.4.2 focused on the important problems of diffraction by edges and smooth convex surfaces (with source and observer both off the surface). Also important are the problems of radiation and mutual coupling associated with conformal antennas and arrays located directly on a smooth convex metallic surface. In the convex surface problem of Section 2.4.2, the source and observer must be at least a few wavelengths away from the surface. On the other hand, either the source or the observer must lie on the convex boundary for the conformal antenna radiation(transmitting)/receiving cases, respectively, whereas both the source and the observer must lie on the convex boundary for the calculation of the mutual coupling between a pair of conformal antenna elements. The rays encountered in the radiation and mutual coupling associated with antennas located conformally on a convex surface are shown in [32,33]. The UTD ray field expressions for the latter two cases are available in [8,32–35]. It is noted that surface rays in general exhibit torsion (or twist) giving rise to interesting polarization effects. The problem of scattering by a smooth convex surface discussed earlier in Section 2.4.2, where neither the source nor the observer lies on the surface, does not contain such torsional ray effects in terms of an explicit torsion factor in the solution even though the surface rays may be torsional. However, the solutions to the problems of radiation and mutual coupling where either the source or observer lies on the surface, and where both the source and observer lie on the surface, respectively, contain explicit torsion factors [8,32,33].

The HF diffraction by the tip of a metallic plane angular sector, as in Fig. 19, or by the tip of a metallic

cone, as in Fig. 20, respectively, have been addressed with some limited success to date. Such problems are far more complex to solve. However, tip diffraction problems including the diffraction by the tip of a metallic pyramidal or other complex surfaces remain to be attacked for providing useful UTD solutions in a fairly accurate and tractable manner for all aspects of incidence and scattering. Some interesting work in this area of high-frequency tip diffraction can be found in [36–47]. One notes that tip diffraction is generally not as strong as edge diffraction except in the shadow boundary transition regions that develop when an edge or surface terminates at a tip.

Although all of the above work discussed thus far in Sections 2.4.1, 2.4.2 and 2.4.3 is limited to perfectly conducting structures, far less work has been performed to date on developing sufficiently general UTD or uniform asymptotic HF solutions for nonperfectly conducting (i.e., nonmetallic) surfaces. Some work in this area involves the diffraction by wedges and cylinders with impedance boundary conditions [12,48–52]. The impedance boundary

conditions simulate the effect of thin material coatings on metallic structures. Clearly, more work needs to be done in developing more rigorous and more general UTD solutions for nonmetallic canonical problems to further extend the applicability of the UTD ray technique for solving an even larger class of practical EM problems.

More recently, the development of GTD/UTD has been extended to treat the HF radiation from large, finite planar periodic arrays of antenna elements and frequency selective surface (FSS) elements, as well as similar large conformal periodic arrays on even larger cylindrical host structures, where the radiation from the entire large,

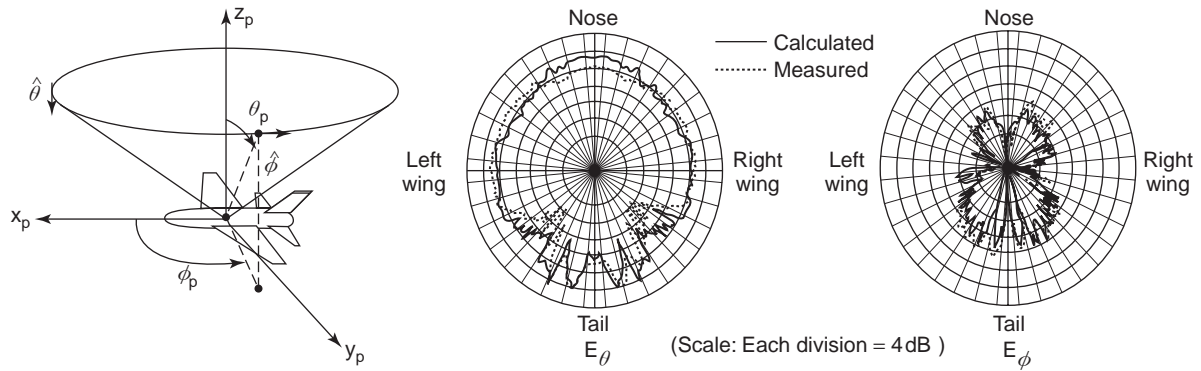

Figure 22. Radiation Pattern of F-16 Monopole antenna mounted on fuselage just behind the cockpit. Again here the plane geometry is approximated to meet UTD assumptions.

finite array can be described in terms of just a few rays [53–56], thus providing a useful picture for array radiation/scattering. In contrast, conventional approaches employ an array element by element field summation method

that, besides being inefficient, hides any physical insights into the large array radiation mechanisms.

Some references to related work on UTD for interior waveguide discontinuity problems may be found in

[57–61]. Also, additional general references to ray methods, such as GO, UTD, and other high-frequency methods such as the equivalent current method (ECM) and PO/PTD, are included [62–79]. Finally, some books that discuss specific HF methods, or HF methods in general, may be found in [28,80–88].

3. SOME ADDITIONAL NUMERICAL EXAMPLES

In Section 2, some simple examples were indicated to illustrate the accuracy of the GTD/UTD. The application of UTD to deal with a slightly more complex antenna problem of how its pattern is affected by a finite ground

plane is available in [89]. More complex problems of radiation by horn and large reflector antennas have been treated successfully by the UTD; these are summarized in [90–92]. Reference [91] also contains examples illustrating the accurate prediction of the pattern of antennas on aircraft in a relatively efficient manner by the UTD, as given in [93,94]. An example of the radiation by a monopole antenna placed just behind the cockpit on a Boeing 737 aircraft and as predicted by the UTD is shown in Fig. 21. The UTD result is compared with a model measurement in Fig. 21. This latter work [94] is based on the NEWAIR code written at the Ohio State University ElectroScience Laboratory by Prof. Burnside and his coworkers; the NEWAIR aircraft antenna code [95] is based on the

UTD. The good agreement between the predicted and measured patterns is readily evident in Fig. 21. Another example is that of the UTD analysis of an antenna on an F-16 fighter plane; the results are shown in Fig. 22 and are taken from [93]. The next example deals with the UTD analysis of an antenna near a space station model. This latter work is based on the NEC-BSC code [96] written by Dr. Marhefka and his coworkers at the Ohio State University ElectroScience Laboratory. The agreement between the UTD analysis of the space station antenna pattern and the corresponding model measurement [97] is also very good, as seen from Fig. 23.

NOTE: Some relevant references may have been left out inadvertently. The author regrets any oversight.

China

1. INTRODUCTION

Retrodirective array reflectors have found many applications in wireless communications, RF identification (RFID), and intelligent transportation systems (ITSs). These reflectors have the characteristic of reflecting an incident wave toward the source direction without any prior information on the source location. Two types of the retrodirective antenna arrays are usually used. One contains the phase-conjugate elements, and the other uses the Van Atta arrangement [1]. In a phase-conjugate retrodirective array [2], each antenna is connected to a mixer, which in turn is pumped by a local oscillator (LO) with double the frequency of the incident wave. When an incident wave (RF signal) is caught by the antenna, it is mixed with the LO signal, leading to an IF signal reradiated out from the same antenna. The IF signal has an approximate frequency as to the incident wave, but with a conjugated phase (opposite in sign). Due to the phase conjugation, all the IF signals from the antennas would thus coherently reach a remote receiver in the wave incident direction, resulting in an array reradiation beam in the direction. This type of retrodirective array has the advantage that the array elements can be arbitrarily located, not necessarily with equal interelement spacing, nor in the same plane; thus it easily conforms to the object surface. (Nevertheless, a large interelement spacing may cause grating reradiating beams in other directions.) Another advantage is that, by changing the LO frequency, the reradiation wave can be easily frequency-modulated. On the contrary, the phase-conjugated array suffers from the disadvantage that it needs a mixer circuit with a large-frequency difference between RF and LO signals for each array element. Also, an LO with double the system frequency and a corresponding distribution network from the LO to the entire array elements are required. These may make the array complicated, bulky, and costly.

The Van Atta retrodirective array, which was first proposed by L. C. Van Atta [1] in 1959, has a much simpler configuration than the phase-conjugated array does. The antennas of the Van Atta array are paired and connected by transmission lines with equal length or length differences equal to multiples of the guided wavelength. The two antennas of each pair are located symmetrically with respect to the array center. Every antenna serves as both receiving and transmitting antennas. The field received by each antenna is, through the connecting transmission line, reradiated from the corresponding paired antenna. Therefore, the phase distribution for the reradiated fields

at the antennas becomes reversal to that for the receiving fields at antennas, thus producing a reradiation beam in the wave incidence direction. Unlike the phase-conjugated array where active devices are always needed, the Van Atta array can be designed with a passive or active type.

Since the Van Atta array has the simplest form of retrodirective array, it has received a great deal of attention in basic theories and various applications after the report of Van Atta. Sharp made an experimental investigation about the backscattering characteristics of the Van Atta array by forming a planar reflector consisting of 16 dipoles [3,4]. He observed that the backscattering of the Van Atta array may have a minimum at normal incidence and suggested that the scattering of dipole antennas may influence the reradiated fields. Researchers such as Appel-Hansen [5] and Fusca [6] also conducted experimental work on the dipole reflectors, and Walther [7] studied an acoustic horn reflector. Other investigators such as Larsen [8] and Nielsen [9] addressed the theoretical basis of Van Atta dipole reflectors. Another field of research regarding the Van Atta reflector emphasized the use of auxiliary active devices in the interconnection transmission line of Van Atta reflectors and its applications. The idea of making Van Atta reflector active by inserting active components in the transmission line was first proposed by Bauer [10], who suggested using modulating phase shifters in the transmission lines and accomplished an amplitude modulation in the reradiated field. Hansen [11] then suggested adding amplifiers in the transmission lines to enhance the backscattering field strength. In the meantime, Davies [12] proposed a way to vary the angle of the radiation field by introducing a mixer in the delay path for a frequency shift. This idea was later applied by Whithers [13].

Numerous applications of the Van Atta reflector were discussed in 1960s because of the conspicuous superiority of the reflector. One proposed application of the Van Atta reflector is in the satellite communications. Passive, active, and semipassive systems have been discussed [11,14,15]. Another possible application of the Van Atta reflector is as a navigation aid, to strengthen the reflected radar signal from a small boat or airplane toward the searching radar, which was discussed mainly by Davies [12]. By the same feature of reflected-signal enhancement, Fusca suggested an ECM (electronic countermeasures) system [6] for military applications based on the idea that the artificial enhanced signal will confuse the enemy radars. Bauer then discussed an IFF (identify friend or foe) system [10] using code modulation in the reflector.

The generous investigation of Van Atta reflectors continued for about 10 years after Van Atta's proposal. In this period, most of the research focused on Van Atta reflectors using bulky antennas such as dipoles and horns. It was not until the early 1990s, when the intelligent transportation system (ITS) [16] became widely discussed, that the study of Van Atta reflectors began afresh. The retrodirective reflectors were developed mostly by using the low-cost printed antennas, including microstrip antennas, slot

antennas, and printed dipoles. ITS-related applications, such as collision warning radars and vehicle communications, were considered when developing these printed Van Atta reflectors. Cohn [17] first proposed a retrodirective transponder based on the Van Atta array for automotive collision avoidance application in 1993. Chung and Chang [18,19] conducted the methods for predicting the scattering field patterns of the printed Van Atta reflectors in both analytical and numerical aspects. Many planar Van Atta reflectors, including those of passive, active, and quasiactive arrays, were developed [20–24]. Others such as Fujita [25] also studied the depolarizing characteristics of the retrodirective reflectors.

The theoretical analysis of Van Atta arrays is introduced in Section 2, where important formulas regarding the reradiation fields of the arrays are derived. Various design examples of planar Van Atta array reflectors, including passive and active types, are described in Section 3. Section 4 depicts the applications of the vehicle-mounting Van Atta reflectors associated with the ITS, and Section 5 gives a brief summary.

2. THEORY OF THE VAN ATTA ARRAY

As shown in Fig. 1, the Van Atta reflector array consists of a number of antenna elements arranged in pairs. The elements in each pair are placed symmetrically about a conveniently selected center, which is common for all pairs. Transmission lines of equal length, or of multiple-wavelength difference, connect the elements of each pair. An antenna element may be placed at the selected array center and connected to an open-circuited transmission line with a length equal to half the length of other lines. Also, the elements may be arranged as a two-dimensional Van Atta reflector array as illustrated in Fig. 2, where the elements located symmetrically to the center of the two-dimensional array are paired by transmission lines with equal length or of multiple-wavelength difference.

To understand how the reflector array operates, consider an N -element linear Van Atta array illuminated by a plane wave incident at an angle θ , as shown in Fig. 3a. Assume that the N elements form M antenna pairs with $M = N/2$. Antennas 1 and N are paired by a transmission line of length l_1 , antennas 2 and $N - 1$ are paired by a transmission line of length l_2 , and so on. The incident field received by the array elements has a phase distribution of $[0, -\Delta, 2\Delta - (N - 2)\Delta, -(N - 1)\Delta]$. Here $\Delta = k_0 d \sin \theta$ is the incident field phase lag between adjacent antennas, $k_0 = 2\pi/\lambda_0$ is the free-space propagation constant, and d is

Figure 1. A four-element Van Atta array reflector.

Figure 2. Antenna arrangement of a two-dimensional Van Atta array reflector.

the interelement spacing. Now consider the m th ($m = 1, 2, \dots, M$) antenna pair. The signal S_m^r received by the m th antenna can be expressed as

$$S_m^r = C_f E_0 G(\theta) e^{-j(m-1)\Delta} \tag{1}$$

where C_f is a feed factor depending on the configuration of the antenna feed, E_0 is the amplitude of the incident field, and $G(\theta)$ is antenna gain at the incident angle θ . This signal, after traveling through the m th transmission line

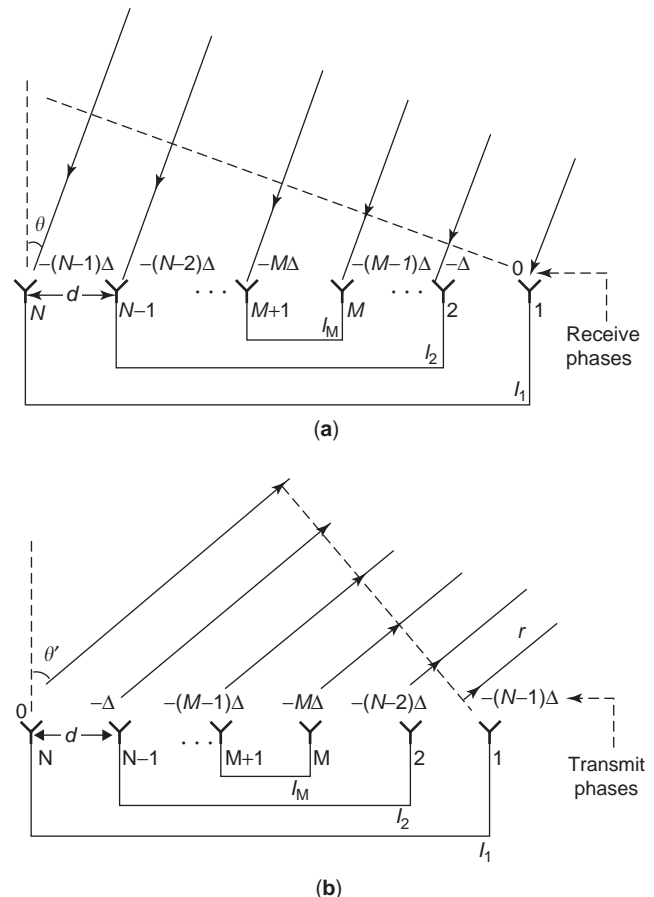

Figure 3. An N -element Van Atta array reflector with (a) receiving phase distribution and (b) transmitting phase distribution.

of length l_m , is fed to the corresponding paired antenna $(N - m + 1)$ and will be radiated out from this antenna. Similarly, through the same transmission line, the signal S_{N-m+1} received by antenna $(N - m + 1)$ is fed to antenna m and will also be radiated out. The signal S_m^f fed to the m th antenna is thus written as

$$S_m^f = S_{N-m+1}^r e^{-jk_g l_m} \quad (2)$$

where k_g is the propagation constant of the transmission line. Using (1) with m replaced by $N - m + 1$, the feeding signal is rewritten as

$$S_m^f = C_f E_0 G(\theta) e^{-jk_g l_m} e^{-j(N-m)\Delta} \quad (3)$$

Since the connecting transmission lines are of equal length or of multiple-wavelength difference, the propagation phase delays $\exp[-jk_g l_m]$ in the transmission lines are the same and equal to $\exp[-jk_g l_1]$. Thus, one obtains

$$S_m^f = C_f E_0 G(\theta) e^{-jk_g l_1} e^{-j(N-m)\Delta} \quad (4)$$

It is seen from (4) that, as shown in Fig. 3b, the signals fed to the array elements have a phase distribution of $[-(N - 1)\Delta, -(N - 2)\Delta \dots -2\Delta, -\Delta, 0]$, which is the reversal of the phase distribution of the incident field received by the array elements. The total reradiation field $E_{\text{rerad}}(\theta', \theta)$ from the array at an observation angle of θ' can be calculated using the antenna array theory [26]

$$E_{\text{rerad}}(\theta', \theta) = \frac{e^{-jk_0 r}}{r} G(\theta') \sum_{n=1}^N S_n^f e^{-j(n-1)\Delta'} \quad (5)$$

with $\Delta' = k_0 d \sin \theta'$. Substituting (4) into (5), one obtains

$$E_{\text{rerad}}(\theta', \theta) = \left\{ \frac{e^{-jk_0 r}}{r} e^{-j(N-1)\Delta} C_f E_0 \right\} e^{-jk_g l_1} \times G(\theta) G(\theta') \sum_{n=1}^N e^{j(n-1)(\Delta-\Delta')} \quad (6)$$

This equation is the bistatic scattering field pattern of the Van Atta array reflector. It is actually a radiation field pattern of the antenna array with excitation from the incident wave. For a given incidence angle θ , the scattering field level varies with the change of the observation angle θ' . As the observation angle coincides with the incidence angle, the scattering field attains a maximum level. The resultant monostatic backscattering field pattern is obtained by letting θ' equal to θ in (6)

$$E_{\text{rerad}}(\theta) = N \left\{ \frac{e^{-jk_0 r}}{r} e^{-j(N-1)\Delta} C_f E_0 \right\} e^{-jk_g l_1} G^2(\theta) \quad (7)$$

where the relationship $\Delta' = \Delta$, when $\theta' = \theta$, has been used. Note that the backscattering field is proportional to the element number N and to the square of the radiation pattern

$G(\theta)$ of the array element. Also, its phase is controlled by the length l_1 of the connecting transmission lines.

To obtain a higher level of backscattering field, more antenna elements may be used in the Van Atta array, which, however, would complicate the layout of the connecting transmission lines, especially for a large planar array. Another way to increase the responding field level is to use the active Van Atta array. The active array may be implemented by inserting an ordinary unilateral amplifier or a bidirectional amplifier on the midway of each transmission line. Figure 4 shows an N -element active Van Atta array with embedded unilateral amplifiers. The N antennas are divided into two groups, one for receiving and one for transmitting. Each group contains M ($= N/2$) elements. Transmission lines of equal length, or of multiple-wavelength difference, are used to pair the antennas in the two groups. Unilateral amplifiers with field gain of A_m , $m = 1, 2, \dots, M$, are implemented in the direction from the receiving antennas to the transmitting antennas. The incident field received by each antenna in the receiving group will travel along the connecting transmission line, be enlarged by the amplifier, and then be fed to the corresponding transmitting antenna. Following the analysis above, the signal S_m^f fed to the m th transmitting antenna is

$$S_m^f = C_f E_0 G_r(\theta) e^{-j(m-1)\Delta} e^{-jk_g l_1} A_m \quad (8)$$

As shown in Fig. 4, these signals have a phase distribution reverse that of the incident fields at the receiving antennas. The total bistatic scattering field is derived as

$$E_{\text{rerad}}(\theta', \theta) = \frac{e^{-jk_0 r}}{r} G_r(\theta') \sum_{m=1}^M S_m^f e^{j(m-1)\Delta'} \quad (9)$$

or

$$E_{\text{rerad}}(\theta', \theta) = \left\{ \frac{e^{-jk_0 r}}{r} C_f E_0 \right\} e^{-jk_g l_1} \times G_r(\theta) G_t(\theta') \sum_{m=1}^M A_m e^{-j(m-1)(\Delta-\Delta')} \quad (10)$$

Figure 4. An N -element active Van Atta array with embedded unilateral amplifiers.

Here $G_r(\theta)$ and $G_t(\theta')$ are the radiation patterns of the receiving and transmitting antennas, respectively. For the active array with identical antennas and amplifiers, $G_r(\theta) = G_t(\theta) = G(\theta)$ and $A_m = A$, the monostatic backscattering field $E_{\text{rerad}}(\theta)$ may be written as

$$E_{\text{rerad}}(\theta) = \frac{N}{2} A \left\{ \frac{e^{-jk_0 r}}{r} C_f E_0 \right\} e^{-jk_g l_1} G^2(\theta) \quad (11)$$

Comparing (11) and (7), it is observed that for a given number of antennas, the backscattering field level of the active Van Atta array using unilateral amplifiers is $A/2$ times higher than that of the passive one, although amplifiers with a gain of A are used. This is because that only the fields received by half of the antennas are amplified by the unilateral amplifiers. To get the merit of the active array, the amplifier's field gain should be greater than 2, or 6 dB. Otherwise, one may use the configuration of active Van Atta array with bidirectional amplifiers. The bidirectional amplifier possesses the characteristic of simultaneously amplifying the signal from both I/O ports with the same gain. As illustrated in Fig. 5, the active Van Atta array is similar to a passive array, but with a bidirectional amplifier embedded midway along each connecting transmission line. Following the procedure from (1) to (6), the bistatic scattering field $E_{\text{rerad}}(\theta', \theta)$ of this active array can be easily derived as

$$E_{\text{rerad}}(\theta', \theta) = \left\{ \frac{e^{-jk_0 r}}{r} e^{-j(N-1)\Delta} C_f E_0 \right\} e^{-jk_g l_1} \times G(\theta) G(\theta') \sum_{n=1}^N A_n e^{j(n-1)(\Delta-\Delta')} \quad (12)$$

where $A_n = A_{N+1-n}$, $n = M+1, M+2, \dots, N$. The corresponding monostatic backscattering field $E_{\text{rerad}}(\theta)$ for the array with identical bidirectional amplifiers is

$$E_{\text{rerad}}(\theta) = NA \left\{ \frac{e^{-jk_0 r}}{r} e^{-j(N-1)\Delta} C_f E_0 \right\} \times e^{-jk_g l_1} G^2(\theta). \quad (13)$$

It is seen that the ratio of the backscattering field level of the active array over that of a passive one is exactly equal to the amplifiers' gain. Also, the active Van Atta

Figure 5. An N -element active Van Atta array with embedded bi-directional amplifiers.

array using bidirectional amplifiers possesses the backscattering field level 6 dB higher than that using unilateral amplifiers. In other words, to get the same field level, only half the number of antennas or amplifiers with 6 dB lower gain are needed in the array of bidirectional amplifiers.

The Van Atta array reflector is usually built on a large metal plate because of antenna design requirements or to shield the transmission lines so as to reduce their scattering. This metal plate, however, would produce an extra strong, varying scattering field and thus deteriorate the retrodirectivity property of the Van Atta reflector, especially in the metal's specular direction. Another mechanism that would influence the reflection characteristic of the Van Atta array is the scattering due to the individual array antennas. Figure 6 illustrates these scattering phenomena for a Van Atta reflector designed using the aperture-coupled microstrip antennas. The total scattering field is composed primarily of three parts: the *reradiated field from the antenna* (RFA), the *scattered field from the terminated antennas* (SFA), and the *scattered field from the partially covered ground plane* (SFG). When a wave is incident the array, some of the power is captured by the antennas and reradiated from corresponding antennas of the same pairs. This is the RFA. In addition, some of the power is scattered by the microstrip antennas and by the partially covered ground plane, corresponding to the SFA and SFG, respectively. The RFA is the dominant contribution of the scattering field for a Van Atta array, and, as derived above, it is proportional to the square of the radiation pattern of the individual array element. The scattered field from the antennas comes from the antenna current induced by the incident wave, which may be calculated by using a numerical method such as the method of moments (MoM) [19]. Finally, the scattered field from the ground plane can be obtained by using the physical optics (PO) method together with the method of equivalent currents (MEC) [18,26]. Figure 7 depicts the theoretical results for the reradiated field (RFA), scattered field (SFA + SFG), and total field (RFA + SFA + SFG) of a common Van Atta array reflector. It is seen that the reradiation

Figure 6. Illustration of the scattering field components from a Van Atta array reflector.

Figure 7. Theoretical backscattering field patterns of a common Van Atta reflector.

field is a slowly varying function of the angle θ , which is the principal contribution to the retrodirectivity of the array reflector. On the contrary, both the amplitude and the phase of the scattered field change quickly with the angle, leading to an oscillatory behavior of the total backscattering field. Since the scattered fields at angles away from the normal of the reflector are much less than the reradiated fields, they can cause only small ripples at these angles. But when the incidence angle is near the reflector normal direction, the scattered field becomes comparable to, if not larger than, the reradiation field. Finally, it is noted that, since the phase of the reradiation field depends on the phase delays in the connecting transmission lines, the total field pattern may be smoothed out by adjusting the lengths of the connecting lines.

3. DESIGN EXAMPLES

In the following text, several Van Atta array reflectors designed using planar antennas and printed transmission lines will be introduced. Since using the printed circuit board (PcB) technique, these reflectors have the advantages of easy fabrication, low cost, and superior conformability to a given body surface, which greatly enhance the merits and extend the application field of the Van Atta array. Passive Van Atta reflectors with one-dimensional and two-dimensional retrodirectivities and active reflectors with unilateral amplifiers and bidirectional amplifiers are described.

Figure 8 shows a printed Van Atta reflector using aperture-coupled microstrip antennas [18]. This two-layer structure creates the antenna and feeding network in two sides separated by the ground plane, leading to a comfort in routing of the feeding network. Three identical *E*-plane subarrays are made to enhance the echo of the reflector. Each linear subarray contains two pairs (four elements) of aperture-coupled microstrip antennas fed by two equal-length microstrip lines ($l_1=l_2=l$) on the reverse side of the ground plane. The distance between subarrays (*s*) and between subarray elements (*d*) are set as $0.7\lambda_0$ and $0.6\lambda_0$, respectively, for a frequency of 10 GHz. The total area of the reflector is $76 \times 68 \text{ mm}^2$. Figure 9 shows the measured pattern of the backscattering field for a retrodirective reflector with $l = 64 \text{ mm}$; that of a plate reflector of the same size is also shown for comparison. It is seen that the retrodirective reflector has quite a smooth pattern. The variation of the field stays within 8 dB in a very wide range of angles (from $\theta = -60^\circ$ to $\theta = +60^\circ$). On the other hand, the plate reflector contributes high returning fields only in the range within $\theta = \pm 5^\circ$. Outside this range, its fields are strongly oscillatory and are much less than those of the retrodirective reflector. As stated above, the phase of the reradiation field depends on the length *l* of the connecting transmission lines. Thus, because of interference between the reradiation field and the scattered field, the pattern of the total backscattering field will change when the length (*l*) of the microstrip lines is varied. To verify this, another reflector with shorter connecting microstrip lines ($l = 62 \text{ mm}$) was measured and compared to the theoretical pattern (see Fig. 10). As predicted by the theory, the total backscattering field near the reflector normal should decrease when the microstrip-line length is reduced. This did happen in the measured field pattern, as can be observed in the figure.

Figure 9. Measured backscattering field patterns for a metal plate reflector and a Van Atta aperture-coupled microstrip array of $l = 64$ mm.

Figure 10. Comparison between measured and calculated backscattering field patterns for the Van Atta aperture-coupled microstrip array of $l = 62$ mm.

Although the aperture-coupled patch antenna has been shown to be a good candidate of the planar Van Atta array element, other planar antennas such as slot antenna and printed dipole antenna can be used to construct the Van Atta array. Figure 11 shows an example of the dual-slot antenna used in a Van Atta reflector [20]. The reflector contains four antenna subarrays, each with six dual-slot antennas appropriately fed and paired by microstrip lines on the backside of the substrate. The dual-slot antenna is formed by cascading two radiating slots via a connecting microstrip line. Owing to the characteristic of the slot antenna that half of the power is radiated backward, a metal plate is placed behind the antenna to enhance the forward radiating power. The two slots are chosen to have the same dimensions and the length l_m of the connecting microstrip line is designed as one guided wavelength λ_g , so that the antenna possesses broadside and symmetric radiation. The measured and calculated E -plane backscattering patterns of the 4×6 retrodirective array reflector at 10 GHz are shown in Fig. 12. The calculated pattern using the method of moments agreed quite well with the measured one. The mainlobe at 0° of the total field pattern is due to the high scattering field from the ground plane. Outside the mainlobe, the variations in the total field pattern eventually follow those of the reradiation field pattern. The small ripples come from the interference of the ground-plane scattering field. It has been suggested [27] that the peak of the backscattering field pattern can be avoided if, when measuring or in applications, the array

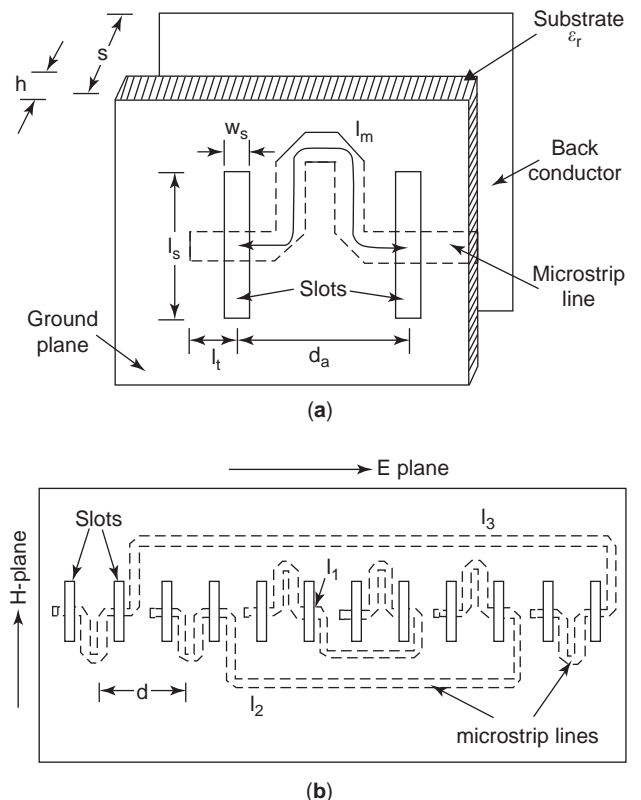

Figure 11. Geometry of dual-slot antenna and top view of six-element linear Van Atta reflector subarray.

Figure 12. Comparison between the measured and calculated field patterns of 4×6 Van Atta dual-slot antenna array.

reflector is tilted several degrees in the H plane to avoid exposure to the specular reflection of the ground plane. Another way to reduce the peak scattering near the broadside direction is to arrange half of the array elements with a quarter-wavelength displacement relative to the other elements, so that the directly scattering field from the first half elements will cancel with that from the other half near the broadside direction [28].

The planar array reflectors described above are retro-directivity in one dimension. They could reflect high fields

only to the source points in the E plane or the H plane of the antenna array. Figure 13 presents a configuration of the two-dimensional Van Atta reflector with retro-directivity in both E plane and H plane [19]. The reflector includes six aperture-coupled microstrip antenna pairs on the antenna substrate (Fig. 13a) linked by $50\text{-}\Omega$ microstrip lines of lengths ranging from l_1 to l_6 on the circuit substrate (Fig. 13b). The lengths l_5 and l_6 are the same and l_1 – l_4 , with differences of multiples of a microstrip-line wavelength. As a result of the opposite feed orientations at the two ends of l_5 (l_6), the differences between l_5 (l_6) and other lines (l_1 to l_4) are odd multiples of half a wavelength. The interelement distances in the E plane and H plane are both chosen as $0.6\lambda_0$ at 10 GHz. Figure 14 shows the measured backscattering field patterns of the reflector in the E plane and H plane. The calculated patterns using the method of moments and the measured patterns of a metal plate of the same size are also shown for comparison. It is seen that the measured patterns agree well with the calculated ones. The relative 10 dB beamwidth is about 130° in both planes, which is much wider than that (18°) of the metal plate. Outside the angles near the normal direction, the reflected fields produced by the Van Atta reflector are, on average, 9 dB higher than those by the metal plate.

An important characteristic of retrodirective arrays is the isolation between the incident wave and the backscattering wave at the source position. One way to increase the isolation is by use of different polarizations for those waves. The basic configuration of such a depolarizing Van Atta reflector is shown in Fig. 15a [29]. It consists of several pairs of dual-polarized antennas. For each pair, the vertical polarization (V-pol) port of one antenna is connected to the horizontal polarization (H-pol) port of the paired antenna, and the H-pol port of the former antenna is connected to the V-pol port of the latter, using transmission lines of equal length or of multiple-wavelength difference. In this configuration, an H-pol (V-pol) beam is automatically formed toward an incoming direction of a V-pol (H-pol) wave. The isolation between the polarization diverse signals ensures minimum interference between received and transmitted signals at the receiving end. A planar depolarizing Van Atta array with retrodirectivity in both *E* and *H* planes is illustrated in Fig. 15b [30], which contains four microstrip antennas operating in two linear orthogonal modes. Figure 16 depicts the measured backscattering field patterns in *E* and *H* planes. For both planes, the backscattering pattern has a 3 dB beamwidth of about 80°. It is noted that by using the depolarizing configuration, the scattering interference from the ground plane is reduced, if not eliminated, to the minimum.

The Van Atta array may be configured as an active reflector by embedded solid-state amplifiers in the interconnection transmission lines. Figure 17 illustrates a four-pair Van Atta aperture-coupled microstrip antenna array with inserted unilateral amplifiers [22]. The transmitting antennas (4',3',2',1') were designed with polarization

Figure 15. (a) Configuration and (b) layout of a 2D depolarizing microstrip Van Atta array reflector.

Figure 16. Measured depolarized field patterns in both *E* plane and *H* plane of the Van Atta array shown in Fig. 15b.

orthogonal (linear) to (with) that of the receiving antennas (1,2,3,4). The interelement distance d between the receiving (transmitting) antennas was chosen as $0.6\lambda_0$, and the distance between antennas 4 and 4' was $0.7\lambda_0$ at 10 GHz. Before being designed into the reflector, a separate unilateral amplifier was made with a measured gain of 11 dB and return loss of -18 dB. The fabricated active Van Atta array had a cross-polarized backscattering field pattern as shown in Fig. 19. This pattern eventually follows the theoretical one, with a 5 dB beamwidth of 80° achieved. Since the cross-polarized reradiated field with amplifier gain is large relative to the copolarized scattering field from the antennas and ground plane, the latter is obviously negligible. Measurement results show that the cross-polarized backscattering fields of a metal plate of the same size are, on average, -25 dB lower than those of the active Van Atta array. The active retrodirective reflector may also be adopted as a transponder. A digital code can be used to control the bias conditions of the amplifiers so that identification or communication messages are produced. It is seen from Fig. 18 that in the range of angles of interest, the backscattering field pattern with amplifiers in OFF state is at least 20 dB down as compared to that with amplifiers in ON state.

Figure 19 presents another demonstration of active Van Atta array designed at 24 GHz [21]. The array contains two linear subarrays, each, in turn, composed of four receiving and four transmitting inset-fed microstrip antennas. Contrary to the previous design, the transmitting antennas have the same polarization as the receiving ones. The embedded HEMT amplifiers have a gain of 10 dB and return loss of -23 dB. Figure 20 shows the backscattering field pattern of the active reflector, compared to that of a metal plate. The reflector's pattern exhibits a narrow peak at 0° , which is due to the strong specular reflection of the array substrate ground. With the exception of this peak, the backscattering pattern of the array in the range from -40° to 40° has variation less than 3 dB and is 10 dB higher than that of the metal plate.

As mentioned earlier, when embedded with unilateral amplifiers, the resultant active Van Atta array can benefit from only half the amplifiers' gain as compared to a passive array. This is because only the fields received by half of the antennas are amplified by the unilateral amplifiers.

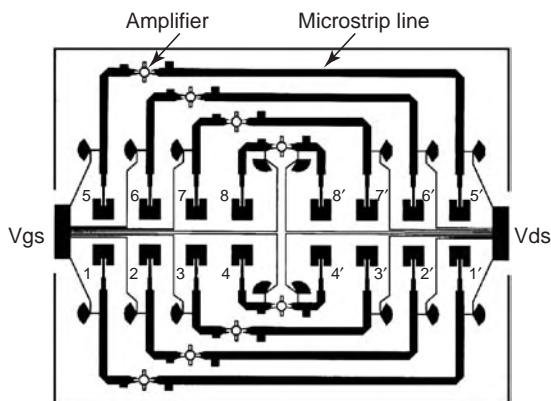

Figure 19. A 24-GHz active Van Atta microstrip antenna array.

Figure 20. Measured backscattering field patterns of the 24-GHz active Van Atta array (—) and a metal plate (---).

To get the full merit of amplifiers' gain, the field received by each antenna should be amplified and then transmitted. One way to achieve this goal is to insert bidirectional amplifiers in the Van Atta array as shown in Fig. 5. Figure 21 depicts the configuration of a bidirectional amplifier proposed by Chung et al. [24], which is constructed by two identical reflection-type amplifiers and a 3-dB 90° hybrid. This bidirectional amplifier possesses the same gain as that of the reflection-type amplifiers, and, due to the symmetry of the configuration, may perform for waves coming from both I/O ports. The measured results of the fabricated bidirectional amplifier show that it provides the transmission gain over the frequency band from 5.76 to 6.88 GHz. At 6.04 GHz, this gain reaches a maximum value of 9.1 dB. Figure 22 is a photograph of a two-element active Van Atta array using the developed bidirectional amplifiers. Printed Yagi antennas with antenna gain of 7.4 dBi and half-power-beamwidth of 55° are used as the radiators in the array. Figure 23 shows its measured backscattering field pattern; that of a four-element passive Van Atta array using the same antennas is also shown for comparison. It is seen that both the patterns are wide. The 3 dB beamwidth of the active array is 74° and that of the passive array is 65° . The backscattering field level of the active array is, on average, 4.5 dB higher than that of the passive one, although the antenna number of the former array is only half that of the latter one.

Figure 21. Configuration of a microwave bidirectional amplifier.

Figure 22. Photograph of a two-element active Van Atta array with bidirectional amplifiers.

Another way to have all the antennas' receiving fields amplified is by using the depolarizing Van Atta array. Figure 24 illustrates such an active retrodirective array with incidence field of V-pol and scattering field of H-pol. Two unilateral amplifiers, one for each direction, are used for the bidirectional amplification in each antenna pair. The field level received by the V-pol port of an antenna is enhanced by the amplifier and then fed to the H-pol port of the corresponding paired antenna. To achieve retrodirectivity of the array, the total phase delay of the transmission line and the amplifier in any path of the same direction should be the same.

4. APPLICATIONS OF THE VAN ATTA ARRAY

Applications of the Van Atta array were widely discussed only a day after Van Atta array was proposed in the 1960s. Since the 1990s, the movements of vehicle safety and intelligent transportation systems (ITSs) have attracted much attention. Collision warning radars and many wireless communication systems are used in moving vehicles. Collision warning radars encounter problems such as clutter from the roadway or roadside objects, which may be more hazardous for smaller cars. This may result in many sources of false alarms. One solution to this problem is to increase the vehicle's effective radar cross section (RCS), which may be achieved by mounting the Van Atta reflectors on a vehicle to increase the scattering beamwidth and thus enhance their "visibility." The Van Atta reflector can also be placed on a potential hazard to increase its echo to an interrogating vehicle radar, thus preventing a possible collision with it. When implemented with modulation circuits, Van Atta reflectors would play a much greater role in these automotive applications. For example, the reflectors mounted at the front and rear of a vehicle would have different modulation codes so that an interrogating vehicle can distinguish between approaching vehicles and those traveling in the same direction. The speed of the Van Atta reflector-bearing vehicle would be included in the modulated return, and thus the interrogating vehicle can distinguish a hazardous closing situation from a normal following situation in which the gap between vehicles is constant or increasing. In essence, the information can be incorporated as part of an intelligent cruise control system. Similarly obstacles and hazards such as bends in the road can be unambiguously identified by the Van Atta reflectors that are coded to indicate the type of fixed obstacle being marked [17].

On the other hand, in ITS applications, various types of information can be exchanged between the system centers and the vehicles by using the wireless communication systems. Among these communication systems, the dedicated short-range communication (DSRC), in which information is exchanged between roadside units (RSUs) and onboard units (OBUs), is one that can fulfill many of the requirements in ITS, and has been widely used for the electronic toll collection (ETC) system. Depending on whether a microwave oscillator is incorporated in the OBU, DSRC can be classified as either an active or a passive system. Although, the active system possesses the advantages of higher sensitivity and wider communication zone, the passive one has transponders with simple

Figure 25. (a) Downlink and (b) uplink of data transmission in DSRC.

circuitry, low consumption power, and low cost. As shown in Fig. 25, the data transmission in the passive DSRC is half-duplex. In the downlink mode, the RSU emits an ASK-modulated left-hand circular polarization (LHCP) wave to the transponder. A detector circuit is established in the transponder to decode the downlink information. In the uplink mode, the RSU simply emit an LHCP continuous wave. The wave is received by the antenna in the transponder, modulated with an ASK or PSK code (containing the uplink information), and then reradiated by the transponder antenna to the RSU. Most of transponders use only one elementary antenna to reradiate the uplink signal, which are limited by the responding signal level. Although the signal level can be increased by using an array antenna in the transponder, it suffers from the drawback of narrow radiation beam, which thus constricts the responding angles of the transponder.

To reduce or eliminate these limitations, the Van Atta array was proposed for use in the transponder design [23]. Figures 26 and 27 show the functional block diagram and the photograph, respectively, of the Van Atta transponder. This card-type transponder has a two-sided configuration, with an area of $12.5 \times 5.5 \text{ cm}^2$. The frontside consists of four LHCP corner-trimmed square microstrip antennas

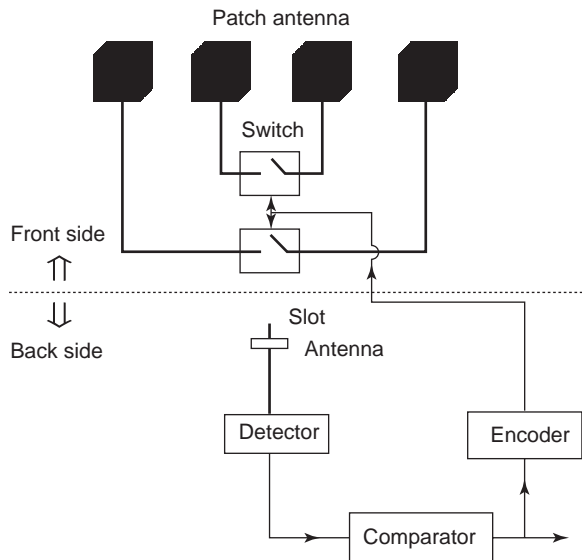

Figure 26. Function blocks of a passive transponder using the Van Atta microstrip antenna array.

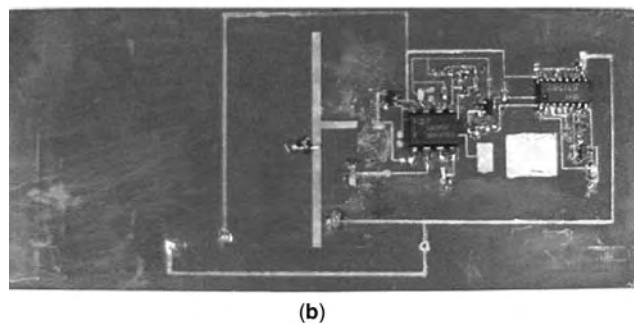

Figure 27. (a) Frontside photo and (b) backside photo of the fabricated card-type 5.8-GHz transponder.

and two pin (positive–intrinsic–negative) diode switches. The two edge antennas and the two middle ones are separately connected by two $50\text{-}\Omega$ microstrip lines, and the switches are embedded midway along the lines. The backside circuit contains a Schottky diode detector and a binary encoder circuit to control the switches on the frontside. A receiving slot antenna is built on the ground plane between the two substrates of the circuits. The slot output signal is connected to the diode detector through a microstrip line on the backside. In the downlink mode, the ASK-modulated wave from the RSU is received by the slot antenna and fed to the diode detector. The detected binary signal is then sent to a voltage comparator to reshape the signal and filter out the noise. In the uplink mode, a continuous wave is received by the slot antenna so that the output from the detector is a small DC voltage. After passing the comparator, this DC voltage will trigger the following encoder circuit to produce a binary voltage code containing the uplink information. This voltage code is then used to control the pin diode switches on the transponder’s frontside so that an ASK/PSK-modulated responding wave is produced. The only power source in the transponder is a 1.5-V-DC standby battery attached on the transponder backside. Only when the communication happens will the battery deliver power to the encoder and switch circuits.

In measuring the transponder performance, a fixed 8-bit binary code of “10101011” as shown in Fig. 28a was designed in the transponder’s encoder circuit. The clock rate for the encoder circuit was set as 16.4 kbps (kilobits per second). In the uplink communication mode, this code was carried by the responding wave to the RSU and detected from the mixing circuit. The detected signal at a distance of 1.5 m is shown in Fig. 28b, which exhibits

Figure 28. (a) Binary code incorporated in the encoder circuit of the transponder for the uplink measurement; (b) signal detected at the RSU in the uplink measurement.

exactly the same code as the original one. For the downlink measurement, a binary code of “10110101” with clock rate of 23 kbps was embedded in the encoder circuit of the RSU and was added to the 5.8-GHz continuous wave. The modulated wave, after being transmitted to the transponder, was then decoded in the transponder’s detector circuit. Although not shown here, the decoded signal did present the same code as that in the RSU.

The Van Atta reflector can also be used to design the OBU of an active DSRC system, where a microwave

source is required. Figure 29 illustrates the circuit diagram of such an active transponder proposed by Luxey and Laheurte [31] for use in a half-duplex communication system. The transponder is a two-element active Van Atta array containing depolarizing antennas, injection-locked oscillators, and amplifiers. The uplink signal is produced in the injection-locked oscillators and fed to the V-pol ports of the antennas for transmitting, and the downlink signal is received by the H-pol ports of the antennas. For retrodirectivity, the two phase delays from the receiving port of one antenna, through the amplifier and oscillator, to the transmitting port of the other antenna should be the same. The operation principle for the downlink mode is similar to that of the passive Van Atta transponder described above. For the uplink mode, an H-pol continuous wave is emitted from the RSU to the transponder and, after received by the antenna and enlarged by the amplifier, is injected to the oscillator of the corresponding element. If its frequency is within the injection-locking bandwidth of the oscillator, the frequency and the phase of the wave from the injection locked oscillator will follow those of the incoming wave [32]. Therefore, the waves produced by the two injection-locked oscillators can radiate with a maximal combination in the wave incoming direction. A PSK modulation can be implemented in the locking signal by tuning the bias voltages of the oscillators, or, an ASK modulation can be obtained by ON/OFF-switching the bias. Using the injection-locked oscillators, this active transponder design has the advantage of simplicity and inexpensiveness, as compared to a conventional transceiver design where a stable and exact microwave source is needed. Also, due to the Van Atta arrangement, this transponder may produce an output signal with higher effective isotropic radiated power (EIRP).

5. SUMMARY

A brief literature survey of the Van Atta retrodirective reflector was discussed initially in this article. The progress of the investigation comprises two main stages, one from 1960 to the early 1970s, and the other from the early 1990s until the present. In the first stage, the reflectors were built by bulky antennas such as dipoles and horns, with proposed application areas in satellite communications, military ECM systems, and small-boat or airplane navigation aids. The second-stage research dealt with planar Van Atta arrays using printed antennas with vehicle-mounting applications such as vehicle communications and collision warning systems. The theory of the Van Atta array was then described, which illustrated that the backscattering field pattern is primarily proportional to the array element number and the square of the element’s radiation pattern. Also pointed out is that the phase delays of the connecting transmission lines may be adjusted to smooth out the backscattering field pattern and to increase the beamwidth. Many design examples using PCB techniques were presented following introduction of the theory. These include Van Atta microstrip antenna arrays with retrodirectivity in one or two incidence planes, and active Van Atta reflectors with

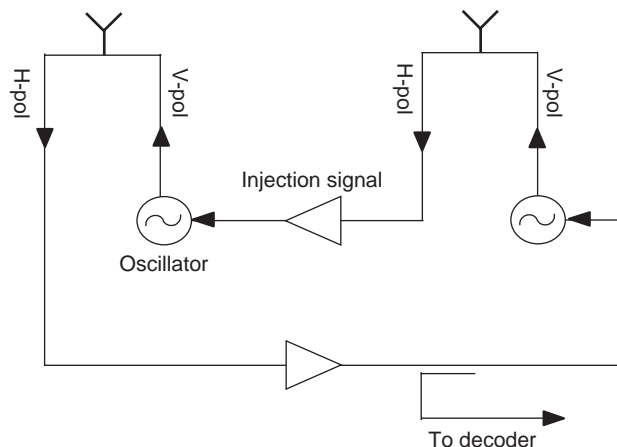

Figure 29. Circuit diagram of an active DSRC transponder using the Van Atta array.

unilateral amplifiers or bidirectional amplifiers. Finally, we have depicted the reflector's applications in the intelligent transportation system, focusing mostly on vehicle collision warning systems and the roadside-to-vehicle dedicated short-range communications.

VARIABLE-FREQUENCY OSCILLATORS

GERMÁN GUTIERREZ
Centellax, Inc.
Carlsbad, California

An *oscillator* is defined as anything that swings back and forth like a pendulum (vibrates) or travels back and forth between two points. An *electronic oscillator* is a device used for producing alternating current (e.g., a radiofrequency or audiofrequency generator). *Frequency* is the number of times that a periodic function repeats the same sequence of values during a unit of time or the number of complete oscillations of a wave per second.

Oscillators are abundant all around us: light, sound, the rotation of Earth, electric AC power, heartbeats, musical instruments, motors, microprocessor clocks, and so on. Some of these oscillatory systems have variable frequency, and some have fixed frequency. We will first

describe all the different types of electronic oscillators to appreciate what determines their operating frequency and how it can be varied.

1. TYPES OF OSCILLATORS

There are two basic kinds of oscillators: sinusoidal and relaxation. The mechanisms that produce these two types of oscillations are different, as are the required conditions for oscillation. Sinusoidal oscillations are represented by RC- and LC-tuned circuits. Their oscillations are continuous and relatively sinusoidal. Relaxation oscillators are represented by multivibrators and ring oscillators. Their oscillations are discontinuous and nonsinusoidal.

Sinusoidal oscillations are created when energy stored in one form is allowed to change uniformly into another form, going back and forth between the two without stopping. Because energy may be transferred between states with minimum loss, some sinusoidal oscillators can be energy-efficient because only small amounts of energy need to be supplied externally to keep the action going. This type of oscillator is associated with linear systems. Sinusoidal oscillators are of two types: feedback and negative resistance.

Relaxation oscillations are characterized by the sequential accumulation and release of energy in one or several storage elements. Energy is accumulated up to a certain level (threshold) and then quickly released (usually dissipated as heat), and then another element (or the same element) in the system begins to accumulate energy until the cycle repeats. The action exhibits positive feedback during reset or relaxation, reinforcing itself and occurring rapidly. This type of oscillator is associated with nonlinear systems. Because all the accumulated energy is periodically dissipated, relaxation oscillators are very energy-inefficient.

This article does not cover chaotic oscillators. Chaotic oscillators do not have a periodic sequence of events that repeat in a unit of time. Related to nonlinear systems, chaotic oscillators occur, for example, in turbulent flows of liquids or in noiselike random signals generated in certain electronic systems.

2. MECHANICAL EXAMPLES

The most elementary types of mechanical oscillators are the spring and mass, and the pendulum, as shown in Fig. 1. In the spring and mass the energy is alternately changing from the spring to the potential and kinetic energy in the mass. At the top of its swing, all the energy is potential energy related to the elevation of the mass. Midway down are kinetic, potential, and spring energies. The pendulum is a well-known example of the oscillation between potential and kinetic energies.

Both systems will slow down because of the friction in the air. The spring also dissipates energy as a result of the internal friction of its metal grains. The pendulum has friction at the hinge. Rather than being strictly oscillators, these mechanical arrangements are examples of damped oscillators. An energy input is necessary to compensate for

Figure 1. Simple mechanical damped oscillators.

the losses and to deliver power to outside loads, for example, to synchronize other mechanical devices.

The windmill is an interesting example of an oscillator (Fig. 2). Its frequency is proportional to the drive level (e.g., the wind strength). The amplitude of the oscillation is, however, fixed. This is the opposite of electronic oscillators, which increase their signal swing in response to more supplied power. However, if we think of the windmill as driving a load, like an AC voltage generator, then there is a relationship between its energy output and the available wind energy. The paddles seem to rotate with the same magnitude, but they deliver changing amounts of energy at varying frequencies.

An example of an oscillatory system that is not sinusoidal, like the pendulum or the windmill, is shown in Fig. 3. The waterdrops accumulate in the glass until the surface tension can no longer hold any more liquid, the water spills over the edge, and the cycle repeats. It is called a *relaxation oscillator* because the energy accumulates in a certain form up to the level that causes the system to relax and let go of the accumulation; then the system resets and restarts the sequence.

3. ELECTRICAL RESONATORS

The electrical equivalents of the mechanical resonator are the series and parallel resonant tanks shown in Fig. 4. They are composed ideally of just an inductor and a capacitor, but there are always losses that are modeled by resistors. The energy is alternatively stored in the capacitor (as an electric field of potential energy) and in the inductor (as magnetic energy). When the capacitor is at full charge, the voltage across the parallel arrangement is at its peak, and when the current through the inductor is at its peak, then the voltage across the tank is zero.

Other popular resonators are transmission line, dielectric, yttrium-iron-garnet (YIG), crystal, and surface acoustic wave (SAW). Resonant tank equivalent circuits at different frequencies of operation can represent all of these.

Figure 2. A windmill produces oscillations of varying frequency in response to the wind force.

Figure 3. Mechanical example of a relaxation oscillator.

4. QUALITY FACTOR (Q)

The Q of a resonator is a useful number to calculate. It is defined as 2 times the ratio of the energy stored in the system to the energy dissipated per cycle [1]. It turns out that Q has two other useful interpretations. It is a measure of how many cycles it takes a damped oscillatory system to decay [2], and it defines the 3 dB bandwidth of a second-order resonator [3]. Q also describes how rapidly the phase changes with frequency near the resonant frequency, indicating how little the frequency will shift with changes that affect a delay in an oscillator loop [4]. Finally, for a series-resonant circuit, Q is the ratio of impedance in L or C divided by R [5]; for the parallel-resonant circuit, Q is the inverse of this equation.

$$Q = 2\pi \frac{\text{peak energy stored in } L \text{ or } C}{\text{energy dissipated per cycle}} \quad (1)$$

$$Q = \pi(\text{number of cycles to decay to } 1/e) \quad (2)$$

$$Q = \frac{\text{resonant frequency}}{3 \text{ dB bandwidth of resonator}} \quad (3)$$

$$Q = \frac{\omega}{2} \times \frac{d\phi}{d\omega} = \frac{\omega}{2} \times \text{rate of phase change with frequency} \quad (4)$$

$$Q = \omega \frac{L}{R} \quad (5)$$

5. SINUSOIDAL OSCILLATORS

5.1. Feedback Oscillators

A general way of thinking about an oscillator is in terms of an amplifier that feeds its output back to its own input

Figure 4. Electrical damped oscillatory systems: series and parallel resonators with loss.

Figure 5. An oscillator viewed as a feedback system in which the output provides its own input.

(Fig. 5). The feedback is controlled by a resonator or a delay element in such a way that the desired frequency and amplitude of oscillation are achieved. Note that the resonator or delay box is still indicated as a two-terminal box with another two-terminal amplifying box connected across it. This could be viewed as a negative-resistance oscillator, as will be discussed later.

5.2. Conditions for Oscillation

Normally, for oscillation to start, the active device provides more energy than is being dissipated in the resonator. This causes the amplitude of the oscillation to grow until it is limited by changes in the active device that reduce its gain. The losses in a system may be linearly related to its amplitude over a limited region, but they grow more rapidly (nonlinearly) over an extended region of amplitude, until they eventually hardlimit the amplitude (e.g., when a barrier is reached).

The requirements for oscillation are that the amplitude of the signal being fed back be large enough to produce an output that can reproduce the feedback (greater than unity loop gain) and that the relative phase between the input and the fed-back input be near zero (so that the feedback reinforces the output). More simply said, the one-way trip around the loop needs to have gain greater than one and zero phase. However, these conditions should not be met at DC; otherwise, the oscillator will latch into a limit state, and no AC oscillation will develop. Additionally, stable oscillations develop only if disturbances in amplitude or phase cause the oscillator to respond by moving back to the unstable point. Finally, reliable oscillators need to have only one frequency at which the conditions for oscillation are met; otherwise, frequency jumps could occur.

5.3. RC Delay Oscillator (Phase Shift Oscillator)

The circuit shown in Fig. 6 is known as the RC (resistor-capacitor) delay oscillator. Three stages of RC delay are used in the feedback path. If the amplifier is inverting, then the RC network needs to produce 180° of phase shift at the frequency of oscillation. Stated differently, the oscillation will occur at that frequency at which the feedback has a phase delay of 180° and the gain is greater than one. Other possibilities to realize the phase delays are to RL (resistor-inductor) delay or lossy transmission-line

Figure 6. RC delay oscillator. For an inverting amplifier, there must be 180° of phase shift in the RC feedback path.

delay. A transmission line is just a distributed RLC delay element. LC delay elements and lossless transmission lines will be covered next.

5.4. LC-Tuned Oscillators

When a tuned circuit is used to define the oscillation frequency, it is desirable to preserve its frequency-selective properties Q . To prevent loading a resonator by the input of an amplifier, a transformer is necessary. Several types of impedance transformation are possible by using coupled inductors, inductive division, or capacitive division. Another possibility is to use another amplifier as a buffer; the input impedance of the buffer is high, and the loading on the resonator is light.

Figure 7 shows two ways of looking at how an amplifier can be connected across a tank circuit using capacitive division of voltage. The arrangement shown on the right is known as the *Colpitts circuit*. Capacitors C_1 and C_2 in series form part of the resonator, and the input loading by the amplifier is reduced by their ratio. The circuit on the left uses the capacitors as a way of getting 180° of phase shift at resonance, while internally completing the loop with an additional 180° resulting from signal inversion. However, the two capacitors are still connected in series to each other and across the inductor, and voltage division takes place across this tank. The advantage of capacitive division over inductive division is that it is easier to realize in an integrated circuit. Split inductors or transformers are more complicated to build than simple inductors.

The arrangements shown in Fig. 8 are known as *Hartley* and *Armstrong oscillators*, respectively. Inductive divi-

Figure 7. Oscillators with capacitive division of voltage, also known as *Colpitts arrangements*.

Figure 8. Inductive division of voltage in Armstrong and Hartley oscillators.

sion, using two inductors or a single inductor with a tap connection, provides the feedback in the Hartley circuit. The input loading is therefore decreased. The Armstrong circuit uses two inductors, L_1 and L_2 , with inductive coupling between them. This may be attractive if the objective is to keep the input and output biases isolated from each other. Moreover, the amount of coupling between the coils can be varied without changing the values of the inductors.

A single-transistor implementation of the capacitively divided tank circuit is depicted in Fig. 9. This circuit is simple because the base bias is provided through the inductor. The value of the collector load resistor needs to be large enough to prevent decreasing the Q of the resonant circuit. The coil and the series connection of the two capacitors make up the resonant circuit. This arrangement can be modified by placing a capacitor in series with the coil (and providing base bias). The series resonant frequency of the coil and the added capacitor can dominate the oscillation frequency, making the circuit less sensitive to variations in the transistor and in the other two capacitors. This modification is known as the *Clapp oscillator*.

The DC-coupled LC oscillator in Fig. 10 is based on a differential amplifier. It has a single-ended tank and a single-ended output. Its output is directly coupled to its noninverting input, and therefore the feedback needs to provide 0° of phase delay because 360° would be impossible with the circuit shown. At resonance, the LC tank presents a purely resistive load to the collector output, and therefore it has no phase delay. Any internal delay through the device will need to be canceled by adjusting the oscillation frequency slightly out of resonance. Using a

Figure 9. Single-transistor implementation of a capacitive division oscillator.

Figure 10. Differential amplifier LC-tuned oscillator with single-ended output. The emitter-follower provides DC-coupled impedance transformation.

variable capacitor would normally control the frequency of this oscillator. A small change in frequency can also be obtained by changing the bias on the differential amplifier.

Tuned oscillators may also use transmission lines, cavities, dielectric resonators, crystals, or YIG resonators to determine their operating frequency. These resonators have equivalent circuits of very high Q . For example, because of the interaction between voltage and mechanical resonance, piezoelectric quartz crystals are much more stable and of higher Q than are LC resonators.

5.5. Use of Varactors

Varactors are used to vary the frequency of resonant LC circuits (Fig. 11). The combined symbol of a capacitor with a diode arrow is used to indicate that they are diodes whose junction depletion capacitance varies. This happens in response to a change in the reverse voltage applied across them. The types of varactor diodes that have the most change of capacitance with voltage are called *hyperabrupt*. The junction between the n region and the p region is made very sharp, and the doping concentrations are very different. This causes the depletion layer on the lightly doped side to move considerably with applied voltage. Since varactors also have loss, they must be selected or designed to minimize the degradation of the resonator's Q .

Figure 11. Resonator arrangements using varactor diodes to tune the center frequency.

The drawing on the left side of Fig. 11 shows a common back-to-back connection of two varactors. Because the voltage that develops in a tank circuit is large, this arrangement offers some cancellation of the variation of the capacitance as a function of the tank voltage. Even-order distortion products are canceled, and the voltage at which the diodes would conduct is increased. The simpler arrangement on the right requires a capacitor to AC-couple the varactor to the inductor so that the inductor does not short-circuit the bias voltage. This circuit is adequate when the signal level is small or when there is no concern about generating harmonics of the tank's fundamental frequency.

5.6. Negative-Resistance Oscillators

Negative-resistance oscillators also can be viewed as one-port oscillators, as opposed to the two-port oscillators used in feedback arrangements. Some electronic devices (e.g., microwave diodes) are two-terminal devices and can be operated only as a one-port device. Therefore, negative-resistance oscillator analysis is the most general in that it includes two- and three-terminal (or more) electronic devices.

To compensate for the losses in a resonant circuit, an active circuit needs to supply power to cancel them. This can be regarded as paralleling the resonator with a negative resistor (Fig. 12). It turns out that most oscillator arrangements can be simplified to this type of model, and an equivalent value for negative R can be calculated. If the negative-resistance "blackbox" is a two-port, which is common, then the other port can be tuned to deliver power to a load.

One possible single-transistor version of a negative resistance oscillator is shown in Fig. 13. The capacitor from emitter to ground makes the input impedance at the base partly negative real and partly capacitive. The inductor at the base can be either series- or parallel-resonated with the input capacitor and with other tuning capacitors or varactors. Note that one could use the collector to deliver power to a load instead of connecting it to the power supply.

6. RELAXATION OSCILLATORS

6.1. Ring Oscillators

Ring oscillators are a popular topology for variable-frequency oscillators used in integrated circuits because they have broad tuning range and require no resonators. They consist of a number of amplifiers or delay stages that may be inverting or noninverting, connected in such a way that

Figure 12. Negative resistance compensates for the losses in a parallel tank resonator.

Figure 13. Negative-resistance oscillator with series resonant tuning.

an odd number of inversions exist around the loop (Fig. 14). The loop is therefore never “happy,” and the result is that an “edge” propagates around the loop. Loops with as little as two buffers are possible, but for large number of stages it is customary to choose prime numbers to prevent the occurrence of multiple modes of oscillation. For example, if we used six buffers, we could have three edges running around the loop, with the result that the frequency would sometimes be 3 times higher. This would happen at random after powering up the circuit.

The frequency of a ring oscillator can be varied in several ways. One popular way is to change the internal delay of each buffer by adjusting the amount of current available to charge and discharge the circuit capacitances. Another way is to vary the amount of load presented at the output of each buffer.

6.2. Astable Multivibrators

Figure 15 shows the main features of an astable multivibrator. It consists of an amplifier with a positive-feedback connection that causes hysteresis in the multivibrator. When one of the inputs causes the output to swing in one direction, the positive feedback changes the switching threshold, reinforcing the input so that there is no hesitation if the input begins to change back. It behaves like a comparator with a moving input threshold. This prevents noisy outputs when the inputs are changing too slowly or when they sit too close to the threshold. In the case of this oscillator, the hysteresis allows the operation of the circuit, which would not occur otherwise. The R and C connected to the inverting input cause this point to vary

Figure 14. A ring oscillator consists of a number of buffers connected in a loop.

Figure 15. Diagram of a bistable oscillator.

exponentially up and down around the hysteresis voltage region. Multivibrators have a broad tuning range.

The astable multivibrator in Fig. 16 is a popular oscillator circuit that is often built in university engineering laboratories and by hobbyists. It is fairly nonlinear because the two transistors take turns being on and off, without spending much time midway. When transistor Q_1 turns on, its collector pulls the base of Q_2 down, through C_2 , keeping it off. Resistor R_3 will in time recharge C_2 and turn Q_2 back on. When this happens, there is positive feedback. As Q_2 turns on, it will turn Q_1 off, and as the collector of Q_1 goes high, it will reinforce Q_2 being on. Next, R_2 will begin to recharge C_1 until Q_1 is turned back on. The RC time constants (R_2C_1 and R_3C_2) need not be the same, and nonsymmetric oscillations can be designed with this circuit. For example, a narrow pulse can be produced. The frequency of oscillation can be varied by changing the value of the resistors (most commonly R_2 and R_3) or by switching different values for the capacitors and using the resistors for fine adjustment. Other possibilities

Figure 16. Example of common multivibrator. The system has two stable points: when Q_1 is on and when Q_1 is off (and Q_2 is therefore on).

Figure 17. Another multivibrator or astable oscillator that needs only one capacitor.

are changing the power supply voltage or the value of the collector load resistors, which are typically smaller than R_2 and R_3 .

Another popular astable multivibrator circuit has a single timing capacitor (Fig. 17). Its frequency is adjusted by changing the value of the current sources. Transistors Q_1 and Q_2 form a cross-coupled pair through Q_3 and Q_4 that acts like an emitter-follower buffer. In this configuration, when one of the two bottom transistors is on, it forces the other transistor off and vice versa, in a latching arrangement with large hysteresis. For example, Q_1 being on forces Q_2 off, which reinforces the state of Q_1 being on. The transistor that is on must supply current to both current sources I and therefore will begin to charge capacitor C until the voltage at its own emitter rises and turns itself off. This happens quickly. The other transistor begins to

charge the capacitor in the opposite direction, and the cycle repeats itself. The frequency of oscillation is linearly proportional to the value of the current in the sources because the capacitor is charged linearly by current and not through a resistor. The waveforms at the emitters of Q_1 and Q_2 are linear sawtooth waves.

The Schmitt trigger oscillator shown in Fig. 18 is also known as the *grounded-timing-capacitor oscillator*. The differential amplifier and two emitter-followers on the right are connected in positive feedback. When the transistor directly on top of the timing capacitor is turned on, it quickly charges it to near the power supply voltage and forces the trigger to switch states. This turns off the top transistor, and the current source begins to discharge the capacitor linearly. When the capacitor voltage is low enough, the trigger switches, and the process repeats. The output waveforms of this oscillator consist of narrow complementary pulses, whereas the voltage across the timing capacitor is a linear sawtooth waveform.

6.3. Voltage-to-Frequency Converters

Voltage-to-frequency converter circuits are used not so much to produce oscillations but rather to measure voltages precisely. They achieve very linear transfer characteristics from voltage to frequency and allow a frequency counter (a digital circuit of high repeatability) to measure the input voltage level. However, as an example of a variable-frequency oscillator, this is the most linear of all.

In the schematic drawn in Fig. 19, the input voltage V_{in} causes current to flow into the precision integrator circuit containing or including C_i . The comparator with hysteresis periodically switches capacitor C_f from the voltage reference V_{ref} to the input terminal of the integrator, discharging it fully. This achieves the transfer of a measure of charge in a way that is independent of the waveform driving the switch, as long as capacitor C_f is given enough time to discharge fully. Note that the polarity of

Figure 18. Detailed schematic of a Schmitt trigger oscillator with the single timing capacitor tied to ground.

Figure 19. Voltage-to-frequency converters are used to measure voltages.

V_{ref} needs to be opposite that of V_{in} , or the capacitor needs to be discharged-inverted. This can be done by connecting the topside of the capacitor to the input and the switch, to the bottom side.

7. PROGRAMMABILITY DESIGN STYLES: HOW TO VARY THE FREQUENCY

Most variable-frequency oscillators are voltage-controlled [i.e., voltage-controlled oscillators (VCOs)]. This is a desirable feature because producing a variable voltage is usually easier than producing a variable current. Even if the frequency control is by variable capacitance, varactors that require a control voltage can be used. In cases where the control variable is naturally current, as in relaxation oscillators or in some ring oscillators, a voltage-to-current converter can be added to make the circuit a VCO.

For sinusoidal oscillators, the presence of a resonant circuit imposes a limited tuning range. Frequency change in these circuits usually uses variable capacitors—or variable resistors in an RC oscillator. In the past, mechanically tuned air dielectric capacitors and even variable inductors were used. Modern designs prefer using varactor diodes. However, the tuning range is limited to less than an octave in a resonant circuit that uses variable components.

To increase the tuning range, different component values can be switched around for different ranges. Usually the inductance is switched, while the capacitance is continuously varied. Mechanical switches have been used in the past, but today switching diodes are preferred because of their small size, lower cost, and higher frequency performance (less parasitics). A popular switching diode is known as *positive-intrinsic-negative* (p-i-n). It consists of three layers of p-type (undoped or intrinsic) and n-type semiconductors. When no current flows through the p-i-n diode, the i (intrinsic) layer acts like a thick dielectric, and

the diode’s capacitance is low. When current is forced through the diode, it exhibits low series resistance. It therefore approximates an ideal switch.

Although their frequency can be varied over only a very small range, crystal oscillators can change frequencies dramatically by switching the crystal element. In some radios, channels are changed by switching crystal values in several oscillators, and their outputs are multiplied or mixed together to produce the desired frequency.

Relaxation and ring oscillators have wide tuning ranges in spite of their poor stability and noise performance. It is easy to tune them over a 10:1 ratio, and with careful circuit design, more than two decades of frequency control are possible. Voltage-to-frequency converters are also easy to tune over broad ranges, although they are relatively slow oscillators.

Table 1 highlights the features of the different oscillators covered. Depending on speed, tuning range, and method of tuning required, a variable-frequency oscillator that meets the required needs can be found. Of course, no single oscillator can simultaneously satisfy all possible needs, and other variables like available materials and cost need to be evaluated.

8. ADVANCED CIRCUITS

Further examples of more sophisticated circuits will be described shortly. The first three examples are differential versions of previously discussed arrangements. Their advantages in rejecting power supply noise and in reducing even-order distortion more than offset the added complexity. Particularly in integrated circuit design, trading the number of components for enhanced response is always a winning strategy. The last circuit shown is an elegant arrangement for a crystal oscillator that has improved output buffering.

A differential LC oscillator with delay tuning has frequency control by varying the delay of the feedback signal (Fig. 20). This works well for low- Q tank circuits that are realized in monolithic implementations. The outputs are directly coupled to the inputs without inversion. The resonant circuit is composed of the series sum of the two inductors and the capacitance across them. The two collectors connected to the tank are operating 180° out of phase. The current at the bottom of the two emitter-followers, which connect to the tank inductors, is varied to change the oscillation frequency. This is done by using another differential amplifier with two output transistors. Less current results in more delay, which the loop compensates for by lowering the frequency of oscillation.

Table 1. Main Features of Variable-Frequency Oscillators

Type	Frequency	Tuning Range	Tuning Means
RC oscillator	Low to medium	Medium	Resistor or capacitor
LC -tuned oscillator	Medium to high	Narrow	Capacitor, switch inductor
Crystal oscillator	Medium	Very small	Voltage, switch crystals
Ring oscillator	Low to high	Wide	Current or capacitor
Astable multivibrator	Low to medium	Wide	Current
Voltage-to-frequency convertor	Low	Very wide	Voltage

Figure 20. Fully differential LC oscillator with delay tuning.

Because of large emitter degeneration, the control voltage produces a near-linear change in the current going into the emitter-followers. For a tank with a Q of less than 10, this circuit achieves a tuning range of over 20% of the central frequency. The inductor is often a planar spiral layout of thin metal sitting on a lightly conductive substrate. The series resistive loss in the inductor and the field-absorbing loss in the substrate dominate the Q of the tank.

A differential version of the negative resistance oscillators is shown in Fig. 21. During operation, transistors Q_1 and Q_2 alternatively turn on and off. The inductor series resonates with the capacitor and with the capacitive input impedance of the two transistors. They present a negative real input impedance when they are on; however, they alternatively turn off, and the real part of the input impedance goes from negative to positive. This simple arrangement provides differential outputs that are useful in several applications in integrated circuit design.

A high-speed, two-stage ring oscillator is depicted in Fig. 22. The buffers consist of slow and fast amplifiers connected in parallel and sitting on top of a differential amplifier. The control voltage allows us to interpolate

Figure 21. Differential version of negative-resistance oscillator.

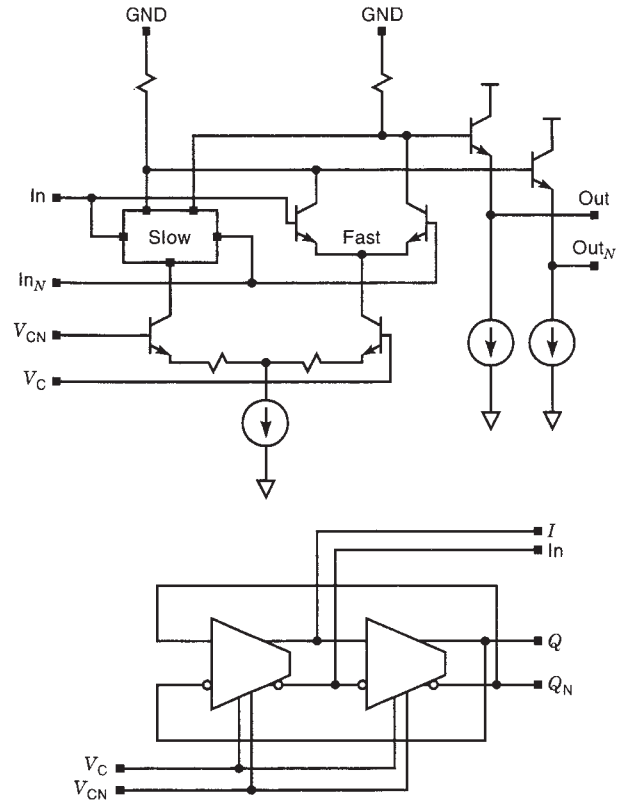

Figure 22. High-speed, two-stage ring oscillator. The frequency is controlled by interpolating the delay of the buffer stages between fast and slow paths.

between slow and fast by splitting the amount of current available at the current source. The differential amplifier has emitter degeneration resistors to linearize the current partitioning as a function of the differential voltage. Two emitter-followers buffer the outputs between stages and improve jitter by improving the voltage transition time. Both the control and the input/output signals are fully differential, resulting in a circuit that is very tolerant to common-mode disturbances. Fully differential oscillators do not depend on reference voltage generators or intrinsic device voltage thresholds to set their operating points. Furthermore, they give us complementary outputs, at twice the differential voltage swing compared to single-ended implementations.

The crystal oscillator with buffered output in Fig. 23 uses two transistors, connected as emitter-followers, in a Darlington arrangement. The input bias current is small, and the resistive loading on the crystal is light. Capacitors C_1 and C_2 connected across the Darlington pair make the input impedance have a negative real part. This arrangement can therefore be viewed as a negative-resistance or one-port oscillator. The oscillation amplitude will be limited by the voltage increase at the emitter of transistor Q_2 , which debiases the transistor and limits the maximum current flowing through it. However, the amplitude at the base of transistor Q_1 should not be so large that it saturates it. The output is taken at the collector of

Figure 23. Crystal oscillator based on Darlington pair used in negative-resistance circuit.

transistor Q_2 , and the load is elegantly isolated from the core of the oscillator.

9. SUMMARY AND SUGGESTIONS FOR FUTURE STUDY

The design of variable-frequency oscillators requires knowledge of the main topologies, the limits of frequency-selective arrangements, the conditions for reliable oscillation, and the available means of tuning, to name the main variables. This article has tried to organize the types of oscillators into two main groups—sinusoidal and relaxation—and has described how their frequencies are changed. A good understanding of a system requires a model of the system. A sinusoidal oscillator can be modeled in two different ways: using feedback and using negative resistance. Relaxation oscillators operating at high frequency can sometimes be modeled in the same way, but in general they are described by their states and their time constants. Simple equivalent circuits and equations for the resonators were presented, attempting to highlight the most intuitive representations.

The variety of oscillators in existence offers many choices, but it also emphasizes the fact that there are unexplored combinations. Particularly because so much of society is influenced by the advances in electronic engineering, and especially integrated circuit engineering, the design of smaller, faster, and cheaper circuits is a very important activity. Variable-frequency oscillators of improved quality are needed today in telecommunications, data transmission, and instrumentation. The components available to design oscillators are constantly undergoing change, most particularly in integrated circuits.

VERY HIGH FREQUENCY RANGE

RICHARD L. CAMPBELL
 Cascade Microtech, Inc.
 Beaverton, OR

1. TIME, FREQUENCY, AND WAVELENGTH

The Very High Frequency (VHF) range extends from 30 MHz to 300 MHz, which means that when a VHF sine-wave signal is observed on an oscilloscope, the trace completes from 30 to 300 million cycles each second. Each cycle takes from 3.3 to 33 nanoseconds. When a VHF signal is radiated into the air by an antenna, it travels at the speed of light. If you could watch the signals travel, like water waves radiating from a stone dropped in a pond, you would observe that the wavelength of 30 MHz signals is 10 meters, and the wavelength of 3 MHz signals is 1 meter. The wavelength and frequency of VHF signals has a profound impact on the hardware we build to use these frequencies.

2. UNIQUE CAPABILITIES OF VHF

2.1. Compact, Effective Antennas

The 30 to 300 MHz frequency range has been popular since radio engineers first discovered how to reliably generate and amplify VHF signals during the 1930s. The VHF range has significant advantages for some common applications over higher and lower frequency ranges. Many of these advantages are related to the size of effective antennas. Antennas interact with radiofrequency waves according to the wavelength of the signals. Antennas for low frequencies (long wavelength) are large, and antennas for high frequencies (short wavelength) are small. For example, the Navy's ELF (extremely low frequency) antenna at 72 Hz covers several counties in the state of Wisconsin, and the EHF (extremely high frequency) 10 GHz

radar that opens the door at the grocery store has an antenna several centimeters across. Neither of these antennas is particularly effective: the 72 Hz antenna in Wisconsin is filled with lossy rocks, dirt, animals, and people, and the little grocery store door-opener antenna is too small to collect much signal.

Nondirectional antennas can be built with dimensions from about 0.1 wavelength to 0.5 wavelength. Antennas that radiate and collect radio energy from a particular direction have larger dimensions from about 0.5 to 5 wavelengths, and highly directional antennas (sometimes called “Pencil Beam” antennas) have dimensions larger than 5 wavelengths. The VHF range, with wavelengths from 1 to 10 meters, allows us to build effective, nondirectional wire or rod antennas with lengths from 10 cm to 5 meters, and directional antennas with dimensions from about 1 meter to 50 meters. Pencil Beam directive antennas for VHF are large and expensive. If a very narrow antenna beam is needed, for example, for a radar system, it usually makes sense to select a frequency above VHF. Some of the first radar systems developed during WWII used VHF bands because engineers had not yet figured out how to generate high power at microwave frequencies.

With effective nondirectional whip antennas less than 1 meter long, and directional antennas with dimensions a little larger than 1 meter, the VHF range is in demand for a number of different radio services. It is very convenient to build good, inexpensive, lightweight nondirectional antennas that may be carried around or mounted on a moving automobile, train, boat, or airplane. The most common type of nondirectional antenna is the vertical whip, as seen on automobiles. Directional VHF antennas, mounted on an antenna rotator or fixed in a particular direction, are often seen on the roofs of buildings. The most common type of VHF directional antenna is the yagi television antenna (named for Yagi and Uda, early twentieth century Japanese inventors).

2.2. Reliable Local Signal Propagation

The convenient size of effective antennas is not the only advantage of the VHF range. Lower frequencies are much more strongly effected by the highly variable electron densities in Earth’s ionosphere. These electron densities vary with height above the earth, position around the earth, from day to night, from day to day, summer to winter, over the 28 day solar rotation period, and over an 11 year cycle related to solar activity. The high frequency or shortwave bands from 3 to 30 MHz are famous for providing worldwide but unreliable radio coverage that varies with the whims of ionospheric weather. Ionospheric effects occur much less frequently at VHF. Television Channel 2 at 54 MHz might experience ionospheric reflected interference from TV stations 1000 km away 10 days a year, and FM broadcast signals near 100 MHz experience long distance propagation even less often.

2.3. Bandwidth

Even if the 3 to 30 MHz range were not susceptible to highly variable ionospheric propagation, it could still only accommodate 4 TV channels, each 6 MHz wide. The VHF

range from 30 to 300 MHz includes 12 TV channels and still has almost 200 MHz left for other services. Almost all of the services permitted to operate below 30 MHz are required to use very narrow bandwidth—typically 6 kHz or less. AM broadcast channels are 10 kHz apart, and high-frequency SSB voice channels may be spaced every 3 kHz. It is possible to send pictures over a 3 kHz channel, but the number of frames per minute is very small. To transmit moving pictures requires much more bandwidth. VHF Television channels are 6 MHz wide. Bandwidth may also be used to improve signal-to-noise ratio and audio fidelity when signals are strong. FM broadcasting, which operates from 88–108 MHz, has 150 kHz wide channels spaced every 200 kHz.

3. RADIO SERVICES ON THE VHF BANDS

With many useful radio activities competing for frequencies in the VHF range, government agencies have assigned frequency bands to a large number of different services. Here is an abbreviated list of frequencies and some of the different services assigned to the VHF spectrum:

- 30–40 MHz Police and Fire
- 46–49 MHz Cordless Telephones, Radio Controlled toys
- 50–54 MHz Amateur Radio
- 54–72 MHz TV channels 2,3,4
- 72–76 MHz Radio Control
- 76–88 MHz TV channels 5,6
- 88–108 MHz FM broadcasting
- 108–135 MHz Aircraft
- 136–144 MHz Space, Weather Satellites
- 144–148 MHz Amateur Radio
- 148–160 MHz Police and Fire
- 162–166 MHz Weather radio and Boats
- 166–216 MHz TV channels 7–13
- 222–225 MHz Amateur Radio
- 225–300 MHz Military

All of these different services operate at once in the VHF range. Some of them operate continuously, like TV stations, some of them occasionally, like cordless phones, and some of them only in emergencies. Government regulations, antennas, and, particularly, VHF radios are all designed to allow these different services to share the VHF range without interfering with each other.

4. VHF RADIO TECHNOLOGY

4.1. Radio Systems

VHF radio systems consist of transmitters, transmitting antennas, the path signals follow between transmitter and receiver, receiving antennas, and receivers. In FM and TV broadcasting, the transmitters and transmitting antennas are large, expensive, and owned by corporations, whereas the receivers are inexpensive and available at the local department store. Communication services usually have a transmitter and receiver sharing the same box (called a transceiver) connected to the same antenna. Handheld transceivers include a battery pack and an antenna all in one common unit.

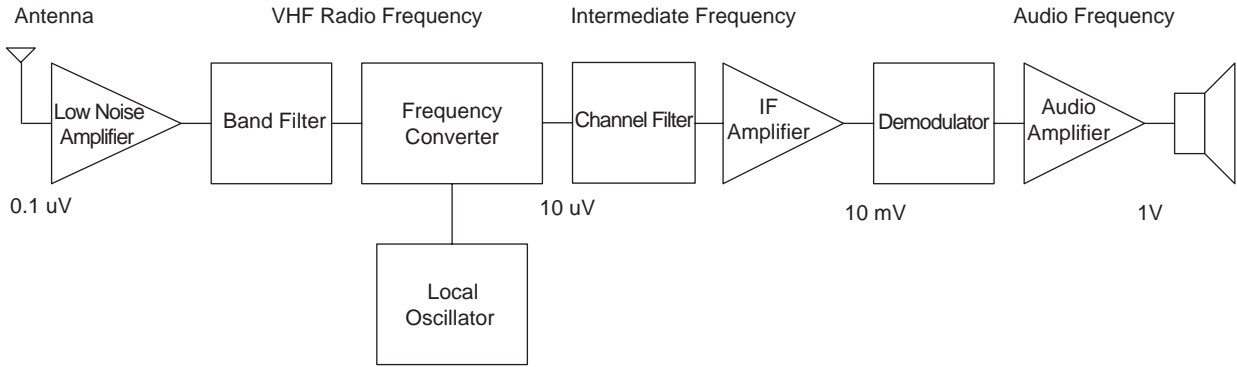

Figure 1. Block diagram of typical VHF receiver.

Figure 1 is the block diagram of a typical VHF receiver, and Fig. 2 is a block diagram of a transmitter. A number of common blocks exist: amplifiers, local oscillators, frequency converters (usually called mixers), filters, modulators, and demodulators. Audio amplifiers operate at much lower frequencies, and intermediate frequency (IF) amplifiers, filters, and demodulators operate in the high-frequency range—often at 10.7 MHz or 21.4 MHz in VHF radio systems. All of the electronic circuits at frequencies below 30 MHz operate within the range of common laboratory instruments, such as oscilloscopes, and use technology familiar to both analog and radiofrequency (RF) designers. In addition, the clock speeds of Digital Signal Processing (DSP) systems continue to increase, and much of the IF signal processing, including modulation and demodulation, is now commonly done in DSP.

The electronic blocks that must operate above 30 MHz in a VHF radio include low noise amplifiers (LNA), mixers, local oscillators, power amplifiers (PA), switches, and RF filters. Above 30 MHz, components and interconnecting wires are large enough that their dimensions have significant impact of circuit operation.

4.2. The Inductance of Interconnecting Wires

VHF electronic design includes some peculiarities, but it is a mature art, and many successful designs have resulted from following a few basic rules. One rule for building

VHF radios, often quoted in 1960s era Amateur Radio VHF Handbooks, is that if component leads are visible, they are too long. The LNA input circuit schematic and sketch in Fig. 3 will illustrate the need for short leads. The circuit includes a 10 nH (nanohenry) inductor, a 46 nH inductor, and a 22 pF capacitor. The 10 nH inductor is just 1 cm of bare copper wire soldered directly from the input connector to ground. At low frequencies, this wire is a short circuit, but at 144 MHz, its inductive reactance is exactly cancelled by the reactance presented by the 46 nH inductor and 22 pF capacitor, so no signal is lost. However, this only happens at 144 MHz if the other inductor in the circuit is 46 nH. What if the 46 nH inductor were soldered into the circuit with a 1 cm lead on each end? Then the inductance would be approximately 10 nH + 46 nH + 10 nH = 66 nH, and the input circuit would resonate at about 130 MHz. Suppose the 22 pF capacitor had 1 cm leads. Each capacitor lead would have about 10 nH, or 10 ohms of inductive reactance at 144 MHz. The 22 pF capacitor has about 50 ohms capacitive reactance at 144 MHz, so the 22 pF capacitor in series with two 10 nH leads would have a reactance of +j10 - j50 + j10 = -j30 ohms. So the 22 pF capacitor looks about 40 percent larger with 1 cm leads at 144 MHz—it looks like about 30 pF. It still looks like 22 pF at low frequencies. However, at some frequency around 250 MHz, a 22 pF capacitor with 1 cm leads stops behaving like a capacitor and acts like a perfect short circuit. Above that series resonant frequency,

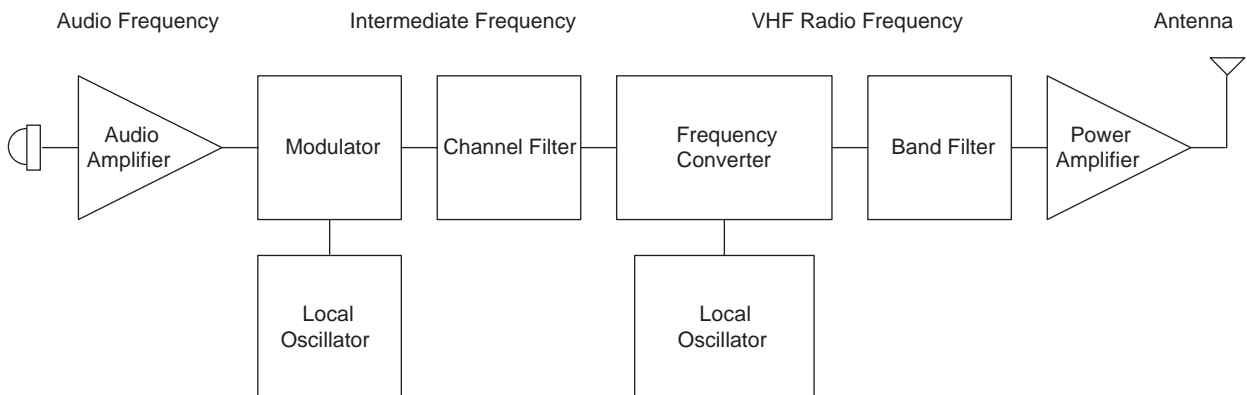

Figure 2. Block diagram of typical VHF transmitter.

Figure 3. Schematic of LNA input circuit.

the capacitor, and its leads, behaves like an inductor, except that it does not pass DC.

Several generations of VHF design engineers struggled with the problem of undesired inductance in both component leads and interconnecting printed circuit board traces, but much of that difficulty is avoided by using surface mount components. A useful rule of thumb is that every surface mount component has about 1 nH of series inductance, as does each millimeter of printed circuit trace. Wise VHF designers minimize the extra inductance in the circuit by keeping the components and layout small, incorporate the extra inductance in the design, and choose circuitry that tolerates small amounts of additional inductance. A common approach to building VHF systems is to design physically small circuit blocks with signal connections that have an impedance of 50 ohms, and interconnect them with 50 ohm characteristic impedance transmission lines.

4.3. The 50 Ohm Environment

VHF circuit blocks are designed to operate in a 50 ohm environment for several very good reasons, including controlling the amplitude and phase of signals, preventing radiation, and compatibility with test equipment. Recall that the wavelength of VHF signals is between 1 and 10 meters. Even 300 MHz signals at the top of the VHF band have 1 meter wavelength, which is likely to be larger than the boxes that radio blocks are mounted inside. However, when it is important to maintain control of the phase of signals between different circuit blocks, a few electrical degrees of phase difference may be significant. An electrical degree is 1/360 of a wavelength, or only 3.3 mm at 300 MHz. Typical components have dimensions of about one electrical degree at 300 MHz. Phase is particularly important in balanced systems, in filters, in oscillators, and when the output of a circuit block is connected through a length of wire to the input of another circuit block. Balance is used to cancel noise and distortion in radio amplifiers and mixers. Perfect balance occurs when signals are 180 electrical degrees apart. A few extra electrical degrees can result in significant degradation of noise and distortion performance. Filters and oscillators depend on well-defined phase relationships to select or generate

one frequency while rejecting others. The need for a well-defined impedance environment becomes clear when we study interconnections between circuit blocks, because signals reflect from boundaries between different impedances, whether the signals are waves in space or waves traveling on transmission lines. Reflected signals result in standing waves.

Figure 4 shows an electromagnetic wave striking a partially reflecting surface. Some of the wave is reflected and some is transmitted. This experiment is easily done with a flashlight and a glass window. The window reflects some of the incident wave because it has a different impedance than air. In space, impedance is the ratio of the magnitude of the E and H fields. Air has an impedance of about 377 ohms, and window glass has an impedance of about 100 ohms. It is possible to get more of the flashlight energy into the glass by matching the impedances using an impedance transformer. Camera and binocular lenses, and some eyeglasses do this by using a coating on the glass. If the same flashlight is shined on a camera lens, much less light is reflected. In an electric circuit, impedance is defined as the ratio of voltage to current. A high-impedance circuit has high voltage and low current, and a low-impedance circuit has low voltage and high current. The standard impedance for radiofrequency instruments and cables is 50 ohms. If a 50 ohm cable connected to a 50 ohm load has a 1 volt rms sine-wave voltage, 20 mA rms current will flow. If this cable is connected to a load with a different impedance, some of the signal will be reflected.

Consider the case illustrated in Fig. 5. To an analog designer at low frequencies, a low-impedance source is considered ideal. Similarly, a high-impedance input is ideal. The low-impedance source in Fig. 5 drives a 30 cm coax cable connected to the high-impedance input of the amplifier. This arrangement works well and is commonly used at audio and low radiofrequencies. Now observe what happens at 144 MHz, in the middle of the VHF band. The signal leaves the low-impedance generator and travels toward the high-impedance amplifier input. The phase velocity of the signal in the cable is about two-thirds the speed of light, so the cable is about a quarter wavelength, or 90 electrical degrees long. Some of the signal power goes

Figure 4. Electromagnetic wave striking a partially reflecting surface.

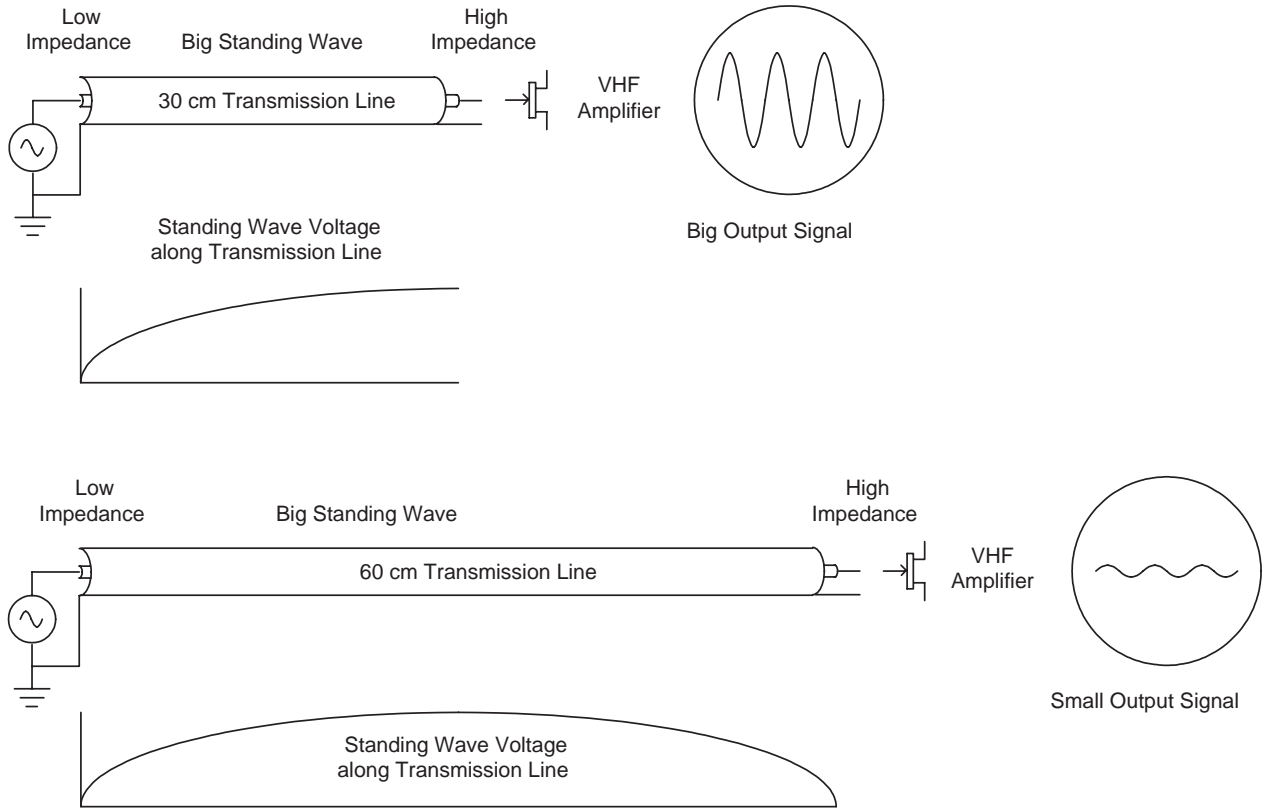

Figure 5. 50 ohm transmission line connected between a voltage source and a high impedance.

into the amplifier, but most of it is reflected. Signals reflected from a high impedance are in phase with the incident signal. The reflected signal travels another 90 electrical degrees back toward the generator, and reflects off the low-impedance generator. Signals reflected from a low impedance experience a 180 degree phase shift. The signal reflected from the generator travels back toward the amplifier input, where it adds to the original signal. The signal at the input of the amplifier is larger than it was, because it has arrived after 180 electrical degrees of travel and 180 degrees of reflection phase shift, for a total of 360 degrees. It adds in-phase with the original signal. The length of transmission line has performed an impedance transformation from the low-impedance source to the high-impedance amplifier input, and the output of the amplifier is large.

Now suppose that the 30 cm cable mysteriously disappears from the bench and a 60 cm cable is borrowed from a nearby lab setup and used to connect the generator to the amplifier. The reflected signal now experiences 360 degrees of travel, plus 180 degrees of reflection phase shift, and it is now out-of-phase with the original signal at the input of the amplifier. The two signals subtract, leaving a very small voltage at the input of the amplifier. The output of the amplifier is now small.

Systems that operate very differently with different lengths of interconnecting cable are a common source of frustration for technicians and engineers with little experience at VHF.

As different blocks in a VHF radio system must be interconnected, and because the length of the interconnecting cables will be a significant number of electrical degrees at VHF, we need a way to control signal reflections. Standard practice at VHF and above is to design system blocks, and even individual components, to present 50 ohm impedances at their terminals, and then interconnect all of the pieces with 50 ohm coax and microstrip transmission lines. Even components designed for 50 ohm terminations must be used with care. Amplifiers and mixers have impedance that changes with frequency, and most filters reflect signals outside the passband. Figure 6 illustrates the passband response and reflection coefficient of a typical narrow bandpass filter. One common technique used to optimize VHF systems with filters is to try different lengths of transmission line while measuring an important system performance characteristic.

Another reason for using coax and microstrip transmission lines to interconnect VHF circuit blocks is that coax and microstrip define the electric and magnetic fields of the traveling signal in a way that prevents radiation. In contrast, antennas configure the electric and magnetic fields to encourage radiation. If VHF circuit blocks are interconnected with simple wires, those wires can become incidental antennas, and radiate most of the signal off into space. Even worse, if an amplifier has wires on both the input and output, the output wire can radiate the signal into space, where it will be picked up by the input wire, and instead of an amplifier, the circuit will be an oscillator.

Figure 6. Bandpass filter with termination impedance plot.

Recall that under the right conditions, a tenth wavelength wire can be an effective antenna. A tenth wavelength at 150 MHz is only 20 cm.

5. NOISE AT VHF

Less atmospheric and Earth noise exist at VHF than at lower frequencies. Often a VHF receiver connected to an antenna through a length of transmission line will hear more internal noise from the losses in the transmission line and the input stage of the LNA than from external sources picked up by the antenna. Receiver sensitivity is thus limited directly by the noise in the receiver input stages and losses in transmission lines. Attention paid to LNA design, and moving the LNA to a location near the antenna (instead of inside the receiver box) can greatly improve receiver sensitivity. Amateur VHF stations with directive antennas aimed at the horizon and well-designed LNAs may hear the increase in background noise as the sun rises.

6. POWER, MODULATION, AND SIGNAL PROPAGATION

The VHF bands are normally used for local coverage, out to about 100 km. Handheld radios may communicate directly with each other out to about 10 km, or over longer distances by using repeater stations located on towers, tall buildings, or hilltops. The effective range of VHF communications systems is highly dependent on local terrain, obstructions near the receiver or transmitter, and the type of antennas used. Most voice communications at VHF use narrowband frequency modulation (FM), with channel bandwidths of about 15 kHz. FM broadcasting uses 150 kHz wide channels for better audio fidelity, and better audio signal-to-noise ratio when the received signals are strong. Stereo and other information is modulated

onto the FM broadcast signal using subcarriers. FM receivers exhibit a capture effect, where the strongest signal captures the receiver and weaker interfering signals are not heard at all, which improves the fidelity of received audio in the presence of interference. VHF Aircraft radios use amplitude modulation (AM) for historical reasons, and because AM receivers do not have a capture effect. If a distant aircraft with a weak signal is calling the tower, it is important for the air traffic controller to know it is there so that stronger stations may be asked to stand by. Amateur Radio Morse code and Single Sideband voice stations with medium-sized yagi antennas and 150 watt amplifiers routinely communicate to about 500 km on a daily basis. These long distance communications are supported by scattering the VHF signals off anomalies in the troposphere. More power and larger antennas allow worldwide VHF communications by bouncing signals off the moon.

7. VHF MEASUREMENTS

At low frequencies, measurements of voltage and current are commonly used to determine whether circuits are working as expected (by engineers and technicians) or hoped (by designers). Although some oscilloscopes are capable of making measurements at VHF, the standard tools on a VHF radio bench include the spectrum analyzer, power meter, signal generators, forward and reflected power meter, noise figure meter, and network analyzer. All of these instruments have 50 ohm ports and standard connectors. The network analyzer measures how well inputs and outputs are matched to the 50 ohm standard, filter passbands and reflections, and amplifier small-signal gain, frequency response, and reverse isolation. Reverse isolation determines how much of what occurs at the amplifier output appears at the input. If reverse isolation is very poor, the amplifier will oscillate when connected to certain loads. If reverse isolation is good enough to prevent oscillation but not much better, loads connected to the output will affect the input impedance of the amplifier, which is significant for LNAs, because they are typically connected to a narrow bandpass filter on the output, and if reverse isolation is only modest, the LNA input impedance will change rapidly at near the edges of the bandpass filter response, which commonly causes the system gain to vary across the desired frequency range. System performance can often be improved by selecting a different length of 50 ohm cable between the LNA and bandpass filter.

8. THE SMITH CHART AT VHF

Simple VHF matching circuits, lumped element transmission lines, reflections and transmissions at boundaries with different impedances, and the effect of different lengths of transmission lines on system performance may be conveniently studied using the Smith Chart. The Smith Chart is a polar plot of reflection coefficient, with curve scales to read impedances. Figure 7 is a simplified Smith Chart with two points plotted. The round point is a reflection coefficient of 0.7 at an angle of 45 degrees, and

Figure 7. Smith Chart.

the square point is a reflection coefficient of 0.25 at an angle of 180 degrees. The Smith Chart is a powerful graphic calculator, and may be used with a pocket calculator (originally a slide rule) to solve a large class of transmission line problems. The Smith Chart approach is so fundamental to the field of radiofrequency engineering that even when it is not used as a calculator, it is used to display the results of radiofrequency measurements and computer simulations. Both the modern network analyzer and RF engineering software packages provide Smith Chart graphical output. The Smith Chart is covered in detail elsewhere in this encyclopedia. As the VHF frequencies were pioneered during the same era that Phil Smith invented his useful chart, VHF technology and the use of the Smith Chart have matured together. More than any other group of technologists, VHF workers are likely to analyze problems and present their results using Smith Charts.

9. VHF COMPONENTS

In 50 ohm systems at VHF, the most common reactive components (inductors and capacitors) have reactive impedance between about 5 and 500 ohms. At 144 MHz, a $-j50$ ohm inductor is 56 nH and a $-j50$ ohm capacitor is 22 pF. We can easily scale from these values to find that a $-j500$ ohm capacitor is 2.2 pF and a $-j5$ ohm capacitor is 220 pF. Similarly, a $+j500$ ohm inductor is 560 nH and a $+j5$ ohm inductor is 5.6 nH. Clearly we need to be very careful using these components at VHF if they have wire leads, because the lead inductance is roughly 1 nH per mm of lead length. If a 5.6 nH inductor with wire leads is mounted on a standard 0.062 inch thick FR-4 printed circuit board, the leads will add several nH to the inductance. Similarly, capacitor lead inductance will increase the effective value of capacitor (decreasing its capacitive reactance). Furthermore, it is wise to recall that inductance is a numerical representation of the ratio of energy in a magnetic field to the current that caused it. It is not the

wire that determines inductance, it is the volume containing the wire and resulting magnetic field. An inductor will behave differently depending on how it is mounted on the printed circuit board. Chip inductors usually have a marking that permits production circuits to be built with the inductor in the same orientation as the working prototype. Capacitance is a numerical representation of the ratio of the amount of energy in an electric field to the voltage that caused it. Chip capacitors are relatively good at containing the electric field within a volume not much bigger than the component. The fact that capacitor leads add inductive reactance to capacitors means that, above a certain value, capacitors stop behaving like capacitors. VHF designers often use the self-resonance of a capacitor and its wire leads or PC board traces to obtain a virtual short circuit at RF that blocks DC. A 220 pF capacitor ($-j5$ ohms at 144 MHz) with a total wire lead and capacitor body inductance of $+j5$ ohms (about 6 mm) has an impedance of $-j5 + j5 = 0$ ohms, which makes a good bypass capacitor, or coupling capacitor between matched amplifier stages.

It is not just the inductance of wire leads that makes components behave differently than expected at VHF. The capacitance between turns of an inductor will make an inductor appear larger than its marked value, which is particularly true for inductors with many turns. It is good practice to avoid capacitors with reactance less than $-j5$ ohms and inductors with reactance greater than about $+j500$ ohms if it is important for their behavior to coincide with their marked value.

Many VHF engineers memorize a set of 50 ohm components at one frequency (i.e., 22 pF and 56 nH at 144 MHz) because it is then easy to scale to different frequencies and impedances. At 48 MHz (one-third of 144 MHz) 50 ohms is 66 pF and 168 nH. At 288 MHz, 50 ohms is 11 pF and 28 nH. For the whole VHF range from 30 to 300 MHz, the most common capacitors will be between 1 pF and 1000 pF (1 nF). 1 pF is about 500 ohms at 300 MHz, and 1 nF is about 5 ohms at 30 MHz. The most common inductors will be between 2.5 nH (5 ohms at 300 MHz) and 2.5 uH (500 ohms at 30 MHz).

9.1. VHF Inductors

Many different configurations of inductors are useful at VHF. In the several hundred nH range, simple self-supporting coils of enameled wire mounted with their own leads above a printed circuit board are particularly effective, and often used in small volume, hand assembled electronics. They are difficult to handle by machine, so small wire coils on a polyethylene form are common in mass produced VHF circuitry. Inductors may be made tunable by moving a threaded powdered iron slug in and out of the polyethylene form. The magnetic field lines around a solenoid coil extend well beyond the dimensions of the coil. Other circuitry, and in particular other inductors in the vicinity of a solenoid, will couple energy out of the magnetic field. Such inductor coupling may be intentional, but often it is not, and the circuit does not perform as expected. Inductor coupling to nearby circuitry may be reduced by shielding the inductors with small metal cans. Subcircuits containing inductors are often surrounded

with metal shields. A shield around an inductor modifies the magnetic field, and usually reduces the energy stored for a given amount of wire and current. As the resistance in the wire is not reduced by the shield, the inductor quality factor Q is degraded. Small shielded inductors typically have about 70% of the Q of the same inductors without shields. Q is improved by using larger shield cans that have less effect on the inductor magnetic field. One way to obtain both high Q and shielding in a compact inductor is by using toroid inductor cores. The magnetic material in the toroid core and the configuration of the winding forces the magnetic field lines into a closed ring shape. Little magnetic field exist outside the physical dimensions of the toroid, and the Q is determined by losses in the wire and toroid core. Several types of inductors are illustrated in Fig. 8.

9.2. Inductor Q

Q is a measure of how much energy is lost (to heat or radiation) per sinusoidal cycle. A bell that rings for a long time has high Q . A cardboard box that goes “thud” when you hit it has very low Q . A useful approximate definition of Q for inductors is the ratio of inductive reactance to series resistance. This definition neglects losses because of radiation or heating of the inductor core. If inductor Q is measured using a Q meter at the desired operating frequency, an inductor model using a larger series resistance may be used. Typical Q s for the inductors used at VHF are from about 30 for small, inexpensive chip inductors, around 100 for small polyethylene core slug-tuned inductors, up to 250 for toroids and large air-core inductors without shields, to about 1000 for silver-plated #12 wire helical resonators. High Q is not necessary or desirable in inductors used to provide DC to a circuit, but they often use large low-resistance wire for current capacity.

Filter circuits need as much Q as possible in the available space. Filter designers trade Q , filter bandwidth, and

loss. Resonator loss is approximately

$$\text{Filter Loss} \sim 20 \log[1 - QL/Qu]$$

Unloaded Qu is the Q of the components used to build the resonator. Usually at VHF, inductor Q is much lower than capacitor Q , so the unloaded Q is approximately the Q of the inductor. Loaded QL is the operating frequency divided by the 3 dB bandwidth of the resonant circuit. For example, a 150 MHz single resonator filter with a 3 dB bandwidth of 15 MHz has a loaded Q of 10. If we built this filter with an inductor with Q of 100, the loss would be

$$20 \log[1 - .1] \sim 1 \text{ dB}$$

which would be a useful filter except at the input to a very sensitive receiver. A filter with three of these resonators would have roughly 3 dB loss. Now if the same filter were built using inductors with a Q of 30, the loss per resonator would be

$$20 \log[1 - .3] \sim 3 \text{ dB}$$

Often we want to build much narrower filters. The 144 MHz amateur band is 4 MHz wide. A three resonator, 4 MHz filter with 3 dB loss has a loaded Q of 36, and would need resonators with an unloaded Q of about 360 to have 1 dB loss per resonator. Small helical resonators can achieve this. For still lower loss, physically larger resonators and thick wire are needed. The highest Q resonators used at VHF are quarter wave sections of large coaxial transmission line. The outer conductors may be 10 cm across, and these cavity resonators are tuned by adjusting the length of the center conductor.

9.3. Capacitors

Fixed capacitors for VHF are usually metal plated on opposite sides of a ceramic or mica wafer. In the past, these capacitors usually had wire leads, but most present day VHF circuitry uses surface-mount ceramic chip capacitors. These capacitors are available in various temperature coefficients. NP0 or COG capacitors have capacitance that changes less than about 50 ppm/degree C. N750 capacitors have a negative 750 ppm temperature coefficient. Electrolytic, tantalum, and many polystyrene and polyethylene capacitors have too much lead inductance to be useful at VHF.

It is convenient to build variable capacitors with air, ceramic, or polyethylene dielectric in capacitance ranges from a few pF to a few hundred pF. Each year physically smaller variable capacitors are introduced, and several manufacturers have variable chip capacitors on the market. Variable capacitors are useful in prototype and small production circuits because it is difficult to consider all of the printed circuit board traces and component lead inductance and interwinding capacitance when designing the circuit. A few variable circuit elements allow the designer to tune out the unknown deviations from ideal behavior.

For precision circuitry like narrow filters and oscillators, it is useful to have precision adjustable capacitors.

Figure 8. Different types of inductors.

Figure 9. Two types of VHF variable capacitors.

Several manufacturers produce air or glass dielectric piston trimmer capacitors with a ceramic or glass body and a moving, cylindrical capacitor piston driven in and out of an insulating cylinder with an outer conductor or second internal plate by a precision lead screw mechanism. Figure 9 is a drawing of two types of VHF variable capacitors.

One type of capacitor that has been used at VHF for at least a half century is the gimmick, illustrated in Fig. 10. It is simply two wires twisted together. Gimmick capacitors are typically 0.5 pF to about 5 pF, and may be easily adjusted by clipping them shorter or twisting the turns tighter. The gimmick capacitor is a useful reminder that capacitors are not just a component that one selects from a catalog, but a device that behaves in a certain way because of the electric field between two conductors.

Figure 10. Gimmick capacitor.

9.4. Resistors

The rules for using resistors at VHF are the same as for lower and higher frequencies: Observe the power rating and be aware of inductance. Some resistors have a cylindrical body with a resistive coat. The precise value of resistance is obtained by making a spiral cut in the resistive coat. Such resistors may have much higher series inductance than expected from their physical size. Other resistors for high power have spiral windings of nichrome wire. Such resistors are inappropriate for radiofrequency use. Chip resistors are the best choice for VHF, as long as their power ratings are observed.

9.5. Transformers, Baluns, Splitters

The VHF frequency range is ideal for building transformers, baluns, splitters, and couplers using small ferrite cores and multiconductor windings of enameled wire. The low-frequency limit of such devices is determined by the permeability of the ferrite core, and the upper frequency limit occurs when the length of the winding becomes a significant fraction of a wavelength. With tiny ferrite cores a few mm in diameter or smaller, it is possible to have many turns on the core with much less than a wavelength of wire, even at 300 MHz. Several manufacturers have extensive product lines of transformers, baluns, splitters, and couplers that approach ideal performance in the VHF range.

A large class of useful device may be constructed from transmission line transformers formed from parallel turns of wire through a small ferrite core or bead. The transmission line transformer has very low resistance to differential currents, and very high impedance to common mode currents. Figure 11 illustrates a simple transmission line transformer constructed of a pair of enameled wires and a ferrite bead and several useful components that may be built by connecting the windings in different ways. Like the gimmick capacitor, it is a reminder that VHF components are just applications of basic physics.

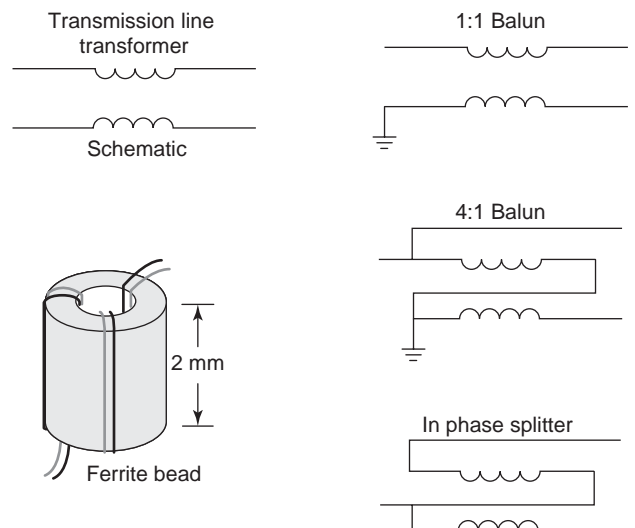

Figure 11. Transmission line transformers.

9.6. Two-Terminal Solid-State Devices

Silicon switching diodes, i.e., the ubiquitous 1N4148, have small enough internal capacitance to be useful for non-critical signal processing at VHF. Schottkey barrier diodes like the HP 5082-2835 have much lower capacitance and well-defined characteristics and are a better choice for repeatable performance and critical circuits. Capacitance is low enough and switching fast enough that small-signal Schottkey diodes have nearly ideal behavior at VHF. PIN diodes are widely used to replace mechanical relays for signal switching at VHF. Variable capacitance diodes are used for tuning filters and voltage-controlled oscillators. Other two-terminal solid-state devices like step recovery diodes and tunnel diodes are occasionally seen in specialized VHF circuitry.

9.7. Frequency Doublers and Diode Ring Mixers

With nearly ideal transformers and diodes, it is easy to build very good diode frequency doublers and mixers over the whole VHF range. Figure 12 is the schematic of a frequency doubler, which is the same schematic as a full-wave rectifier power supply, only in this case it is the double frequency component and not the DC that is of interest. The DC voltage is connected to ground in the circuit shown, but it may also be used as an indicator of drive and output level. If the diodes are reversed, it is a

negative voltage, which might be useful for biasing circuits elsewhere in the VHF radio. The output power is typically between 6 and 10 dB lower than the drive level, over a very wide frequency range. Both doubler ports are reasonably well matched to 50 ohms. If the waveforms are sketched (or reviewed in a book on DC power supply design), it is clear that the input signal needs to be a good sine-wave for frequency doubling to occur. Figure 13 is the standard diode ring double balanced mixer. This mixer works well with 50ohm terminations on all ports, requires about 5 milliwatts of local oscillator drive, and can be built for any frequency from audio to 1 GHz by selecting the appropriate transformers. At VHF, it typically has conversion loss of about 6 dB, port-to-port isolations of around 40 dB, and an input third-order intercept of +17 dBm.

Diode ring mixer and frequency double transformers may be hand wound using small toroid cores for the lower VHF frequency range, but much smaller cores are useful to obtain the best performance at frequencies above 200 MHz. Commercial transformers are available in a wide range of sizes and configurations. Other mixers using passive FETs and integrated Gilbert Cell mixers are commonly used at VHF.

9.8. Three-Terminal Active Devices

Many silicon NPN transistors such as the common 2N5179 work well as oscillators and amplifiers through

Figure 12. Diode frequency doubler.

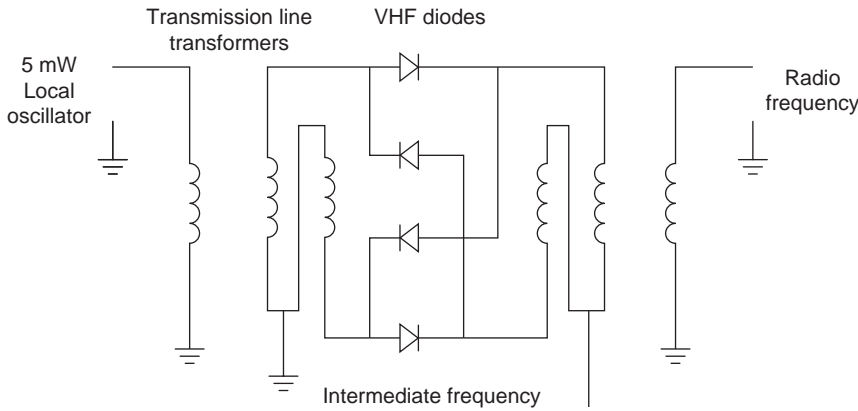

Figure 13. Diode ring mixer.

the entire VHF range. Discrete amplifier designs permit the designer to tailor the circuitry to exactly the needs of the system and make most efficient use of power supplies by using RF inductors instead of resistors as collector loads. JFETs, such as the J310, are also very useful throughout the VHF range. Figure 14 is a typical amplifier using the U310, the metal can version of the J310. The metal can is internally connected to the device gate, and the can is soldered to the printed circuit ground plane to build a common gate amplifier.

9.9. MMICS

A family of silicon monolithic microwave integrated circuits is available that operates from DC to past 1 GHz. Several of these devices, including the MAR-2 and MAV-11, are particularly useful at VHF. The MAR-2, in addition to providing gain, a modest noise figure, and a few milliwatts of output power, has nearly perfect 50 ohm match on both input and output ports, so it is very useful as a basic gain

element in systems with filters and other ill behaved impedances. The MAV-11 had a good enough noise figure to be used as an LNA in modes VHF receiver systems, and 50 milliwatts of output power capability. The disadvantage of these MMIC amplifiers is that half of the power is dissipated in the collector bias resistor, so they are less efficient than well-designed discrete amplifiers and less attractive for battery operated equipment. Their broad bandwidth also requires that bypassing, shielding, and filtering extend to cover the entire gain range of the MMIC, even if the radio is being designed only for a narrow sliver of the VHF spectrum.

9.10. Packaged Filters

Bandpass, highpass, lowpass, and allpass filters may be built in the VHF range using several different technologies including inductors and capacitors, helical resonators, quartz crystals, and surface acoustic wave devices. Bandpass filters for commercially important frequencies

Figure 14. 144 MHz LNA.

Figure 15. Lumped equivalent transmission line.

are available from a number of sources. If the desired filter is not available in the catalog, an analog circuit simulator can be used to design filters using standard slug tuned inductors and chip capacitors. When the percentage bandwidth is modest (filter bandwidth is between 5% and 20% of the center frequency), these filter simulations tend to agree fairly well with measured performance.

9.11. Power Amplifiers

VHF amplifiers for a few watts through about 50 watts may be designed and built using discrete bipolar or FET power devices, or complete amplifier modules may be purchased for many different VHF frequency ranges. Broadband low-distortion amplifiers are used to distribute cable TV signals. From 50 watts to a few hundred watts, discrete transistor amplifiers are often combined using power splitters and combiners. Above a few hundred watts, vacuum tubes become practical and compete with large solid-state amplifiers.

9.12. Lumped Element Transmission Lines

A radiofrequency designer often needs a transmission line with a particular electrical length to obtain a specific phase shift. In the VHF range, lengths of coax cable are short enough that they are sometimes used in circuits. In very small circuits, and at the low end of the VHF range, coax cables may be too long to fit in the available space. A lumped element equivalent transmission line may be made using pi network sections of alternating inductors and capacitors. Figure 15 shows a quarter wavelength 50 ohm coaxial line at 144 MHz and its equivalent lumped element circuit. At VHF, lumped element equivalent transmission lines made up of surface-mount components are much smaller than coax cables, and much less expensive.

9.13. VHF Circuitry

VHF circuits operate at a high enough frequency that it is important to minimize lead lengths and pay attention to making layouts compact, but are not so high that completely different circuit techniques must be developed. A VHF amplifier schematic and circuit might look just like one for 10 MHz, but with a more compact layout. In contrast, an Ultra High Frequency (UHF) amplifier circuit is often distributed along a length of 50 ohm microstrip transmission line, with the interconnecting line lengths

just as important as the component values. Microstrip transmission line circuits are also common at the upper frequency end of the VHF range, and for power amplifiers. VHF circuits often employ a mix of components with wire leads and chip components, mounted on opposite sides of the same circuit board.

9.14. Shielding

As VHF circuit board layouts occupy a significant fraction of a wavelength, they radiate more RF energy than radio circuits at lower frequencies. VHF designers often include metal shield cans around VHF amplifier, filter, and oscillator circuits to keep the desired signals inside and undesired signals out. A VHF filter with an ultimate stop-band rejection of 60 dB when connected to measurement equipment on the bench may have only 40 dB when mounted on a radio printed circuit board. Metal shields soldered over the input and output circuits can improve isolation.

10. FURTHER INFORMATION

VHF Engineering is a mature art that forms a bridge between high-frequency radio design and microwave technology. Many professional VHF engineers are also active as amateur radio designer/builders, and the amateur radio literature provides a good catalog of accepted and proven VHF circuits and techniques. Both the American Radio Relay League (ARRL) and Radio Society of Great Britain (RSGB) publish extensive handbooks on practical HF and VHF technology. A recent copy of the ARRL Handbook for the Radio Amateur is often found on the HF and VHF engineer's bookshelf. More specialized, very practical VHF information is available in the Proceedings of the Central States VHF Conference, also published by ARRL. Much of the emphasis in professional radio engineering for the past several decades has been focused on high-volume consumer microwave electronics like cell phones and wireless local area networks, so it may not be easy to find practical applied VHF engineering information in the recent professional literature. Several journals, including RF Design and High Frequency Electronics, offer a good selection of articles on practical VHF technology. Committee MTT-17 of the Institute for Electrical and Electronic Engineers has a Website devoted to HF, VHF, and UHF Technology.

1. INTRODUCTION

The *voltage-to-frequency converters* (VFCs) belong to the category of the *oscillator* circuits. The function of an oscillator is to produce periodic time-varying signals with only DC excitations.¹ These signals may have quite diverse waveform shapes such as triangular, square, impulsive, exponential, and sinusoidal. For some oscillator applications, the shape of the generated signal is an important design criterion, for instance, in the production of periodic sweep voltages for display systems or in the generation of quasisinusoidal signals for testing and instrumentation purposes. In other applications, the most important design criterion is the signal *frequency*, while the spectral purity of the signal remains secondary. This is, for instance, the case for oscillators used to generate clock signals for timing purposes and also for VFCs.

The function of VFCs is to convert the value of an analog *input* voltage or current into an *output* frequency; that is, they must generate signals of any shape whose frequency is a faithful representation of the analog input data. Thus, they also belong to the category of the *data converter* circuits, whose function is to convert the information among different domains with minimum degradation of the information itself. From this point of view, the VFCs have some similarities with the analog-to-digital converters (ADCs), whose function is to convert an analog data into a digital word with the minimum error possible.

¹In practice, the excitations may not strictly be DC, but AC signals whose frequency is smaller, commonly much smaller, than that of the signal generated by the circuit.

In the case of VFCs the domain of the transformed information is the frequency of a signal, instead of a digital word, and the aim is to obtain the smallest possible error in the voltage-to-frequency mapping. The design criteria for VFCs include the following [14]:

- *Dynamic range*, the range of input voltage values where the transformation takes place. A related magnitude is the *frequency range*—the range of output frequencies that corresponds to the input voltage range; 60 dB and larger dynamic ranges² are commonplace.
- *Linearity* of the voltage-to-frequency map, $f_0 = F(v_{in})$. This map is required to be highly linear,

$$F(v_{in}) = k \cdot v_{in} + E(v_{in}) \quad (1)$$

with error $E(v_{in})$ much smaller than 1% of full scale.

- *Scale factor accuracy and stability*. The parameter k in Eq. (1) must be externally set for given voltage-to-frequency gain. After its setting, the gain must remain stable with temperature (≤ 100 ppm/ $^{\circ}$ C), aging, and changes of the power supply ($\leq 0.1\%$ /V).

Such requirements are related to the main application area of the VFCs, namely, the encoding of information for telemetry or remote control. In these applications, the analog data are converted into frequency at the emitter front end using a VFC. The generated signal is then transmitted through an optical or radiolink—a process in which the signal frequency remains essentially unchanged. Then, at the receiver front end, the analog data are recovered from the signal frequency by using a *frequency-to-voltage converter* (FVC).

From the construction point of view, the VFCs are in the same category as the so-called voltage-controlled-oscillators (VCOs), in the sense that the circuit structures employed to realize VFCs and VCOs are actually quite similar. However, the typical applications of VCOs usually demand low precision in the voltage-to-frequency map and, in some cases, high spectral purity. In this article, we will start by presenting a broad overview of the different circuit structures that qualify to generate periodic signals with voltage-controlled frequency. Then, we will focus on structures that are better suited to achieve accuracy in the voltage-to-frequency mapping.

2. BASIC CONCEPTS AND MODELS FOR OSCILLATOR DESIGN

Circuit synthesis is the process of interconnecting circuit components so as to realize some targeted behavior. The first step for systematic circuit synthesis is to identify mathematical descriptions for the targeted behavior. In the case of oscillators, the target is to obtain a steady-state

²The dynamic range (DR) can be expressed in a number of equivalent bits b by using the expression $DR = 6.02 \cdot b + 1.76$. Thus, 60 dB dynamic range corresponds to an equivalent resolution of 9.7 bits.

Figure 1. *N*-shaped characteristics necessary to implement oscillator circuits and associated piecewise-linear approximation.

cyclic solution with only DC excitations. For VCOs and VFCs, the timing of these cyclic solutions must also be electronically controllable.

“The simpler, the better” is a basic motto for electronic circuit design. In the case of oscillators, two ineludible (inevitable) ingredients are dynamics and nonlinearity. Thus, oscillator circuits must contain capacitors and/or inductors together with nonlinear elements. Strictly speaking, the dynamics must be at least of second-order type—meaning that the corresponding circuit requires at least two energy storage elements. With regard to the nonlinearity, the simplest one is the *N*-like shape of Fig. 1a, which can be approximated by a series expansion

$$\zeta(x) = -\eta_{\text{NI}} \cdot x + \eta_{\text{NE}} \cdot x^3 \quad (2)$$

where η_{NI} and η_{NE} are real parameters that can be used to fit the required function shape. Alternatively, Fig. 1a can be approximated by the *piecewise-linear* curve depicted in Fig. 1b, where the fitting is realized through the real parameters γ_{NI} and γ_{NE} .

2.1. Basic Oscillator Model

The basic oscillator model is built by combining the ingredients above into

$$\begin{aligned} \tau_x \frac{dx}{dt} &= -y - \zeta(x) \\ \tau_y \frac{dy}{dt} &= x \end{aligned} \quad (3)$$

Figure 2a shows a conceptual realization of this equation using two integrators, one adder and one block with nonlinear transfer function $\zeta(x)$ —all realizable in electronic form. Figures 2b and 2c show realizations using capacitors, inductors, and nonlinear resistors; it is easy to confirm that Fig. 2b maps onto Eq. (3) for $x = v$, $y = Ri_L$, $\tau_x = RC$, $\tau_y = L/R$, and assuming that the resistor has a voltage-controlled characteristic $iR = \zeta(v)$; similarly, Fig. 2c maps onto Eq. (3) for $x = Ri_L$, $y = v_C$, $\tau_x = L/R$, $\tau_y = CR$ and assuming that the resistor has a current-controlled characteristic $v = \zeta(iR)$.

The model of Eq. (3) generates stable oscillations—called *limit cycles*—due to the dynamic *equilibrium* between two opposite forces: one *expansive*, the other *contractive*. The expansive force occurs for $|x| < \delta$ because of the negative slope of the nonlinearity in this region (see

Fig. 1b).³ This negative slope can be realized only through an active element that injects energy into the system, thereby causing $|x|$ to increase with time. On the other hand, the contractive force occurs for $|x| > \delta$ as a result of the positive slope of the nonlinearity in this region. Because of this positive slope, the system dissipates energy and, consequently, $|x|$ decreases with time.

The actual trajectories in the transient evolution toward the limit cycle depend on the values of the parameters τ_x , τ_y , γ_{NI} , γ_{NE} , and δ . The shape of the limit cycle orbit and the frequency of the motion are also dependent on these values. Finding closed relationships among the shape and frequency, on one side, and the parameter values, on the other, is not even possible in the more general case. However, for our purposes here it suffices to study the approximated solutions in two particular cases. First, we find it convenient to rewrite Eq. (3) in terms of a normalized time variable $\tau = t/\tau_0$ with $\tau_0 \equiv \sqrt{\tau_x \tau_y}$. It yields

$$\begin{aligned} \frac{dx}{d\tau} &= \alpha[-y - \zeta(x)] \\ \frac{dy}{d\tau} &= \frac{1}{\alpha}x \end{aligned} \quad (4)$$

where $\alpha = \sqrt{\tau_y/\tau_x}$. The two particular cases of interest occur for extreme values of the parameter α ; they are respectively called the *harmonic oscillator case*, corresponding to $\alpha \ll 1$, and the *relaxation oscillator case*, corresponding to $\alpha \gg 1$.

2.2. Harmonic Oscillator Case

This corresponds to $\alpha \ll 1$, namely, to $\tau_y \ll \tau_x$. For a better understanding of what happens in this case, it is

³In the electronic implementation of Figs. 2b and 2c, the negative slope is caused by a negative resistance. This negative resistance injects energy into the two other circuit components, namely, the inductor and the capacitor. Because these latter elements do not dissipate energy, but simply store it, the total energy increases and this manifests itself as an increase of the signal amplitude. On the other hand, the positive slope is caused by a positive resistance that dissipates part of the energy stored in the energy storage part of the circuit. At the equilibrium there is balance between the energy injected and the energy dissipated, the circuit energy remains unchanged, and the movement is due to a continuous interchange of this energy between the inductor and the capacitor.

Figure 2. Conceptual realization of the basic oscillator model in Eq. (3) (a) and LC realizations for $x = v, y = Ri_L, \tau_x = RC, \tau_y = L/R$ (b) and for $x = Ri_L, y = v_C, \tau_x = L/R, \tau_y = CR$ (c).

convenient to recast Eq. (4) into the following scalar form

$$\frac{d^2x}{d\tau^2} + \alpha \frac{d\xi}{dx} \frac{dx}{d\tau} + x = 0 \quad (5)$$

obtained after differentiating the top expression in Eq. (4) and using the bottom expression to substitute $dy/d\tau$.

Assume first that the nonlinearity is null. Then $d\xi/dx = 0$ and the solution of Eq. (5) for initial conditions $x(0) = x_0$ and $dx/d\tau|_{\tau=0} = 0$ is $x(\tau) = x_0 \cos(\tau)$, and hence

$$x(t) = x_0 \cos(\omega_0 t) \quad (6)$$

where $\omega_0 \equiv 1/\tau_0$. Obviously, such a solution could not be maintained in practice because of the unavoidable energy dissipation, which is why nonlinearity is needed for practical oscillator design. However, because $\alpha \ll 1$, the second term in Eq. (5) is negligible and at the limit cycle $x(t)$ is quas sinusoidal; $x(t) \approx \rho \cos(\omega_0 t)$ with the amplitude for fixed α and τ_0 depending on γ_{NI}, γ_{NE} , and δ .

The set of drawings in Fig. 3 illustrate the harmonic oscillation case. On one hand, they are intended to highlight the dynamic equilibrium process underlying the onset of oscillations. On the other, they give insight on the influence of the model parameters. All the drawings are for $\tau_x = 10, \tau_y = 0.1$, and $\delta = 1$. The three drawings at the top are for $\gamma_{NE} = 1$ and $\gamma_{NI} = 1$. The one on the left in this subset shows the solution trajectories in the x - y plane for different initial conditions. The opposed expansive and contractive forces are highlighted by this figure. Their equilibrium results in the system evolving toward a limit cycle from any initial condition located either inside or outside it. The waveform at the center in the top set of figures shows $x(t)$ at the steady state. Because this steady

state is obtained as the result of a nonlinear equilibrium process, this waveform is not a pure sinusoidal, but contains harmonics. The spectrum on the right shows these harmonics. The three drawings in the center row in Fig. 3 are for $\gamma_{NE} = 1$ and $\gamma_{NI} = 0.2$. Here the frequency is practically the same as in the previous case, although the amplitude and distortion of $x(t)$ are now smaller. On the other hand, the evolution from inside the limit cycle toward the limit cycle itself is much slower. However, the last set of drawings, for $\gamma_{NE} = 1$ and $\gamma_{NI} = 3$, again display practically the same frequency but much larger amplitude and distortion, and a very fast evolution to the limit cycle.

The following observations on the influence of parameters can be made regarding the harmonic oscillator case:

- The oscillation frequency is basically set by $\tau_0 = \sqrt{\tau_x \tau_y}$. The voltage control of this frequency is hence achieved through electronic tuning of the time constants τ_x and τ_y . For the LC circuits of Figs. 2b and 2c, the frequency can be made voltage-controlled by resorting to the use of tunable capacitors or inductors [15,17,25].
- On one hand, for given values of $\tau_x, \tau_y, \gamma_{NE}$, and δ , the larger γ_{NI} , the larger the signal amplitude and the signal distortion; also, the faster the dynamic evolution toward the limit cycle from the inside. On the other hand, for given values of $\tau_x, \tau_y, \gamma_{NI}$, and δ , the smaller γ_{NE} , the smaller the signal distortion, although the speed of the dynamic evolution towards the limit cycle from the inside does not change with γ_{NE} . Finally, the value of δ influences the signal amplitude, but has no influence on either the signal distortion or the speed of the evolution towards the limit cycle.

2.3. General Harmonic Oscillator Model

Figure 2a can be redrawn as depicted in Fig. 4a, consisting of the interconnection of a linear dynamic block with transfer function in the s domain given by

$$H(s) = \frac{X(s)}{Z(s)} = \frac{s \frac{1}{\tau_x}}{s^2 + s \frac{\gamma_{NE}}{\tau_x} + \frac{1}{\tau_x \tau_y}} \quad (7)$$

and a nonlinear block with transfer characteristics $\zeta(x)$. Note that the linear block acts as a bandpass filter with resonant frequency $\omega_0 \equiv 1/\tau_0$ and quality factor $Q = 1/(\gamma_{NE}\alpha)$. Note also that the gain of this filter at the resonant frequency is $1/\gamma_{NE}$; and that the nonlinear block gains $\gamma_{NE} + \gamma_{NI}$ inside its inner linear region.

Assume $x(t) \approx \rho \cos(\omega t)$. The system can oscillate, provided the amplitude and the phase of this signal are maintained while the signal is being transmitted across the loop. Consider first the phase. On one hand, the nonlinearity is static, and does not produce any phase shift. On the other hand, the phase of the linear block is null only for $\omega = \omega_0$, which is why the oscillation actually occurs at this frequency. Now consider the amplitude. On one hand,

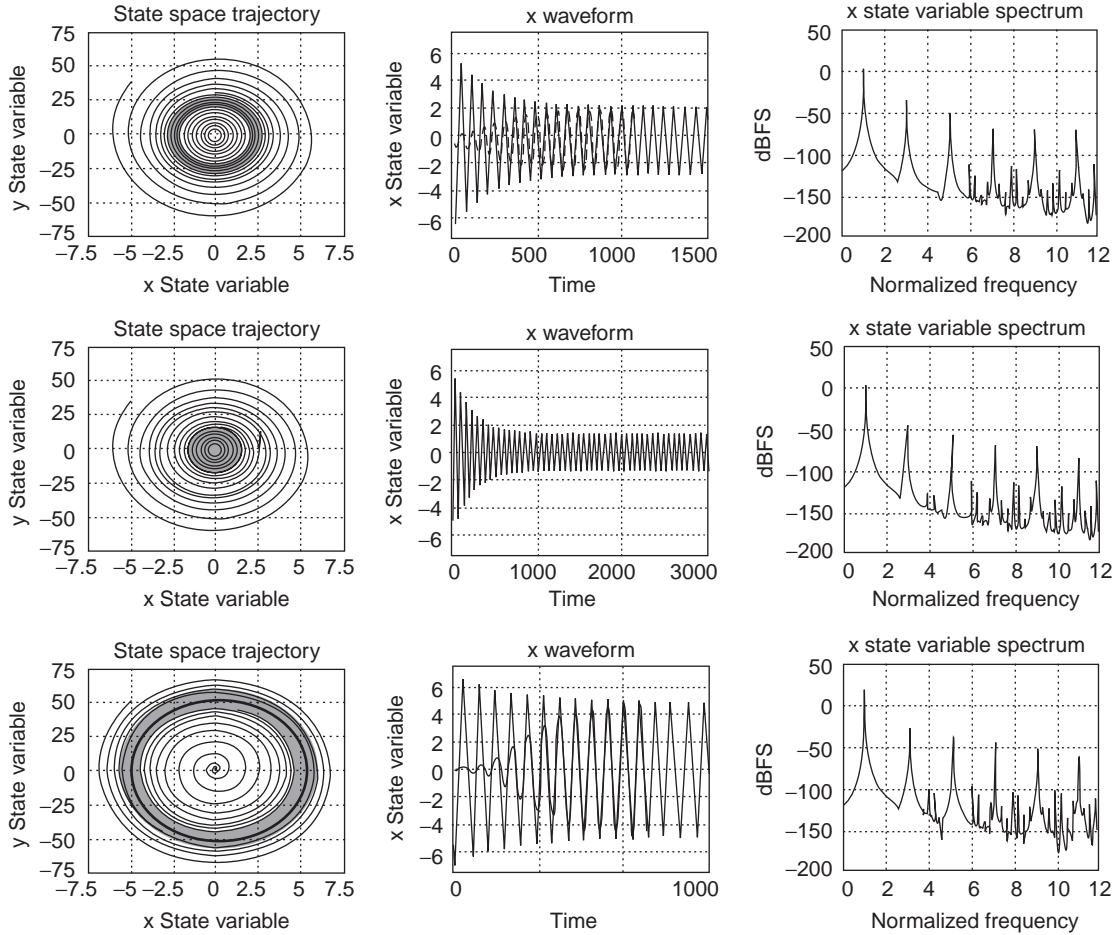

Figure 3. Trajectories, signals, and spectrum for the oscillator model in the harmonic oscillation case for $\tau_x = 10$, $\tau_y = 0.1$, and $\delta = 1$. The three drawings at the top are for $\gamma_{NE} = 1$ and $\gamma_{NI} = 1$; those in the center row are for $\gamma_{NE} = 1$ and $\gamma_{NI} = 0.2$, and the drawings at the bottom were obtained for $\gamma_{NE} = 1$ and $\gamma_{NI} = 3$. We see that the oscillation frequency is practically the same in the three cases (basically set by $\tau_0 = \sqrt{\tau_x \tau_y}$). We also observe that the larger γ_{NI} , the larger the signal amplitude and distortion, while the dynamic evolution toward the limit cycle is faster.

for $\rho < \delta$ the loop has a gain of $1 + \gamma_{NI}/\gamma_{NE}$, larger than unity, so that the amplitude grows while the signal transverse the loop. On the other hand, for $\rho > \delta$, the gain is compressed because of the saturation nonlinearity. The compression increases with ρ until a critical amplitude value ρ_0 is reached where the effective gain is unity.

Figure 4b shows the block diagram of a generic harmonic oscillator model. On the basis of the explanations given for Fig. 4a, the following statements are made for this generic model:

- The phase shift of the linear block must be frequency-dependent and null at a single frequency $\omega = \omega_0$, which is the oscillation frequency. The sharper the phase-versus-frequency characteristics of the linear block around this zero-phase frequency, the higher the accuracy of the oscillation frequency setting.
- Now consider the oscillation amplitude. On one hand, the loop gain at the zero-phase frequency must be larger than unity for low amplitudes. This ensures

that the oscillations will start. On the other hand, the compression exercised by the nonlinear block must render the loop gain smaller than unity for large amplitude values. The oscillation occurs at the amplitude for which the compressed loop gain at the zero-phase frequency is just unity.

This can be applied to the *ring oscillator* structure of Fig. 5a, commonly employed in VCOs. It is composed of N identical stages, each with linearized transfer function [23]

$$F(s) = \frac{-G_m R}{1 + sRC} \quad (8)$$

connected into a feedback loop. On one hand, note that each stage produces a phase shift of $\pi - \text{atan}(\omega RC)$; the zero-phase frequency is hence readily calculated as

$$f_0 = \frac{1}{2\pi RC} \tan \frac{\pi}{2N} \{3 + (-1)^N\} \quad (9)$$

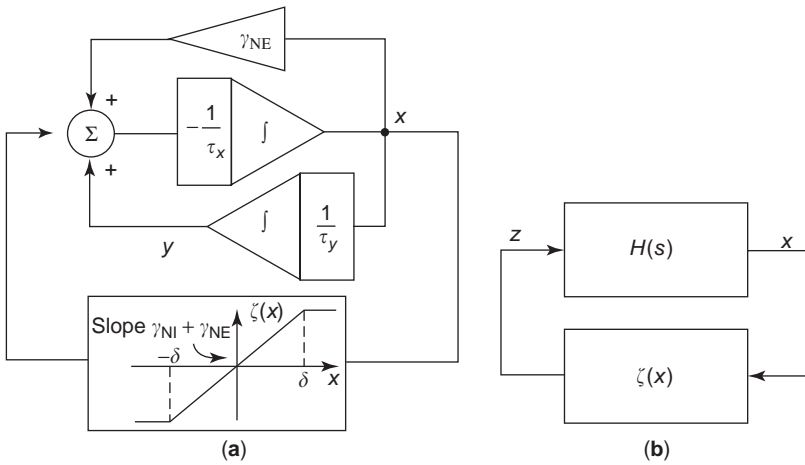

Figure 4. (a) Representation of the basic oscillator model in Fig. 2a as the interconnection of a linear dynamic block and a nonlinear block and (b) general harmonic oscillator model with these blocks. The phase shift of the linear block is null at the oscillation frequency, and the oscillation occurs at the amplitude for which the loop gain is just unity.

On the other hand, the nonlinearity, and hence the control of the oscillation amplitude, is inherent to the active devices used to realize the transconductors. For the simple circuits typically employed in these transconductors, such as, for instance, those in Fig. 5b, the transconductance decreases with the signal amplitude. Hence the condition for the generation of oscillations is $G_m R > 1$.

2.4. Relaxation Oscillator Case

This case corresponds to α in Eq. (4) being much larger than unity, namely, to $\tau_x \ll \tau_y$. In the limit, as $\alpha \rightarrow \infty$, its factor in the top equation of Eq. (4) becomes negligible and hence

$$y = -\zeta(x) \tag{10}$$

meaning that the shape of the limit cycle fits with the nonlinear function $-\zeta(x)$, drawn with a thick solid trace in Fig. 6a.

This piece of information has to be complemented with analysis of the solution trajectories of Eq. (4) for the different linear pieces of $-\zeta(x)$. Let us consider first the inner piece, where $y = \gamma_{NI}x$. Analysis obtains

$$x(\tau) \approx -\frac{1}{\gamma_{NI}} [y(0) - \gamma_{NI}x(0)] e^{\alpha \gamma_{NI} \tau}$$

$$y(\tau) \approx [y(0)] e^{\alpha \gamma_{NI} \tau} \tag{11}$$

valid for $|x| < \delta$. Note that in the limit for $\alpha \rightarrow \infty$, $y(\tau)$ remains practically constant while the system evolves in this inner region. Quite on the contrary, $x(t)$ changes at very high speed; either decreasing, for $y(0) > \gamma_{NI}x(0)$, or increasing, for $y(0) < \gamma_{NI}x(0)$. The arrows drawn with thin solid lines in Fig. 6a indicate the direction and sense of the trajectories in this inner region. From this picture, it is readily inferred that the nonlinearity inner piece is not part of the limit cycle.

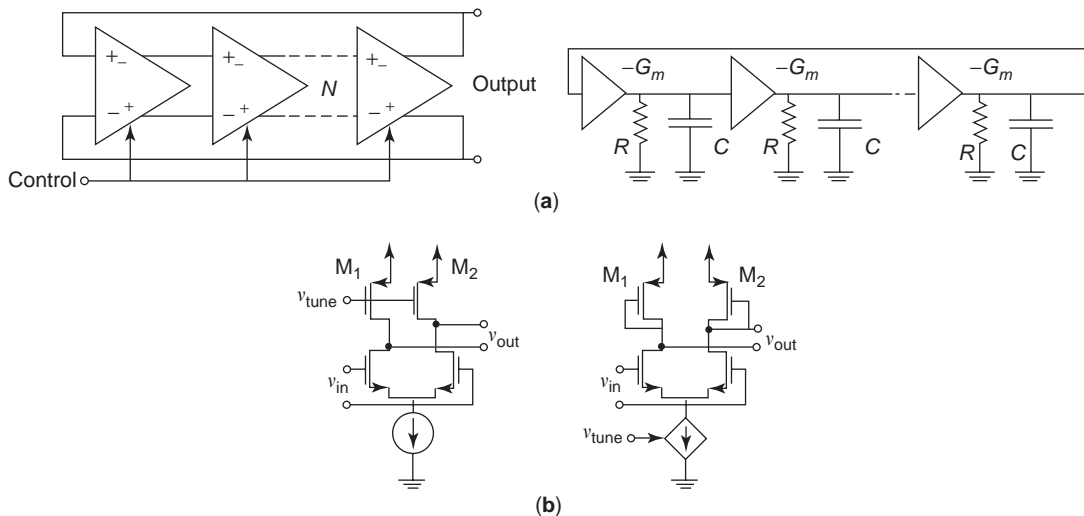

Figure 5. (a) Ring oscillator structure and its linearized model as a specific example of Fig. 4; (b) simple typical circuit realizations for the tunable transconductors.

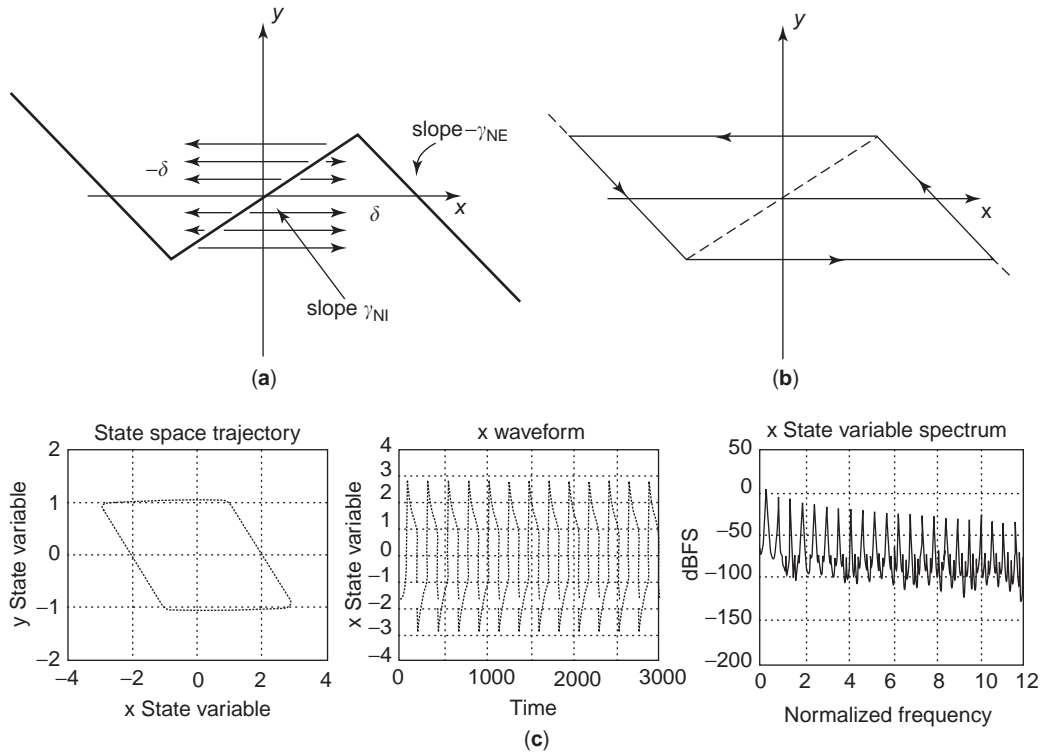

Figure 6. The limit cycle in the relaxation case fits with the nonlinear function $\zeta(x)$ in (a) as depicted in (b), where we assume that the horizontal transitions occur instantaneously. The bottom drawing (c) shows the limit cycle, the $x(t)$ waveform, and its spectrum for $\tau_x = 0.1$, $\tau_y = 10$, $\delta = 1$ and $\gamma_{NE} = \gamma_{NI} = 1$.

Let us now consider the outer pieces, where $y = -\gamma_{NE}x \mp \beta$, where the minus sign is for the left-hand piece; the plus sign, for the right-hand one; and β is the absolute value of the ordinate at the origin. Analysis obtains a fast transient across a quasihorizontal trajectory followed by a slow asymptotic behavior whose trajectory is described by

$$x(\tau) \approx -\frac{1}{\gamma_{NE}} [y(0) - (\mp\beta)] e^{-(1/\gamma_{NE})\tau} \tag{12}$$

$$y(\tau) \approx [y(0) - (\mp\beta)] e^{-(1/\gamma_{NE})\tau} \mp \beta$$

Note that this slow asymptotic behavior results in trajectories that fit exactly with the corresponding outer piece of the nonlinear function.

Summarizing these considerations, the limit cycle can be built as shown in Fig. 6b, where we assume that the horizontal transitions occur instantaneously. Thus, the oscillation frequency is basically determined by the time invested in making the asymptotic evolutions on the outer pieces of the nonlinearity, which can be calculated from Eq. (12) as

$$T_c = 2\tau_y \gamma_{NE} \ln \frac{\beta + \gamma_{NI}\delta}{\beta - \gamma_{NI}\delta} \tag{13}$$

These summary considerations are confirmed by the simulations depicted in Fig. 6c, which shows the limit cycle,

the $x(t)$ waveform, and its spectrum for $\tau_x = 0.1$, $\tau_y = 10$, $\delta = 1$ and $\gamma_{NE} = \gamma_{NI} = 1$.

At this point let us explore the implications of the conditions leading to the relaxation oscillator case on the LC circuits of Figs. 2b and 2c. These conditions are met by making $C \rightarrow 0$ in the former case; and by making $L \rightarrow 0$ in the latter. For circuit implementation purposes, these negligible elements can be considered parasitics and, hence, the relaxation oscillator can be built by simply connecting either an inductor or a capacitor to a nonlinear resistor. Figure 7 shows these realizations, where the nonlinear resistor is N-shaped for Fig. 7a and S-shaped for Fig. 7b.

3. CONVERTERS BASED ON MULTIVIBRATORS

Since the frequency in oscillators can be controlled by means of tunable capacitors, resistors, or inductors, any oscillator can be used to translate a voltage into a frequency, provided that the voltage to be converted is that used to tune the devices [15,17,25]. However, in the case of harmonic oscillators, these mechanisms do not provide a good enough linear dependence of the output frequency on the input voltage, nor temperature stability for most voltage-to-frequency applications. They are used instead in PLL (phase-locked loop) applications, many allowing nonlinearities up to several tens of percent and temperature-induced variations as long as the tuning range accommodates them [24]. The jitter in these circuits is

Figure 7. Simplified first-order abstractions for a relaxation oscillator. The conditions leading to the relaxation oscillator case on the LC circuits of Figs. 2b and 2c are met by making $C \rightarrow 0$ in the former case (a) and $L \rightarrow 0$ in the latter (b).

also lower than in relaxation oscillators, which make them more appropriate for timing applications [11]. Multivibrators usually have poor timing accuracy for frequencies above a few hundred kilohertz because of the random fluctuations of the threshold levels and charging and discharging currents and their increasing importance with respect to shorter clock periods [1], but they provide the best linearity and temperature and supply stability at medium to low frequencies, as well as wide control and

signal ranges [8]. Since the latter are features required for voltage-to-frequency conversion, most VFCs on the market are based on multivibrators; thus we will focus our approach on the following.

Implementations of VFCs are usually based on capacitors as energy storage elements, and the nonlinear resistor in Fig. 7b is commonly implemented as depicted in Fig. 8a. The current switches in Fig. 8a are set to the Ch or Dh position by the reversal block, corresponding to the

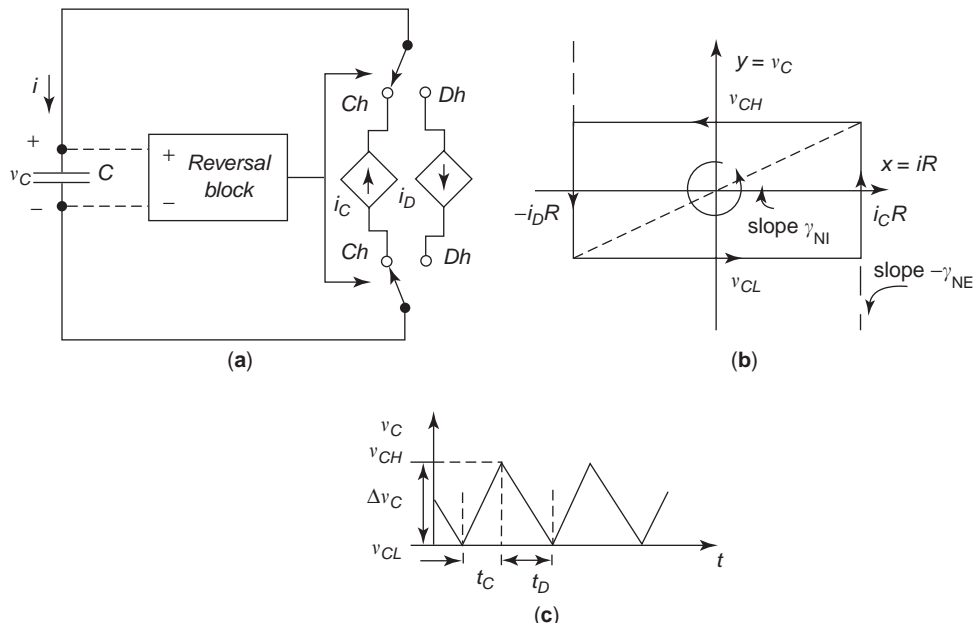

Figure 8. Realization of relaxation oscillators based on Fig. 7b. The reversal block controls the switches to alternatively charge and discharge the capacitor (a). The associated cyclic diagram corresponding to the general case in Fig. 6 is shown in (b), while (c) depicts the resultant waveform.

charging phase and the *discharging phase*, respectively. During the charging phase, the current i_C enters the capacitor input node (+) and the voltage v_C grows, while it decreases during the discharging phase, wherein the current i_D leaves the capacitor input node. The circuit operation consists in the succession of these two phases in a cyclic behavior. The period of the cycle is determined by (1) the value of i_C and i_D and the capacitance C associated with the *timing capacitor*, which set the rate for the voltage v_C to change inside each phase, and (2) the reversal block, which senses v_C and turns the switches to the *Ch* or *Dh* positions. Assuming constant values for the currents i_C and i_D , the time intervals corresponding to the charging and discharging phases are (see Fig. 8c)

$$t_C = \frac{C(v_{CH} - v_{CL})}{i_C} \quad t_D = \frac{C(v_{CH} - v_{CL})}{i_D} \quad (14)$$

where v_{CH} and v_{CL} are the top and bottom limits, respectively, of the voltage swing in the capacitor terminals. In the specific case of having $i = i_C = i_D$, the time invested in a cycle is

$$T_c = t_C + t_D = \frac{2C(v_{CH} - v_{CL})}{i} \quad (15)$$

where we have supposed that the delay associated with the reversal block and the current switches is negligible, which corresponds to the assumption $\tau_x \ll \tau_y$ in the previous section. Actually, the expression for T_c above is also derived from Eq. (13) by making $\gamma_{NE} \rightarrow \infty$, which provides

$$T_c = 4\tau_y\gamma_{NI} \quad (16)$$

for the time invested in completing the cyclic diagram in Fig. 8b (see also Fig. 6). Note that Eq. (16) yields Eq. (15) if γ_{NI} is obtained from Fig. 8a as

$$\gamma_{NI} = \frac{v_{CH} - v_{CL}}{2iR} \quad (17)$$

and taking into account that $\tau_y = RC$.

The VFCs currently on the market can be classified into two major types that follow the previous approach: the *Schmitt trigger converters* and the *charge balancing converters*. The main difference between both types lies in the role that the reversal block plays. In the former, the reversal block works like a Schmitt trigger, which senses $v_C(t)$ and turns the current switch to the position *Ch* or *Dh* any time it reaches the low v_{CL} and high v_{CH} threshold values, respectively. Thus, the reversal block imposes the thresholds v_{CH} and v_{CL} , and sets directly the voltage swing ($v_{CH} - v_{CL}$) in the capacitor during the circuit operation. Equation (14) applies here, and the frequency of the waveform associated with v_C is determined by means of voltage-controlled current sources, thus causing $i_C = K_C v_{in}$ and $i_D = K_D v_{in}$ to obtain

$$f = \frac{1}{t_C + t_D} = \frac{K_C K_D v_{in}}{(K_C + K_D)C(v_{CH} - v_{CL})} \quad (18)$$

where v_{in} is the input voltage that is converted into the frequency f . In the particular case of having $K_C = K_D$, we get a symmetric triangle-shaped periodic signal.

On the other hand, in charge-balancing-type converters, the reversal block does not impose lower and upper limits or thresholds to the voltage drop in the capacitor, but a fixed duration of the charging phase T_0 . These circuits also are built to fulfill $i_C = i_0 - i_D$, where i_0 is a constant current. The basic working principles are similar to those in the Schmitt trigger converters, and the circuit evolves in a cycle with successive charging and discharging phases. Let us begin in a certain point inside the discharging phase. The voltage v_C ramps down until it equals a lower threshold v_{CL} . At this time, the switch is turned to *Ch* by the reversal block and the capacitor is charged but now for a fixed period T_0 . Thus, the voltage v_C changes by an amount given as

$$\Delta v_C = \frac{i_C T_0}{C} = \frac{(i_0 - i_D) T_0}{C} \quad (19)$$

Once this charging phase is concluded, the switch is set to *Dh* by the reversal block and the capacitor is discharged by i_D until the lower threshold is reached again; hence the voltage v_C falls an amount of Δv_C and the duration of this phase is

$$t_D = \frac{C \Delta v_C}{i_D} = \left(\frac{i_0}{i_D} - 1 \right) T_0 \quad (20)$$

Since T_0 and i_0 are constant values, the frequency is changed by tuning i_D in Eq. (20). If $i_D = K_D v_{in}$, we obtain the following expression for the frequency of $v_C(t)$:

$$f = \frac{1}{t_C + t_D} = \frac{i_D}{i_0 T_0} = \frac{K_D v_{in}}{i_0 T_0} \quad (21)$$

In the following section we will show implementations of these two classes of converters and discuss design issues and nonidealities.

4. SCHMITT TRIGGER CONVERTERS

4.1. Direct Implementation

Figure 9a shows a straightforward implementation of a Schmitt trigger type converter with a grounded capacitor. Two possible realizations of the Schmitt trigger block are also depicted in Fig. 9b [14]. In the single-comparator-type Schmitt trigger on the left of Fig. 9b, for very low values of v_i the comparator output is low and the current switch is open; thus the voltage reference at the inverting input is

$$v_{iH} = V_{CC} \frac{R_2 + R_3}{R_1 + R_2 + R_3} \quad (22)$$

For increasing values of the input voltage, eventually the reference in Eq. (22) is crossed and the comparator output changes and turns the switch on; thus the resistor R_3 is short-circuited. Hence, if the input voltage decreases at

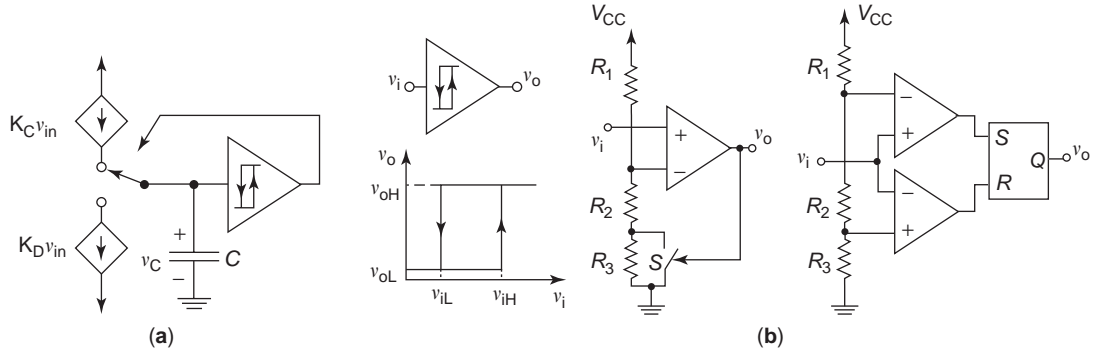

Figure 9. (a) Direct implementation of a Schmitt trigger VFC converter, where the reversal block in Fig. 8 is implemented by a Schmitt trigger circuit; (b) two realizations of the Schmitt trigger block.

this point, the new reference voltage at the inverting input of the comparator is

$$v_{iL} = V_{CC} \frac{R_2}{R_1 + R_2} \quad (23)$$

Note that Eqs. (22) and (23) constitute the high and low threshold voltages, respectively, of the single-comparator Schmitt trigger. The main drawback of this circuit is that the parasitic capacitors at the nodes between the resistors have to be charged and discharged every time the switch is closed or opened, which is a time-consuming task and causes errors that limit the high-frequency capability of the circuit. A better behavior is obtained by using two comparators and fixed voltage references to define the threshold values. The right part of Fig. 9b shows the dual-comparator Schmitt trigger, which is based on this approach and whose threshold voltages are determined by the resistor ladder as

$$v_{iL} = V_{CC} \frac{R_3}{R_1 + R_2 + R_3} \quad v_{iH} = V_{CC} \frac{R_2 + R_3}{R_1 + R_2 + R_3} \quad (24)$$

Besides other general limitations that will be seen later, the basic disadvantage of this strategy is the poor supply voltage stability, due to the dependence of the threshold values on V_{CC} . Table 1 shows the typical performance parameters associated to the NE566 [19], which follows the direct approach in Fig. 9a and whose maximum drift with supply voltage is 2%/V.

4.2. Emitter-Coupled Multivibrator

Instead of a grounded capacitor, the circuit in Fig. 10 uses a floating one that is charged and discharged by means of the bias current sources i_C and i_D . Basically, the circuit

fixes the voltage at one terminal of the capacitor, for instance, the emitter of Q_3 , to a nearly constant voltage V_M , while the other terminal is connected to the current source i_C that charges it. Eventually, the voltage in the latter drops enough to allow the base-to-emitter voltage of Q_2 to reach the transistor threshold, which causes the voltage at the base of Q_3 to fall and the transistor is turned off. The voltage at the emitter of Q_2 is now fixed to two base-to-emitter drops below the supply voltage and the capacitor is being discharged by i_D . Since the circuit is symmetric, the process is repeated periodically. Let us split the cycle in periods related to important events in order to derive the expression of the output wave frequency:

- Figure 10b shows the circuit working somewhere in the cycle with the transistor Q_2 and the diode D_1 in the cutoff region, which is indicated by using a white trace. Consider the clamping block in Fig. 10a formed by one diode and one resistor in parallel. The voltage drop across this block is depicted in Fig. 10a, as well as the response to a step in the current I_D . As long as Q_2 is off, the voltage across the block equals zero if we neglect the base and leakage currents. Since Q_1 and Q_3 are on, the voltage at node B is clamped to $V_M = V_{CC} - 2V_{BEon}$ approximately. On the other hand, the current source i_C is charging the capacitor with a constant current; thus the voltage at the emitter of Q_2 falls to a lower threshold V_L beyond which Q_2 is no longer cut off. Since D_2 and Q_4 are on, such a limit is given by the equation

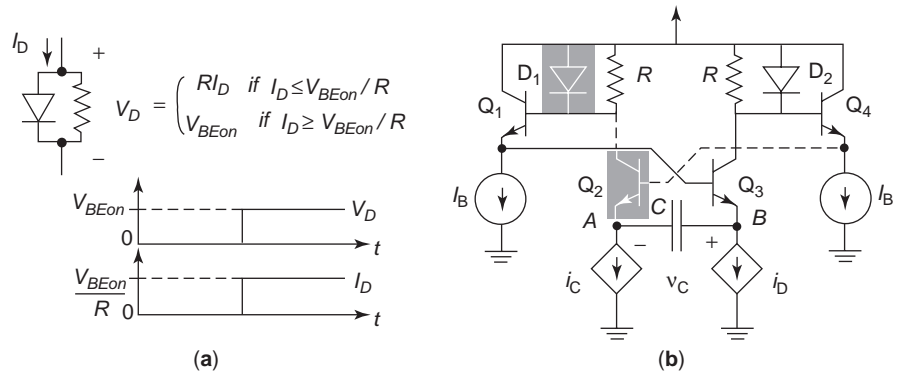

$$V_L = V_{CC} - (V_{D2} + V_{BEQ4} + V_{BEQ2}) \approx V_{CC} - 3V_{BEon} \quad (25)$$

- Once the voltage at node A reaches V_L , the transistor Q_2 turns on and its collector current makes the voltage drop across the left clamping block rise to V_{BEon} ; thus the base of Q_1 drops to $V_{CC} - V_{BEon}$ and the emitter of Q_1 follows this voltage, and hence the voltage at the base of Q_3 is now $V_{CC} - 2V_{BEon}$. Since its emitter was fixed to the same voltage, the transistor Q_3 turns off. Note that at this point, the voltage drop across the capacitor is $v_C = V_B - V_A = V_{BEon}$.

Table 1. Typical Performance Parameters of the NE566

Maximum operating frequency	1 MHz
Sweep range	10–1
Frequency drift with supply voltage	0.2%/V
Frequency drift with temperature	600 ppm/°C
FM distortion ($\pm 10\%$ deviation)	0.4%

Figure 10. Emitter-coupled multivibrator. The clamping block in (a) causes a voltage drop of value V_{BEon} for a current $I_D \geq V_{BEon}/R$, that makes the basis voltage of Q_2 fall, thus it is cut off and the capacitor is charged through i_C . The situation remains until the voltage drop at the emitter of Q_2 is low enough to turn on Q_2 , thus the clamping block at the top-left corner cuts off Q_3 and the situation is reversed. The process is repeated cyclically.

- Since Q_3 is cut off, its collector current vanishes and the voltage drop across the right clamping block goes down to zero. As a consequence, the voltage at node A is pulled up to the value $V_{CC} - 2V_{BEon}$. On the other hand, since the switching time is very short, the capacitor remains charged and the voltage increment is translated into an increment in the voltage at node B, which reaches the value

$$V_H = V_{CC} - V_{BEon} \tag{26}$$

- Note that the situation is symmetric to that in the first point, but now the voltage at node A remains constant while the current source i_D discharges the capacitor, which is equivalent to the initial point above.

From the previous discussion we conclude that in each charging or discharging phase, the voltage at one capacitor terminal A or B remains constant, while the other changes from the voltage V_H to V_L . It is then easy to derive the voltage increment in the capacitor:

$$\Delta v_C = v_{CH} - v_{CL} = (V_H - V_M) - (V_L - V_M) = 2V_{BEon} \tag{27}$$

Since the problem is equivalent to that treated in the previous section, Eq. (18) is also valid here and the frequency of oscillation is given by the expression

$$f = \frac{Kv_{in}}{4CV_{BEon}} \tag{28}$$

where $K_C = K_D = K$.

4.3. Improved Emitter-Coupled Multivibrator

Since the base-to-emitter voltage has a strong temperature coefficient, the circuit in Fig. 10 has as a main drawback: the dependence of Eq. (28) on temperature. One strategy to compensate this dependence consists of making sure that the current that charges and discharges the capacitor is dependent on the temperature for canceling the global dependence [14]. Such an approach achieves circuits whose output frequency does not change with temperature for $v_{in} = 0$, while there is a dependence for values of v_{in} different from zero. Another strategy tries to

make $\Delta v_C = v_{CH} - v_{CL}$ equal to a quantity very stable under temperature variations. That is the strategy followed in the circuit of Fig. 11, which basically works in the same way as the previous one in Fig. 10. The main difference consists in the change of the voltage values used to clamp the collectors of Q_1 and Q_2 . For this purpose, the simple diodes in Fig. 10 are substituted by a more complex circuitry depicted at the top of Fig. 11. In addition to the current sources, the circuit uses two reference voltages to implement the strategy: a very stable voltage reference V_R and the reference voltage $V_{CC} - 2V_{BEon}$ generated by D_5 and D_6 . In addition, one diode bridge derives the voltages at the collectors of Q_1 and Q_2 from these references.

Figure 11 illustrates the same situation as in Fig. 10, where Q_1 was cut off, the voltage at node B was fixed, and the capacitor was being charged by i_C . The same process continues in Fig. 11, where the devices in white are off, but the voltages at the collectors of Q_1 and Q_2 are set to $V_{CC} - V_{BEon}$ and $V_{CC} - V_R - V_{BEon}$, respectively, by the top circuitry referred to above. Taking into account the voltage drops across the emitter-followers as well as that

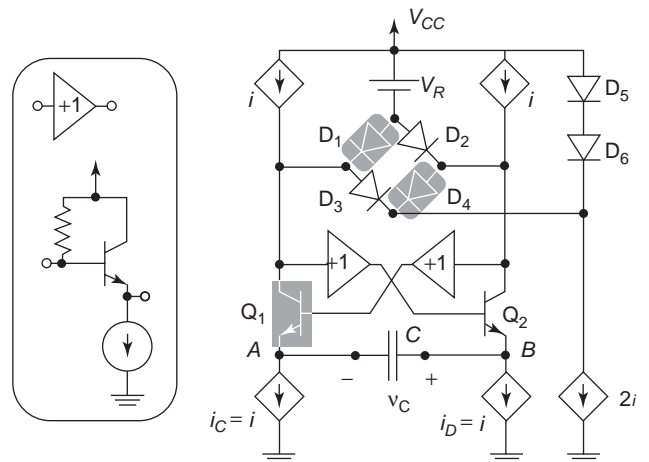

Figure 11. Improved emitter-coupled multivibrator. The clamping circuitry is redesigned to make the voltage variations at the capacitor depend on a voltage (V_R) very stable against temperature change; thus the frequency drift with temperature is improved.

in Q_2 , the voltage at B is

$$V_M = V_{CC} - 3V_{BEon} \quad (29)$$

and the voltage at A beyond which Q_1 is no longer off is

$$V_L = V_{CC} - V_R - 3V_{BEon} \quad (30)$$

When this limit is reached, the situation is reversed, Q_1 is turned on, and Q_2 is turned off. At this point, the voltage across the capacitor is $v_C = V_B - V_A = V_M - V_L = V_R$, and the final voltage at B after the switching will be

$$V_H = V_M + V_R = V_{CC} - 3V_{BEon} + V_R \quad (31)$$

Now, from Eqs. (29)–(31), $\Delta v_C = v_{CH} - v_{CL} = (V_H - V_M) - (V_L - V_M) = 2V_R$, and Eq. (18) reduces to

$$f = \frac{KV_{in}}{4CV_R} \quad (32)$$

The frequency of oscillation can now be stable if V_R is designed carefully to have a low temperature coefficient, which is described later. Table 2 shows some typical parameters of the AD537 [2]. The data refer to the current-to-frequency converter block without accounting for the deviations introduced by the voltage-to-current converter at input.

5. CHARGE-BALANCING CONVERTERS

The other major class of commercial voltage-to-frequency converters are based on a charge balancing system. As mentioned in Section 3, these circuits are characterized by having a fixed length in time in the charging phase. We can classify them into two major categories, those based on one-shot timers and those synchronized to a clock signal.

5.1. Charge-Balancing Converters Based on One-Shot Timers

Figure 12 illustrates a typical implementation of these converters, whose working principle we now describe. Suppose that $v_C \leq v_{in}$; then the comparator provides a high output. As a consequence, the one-shot timer output rises and the current switch is set to the Ch position. This behavior of the one-shot continues under the startup conditions or in the case of a change in the input voltage, and the frequency of the timer output signal is zero. Once the condition $v_C > v_{in}$ is reached, the one-shot (timer) is reset and the current switch is set to the Dh position; thus the capacitor is discharged through R . However, as soon as the condition $v_C \leq v_{in}$ is fulfilled again, the timer is triggered and the switch is turned to Ch again to allow the current

flow into the integrator. This time the one-shot timer operates as usual and generates a pulse of fixed duration t_{os} ; thus a packet of charge is injected in the RC integrator and v_C ramps upward by an amount

$$\Delta v_C = t_{os} \frac{dv_C}{dt} = t_{os} \frac{(i_0 - i_D)}{C} \quad (33)$$

which is enough to make $v_C > v_{in}$; thus the one-shot is reset and the capacitor is discharged again until v_C reaches v_{in} . If $\Delta v_C \ll v_C$, we can approximate $i_D \approx v_{in}/R$, which is a constant current that discharges C ; thus the time t_D is given by

$$t_D \approx \frac{|\Delta v_C|}{\left| \frac{dv_C}{dt} \right|} = \frac{t_{os}((i_0 - i_D))/C}{\frac{i_D}{C}} = t_{os} \left(\frac{i_0 R}{v_{in}} - 1 \right) \quad (34)$$

The cycle is repeated again as soon as v_C equals v_{in} ; thus the output of the one-shot timer is a periodic signal whose frequency is

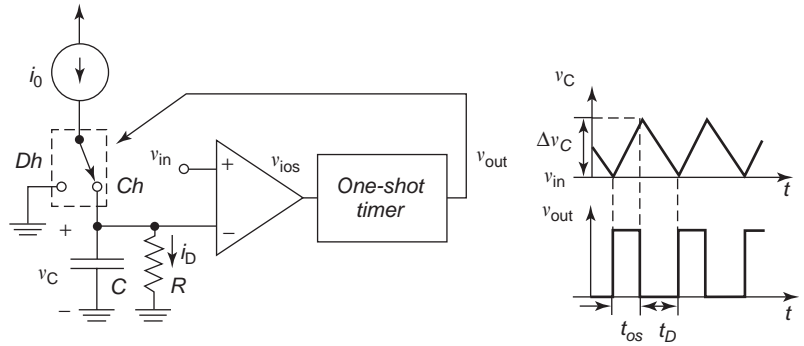

$$f = \frac{1}{t_{os} + t_D} = \frac{v_{in}}{t_{os} i_0 R} \quad (35)$$

Note that this coincides with Eq. (21) for $K_D = 1/R$ and $T_0 = t_{os}$. The circuit in Fig. 12 has two main drawbacks: (1) the change of v_C causes an error in the charging current due to the finite output impedance of the current source that generates it, as well as in the discharging current i_D , which is not constant as supposed above; and (2) the passive RC integrator is very slow, especially for large input voltage changes, which require a large amount of charge to be injected in or extracted from the capacitor. Both aspects can be improved by using an active integrator, as Fig. 13 depicts for two possible and similar approaches [3,26]. The negative feedback provides low impedance at the inverting input terminal of the integrator, whose voltage remains nearly constant; thus the error in the charging and discharging currents is reduced. Equations (33)–(35) are valid in Fig. 13b, but now $i_D = v_{in}/R$ “exactly.” With respect to Fig. 13a, v_C diminishes in the reset mode; thus the derivative in Eq. (33) is negative, as is the voltage increment, but Eqs. (34) and (35) are valid. In both cases, the output current of the op amp (operational amplifier) in the integrator is the same for the charging and the discharging modes, which improves the dynamic response because this minimizes the transients. In addition, Fig. 13a provides high impedance for the input terminal, which can be useful for applications with low load requirements. Finally, note that the capacitance of the integrating capacitor does not appear in Eq. (35) and thus does not directly influence the output frequency. However, it certainly influences the shape of $v_C(t)$, because if C is too small, Δv_C in Eq. (33) could become too large and exceed the linear range of the integrator. In Ref. 16, a nonlinearity error of $\pm 0.024\%$ FS ($f = 10$ – 11 kHz) is reported for the approach in Fig. 12, while it is reduced to 0.006% FS for the improved converter in Fig. 13b.

Table 2. Typical Performance Parameters of the AD537

Frequency range	0–150 kHz
Nonlinearity ($f_{max} = 100$ kHz)	0.25% max
Error drift with temperature (0–70°C)	30 ppm/°C
Error drift with supply voltage	0.01%/V

Figure 12. Basic diagram of a charge-balancing converter based on a one-shot timer. The charging phase has fixed length in time, which is the width of the pulse generated by the one-shot timer (t_{os}) when it is triggered by the comparator. For $\Delta v_C \ll v_C$, the average voltage at the comparator inverting input is v_{in} , thus $i_D \approx v_{in}/R$. The average current injected in the bottom integrator must equal i_D and depends on the rate the one-shot timer is triggered with; hence this rate depends on v_{in} .

The input voltage offset V_{off} of the comparator in Fig. 12 and the integrators in Fig. 13 introduce an error

$$\epsilon_f = \left| \frac{V_{off}}{t_{os} i_0 R} \right|$$

in the expected output frequency—an effect that can be significant, especially for low frequencies, in terms of relative error. On the other hand, precision and low-temperature coefficient current sources to derive i_0 are generated on-chip by means of a voltage bandgap reference and a precision voltage-to-current conversion circuit (see Section 8), while further reflections and replications should also be carried out by cascode current mirrors. Nevertheless, accuracy as well as high-frequency capability of these converters is determined primarily by the precision of the one-shot section.

Figure 14 shows the simplest form of an exponential-ramp-type one-shot timer [14]. The principle of operation is as follows. As long as the flip-flop is reset (low input), the voltage at the output \bar{Q} is high and the current switch (which can be implemented in the simplest way by a grounded transistor) is open; thus the voltage drop in the capacitor is zero. If the circuit is triggered by a high input, the outputs Q and \bar{Q} of the flip-flop are set to a high voltage and a low voltage, respectively; thus the switch is turned off and the capacitor is charged through R , and $v_{C_{os}}$

grows exponentially with a time constant of RC_{os} . However, as soon as the reference voltage at the noninverting input (which is determined by the voltage divider formed by R_a and R_b) is reached, the comparator output changes to a low voltage value and the flip-flop is reset; hence the switch is closed and the capacitor is discharged quickly. Simple calculations on the circuit formed by the supply voltage source, R , and C_{os} provides

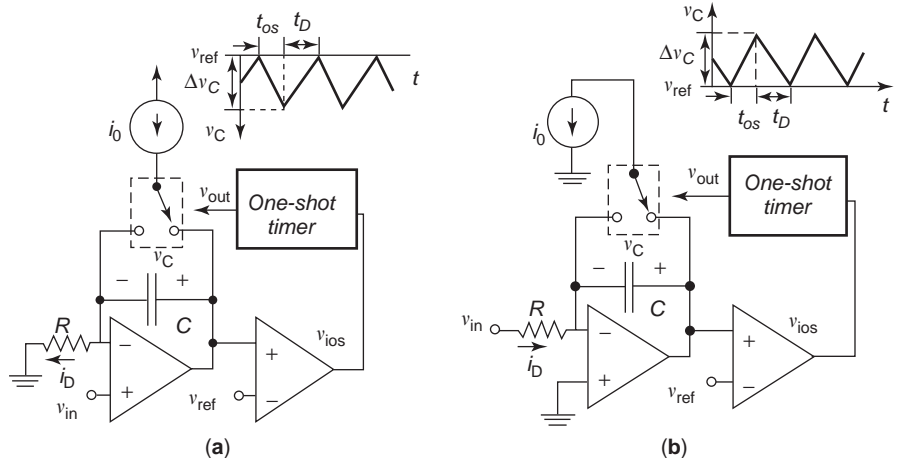

$$t_{os} = RC_{os} \ln \left(1 + \frac{R_a}{R_b} \right) \tag{36}$$

The voltage divider formed by R_a and R_b is usually implemented on-chip and the accuracy obtained for the ratio R_a/R_b is within $\pm 1\%$, and does not depend on the temperature. Thus, the precision, as well as the temperature stability in the expected t_{os} , are determined mainly by the resistor R and the capacitor. However, for small values of t_{os} , the time delays in the input comparator, the flip-flop, and the switch limit the accuracy. In addition, for low frequencies the leakage currents in the capacitor and the switch introduce an error in the timing prediction.

5.2. Synchronized Charge-Balancing-Type Converters

Further improvements can be achieved by replacing the one-shot timer by circuitry clocked by a precise oscillator, usually a crystal one, which determines the charging

Figure 13. Improved converters based on one-shot timers. The use of active integrators instead of the passive one in Fig. 12 achieves smaller errors and improves the dynamic response.

Figure 14. Exponential-ramp-type one-shot timer.

phase duration [4,27]. Figure 15 shows the circuit which results from substituting the one-shot timer with a block composed of one bistable and one AND logic gate, which works as follows. If the integrator output crosses the threshold v_{ref} , the comparator places a high value at the bistable input (suppose that \bar{Q} is high). However, the output does not follow it immediately as in Fig. 13b, but is synchronized with the clock by the flip-flop and changes at the next clock rising edge. At the same time, the output complement (low value) is put at the flip-flop input by the feed-back loop; thus the output, will go back down at the next rising edge of the clock, and the duration of the output pulse will be just one clock cycle. Note that the circuit operates in the charging phase as long as the output is high, thus T_{CLK} replaces t_{os} in Eqs. (33)–(35), which remain valid. However, since the output is now synchronized, its frequency must be a multiple of the clock frequency

$$f = \frac{1}{T_{CLK} + T_{CLK} \times i_S \left(\frac{t_D}{T_{CLK}} \right)} = \frac{1}{T_{CLK} \left[1 + i_S \left(\frac{i_0 R}{v_{in}} - 1 \right) \right]} \quad (37)$$

where i_S means the next superior integer of the argument. Table 3 shows some typical performance parameters of the synchronized converter AD652 [4].

In addition to other design issues that will be discussed in the next section, Fig. 15 has a specific problem to solve due to the lack of synchronism between the input voltage and the clock. The latter could cause the comparator

Table 3. Typical Performance Parameters of the AD652JP

Gain temperature coefficient	
$f_{\text{CLOCK}} = 200 \text{ kHz}$	$\pm 25 \text{ ppm}/^\circ\text{C}$
$f_{\text{CLOCK}} = 4 \text{ MHz}$	$\pm 25 \text{ ppm}/^\circ\text{C}$
Linearity error	
$f_{\text{CLOCK}} = 200 \text{ kHz}$	$\pm 0.002\%$
$f_{\text{CLOCK}} = 4 \text{ MHz}$	$\pm 0.02\%$
Power supply rejection ratio	$0.001\%/V$

output to change at the same time as the clock arrives at the D flip-flop. Since the latter are usually designed to work synchronously, a setup time must be respected for the input signal to change before the clock edge, otherwise there could be metastability problems that do not guarantee a correct value of the flop output; thus t_C can be shorter or larger and the circuit does not work properly. Is it possible to avoid this problem by building the D flip-flop with two flip-flops in cascade or with a flip-flop and a latch in cascade [4], as shown in the right part of Fig. 15, where the clock edge for both flops is delayed. The simplest way to have delayed edges for both flops consists in using the clock falling edge to trigger the first flip-flop, while the second flop is triggered by the rising edge; thus they are delayed half a clock cycle. With this strategy, the metastability of the first flip-flop has ended by the time the second flip-flop is clocked, and the pulsewidth of the output is a clock cycle; thus there is not error in t_C .

5.3. Sigma-Delta Modulators

Figure 16 shows a first-order sigma-delta modulator. It basically consists in a loop with a 1-bit analog-to-digital converter, which is the latched comparator, and a 1-bit digital-to-analog converter in the feedback path. Provided the loop has enough gain, the difference between the analog input and the D/A converter output is minimized and the average value of the D/A output must approach that of the input signal. Similarly, the averaging of the comparator output provides a digital word that represents the analog input. This averaging is described later as part of

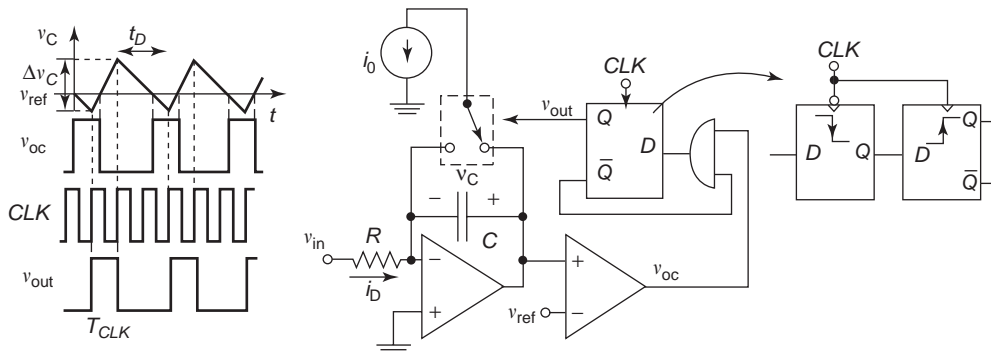

Figure 15. Synchronized charge-balancing converter. The one-shot timer is replaced by externally clocked circuitry. The charging phase length is now fixed by the clock period, which is supposedly very accurate.

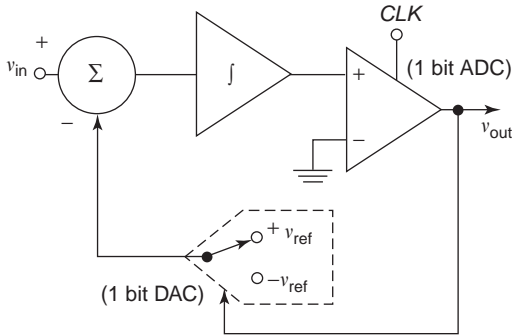

Figure 16. Sigma-delta modulator as synchronized charge-balancing voltage to frequency converter.

the processing required to obtain a digital word from the frequency output of a VFC (digital processing discussed in Section 8); thus sigma-delta modulators can be viewed as synchronized charge-balancing voltage-to-frequency converters (where the charge is injected into or removed from the integrator for the DAC output to track the input voltage). In fact, the transfer function of the AD7740 [5] is $f = 0.1f_{\text{CLK}} + 0.8(v_{\text{in}}/v_{\text{ref}})f_{\text{CLK}}$.

Since sigma-delta modulators can be built currently with cheap CMOS technology, the main advantage of this approach is the cost. The AD7741 [7] with 2.76 MHz at 0.024% of *FoutMax at Nonlinearity* costs 5 times less than the synchronous AD652 with 2 MHz at 0.01% of *FoutMax at Nonlinearity*. In addition, they need fewer external components.

6. DESIGN ISSUES AND LIMITATIONS OF CONVERTERS BASED ON MULTIVIBRATORS

Although some design aspects relative to the design and nonidealities have already been discussed in previous sections, for more clarity, some others regarding all the converters based on relaxation oscillators are examined here. Specifically, note that Eqs. (15) and (18) have been derived without taking into account the deviations from the ideal case. Let us now show some real implementations of formerly ideal blocks and discuss deviations from the ideal case and their consequences in the output wave shape.

6.1. Implementation of the Voltage-Controlled Current Sources

Many VFCs described above use voltage-controlled current sources to implement the charging and discharging currents in Fig. 8, where $i_C = K_C v_{\text{in}}$ and $i_D = K_D v_{\text{in}}$. Such a proportional relationship is obtained readily with a resistor, but a transistor is needed to isolate the control node from the output, which is depicted in Fig. 17a. Such a circuit provides the reference current

$$i_{\text{ref}} = \frac{v_{\text{in}} - v_{\text{BEon}}}{R} - i_B \quad (38)$$

which acts as charging or discharging current. However, note that this circuit provides a current that is not

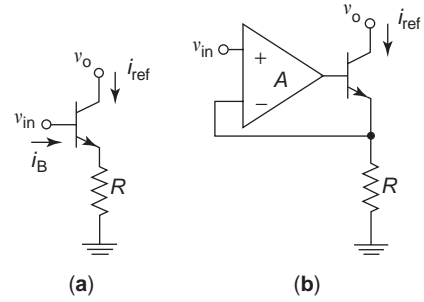

Figure 17. Controlled current source implementation.

proportional to v_{in} , but contains an offset that equals $-(v_{\text{BEon}}/R + i_B)$. Besides modifying the intended proportional relationship, the added term has a strong temperature coefficient, since the base to emitter voltage varies with the temperature as $-2 \text{ mV}/^\circ\text{C}$.

A common alternative for eliminating the dependence of i_{ref} on V_{BEon} places the transistor in a negative-feedback loop as shown in Fig. 17b. If we neglect the base current, the output reference current for this circuit is

$$i_{\text{ref}} = \frac{A}{(A+1)R} v_{\text{in}} - \frac{v_{\text{BEon}}}{(A+1)R} \quad (39)$$

Note that for $A \gg 1$ the term depending on V_{BEon} vanishes and the reference current equals

$$i_{\text{ref}} \approx \frac{v_{\text{in}}}{R} \quad (40)$$

which is proportional to v_{in} . The higher the value of the input amplifier A , the larger the accuracy of Eq. (40). In addition, a MOS transistor can replace the bipolar one in Fig. 17b to reduce the error introduced by neglecting the base current, due to the high impedance associated with the gate of MOS transistors.

6.2. Finite Output Resistance of the Constant Currents

The current source depicted in Fig. 17b still has a nonideal behavior that can introduce deviations in the expected output current. Specifically, since the collector current depends on the collector-to-emitter voltage drop because of the BJT baselength modulation, the current i_{ref} varies with v_o , and this causes an error if the output node directly drives the terminals of the capacitor in Fig. 8, because the voltage drop in the capacitor changes as a consequence of the circuit operation. We can model this dependence on the output node voltage by means of a resistor in parallel with an ideal current source whose value is the expected one. This is illustrated in Fig. 18, where the Thévenin equivalent is also depicted. If the circuit is now connected to the timing capacitor, the voltage v_C does not follow a linear behavior with t , but a well-known exponential behavior. As a consequence, the time to charge or discharge the capacitor an amount Δv_C is longer than expected, which is indicated in Fig. 18a by means of the error ε_t . For the circuits described above, this means longer

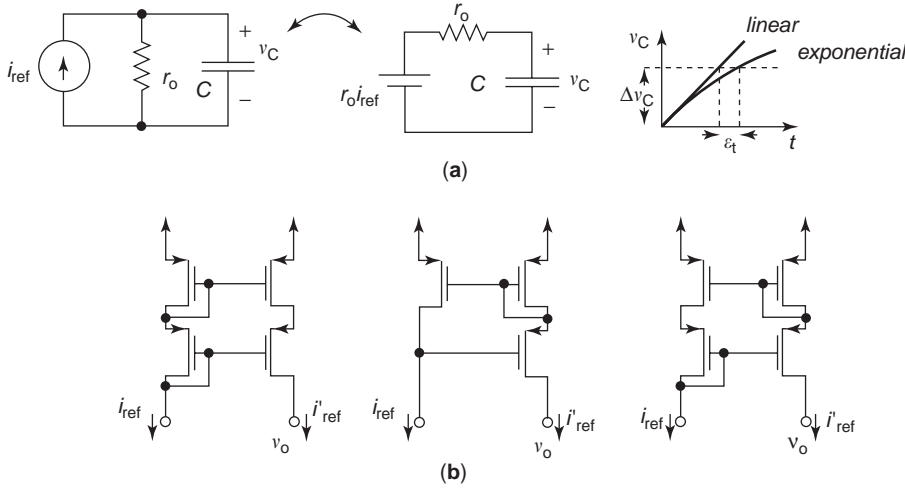

Figure 18. Current source finite output resistance: timing error (a) and common cascode strategies to increase the output resistance (b).

periods or lower frequencies than those in the ideal case. In order to improve the output impedance of the current source, several cascode configurations have been reported [13]. Some common ones are depicted in Fig. 18b, where the current i'_{ref} equals i_{ref} but the output resistance $\partial v_o / \partial i'_{\text{ref}}$ is much higher than $\partial v_o / \partial i_{\text{ref}}$ of circuit in Fig. 17.

6.3. Dependence of Frequency on Temperature and Voltage Supply Variations

The temperature stability of the converter output frequency depends on many factors, some of which have already been discussed. First, in order to improve the temperature stability, we should avoid circuits like that in Fig. 10, whose output frequency depends directly on parameters such as V_{BEon} , which has a large temperature coefficient. Other circuits described above must still be designed carefully to avoid drift.

First, voltage references and charging currents have a large influence on temperature stability. For instance, the voltage source V_R in Eq. (32) must be designed to compensate the temperature dependence. Figure 19a shows an example circuit capable of generating a reference

voltage V_R with a low-temperature coefficient [13]. Such a circuit utilizes the different sign of the temperature coefficients associated with the voltage-to-emitter drop in a BJT and the thermal voltage V_T . The inset box in Fig. 19b encloses a circuit capable of generating a current that is proportional to V_T . As long as the voltage at both output terminals A_1 and A_2 is the same (i.e. $V_{A1} = V_{A2}$), the current I_2 is given by the equation

$$I_2 = \frac{(V_{\text{BE,Q1}} - V_{\text{BE,Q2}})}{R_2} = \frac{V_T}{R_2} \ln\left(\frac{nI_1}{I_2}\right) \quad (41)$$

Two possible approaches to force $V_{A1} = V_{A2}$ are illustrated in Fig. 19b. The circuit at the top of Fig. 19b uses a negative-feedback loop with an operational amplifier that ensures zero differential input; thus $V_{A1} = V_{A2}$. Since the voltage drop across resistors R_1 and R_3 is the same, we can derive the following expression for V_R in Fig. 19b:

$$V_R = V_{\text{BE,Q1}} + \frac{R_3 V_T}{R_2} \ln\left(\frac{nR_3}{R_1}\right) \quad (42)$$

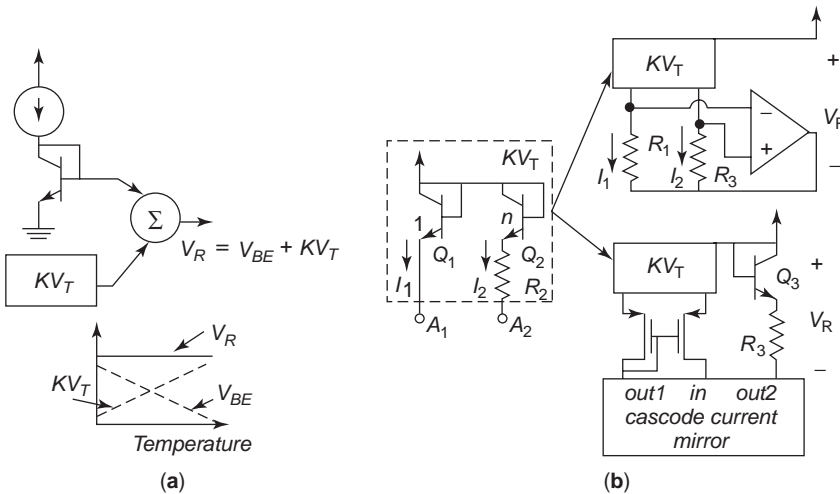

Figure 19. Bandgap reference voltage: (a) the voltages V_{BE} and V_T temperature coefficients of opposite sign, thus they compensate the global dependence of V_R ; (b) two realizations of this approach.

Another strategy uses cascode transistors to get $V_{A1} = V_{A2}$. This is the approach followed by the circuit at the bottom of Fig. 19b, where the reference voltage is

$$V_R = V_{BE,Q3} + \frac{R_3 V_T}{R_2} \ln(n) \quad (43)$$

The reference voltage in Eq. (42) and Eq. (43) is made independent of the temperature variations by choosing properly the circuit and device parameters to achieve

$$\left. \frac{dV_R}{dT} \right|_{T=T_0} = 0$$

(see Ref. 13 for more details).

On the other hand, stable current sources can be obtained by driving the circuit in Fig. 17b with a stable voltage source like that in Fig. 19, which is the strategy followed by many commercial VFCs like the AD537 [2]. Another element that affects the temperature stability is the dependence on the temperature of the Schmitt trigger thresholds, specifically that of the difference $\Delta v_C = v_{CH} - v_{CL}$ in Eq. (15). We have already discussed the particular case of the emitter-coupled circuit in Fig. 11. With regard to the direct implementation in Fig. 9, the reference voltages and the comparator offsets are the main sources of drift. In both cases contributions to global drift are a few tens of ppm $^\circ$ C.

In the case of the charge-balancing converters, note that Δv_C is determined mainly by the charging and discharging currents and by the parameter T_0 in Eq. (21). The drift of T_0 in converters based on one-shot timers is due mainly to the resistance R and the capacitance C_{os} in Eq. (36) and Fig. 14, which are usually external in most commercial VFCs. Finally, the stability of T_0 is obviously improved when such a parameter is determined by a precise external clock as in the synchronous converters.

On the other hand, frequency drift with the supply voltage is also due mainly to variations of the charging and discharging currents as well as that of Δv_C . Bandgap references like those described above also provide supply independent biasing.

6.4. Finite Sensing Node Impedance and Leakage Currents

Note that Fig. 8 assumes infinite impedance in the reversal block-sensing input nodes. Real implementations, however, seldom present such a feature. Specifically, if the reversal block is built with bipolar transistors in the input stage, bias currents have to be provided from the input to the sensing nodes. Such currents are usually in the range of a few hundred nanoamperes and add to or subtract from charging and discharging currents. MOS transistors can be used instead, to implement almost infinite input impedance, thanks to the isolation provided by the gate oxide. In addition, junction leakage or dielectric absorption currents can also be added to or subtracted from charging currents, thus also affecting the output frequency. However, these currents are commonly at a low nanoampere range. Hence, errors due to these base and leakage currents can be usually tolerated as long as the

charging and discharging currents are in the range of $\geq 10 \mu\text{A}$ [14].

6.5. Finite Switching Times

The switching times in Fig. 8 have been neglected in computation of the output frequency in Eq. (18). However, they are not zero in real implementations and limit the frequency capability of the converter. The elements that contribute to the delay in switching are mainly the length of the feedback path and the delays of the blocks along it, while the gain of the active devices, the parasitic capacitances, and the internal current levels determine such delays.

6.6. Output Interfacing

The output stage of the commercial VFCs is designed to allow easy interfacing to all digital logic families. Hence, BJT open collector or both uncommitted collector and emitter interfaces are provided. External pullup resistors and proper biasing complete the interface and determine the risetimes and output logic levels that are adequate for each specific application. Internally, some interface circuitry is needed to drive the base of the output BJT for circuits like that on the right in Fig. 11 [2], while it is not necessary in one-shot-based converters like those described in Refs. 3 and 26, whose one-shot output drives it directly. Synchronous converters also may use a one-shot timer to drive the output transistor, which allows the pulsewidth of the frequency output to be controlled by means of an external capacitor.

6.7. External-Component Selection

Timing capacitors in the converters described above, as well as resistors in Figs. 12, 14 and 15, are usually external components in commercially available VFCs. Special care must be taken to select these components in order to preserve performance. High linearity and low temperature coefficients for the resistors and the capacitors are required. In addition, the latter should not leak, since dielectric absorption can affect the linearity and offset of the transfer function.

7. FREQUENCY-TO-VOLTAGE CONVERSION

The complementary operation of that carried out by the voltage to frequency converters is the frequency to voltage conversion, which is performed by the *frequency-to-voltage converters* (FVCs). This task can be often implemented by the same ICs that perform the V/F conversion, and it is applicable in areas such as telemetry, motor speed control, as well as to build interfaces for sensors whose output is in the form of a variable frequency or pulsetrain [14,20]. Figure 20a shows how this conversion can be accomplished by means of an integrator and a current switch that is driven by the frequency signal in the so-called pulse-integrating FVCs. The switch can also be driven by the output of a one-shot timer (see Fig. 20a), which reduces the integration time, thus allowing small increments in the output voltage without needing too large capacitors. The average

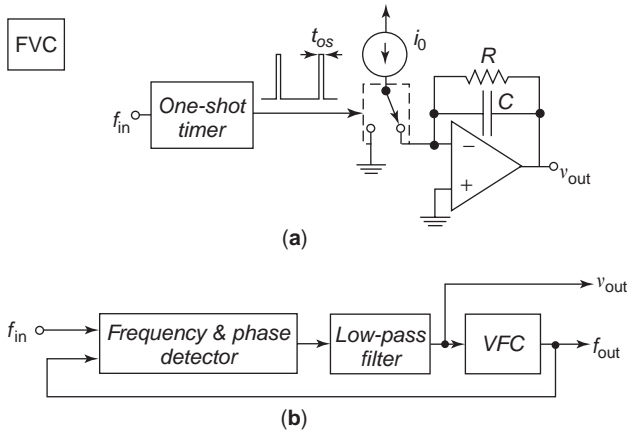

Figure 20. Frequency-to-voltage converters: (a) pulse-integrating converters, where the charge packets are injected in the integrator at a rate determined by the input frequency; (b) phase-locked-loop-type converters, where the lowpass filter output voltage in a PLL is proportional to the deviations of the input signal frequency.

output voltage in Fig. 20a can be calculated by assuming that in the steady state the whole current will flow through the resistor R thus

$$v_{out} = -Ri_0t_{os}f_{in} \quad (44)$$

where $i_0t_{os}f_{in}$ is the average current injected by the top current source in the integrator. A simpler passive integrator could be used instead of the active one in Fig. 20a, but the latter reduces the error caused by the finite output impedance of the current source (this can also be accomplished by means of cascode transistors [21]) and speeds up the converter response time. Since the current is injected in the integrator in packets of size i_0t_{os} , the output voltage has an AC ripple riding on it whose peak-to-peak value is

$$(\Delta v_{out})_{pp} = \frac{i_0t_{os}}{C} \quad (45)$$

It is possible to reduce the ripple by increasing the capacitance C in Eq. (45), but it also will enlarge the time constant associated to the integrator $\tau=RC$; thus the

response time is slow. This is a common tradeoff in the design of these circuits. One strategy to reduce the ripple while keeping the dynamic response consists in filtering the output. As reported in Ref. 22, a passive RC filter exhibits low ripple at all frequencies, but it is slow. The lowest ripple at high frequencies is achieved by an active filter, which also provides much faster step response than does the RC filter. Finally, is it possible to cascade a second active filter on the converter’s output to reduce the ripple at moderate frequencies.

Another approach to convert a frequency into a voltage is implemented by the phase-locked-type FVCs [22]. Figure 20b shows a phase-locked loop (PLL), which basically works as follows. The frequency–phase detector provides an output voltage that is proportional to the difference between the output and input signal phases. After filtering, this voltage is converted back into the output frequency by a V/F converter. The feedback loop locks the phase difference between both input and output signals. The filter output voltage is proportional to the deviations of the frequency of the input signal; thus the circuit also performs a frequency-to-voltage conversion. This converter operates over a wide frequency range of 1 or 2 or 3 decades and responds quickly to frequency changes while it does not have any inherent ripple.

Finally, pulse-integrating converters are open-loop versions of the charge-balancing-type converters described in Section 5; thus their accuracy, linearity, and stability are basically the same as those obtainable from their related VFCs. With respect to Fig. 20b, the high linearity provided by the VFC, which is not required for most PLL applications, is exploited here to ensure an ultralinear FVC.

8. APPLICATIONS

This section describes some typical applications of the voltage-to-frequency converters, which we classify in five major fields: telemetry and remote control, isolation, digital processing, communication and signal processing, and artificial neural networks.

8.1. Telemetry and Remote Control

Data acquisition of remote sensors is seldom possible without transforming the DC sensor output signal, because it is physically unreachable or because of the

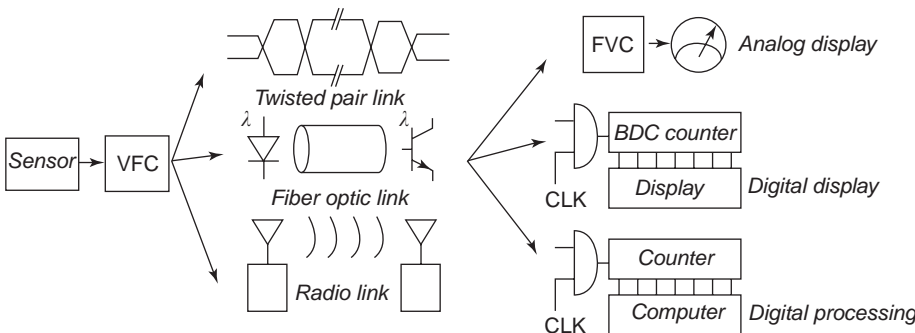

Figure 21. Telemetry with VFC. The voltage signal from a sensor is translated into a frequency signal to be transmitted through twisted-pair or fiber optic links or radiolinks. On the other side, the signal can be converted back into a voltage to drive an analog display or an actuator, or can be processed digitally.

Figure 22. Isolation with VFCs. The frequency signal from a VFC can be transmitted through magnetic (a) or optic (b) couplers to implement galvanic isolation, thus preventing damage due to high bias voltages, or unreasonable current leakage.

vulnerability of DC signals to be degraded when they have to travel long distances through noisy channels [10,12,17,20]. Once converted to frequency signals, they can be transmitted by wires, radio links, or fiberoptic links and processed digitally or converted back into a DC signal to drive an actuator. The latter is performed by a frequency-to-voltage converter, as shown in Fig. 21.

8.2. Isolation

Some applications require galvanic isolation of the sensor and the data-processing unit in order to prevent unreasonable current leakage, or to prevent damage due to high bias voltages, which are often of several volts. Typical isolation interfaces use magnetic or optical couplers [10,17] like those depicted in Fig. 22.

8.3. Digital Processing

The output frequency signal from a VFC can be easily translated into a digital code in order to be processed, stored, or displayed by conventional digital circuits and systems [9,18,20,28]. Actually, this procedure implements an A/D converter while transforming the DC input of the VFC into a digital word. Figure 23a shows the simplest way to carry out this A/D conversion, where a counter, which is only enabled for a given interval T_G termed *gate time*, counts the transitions of the input signal. Thus, after this known period, the counter stores the decimal value $N = f \times T_G$, which encodes the input voltage in a binary number. Another approach is illustrated in Fig. 23b and

uses two counters, one to count the transitions of the input signal and the other to act as a timer that generates an interruption to a microcomputer that reads the content of the first counter and resets it. In both cases, if $FS = f_{max} - f_{min}$ is the full-scale frequency range, the resolution of the A/D converters will be

$$n = \log_2(FS \times T_G) \tag{46}$$

where n is the number of bits of the output digital word. Hence, the larger the gate time, the larger the resolution, which is also limited by the resolution of the VFC. Commercial VFCs provide resolutions as high as 13 bits. Note that the input frequency must remain constant during the gate time for proper conversion; otherwise an average of the input frequency is computed. In addition, since the input signal and the clock are not synchronized, one cycle of the frequency signal can be lost or counted if the transition is just after or before the edge of the clock signal, which causes an error of ± 1 in the result stored in the counter.

8.4. Communication and Signal Processing

Since voltage-to-frequency converters are actually VCOs, they can be used in phase-locked loops in applications such as jitter reduction, skew suppression, frequency synthesis, clock recovery, or FM modulation [24]. However, special care must be taken in order to reduce the jitter and enhance the spectral purity of the output signal, such as use of the differential mode in signal and control paths and guard rings to isolate the noise sources. High linearity is not a key issue in PLL applications, except that described in the Section 7, where nonlinearity degrades the loop stability but can be of several tens of percent. Higher linearity is required for FM modulation, where distortion in the detected signal must be below 1%. Figure 20b depicts a PLL that uses a voltage-to-frequency converter as a voltage controlled oscillator.

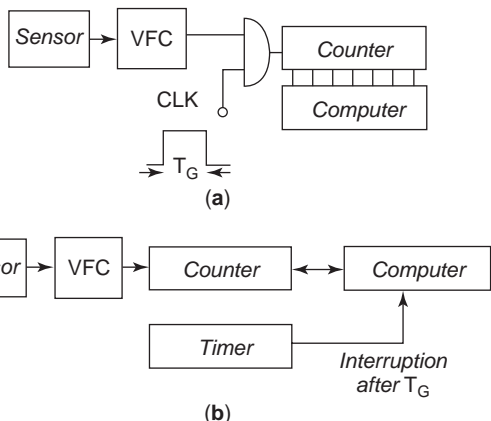

Figure 23. Digital processing of the output frequency signal of a VFC. The transitions in a fixed time interval T_G are counted and the average frequency is computed.

VOLTERRA MODELING IN ANALOG, RF AND MICROWAVE ENGINEERING

MICHAEL B. STEER
 KHALED M. GHARAIBEH
 North Carolina State University

1. INTRODUCTION

Volterra techniques are used in radiofrequency (RF) and Microwave engineering primarily in modeling the input-output characteristics of nonlinear circuits and systems that operate with limited bandwidth signals. Volterra models capture frequency-dependent effects within the band. Two forms of the Volterra model exist; one being in the time-domain invoking Volterra kernels in what is in effect a multidimensional convolution; and the other being a frequency-domain form with what are called Volterra nonlinear transfer function akin to the transfer functions of linear circuits but, of course, extended to handle nonlinearities. The mathematics of Volterra links the kernels and the nonlinear transfer functions, so provides a mathematically rigorous way of modeling circuits in the frequency-domain even though the underlying nonlinear processes are in the time-domain.

When dealing with RF and microwave circuits, it is most convenient to work in the frequency-domain. In the case of communication circuits, many of the important performance parameters are specified in the frequency-domain such as maximum allowable intermodulation distortion and spectral regrowth levels. In the frequency-domain we have a well established set of tools—including Fourier analysis, phasors, and linear transfer functions—essential to the design of linear analog circuits and systems. Volterra analysis builds on these established tools and extends them to handle nonlinearities.

Volterra behavioral modeling coupled with system-level simulation tools can be used to predict the system performance, provide insight into the sources of performance-limiting elements, enable system-level tradeoffs, and lead to the development of predistortion techniques. Volterra nonlinear transfer functions are used in their full generality only for weakly nonlinear circuits because of the difficulty of extracting higher order elements of the Volterra model. Instead, various levels of simplification are used relating to particular characteristics of the stages being modeled and the availability of an extraction procedure.

The fundamentals of Volterra modeling are contained in Volterra's book, *Theory of Functionals and of Integral and Integro-Differential Equations* [1], published in 1930. Volterra series-based methods can model input-output systems that, in the time-domain, are described by the nonlinear differential equation

$$f \left[\frac{d^p y(t)}{dt^p}, \dots, \frac{dy(t)}{dt}, y(t), \right. \\ \left. \frac{d^p w(t)}{dt^p}, \dots, \frac{dw(t)}{dt}, w(t) \right] = 0 \quad (1)$$

where $w(t)$ is the input and $y(t)$ is the output. The above relationship describes an expansion of the input-output characteristics at a single time t . Thus the inherent assumption is that past events are captured by the expansion around the present timepoint. That is, with enough derivatives, the effect of past events can be captured. Thus, a range of effects can be captured including causality, stability, continuity, and limited memory. Chaos, subharmonic generation, hysteresis, and hard limiting can not be so represented. Thus, Volterra methods are best suited to modeling weak to moderately nonlinear circuits. However, the key is that Volterra methods provide a theoretical underpinning for the use of other basis function expansions that extend the range of applicability.

Following the chronological order by jumping into Volterra series analysis is too great a step to make. The discussion here begins with the power series analysis of nonlinear systems, which is used to introduce the concept of intermodulation products and relating time- and frequency-domain descriptions.

2. POWER SERIES BEHAVIORAL MODELING

Now consider the unilateral memoryless nonlinear system of Fig. 1 described by the memoryless polynomial model

$$y(t) = \sum_{l=1}^{\infty} a_l w(t)^l \quad (2)$$

Figure 1. A unilateral nonlinear system.

where the input $w(t)$ is the sum of three sinusoids:

$$w(t) = c_1 \cos(\omega_1 t + \phi_1) + c_2 \cos(\omega_2 t + \phi_2) \\ + c_3 \cos(\omega_3 t + \phi_3) \quad (3)$$

To simplify the trigonometry that follows, let $\alpha_1 = \omega_1 t + \phi_1$, $\alpha_2 = \omega_2 t + \phi_2$, and $\alpha_3 = \omega_3 t + \phi_3$, so that

$$w(t)^l = [c_1 \cos(\alpha_1) + c_2 \cos(\alpha_2) + c_3 \cos(\alpha_3)]^l \\ = \sum_{p=0}^l \sum_{k=0}^p \binom{p}{k} \binom{l}{p} c_1^k c_2^{p-k} c_3^{l-p} \\ (\cos \alpha_1)^k (\cos \alpha_2)^{p-k} (\cos \alpha_3)^{l-p} \quad (4)$$

This equation includes a large number of components, the radian frequencies of which are the sum and differences of ω_1 , ω_2 , and ω_3 . These result from multiplying out the term $(\cos \alpha_1)^k (\cos \alpha_2)^{p-k} (\cos \alpha_3)^{l-p}$. In general, the frequencies of the components of y are $n_1 \omega_1 + n_2 \omega_2 + n_3 \omega_3$ and the order of intermodulation $n = |n_1| + |n_2| + |n_3|$. The total output is the sum of all individual intermodulation products. Volterra nonlinear transfer function analysis is based on exactly the same concepts.

3. VOLTERRA SERIES ANALYSIS

A general Volterra series model of a nonlinear system is described by the following functional expansion of continuous functions:

$$y(t) = \sum_{n=0}^{\infty} F_n(w(t)) = \sum_{n=0}^{\infty} y_n(t) \quad (5)$$

where $F_n(w(t))$ is the Volterra functional. If the nonlinear system is time invariant, then it can be expressed as

$$F_n(w(t)) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_n(\lambda_1, \dots, \lambda_n) \\ \prod_{i=1}^n w(t - \lambda_i) d\lambda_i \quad (6)$$

where $h_n(\lambda_1, \dots, \lambda_n)$ is the n -dimensional Volterra kernel, which can be made symmetric (with respect to its arguments) without loss of generality and leads to a unique set of Volterra kernels. Thus, Fig. 2 shows a graphical representation of the Volterra model in the time-domain with Volterra kernels, whereas Fig. 3 shows the model in the frequency-domain with Volterra nonlinear transfer functions.

The n th order kernel, h_n , is called the nonlinear impulse response of the circuit of order n . Equation (6) is then interpreted as an n -dimensional convolution of an n th order impulse response (h_n) and the input signal (w). The total response $G(w)$ is the summation of the different order responses $F_n(w)$. For a linear system, only a first-order response exists, so that the total response of the

Figure 2. A block diagram of the general Volterra model.

system is the conventional convolution integral

$$y(t) = F_0 + \int_{-\infty}^{\infty} h_1(\tau)w(t - \tau) d\tau \quad (7)$$

where F_0 is just a DC offset.

It is more convenient to write Eq. (6) in terms of the n -dimensional Volterra transfer functions because these functions are usually easier to extract than their corresponding time kernels. Therefore $y_n(t)$ can be expressed as

$$y_n(t) = F_n(w(t)) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} H_n(f_1, \dots, f_n) \times \prod_{i=1}^n W(f_i) e^{j2\pi f_i t} df_i \quad (8)$$

where $H_n(f_1, \dots, f_n)$ is the n -dimensional Volterra Transfer Function (TF), which results from the n -dimensional Fourier transform of $h_n(\lambda_1, \dots, \lambda_n)$:

$$H_n(f_1, \dots, f_n) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_n(\lambda_1, \dots, \lambda_n) \times e^{-j2\pi(f_1\lambda_1 + \dots + f_n\lambda_n)} d\lambda_1 \dots d\lambda_n \quad (9)$$

and consequently

$$h_n(\lambda_1, \dots, \lambda_n) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} H_n(f_1, \dots, f_n) \times e^{j2\pi(f_1\lambda_1 + \dots + f_n\lambda_n)} d\lambda_1 \dots d\lambda_n \quad (10)$$

and therefore, the frequency-domain description of the n th order response can be expressed as

$$Y_n(f) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} H_n(f_1, \dots, f_n) \times \delta(f - f_1 - \dots - f_n) \prod_{i=1}^n W(f_i) df_i \quad (11)$$

This frequency-domain form is the form in which the Volterra model is most frequently used in modeling RF and

microwave circuits. The important concept here is that the total response of a signal is the summation of a number of responses of different order. This scheme only works as the order n increases, the contribution to the response gets smaller and eventually insignificant. The reason this works for many RF and microwave circuits is that the overall response is close to linear, and nonlinear behavior is a departure from linearity. This insight was provided by Wiener who applied this type of functional series to the analysis of nonlinear systems in 1942 [2]. He suggested that a weak nonlinearity could be represented with just the first few terms of such a series. His ideas have subsequently been developed by many researchers including milestones described by Bedrosian and Rice [3]; by Bussgang, Ehrman, and Graham [4]; and by Wiener and Spina [5].

4. BEHAVIORAL MODELING IN THE FREQUENCY-DOMAIN

Central to application of the Volterra methods is extraction of the Volterra nonlinear transfer functions, which can be derived algebraically [3,6,7], experimentally [8–10], or numerically [11]. This process is called system identification, and most of what is published on Volterra modeling of circuits and systems is about the choice of functionals that describe the physical process and the appropriate parameter extraction procedure. Therefore, if the input to a nonlinear system can be described by a multifrequency input of the form

$$w(t) = \sum_{k=0}^K w_k(t) = \sum_{k=0}^K |W_k| \cos(\omega_k t + \phi_k) = \sum_{k=-K}^K W_k e^{j\omega_k t}$$

then the n th order output can be written as

$$y_n(t) = \sum_{q_1=-K}^K \dots \sum_{q_n=-K}^K H_n(f_{q_1}, \dots, f_{q_n}) \prod_{i=1}^n W_{q_i} e^{j2\pi f_{q_i} t} df_i \quad (12)$$

The term $H_n(f_{q_1}, \dots, f_{q_n})W_{q_1} \dots W_{q_n}$ is an n th order intermodulation product of frequency $(f_{q_1} + \dots + f_{q_n})$, and $f = \sum_{k=1}^N n_k f_k = \sum_{i=1}^N f_{q_i}$ is the output frequency. In Wiener analysis, the relationship between positive and negative frequencies ($f_{-q} = -f_q$) is defined by $W_{-q} = W_q^*$. The set of q_k 's describes an intermodulation product to calculate a response of a certain order, all intermodulation products of that order are summed. Each intermodulation product is a product of the input phasors and the appropriate nonlinear transfer function. The nonlinear transfer functions (the H_n) do not depend on the input and are only determined by the nonlinearity. Thus, if $n=4$ and $q_1=1$, $q_2=-2$, $q_3=-2$, and $q_4=3$, the intermodulation product

so defined has frequency $(f_1 + f_{-2} + f_{-2} + f_3)$, or $(f_1 + -2f_2 + f_3)$, and is given by

$$H_4(f_1, -f_2, -f_2, f_3)(\hat{W}_2^*)^2 \hat{W}_1 \hat{W}_3 \quad (13)$$

The intermodulation product of Eq. (13) is only one of the fourth-order intermodulation products. To obtain the total response of the nonlinear system, all intermodulation products of a particular order and for all orders must be summed as illustrated in Fig. 3.

5. RELATIONSHIP BETWEEN VOLTERRA AND POWER SERIES

Power series expansion analysis of a nonlinear subsystem is straightforward and is a convenient way to introduce the basic principles of Volterra nonlinear transfer function analysis. A Generalized Power Series (GPS) model was pioneered by Steer [12] and is used to determine the steady-state frequency-domain description of the output of a nonlinear system. Therefore, if the input to a nonlinear system can be described by a multifrequency input of the form (13), then the output can be represented by a GPS as [13]

$$y(t) = A \sum_{n=0}^{\infty} a_n \left[\sum_{k=0}^K b_k w_k(t - \tau_{n,k}) \right]^n \quad (14)$$

where b_k are real coefficients, a_n are complex coefficients, and $\tau_{n,k}$ is a time delay that depends on the power series order and the index of the input frequency component.

The inclusion of complex coefficients and frequency-dependent time delays allows a variety of systems to be modeled. The GPS was proved to be equivalent to the single-frequency approximation of the Volterra series in [13,14]. Parameter extraction can be done by measuring the response to a multifrequency input. In fact, the equivalence of Volterra and GPS series makes the multifrequency

excitation suitable to developing the Volterra transfer functions in the frequency-domain of the form

$$H_n(f_{q_1}, \dots, f_{q_n}) = A a_n \prod_{i=0}^n b_{q_i} e^{j2\pi f_{q_i} \tau_{n,q_i}} \quad (15)$$

Instantaneous model, as provided by a power series model, leads to a straightforward way of handling nonlinearities in the frequency-domain. Combining an instantaneous model with linear filters creates complex models suitable for modeling RF and microwave circuits. Instantaneous models have both meaning in the time-domain and in the frequency-domain, and a number of mapping techniques have been developed to calculate the phasors of a signal at the output of an instantaneous model given the phasors at the input of the model. For example, with power series, an elegant input-output phasor mapping exists [15], for any analytic function an arithmetic mapping exists [16], and for any instantaneous function an inverse Fourier transform of a set of input phasors yields a time-domain signal that can be applied to the instantaneous functional and the output then Fourier transformed to obtain the output phasors.

6. BEHAVIORAL MODELING OF RF AND MICROWAVE CIRCUITS—THE BLACK BOX APPROACH

In modeling RF and microwave circuits, a priori knowledge is available because nonlinearity originates from active devices. Therefore, this nonlinearity takes input-output characteristics that are well known a priori, and then the modeling problem reduces to estimating system parameters using classic parameter estimation theory such as least squares and its variants.

Lee and Schetzen [17], developed an approach for measuring Volterra kernels leading to the complete identification process of a Volterra system. Wang and Brazil [18] developed a discrete time-frequency approach for the estimation of Volterra model kernels. However, these methods become inefficient and even computationally prohibitive for high-order kernels, and so are limited to third-order nonlinearity. Provided the system is weakly nonlinear, these methods are powerful and comprehensive approaches.

A wide variety of Volterra model variants have been developed in the literature to overcome the computational complexity of developing Volterra kernels when the system has finite memory. The structural classification of nonlinear systems was based on a theory developed by Korenberg [19], which states that any finite memory nonlinear system can be represented by a finite number of parallel Linear-Nonlinear (L-N) or Nonlinear-Linear (N-L) cascades of alternating linear and nonlinear operators. Boyd and Chua [21] showed that the I-O measurements alone are sufficient to classify these structures because of the unique I-O mappings. Therefore, dependent on the measured data, a certain structure can be accepted or rejected based on satisfying the kernel relationships constituting a sufficient and necessary condition for a system to have a given structure. Parameter estimation of these

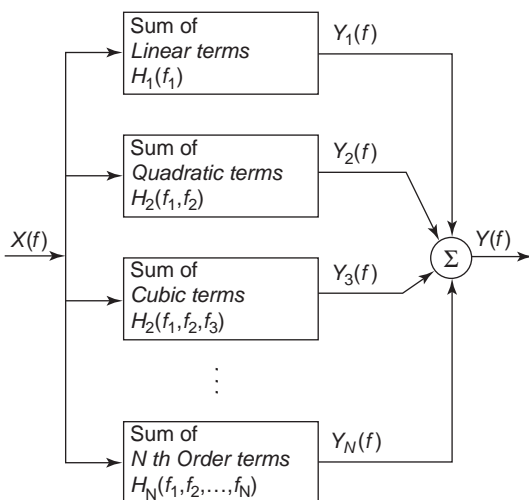

Figure 3. Architecture of Volterra nonlinear transfer function analysis.

structures is usually based on measuring the first- and second-order Volterra or Wiener kernels, which are used to define the linear filters incorporated in the given structure. In the following, the major approaches for nonlinear amplifier modeling are reviewed with emphasis on their parameter estimation techniques.

6.1. Single Frequency Volterra Models

Single frequency Volterra models represent a simplified version of a Volterra system by simplifying the branches of the general model, see Fig. 2, into cascades of L-N or N-L subsystems. These configurations simplify parameter estimation and reduce computational complexity because all spectral calculations required involve only a single frequency variable instead of several [22]. Single frequency Volterra models take one of the following topologies: filter-nonlinearity (FN) model and nonlinearity-filter (NF).

A single frequency FN Volterra model is shown in Fig. 4 and is characterized by a Volterra kernel that has the property

$$\begin{aligned} h_n(\lambda_1, \dots, \lambda_n) &= a_n h_n(\lambda_1) h_n(\lambda_2) \dots h_n(\lambda_n) \\ &= a_n \prod_{i=1}^n h_n(\lambda_i) \end{aligned} \quad (16)$$

which can be contrasted to the general form in Eq. (6), and it follows that the Volterra transfer function is

$$H_n(f_1, \dots, f_n) = a_n \prod_{i=1}^n H_n(f_i) \quad (17)$$

For the NF Volterra model shown in Fig. 5, the Volterra kernel has the property

$$\begin{aligned} h_n(\lambda_1, \dots, \lambda_n) &= h_n(\lambda_1) \\ &\times \delta(\lambda_1 - \lambda_2) \dots \delta(\lambda_{n-1} - \lambda_n) \end{aligned} \quad (18)$$

and it follows that

$$H_n(f_1, \dots, f_n) = H(f_1 + \dots + f_n) \quad (19)$$

The primary advantage of the single frequency Volterra model is the simplicity of its parameter extraction. However, it does not represent the broad variety of systems that the general Volterra model does, single frequency

Figure 4. Filter-nonlinearity Volterra model.

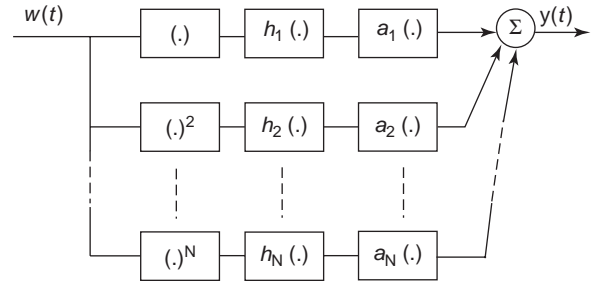

Figure 5. Nonlinearity-filter Volterra model.

model offers a significant simplicity of nonlinear system analysis.

Parameter extraction for the single frequency Volterra model was discussed in [22] using cross-correlation spectral analysis performed on time-domain measured data. These models are regarded as polyspectral models and they showed good performance for TWT high-power amplifiers [22]. A detailed analysis of the identification process can be found in [22,23]. Model parameters were also extracted using multifrequency excitation [24], but only third-order nonlinearity was considered.

6.2. Block Models

Block models refer to a class of models where a system is represented by a single cascade of linear and nonlinear elements. These models are popular because of the simplicity of their parameter extraction using either direct Vector Network Analyzer (VNA) measurements or cross correlation of time-domain measured data [22]. These models, although intuitively reasonable, are theoretically special cases of the Volterra model and therefore kernel relationships can be developed.

6.2.1. The Two-Box and Three-Box Models. A simplified version of the Volterra model is the two-box structure, which takes the following form of the Volterra kernel in the frequency-domain:

$$H_n(f_1, \dots, f_n) = a_n H_1(f_1) \dots H_1(f_n) \dots \quad (20)$$

and for the three box model:

$$\begin{aligned} H_n(f_1, \dots, f_n) &= a_n H_1(f_1) \dots H_1(f_n) \\ &\times H_2(f_1 + \dots + f_n) \end{aligned} \quad (21)$$

These forms of the Volterra kernels, Eqs. (20) and (21), provide a great simplification over the general form because they can be realized by the models shown in Fig. 6. These structures have been successful in representing a wide class of nonlinear systems where the nonlinear operation can be modeled as a cascade of linear operations that represent the finite memory of the system and of a memoryless nonlinearity. These models are called Wiener-Hammerstein models and are used to model a wide variety of nonlinear systems [19,25–28]. Parameter

Figure 6. Block models: (a) two-box model; and (b) three-box model.

extraction of such models are usually based on measuring first- and second-order Volterra kernels [29].

6.2.2. Parallel Cascade Model. The parallel cascade model takes the following form of the Volterra kernel in the frequency-domain:

$$H_n(f_1, \dots, f_n) = \sum_{p=1}^P a_n H_{1,p}(f_1) \dots H_{1,p}(f_n) \times H_{2,p}(f_1 + \dots + f_n) \tag{22}$$

Here, p is the number of branches and it represents the memory depth. The above kernel relationship enables the realization of the Volterra model as a parallel cascade of linear and nonlinear elements, as shown in Fig. 7 [19,20,29], which enables the reformulation of the system equations in the time-domain [29], as

$$y(t) = \sum_{p=1}^P y_p(t) \tag{23}$$

where

$$y_p(t) = z_p(t) * h_{2,p}$$

and

$$z_p(t) = \sum_{r=0}^{N_p} a_{r,p} u_p^r(t)$$

$$u_p(t) = h_{1,p}(t) * w(t)$$

where $*$ is the convolution operator and N_p is the maximum order of the polynomial in branch p .

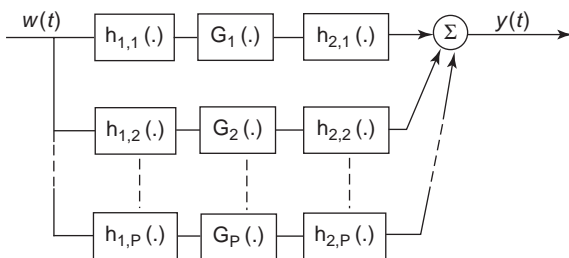

Figure 7. Parallel cascade Volterra model.

Note that the parallel cascade model represents the system by a finite number of branches with polynomials of finite order. This model was proven adequate for modeling a finite-memory Volterra model having a finite order. In [19], Korenberg derived an upper bound for the number of cascades required for representing a finite-memory system. Parameter extraction of this model was discussed in [19] using time-domain measurements. In a recent work [20], system parameters were developed using measured two-tone test with varying frequency separation.

6.3. Memoryless and Quasimemoryless Models

Perhaps the most commonly used model for modeling distortion in power amplifiers is the memoryless model. This model is characterized by a constant Volterra transfer function over frequency, i.e.,

$$H_n(\underline{f}) = H_n(\underline{0}) = a_n \tag{24}$$

where the under bals indicate an n -dimensional vector, and it follows that the corresponding Volterra kernel is

$$h_n(\lambda_1, \dots, \lambda_n) = a_n \delta(\lambda_1) \delta(\lambda_2) \dots \delta(\lambda_n) \tag{25}$$

Therefore, the model reduces to a power series model with either real or complex coefficients of the form

$$y(t) = \sum_{n=1}^N a_n w^n(t) \tag{26}$$

The system is called memoryless if the coefficients a_n are real. These coefficients can be developed from AM-AM power sweep measurements of single tones using a VNA. The system is called quasimemoryless if the coefficients are obtained from AM-AM and AM-PM measurements where polynomial fitting yields a complex power series. The quasimemoryless system takes into account short-term memory effects, which are manifested as a phase shift in the output waveform that is a function of the input power level. The power series model obtained is popular for its simplicity and the fact that distortion can be directly related to its parameters (coefficients), as will be seen in the following chapter. However, it has its limitations because it does not take into account the long-term memory effects, which makes it inadequate for modeling wideband and multichannel systems.

7. CIRCUIT SIMULATION USING VOLTERRA METHODS

It is also possible to use Volterra methods to analyze nonlinear circuits in the frequency-domain using Volterra-based methods.

The so-called method of nonlinear currents, most recently described by Crosmun and Maas [11], has applicability to nonlinear circuits with large signals. In this method, a circuit is first solved for its linearized response described by zero- and first-order Volterra nonlinear transfer functions. Considering only the linearized response allows standard linear circuit nodal admittance

matrix techniques to be used. The second-order response, described by the second-order Volterra nonlinear transfer functions, can then be represented by controlled current sources. Thus, the second-order sources are used as excitations again enabling linear nodal admittance techniques to be used. The process is repeated for the third- and higher order node voltages and is easily automated in a general purpose microwave simulator. The process is terminated at some specified order of the Volterra nonlinear transfer functions, which is a noniterative technique but relies on rapid convergence of the Volterra series.

Volterra techniques can also be used in a spectral balance procedure [30,31]. With the advent of powerFul and well developed harmonic balance procedures, little incentive exists to use Volterra techniques to model RF and microwave circuits.

One more technique exists that is becoming important. In many situations, a small signal interacts with a large signal. Derivation of the large-signal waveform permits a weakly nonlinear time-varying Volterra series description of the circuit [6,32], which is an extension of the linear conversion matrix concept [33] to include nonlinear dependencies on the level of the small signal but special condition on the LO waveform, such as being sinusoidal current, are typically required.

8. CONCLUSION

Volterra series provide the theoretical underpinning of behavioral modeling in RF and microwave engineering. The classic Volterra model is limited to weakly nonlinear systems because of the difficulty in extracting the Volterra nonlinear transfer functions of order higher than third order. Volterra modeling theory illustrates that nonlinear RF and microwave circuits can be modeled as a sequence of cascaded linear frequency variant blocks and nonlinear instantaneous blocks represented by frequency independent functionals. It is easy to handle the linear blocks in the frequency-domain and a variety of instantaneous functional descriptions are used to model the nonlinear block. Various schemes have been developed for evaluating the functionals in the frequency-domain so that an output set of phasors can be calculated from an input set of phasors.

WAVEGUIDE ANTENNAS

WINIFRED E. KUMMER
Raytheon Systems Company

Waveguide antennas are useful for a variety of airborne, ground-based, space, and missile applications in the microwave frequency band because they offer high radiating efficiency, a high degree of control over the radiation pattern, compact architecture, and low weight. The high radiating efficiency and compact architecture, namely, the small depth compared with a parabolic reflector antenna with equivalent gain, combine to optimize the use of the available aperture area. Accurate control of the radiation pattern allows designing arrays with a radiation pattern envelope tailored to the specific application. The low weight minimizes the impact on the installation and allows mounting the antenna on a mechanical gimbal assembly to scan the radiation pattern. A waveguide slot array designed to mount on a gimbal for an airborne radar application is shown in Fig. 1.

In waveguide slot arrays the radiating and transmission structures are inexorably intertwined, thus it is appropriate to treat the history of the waveguides together with that of slot radiators. In the 1930s, G. C. Southworth [1] at Bell Telephone Laboratories investigated electromagnetic propagation in hollow waveguides. Carson, Mead, and Schelkunoff performed the accompanying theoretical analysis [2]. Independent work by Barrow of MIT [3] was published at about the same time [4]. The analysis of waveguides and slot radiators in terms of transmission

lines is also because of Schelkunoff [5]. Another aspect of array work is the need for pattern synthesis. S. A. Schelkunoff's classic 1943 paper [6] and the subsequent C. L. Dolph [7] paper on the synthesis of equal sidelobe levels were used by T. T. Taylor [8] to achieve practical array designs. The major work on waveguide slot arrays during World War II was carried out in Canada at McGill University by W. H. Watson and his colleagues [9]. The basis of their work included A. F. Stevenson's [10] analysis of the behavior of radiating slots in waveguides. Significant advances were made at the MIT Radiation Lab and are summarized in S. Silver's book [11]. Further work was carried out by members of this group and others at Hughes Aircraft Co. in Culver City, CA [12]. A. A. Oliner [13,14] and others refined Stevenson's theory at Polytechnic Institute of Brooklyn. R. S. Elliott and his students at UCLA, and numerous other researchers worked to further refine the design process.

The rectangular waveguide is the guide geometry used for most waveguide slot arrays because it provides a compact, low-loss transmission line that contributes to the high efficiencies achievable with these arrays. The basic radiating element, a single rectangular slot located in an infinite ground plane, is the complement to a dipole radiator [15] and, like the dipole, produces a broad radiation pattern. The radiating slot in the rectangular waveguide is realized in a variety of configurations, thus providing flexibility for the designer. The slot radiation characteristics are controlled by adjusting the slot location on the waveguide and the slot length and width.

An array of slots with a specified aperture distribution generates a highly directive or specially shaped radiation pattern. Arrays of slots are created by placing slot radiators in a waveguide to create a linear array and by joining a number of these waveguides with a power-divider network to create a planar array. Slots are used to couple energy between waveguides, and these coupling slots provide a compact way to realize the power-divider network. The closed-feed network eliminates the spillover loss suffered in horn-fed reflectors and other space-fed antennas. The aperture distribution is determined by the radiating slot characteristics and the power dividers in the feed network. The designer adjusts these parameters to achieve a high degree of control of the aperture distribution and thereby achieves a low-sidelobe or shaped-beam radiation pattern. The design process for these arrays is complex because of the need to accurately characterize the relationship between the slot geometry and performance and also because of interactions between the various elements of the array. The characteristics of the individual elements are derived from the interaction of the slot with the modes in the waveguide, and a simple lumped-circuit model is used to approximate the slot characteristics. The initial array design approach uses these lumped circuit elements to approximate array performance. The lumped-circuit model neglects interactions between the elements created by radiated and internal electromagnetic coupling.

Figure 1. Waveguide slot array for an airborne radar application. (Courtesy of Raytheon Systems Co.)

Refinement of the design to compensate for the interactions is done with experimental hardware or sophisticated electromagnetic simulation software.

1. WAVEGUIDE RADIATING SLOTS

A rectangular slot cut into a metallic ground plane radiates when an electric field is excited across the slot. The electric field distribution in the slot must meet the boundary condition that the tangential electric field at the slot boundary is zero. The lowest mode that meets the boundary conditions has a constant electric field directed across the width of the slot with a cosinusoidal distribution along the length of the slot:

$$E^s(x, z) = \hat{x} \frac{V^s}{w} \cos(\pi z/l) \text{ for} \quad (1)$$

$$-w/2 < x < w/2, \quad -l/2 < z < l/2$$

where V^s is the peak voltage across the slot. The far-field radiation pattern of the slot located in an infinite ground plane is calculated by using Babinet's principle [15] (or image theory). For a slot located in the $x-z$ plane, this results in a radiation pattern given by

$$E_\phi = E_\phi(\theta, \phi) \frac{e^{-jkR}}{R} \quad (2)$$

$$E_\phi(\theta, \phi) = \frac{-jV^s k \sin \theta \cos(kl/2 \cos \theta)}{l (\pi/l)^2 - k^2 \cos^2 \theta}$$

If the slot size is adjusted to the lowest resonance, the loss because of reactive energy is minimized, and the slot coupling is enhanced. At resonance, when the slot is assumed to be equal to one-half the free space wavelength, the radiation pattern becomes

$$E_\phi(\theta, \phi) = \frac{-jV^s \cos(\pi/2 \cos \theta)}{\pi \sin \theta} \quad (3)$$

The directivity for a radiator measures the focusing effect of the radiator and is defined as the directivity relative to that for an isotropic radiator:

$$D(\theta, \phi) = \frac{4\pi P(\theta, \phi)}{\int_0^{2\pi} \int_0^\pi P(\theta, \phi) \sin \theta d\theta d\phi} \quad (4)$$

and the power is given by

$$P(\theta, \phi) = \frac{1}{2} \sqrt{\frac{\epsilon}{\mu}} |\mathbf{E}(\theta, \phi)|^2 \quad (5)$$

The gain of the element is given by the directivity minus any losses in the antenna. The directivity and gain are typically quoted in decibels. For a resonant slot, assuming that radiation occurs only above the ground plane, the peak directivity is 5.6 dB above that of an isotropic radiator.

1.1. Rectangular Waveguide Modes

The field in a waveguide slot is created by a displacement current caused by disruption of the currents generated on the waveguide walls by the energy in the waveguide modes. A metal-walled rectangular waveguide has a set of waveguide modes that satisfy the boundary conditions imposed on the fields by the metallic walls. These modes are classified into two types: the transverse electric (TE), which has only a magnetic field component in the direction of propagation, and the transverse magnetic (TM), which has an electric field component only in the direction of propagation. The complete sets of field components for these modes for a lossless waveguide are as follows [16]: for the TE_{mn} modes,

$$H_z = \cos\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z}$$

$$H_x = -\frac{\gamma_{mn}}{j\omega\mu} E_y = \frac{m\pi\gamma_{mn}}{k_{mn}^2 a} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z}$$

$$H_y = \frac{\gamma_{mn}}{j\omega\mu} E_x = \frac{n\pi\gamma_{mn}}{k_{mn}^2 b} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z}$$

$$k^2 = \left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 \quad (6)$$

and for the TM_{mn} modes,

$$E_z = \sin\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z}$$

$$E_x = -\frac{\gamma_{mn}}{j\omega\mu} H_y = -\frac{m\pi\gamma_{mn}}{k_{mn}^2 a} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z} \quad (7)$$

$$E_y = \frac{-\gamma_{mn}}{j\omega\mu} H_x = \frac{n\pi\gamma_{mn}}{k_{mn}^2 b} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) e^{-\gamma_{mn}z}$$

The waveguide mode propagates unattenuated, except for ohmic losses, for frequencies where the propagation constant

$$\gamma_{mn} = \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 - k^2} \quad (8)$$

is imaginary. The wavelength at which this first occurs, the cutoff wavelength, is given by

$$\lambda = 2\sqrt{(m/a)^2 + (n/b)^2} \quad (9)$$

For almost all applications, it is desirable to operate with only a single propagating mode. The mode with the lowest cutoff frequency, the TE_{10} mode, is used. The guide dimensions are chosen to allow only this mode to propagate over the desired frequency range. The ohmic losses increase as the frequency approaches the cutoff frequency, therefore it is generally desirable to operate at least 20% above the waveguide cutoff frequency. It is also preferable to operate a similar amount below the onset of the next propagating mode. The waveguide fields for the dominant TE_{10} mode

are given by

$$\begin{aligned} H_z &= j \cos\left(\frac{\pi x}{a}\right) e^{\mp j\beta_{10}z} \\ H_x &= \mp \frac{\beta_{10}}{\pi/a} \sin\left(\frac{\pi x}{a}\right) e^{\mp j\beta_{10}z} \\ E_y &= \frac{\omega\mu_0}{\pi/a} \sin\left(\frac{\pi x}{a}\right) e^{\mp j\beta_{10}z} \end{aligned} \quad (10)$$

where the upper sign denotes a wave traveling in the $+z$ -direction and the lower sign denotes a wave traveling in the $-z$ -direction. The propagation constant for this mode is given by

$$\gamma_{10} = j\beta_{10} = j\sqrt{k^2 - \left(\frac{\pi}{a}\right)^2} \quad (11)$$

and the wavelength in the guide is given by

$$\lambda_g = \frac{\lambda}{\sqrt{1 - \left(\frac{\lambda}{2a}\right)^2}} \quad (12)$$

The relationship $\mathbf{J} = \mathbf{1}_n \times \mathbf{H}$ gives the electric currents flowing on the broadwall surface of the waveguide for this mode as

$$\begin{aligned} J_x &= j \cos\left(\frac{\pi x}{a}\right) e^{-j\beta_{10}z} \\ J_z &= \frac{-\beta_{10}}{\pi/a} \sin\left(\frac{\pi x}{a}\right) e^{-j\beta_{10}z} \end{aligned} \quad (13)$$

1.2. Waveguide Slot Radiation Mechanism

If slots are cut into the waveguide in locations where they interrupt the current flow, shown in Fig. 2, a displacement current is setup across the slot and radiation occurs. The amount of radiation is determined by the amount of current intercepted and is controlled by adjusting the slot position on the waveguide and its length and width. A variety of locations create slots with significant amounts of radiation. Slots are also made to radiate by introducing

Figure 2. Rectangular waveguide current distribution for the TE_{10} mode.

Figure 3. Waveguide radiating slots and their lumped-element circuit models: offset longitudinal shunt slot, and angled and transverse series slot.

discontinuities into the waveguide, such as probes, wires, posts, and irises.

The slot scatters energy in the waveguide in addition to radiating energy. The slot acts as an obstacle in the equivalent transmission line, and it is modeled as a lumped-circuit element in a two-wire transmission line [15]. The lumped-circuit model has a resistive component representing the power lost to the radiated fields and a reactive component representing the stored energy. The backward and forward scattered waves for a slot in the waveguide wall are calculated from [10].

$$\begin{aligned} B_{10} &= \frac{1}{2S_a} \int_{\text{Slot}} (jE_t K_t + E_z K_z) e^{-j\beta_{10}z} dS \\ A_{10} &= \frac{1}{2S_a} \int_{\text{Slot}} (jE_t K_t - E_z K_z) e^{+j\beta_{10}z} dS \end{aligned} \quad (14)$$

where S_a is twice the Poynting energy flux for the dominant mode, \mathbf{E} is the electric field in the slot, and \mathbf{K} is the surface current density on the waveguide wall if the slot were not present. The scattering characteristics are used to compute the equivalent circuit characteristics and their dependence on the slot location and geometry. The slots are characterized by their location and orientation in the waveguide and by their equivalent circuit characteristics. Several slot geometries and their equivalent circuit models are shown in Fig. 3.

1.3. Waveguide Radiating-Slot Geometries

1.3.1. Offset Longitudinal Shunt Slot. A narrow slot located along the waveguide broadwall centerline does not radiate a significant amount of energy because it causes minimal disruption to the current flow on the waveguide walls. As the slot is offset from the waveguide centerline, it intercepts more of the waveguide currents, and the amount of power radiated becomes significant. The phase of the radiated field is reversed if the slot is located on the opposite side of the waveguide centerline. For an offset slot, it is a reasonable approximation to assume that the fields in the slot are symmetrical, and it can be shown that the scattering from the slot in the waveguide is also symmetrical. This symmetrical scattering corresponds to a shunt obstacle for the lumped-circuit model. The scattering

for the slot is given by [17].

$$B_{10} = A_{10} = \frac{j2V^s(\pi/a)^2(\pi/l)}{\omega\mu_0 ab\beta_{10}[(\pi/l)^2 - \beta_{10}^2]} \cos\left(\frac{\beta_{10}l}{2}\right) \sin\left(\frac{\pi x}{a}\right) \quad (15)$$

This assumes a narrow offset slot with only an E_x component that has the cosinusoidal distribution given in Eq. (1). This can be related to the modes in a two-wire transmission line to calculate the conductance of the lumped-circuit element:

$$\frac{Y}{G_0} = K_1 f(x, l) \frac{V^s}{V}$$

where

$$K_1 = \frac{2\pi}{ja} \sqrt{\frac{2}{kG_0\eta\beta_{10}ab}} \quad (16)$$

and

$$f(x, l) = \frac{(\pi/l) \cos(\beta_{10}l/2)}{(\pi/l)^2 - \beta_{10}^2} \sin N(\pi x/a)$$

where x is the slot offset from the centerline and G_0 is the characteristic conductance of the guide. At resonance, when the slot length is one-half a free-space wavelength, the scattering coefficient is given by

$$B_{10} = \frac{j2V^s}{\omega\mu_0(\beta_{10}/k)ab} \cos\left(\frac{\pi\beta_{10}}{2k}\right) \sin\left(\frac{\pi x}{a}\right) \quad (17)$$

and the slot is represented by a shunt conductance. The conductance value is a function of the slot offset and the waveguide dimensions. The dependence of the conductance on the slot offset is given by [10,18]

$$\begin{aligned} \frac{G}{G_0} &= g = g_1 \sin^2 \frac{\pi x}{a} \\ g_1 &= 2.09 \frac{\lambda_g a}{\lambda b} \cos^2 \left(\frac{\pi \lambda}{2\lambda_g} \right) \end{aligned} \quad (18)$$

These equations are useful for understanding the slot characteristics but are not accurate enough for many design applications. The amount of radiation from the slot is controlled primarily by the offset and length as expressed previously but also depends on the slot width and the thickness of the wall in which the slot is cut. The slot resonant frequency must also be determined accurately. The slot is defined to be resonant when the phase of the scattered field is 180° out of phase with the incident wave. The resonant frequency occurs when the slot length is approximately one-half of a free-space wavelength, but the exact frequency is also a function of the slot offset, width, and thickness. The characteristics of the slot are determined more accurately by using an electromagnetic simulation technique, such as the method of moments [19], or by

Figure 4. Offset shunt-slot resonant frequency and conductance for various slot lengths and offsets.

careful measurements. Figure 4 shows the variation of the slot conductance and resonant frequency as the offset and length are varied. The slot characteristics were calculated by using a computer simulation based on the method of moments formulation described in Khac [20], with slot thickness effects added. The variation of the slot admittance normalized to the peak conductance values versus frequency relative to the resonant frequency for a slot in full height ($2.3 \text{ cm} \times 1.0 \text{ cm}$) X-band (8 GHz to 12 GHz) waveguide is shown in Fig. 5. Away from the resonant frequency, the slot becomes reactive, and the radiation is reduced. The variation with frequency is relatively insensitive to the slot offset and length, so the curves are applicable over a wide range of offset and length values. If the slot offset is large or the waveguide height is reduced

Figure 5. Variation of normalized conductance and admittance for an offset-shunt slot relative to the resonant frequency.

considerably, $b < a/4$, the fields in the slot are less symmetrical, and the slot behaves less like a pure shunt element [21]. For these cases a more complicated circuit model is required, or the scattering matrix description should be used instead of a lumped-circuit model.

1.3.2. Broadwall Series Slots. A slot cut transversely across the waveguide broadwall radiates when centered in the waveguide, and the amount of radiation is controlled by adjusting the offset. For this element, the forward scattered field is opposite in sign to that of the backscattered field, so this slot is modeled as a series element. The normalized series resistance for this element is given by

$$\frac{R}{R_0} = r = r_1 \cos^2\left(\frac{\pi x_1}{2}\right) \quad (19)$$

$$r_1 = 0.523 \left(\frac{\lambda_g}{\lambda}\right)^3 \frac{\lambda^2}{ab} \cos^2\left(\frac{\pi \lambda}{4a}\right)$$

The maximum coupling for this element occurs when the slot is centered. This slot has a high coupling value, but the range of coupling attainable is limited because the slot length restricts the range of offsets, and the slot is confined to the broadwall.

A slot located along the waveguide centerline also radiates when rotated at an angle relative to the centerline. The forward scattering from this element is opposite in phase to that of the backscattered field, and hence it is modeled as a series lumped element. The amount of power coupled is controlled primarily by the slot angle and is adjustable over a wide range of coupling values.

$$\frac{R}{R_0} = r = 0.131 \left(\frac{\lambda}{\lambda_g}\right) \frac{\lambda^2}{ab} \left[I(\theta) \sin \theta + \frac{\lambda_g}{2a} J(\theta) \cos \theta \right]^2$$

$$\left. \begin{aligned} I(\theta) \\ J(\theta) \end{aligned} \right\} = \frac{\cos\left(\frac{\pi \zeta}{2}\right)}{1 - \zeta^2} \pm \frac{\cos\left(\frac{\pi \eta}{2}\right)}{1 - \eta^2} \quad (20)$$

$$\left. \begin{aligned} \zeta \\ \eta \end{aligned} \right\} = \frac{\lambda}{\lambda_g} \cos \theta \mp \frac{\lambda}{2a} \sin \theta$$

The resonant frequency for this slot is relatively insensitive to the slot angle. The polarization characteristics of the slot rotate with the slot orientation and generate a cross-polarization component that limits its usefulness in systems where polarization purity is required.

1.3.3. Narrow-Wall and End-Wall Slots. Transverse angle slots located in the narrow wall of the waveguide are also used as radiating elements. The height of the narrow wall is typically less than the half free-space wavelength required for a resonant slot. So to achieve resonance, the ends of the slot are extended into the broadwall. The coupling is controlled by the slot angle and the depth to which the slot extends into the broadwall. This slot exhibits a

cross-polarization component that varies with the slot angle. This geometry is difficult to model accurately.

Slots located in the shorted end of a waveguide are used for phased-array applications. The slot radiation is created by the disruption of the currents in the terminating short of the waveguide. For most phased-array applications, the slot characteristics are chosen to provide the best match in the array environment, and the power to the slot is controlled by the feed network. Open-ended waveguides are frequently used for scanned-array applications.

2. WAVEGUIDE COUPLING SLOTS

In addition to their function as radiating elements, slots are also used to couple energy between waveguides. The electric field excited in the slot by the incident mode at the input port excites fields in the coupled waveguide. In conjunction with linear radiating slot arrays, the coupling slots provide the building blocks for the planar slot array. The slot configurations described for the radiating elements are also applied as coupling elements. Coupling between the broadwalls is useful to create arrays with minimal depth, and coupling is achieved with the waveguides parallel or perpendicular to each other.

The coupling slots can be modeled by using lumped-circuit elements. For these elements, a transformer between two sets of two-wire lines models the coupling characteristics, and a reactive element models the stored energy in the slot. The slot-coupling ratio determines the turns ratio for the transformer model. The slot is described in terms of its lumped-element characteristics in each of the lines. The element may be a series-series, shunt-shunt, or shunt-series element depending on its orientation in the two waveguides.

2.1. Coupling-Slot Characterization

The characteristics of these elements are determined by a method similar to that for the radiating elements. The forward and backward scattering components are the same as those for the radiating slot given in Eq. (14). Now they are applied in both the input and coupled guides to give the backscattered, forward scattered, and coupled fields. The coupling coefficient between the waveguides is a function of the slot characteristics in the two waveguides and the characteristic impedances of the two guides. The power balance requirement is applied to the junction to show that the coupling coefficient can be calculated from the ratio of the scattered fields and characteristic impedances in the two guides. The scattered-field terms are the same as those derived for the radiating slot except for the value of the coefficient of the field in the slot. For the coupling slot, the ratio of the scattered fields in the two guides is independent of the value of the coefficient, so it need not be determined. The coupling ratio for the slot is given by [22]

$$M = \frac{a_1 b_1 Y_1 |B_1|^2}{a_2 b_2 Y_2 |B_2|^2} \quad (21)$$

where Y_1 and Y_2 are the characteristic impedances in the input and coupling guides, respectively, and B_1 and B_2 are the backscattered fields in the two guides. The value of $1/\sqrt{M}$ gives the turns ratio for the transformer in the lumped-circuit model.

2.2. Coupling-Slot Geometries

The series-series angle slot is a convenient element for broadwall coupling between transverse waveguides because the coupling is controlled by adjusting the slot angle without changing the relative locations of the waveguides and a wide range of coupling values is attainable. This slot and its equivalent circuit model are shown in Fig. 6. The coupling value for this element at resonance, assuming a narrow rectangular slot with zero thickness, is given by

$$M = \frac{a_2 b_2 \lambda_{g_2}}{a_1 b_1 \lambda_{g_1}} \left[\frac{I_1(\theta) \sin \theta + \frac{\lambda_{g_1}}{2a_1} J_1(\theta) \cos \theta}{I_2(\theta) \sin \theta + \frac{\lambda_{g_2}}{2a_2} J_2(\theta) \cos \theta} \right]^2 \tag{22}$$

where the expressions in the equation are the same as those defined in Eq. (20) for the angled radiating slot. The transverse series-series slot, which is the limiting case for the angled series-series slot, provides large coupling values between the guides.

The offset shunt-series coupling slot provides coupling between transverse waveguides. The slot is oriented as an offset shunt slot in one waveguide and a transverse series slot in the other. The coupling values are adjusted by changing the slot offset that is equivalent to moving the location of the shunt waveguide relative to the slot. The

Figure 6. Series-series angle slot coupling element and its lumped-element circuit model.

coupling value for this slot at resonance is given by

$$M = \frac{1}{4} \frac{a_2 b_2 \lambda_{g_1} \lambda_{g_2}}{a_1^3 b_1} \left[\frac{1 - (l/a_2)^2}{1 - (2l/\lambda_{g_1})^2} \right]^2 \frac{\cos^2(\beta_1 l/2) \sin^2(\pi x_1/a_1)}{\cos^2(\pi l/2a_2) \cos^2(\pi x_2/a_2)} \tag{23}$$

where waveguide 1 contains the shunt-slot orientation.

These approximate values for the slot coupling depend on the accuracy of the assumption made for the field in the slot and neglect effects, such as slot thickness and the reactive component of the slot, as the frequency departs from the resonant frequency. More accurate models for the slot are derived by the method of moments [23]. Computer simulation tools based on the finite-element method [24] are also suitable for modeling coupling slots because they operate in a closed structure. This differs from the radiating slot case, which does not lend itself well to this type of model because the problem is unbounded.

3. LINEAR SLOT ARRAYS

A linear array of slots serves alone as an antenna or as a building block for a planar array. The far-field radiation pattern for a linear array of N elements located along the z -axis is given by

$$S(\phi, \theta) = A(\phi, \theta) \sum_{n=1}^N V_n e^{jkz_n \cos \theta} \tag{24}$$

The $A(\phi, \theta)$ term is the radiation pattern of a single radiating element, which is assumed to be the same for all elements in the array. The element pattern is similar to that given in Eq. (2), but it is modified by the array environment. The summation term represents the array factor where V_n are the excitation values and z_n are the element locations. The excitation values of the elements are chosen to generate a specified array radiation pattern. Slot-radiating elements allow controlling the excitations to achieve the desired pattern characteristics.

Linear arrays are divided into two categories: the standing-wave array (or resonant array) and the traveling-wave array (or nonresonant array). The antenna and system performance requirements dictate the choice between the two configurations. In the standing-wave array, the slot locations are chosen to maximize the coupling at the design frequency, and the waveguide is terminated with a short circuit. This creates an efficient antenna, but the bandwidth is limited. In the traveling-wave array, the slot spacings are nonresonant, and the waveguide is terminated with an absorptive load. The traveling-wave array operates over a larger frequency bandwidth than the standing-wave array, but the power absorbed by the load reduces the radiating efficiency. It is difficult to generate a beam perpendicular to the guide with the traveling-wave array, and it also exhibits beam scan with frequency.

3.1. Standing-Wave Arrays

For the resonant array, standing-wave fields are created in the waveguide by terminating the waveguide with a metal

wall to create a short circuit. The slot locations relative to the short circuit are chosen to maximize the array radiation coupling. For series elements, such as the angled series slot, the slots are located multiples of a half guide wavelength from the short circuit. For shunt elements, such as the offset-shunt slot, the maximum coupling locations are multiples of a half guide wavelength from an open circuit, which is achieved by locating a short circuit at one-quarter guide wavelength from the nearest slot. For broadside operation, the slots are located in the guide to achieve a uniform phase distribution. A uniform phase distribution is achieved by locating the slots at one guide-wavelength intervals. However, this results in an array spacing greater than one free-space wavelength, which creates multiple main beams and reduces the antenna gain and performance. The spacing can be reduced to one-half guide-wavelength intervals by alternating the slot offsets to compensate for the 180° phase reversal in the guide.

3.1.1. Circuit Model for Resonant Linear Array. A circuit model of the array provides a good starting point for predicting the array performance and for determining the slot dimensions. The array is modeled by using the lumped-circuit elements for the individual slots, transmission line sections representing the waveguide sections, and a short circuit termination. An offset-shunt-slot linear array and its circuit model are shown in Fig. 7. The transmission matrix is defined as [25]

$$\begin{bmatrix} V_i \\ I_i \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_{i+1} \\ I_{i+1} \end{bmatrix} \quad (25)$$

A section of transmission line of length d with a propagation constant β and a characteristic impedance Z_0 has a transmission matrix

$$\begin{bmatrix} \cos(\beta d) & jZ_0 \sin(\beta d) \\ \frac{j}{Z_0} \sin(\beta d) & \cos(\beta d) \end{bmatrix} \quad (26)$$

The transmission matrices for the shunt element with admittance Y and series element with impedance Z are

$$\begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix} \text{ and } \begin{bmatrix} 1 & Z \\ 0 & 1 \end{bmatrix} \quad (27)$$

To achieve a satisfactory design, the coupling values for the individual slots must be chosen so that the reflection coefficient at the array input achieves the required value, and so that the relative coupling from the slots generates the desired radiated phase and amplitude distribution for the array. The input match to the array and its variation with frequency is modeled by cascading the transmission matrices for the slots and the waveguide sections. At the array resonant frequency the normalized input conductance or resistance for an array of N shunt or series slots

Figure 7. Waveguide linear array of offset longitudinal shunt-slot radiators and its transmission line circuit model.

reduces to

$$\frac{Y_i}{Y_0} = \sum_{n=1}^N \frac{Y_n}{Y_0}$$

or

$$\frac{Z_i}{Z_0} = \sum_{n=1}^N \frac{Z_n}{Z_0} \quad (28)$$

The input reflection coefficient is given by

$$\Gamma_i = \frac{1 - Y_i/Y_0}{1 + Y_i/Y_0} = \frac{Z_i/Z_0 - 1}{Z_i/Z_0 + 1} \quad (29)$$

To achieve an input match for an end-fed standing-wave array, the slot parameters should be chosen so that the slot conductances or impedances sum to one. The slot conductances must also be selected to obtain the amplitude distribution required to achieve the desired radiation pattern. If the slots are all assumed to be resonant and the desired distribution is all equiphase, the ratios of the slot conductances are proportional to the relative slot radiated powers. This gives a set of N equations that can be solved to give the required slot conductances for a shunt-slot array:

$$\frac{G_i}{G_0} = \frac{G_1}{G_0} \sum_{n=1}^N \frac{P_n^r}{P_1^r}$$

$$\frac{G_n}{G_0} = \frac{G_m}{G_0} \frac{P_n^r}{P_m^r}$$

The offset-shunt slot is a commonly used element for linear arrays. It offers a wide range of conductance values and linear polarization. The slot offsets and length can be computed using the equations for the offset shunt slot given earlier, or interpolated from a graph, such as Fig. 4.

3.1.2. Array Mutual-Coupling Effects. The simple circuit model design is useful for understanding the slot array or for determining a set of initial design values, but it is not accurate enough for most applications. The assumption was made that the slots in the array have the characteristics of an isolated slot. In the array environment, the slots are affected by the presence of the other slots, and slots at the edge of the array exhibit behavior that differs

significantly from that of slots in the center of the array. If neglected, these effects result in an array where the input reflection coefficient and radiation pattern depart significantly from the desired values. The characteristics of the isolated slot were determined by using a single source of excitation for the slot: the incident waveguide mode. Multiple sources in the array environment excite the slot: the incident field, the fields scattered in the waveguide by the other slots in the guide, and the radiated fields from all the other slots. The characteristics for each slot are influenced by all the other slots in the array to some extent, so a slot's configuration cannot be determined independently. A series of simultaneous equations is required to perform the array design. Elliott [17] has developed a series of design equations that account for the internal and external mutual coupling effects:

$$\frac{Y_p^a/G_0}{Y_n^a/G_0} = \frac{f_p}{f_n} \frac{V_p^s}{V_n^s} \frac{V_n}{V_p} \quad (30)$$

$$\frac{Y_n^a}{G_0} = \frac{2f_n^2}{\frac{2f_n^2}{Y/G_0} + j(\beta_{10}/k)(k_0b)(a/\lambda)^3 \sum_{m=1}^{N'} \frac{V_m^s}{V_n^s} g_{mn}}$$

$$f_n(x_n, l_n) = \frac{(\pi/l) \cos(\beta_{10}l_n)}{(\pi/l_n)^2 - \beta_{10}^2} \sin\left(\frac{\pi x_n}{a}\right)$$

$$g_{mn}(x_n, l_n, x_m, l_m) = \int_{-l_m/2}^{l_m/2} \cos(\pi \zeta'_m/l_m) \int_{-l_n/2}^{l_n/2} \cos(\pi \zeta'_n/l_n) \left[\frac{\partial^2}{\partial \zeta_n'^2} + k_0^2 \right] \frac{e^{-jk_0R}}{R} d\zeta_n' d\zeta_m' \quad (31)$$

The Y_n^a/G_0 are the active slot admittances in the array environment, the V_n^s, V_n are the slot and the waveguide mode voltages, and the g_{mn} terms represent the external mutual coupling effects between the slots. The set of equations is applied iteratively along with the equation for the required input impedance to determine the slot offsets and lengths. These equations assume an ideal cosinusoidal distribution in a narrow slot, and may not be accurate enough for some applications. A more thorough analysis, where the field distribution in the slots are unknowns that must be determined, provides a more accurate model of the impact of element mutual coupling on array performance [26]. The computational requirements for a rigorous analysis may limit the size of the array for which it is applicable. A good approximation to the final design should be found first by using an approximate method to reduce the number of iterations required.

3.1.3. Variation of Performance with Frequency. The design achieves the desired input match at the design frequency, but the input match of the linear array degrades as the frequency moves away from resonance. This effect is modeled using the transmission matrices by adjusting the propagation constant in the transmission line sections and including the variation of the slot admittance with frequency. The bandwidth is generally defined as the

frequency range over which the input reflection coefficient remains below a specified level. The bandwidth is determined primarily by the number of elements in the array, and it degrades as the number of elements in the array increases. Watson [9] derived an approximate expression for the variation of the input reflection coefficient that neglects the multiple reflections:

$$\Gamma = \frac{2 - \sum_{n=1}^N Y_n/Y_0 - e^{j2N\beta d} \sum_{n=1}^N Y_n/Y_0 e^{-j2n\beta d}}{\left(2 + \sum_{n=1}^N Y_n/Y_0\right) e^{j2N\beta d} + \sum_{n=1}^N Y_n/Y_0 e^{j2n\beta d}} \quad (32)$$

The array excitations also change away from the center frequency because the slot locations relative to the standing wave in the guide are no longer optimum and the slot radiation characteristics also exhibit frequency variation. This causes pattern degradation and main-beam distortion. The effects are modeled by using the circuit model to determine the slot excitations and computing the far-field pattern generated by these excitations.

3.2. Traveling-Wave (Nonresonant) Arrays

For the nonresonant array, the array distribution is generated by progressively coupling energy from the waveguide mode as it travels down the guide. The element spacings are chosen to be nonresonant, and the waveguide is terminated with a matched load. The design process differs from that of the standing-wave array because the reflections from the slots do not add coherently at the input. The input reflection is controlled by the destructive interference because of the nonresonant spacing, and the reflection coefficients of the individual elements are kept small to minimize the reflection. The traveling-array input-match bandwidth does not decrease as the array size increases, unlike that of the resonant array. The resonant slot spacing case for a broadside beam is avoided because the summation of the individual reflections creates a large reflection. The traveling wave generates a linear phase slope across the aperture that corresponds to a scanned beam with the beam pointing direction given by [27]

$$\cos \theta_0 = \lambda/\lambda_g - \lambda/2d \quad (33)$$

for an array with alternating slot offsets. The beam scans with frequency because of the change in the guide wavelength. This frequency-scanning effect is often exploited by making the waveguide path length between the slots greater than the array spacing to enhance the amount of scan for a given frequency change [28]. The beam position for this case is given by

$$\cos \theta_0 = d_g \lambda/d\lambda_g - \lambda/2d \quad (34)$$

3.2.1. Circuit Model for Nonresonant Arrays. The circuit model for the traveling-wave array is similar to that used for the resonant array, but a matched-load termination

replaces the terminating short, and the line lengths are adjusted to reflect the nonresonant spacing. The initial design is simplified by assuming that the scattering from each slot is small, and hence multiple reflections are neglected. With this assumption and a perfect load termination, the reflection coefficient at the waveguide input is given by

$$\Gamma_i = \sum_{n=1}^N \rho_n e^{-j2n\beta d} \quad (35)$$

where the reflection coefficient for a resonant slot

$$\rho_n = \frac{-2G/G_0}{2 + G/G_0} \quad (36)$$

Neglecting the slot reflections, the ratios of the slot radiated powers for a traveling-wave array of resonant shunt elements are given by

$$\frac{P_n^r}{P_1^r} = \frac{G_n/G_0}{G_1/G_0} \prod_{i=1}^{n-1} \left(1 - \frac{G_i}{G_0}\right) \quad (37)$$

where the product term gives the decrease in the power along the guide caused by radiated energy. The ratio of the power remaining after the final element is absorbed in the load termination relative to the input power is given by

$$\frac{P_l}{P_i} = \prod_{n=1}^N \left(1 - \frac{G_n}{G_0}\right) \quad (38)$$

If the waveguide loss is significant, the attenuation factor $e^{-\alpha z}$ should be included in the power calculation. The initial design process requires solving these equations to achieve both the desired amplitude distribution and an acceptable value for the power lost to the load. For the traveling-wave array, it is advantageous to have a longer array because this reduces the amount of power that must be absorbed in the load termination. The range of coupling values available for the radiating elements also affects the amount of power that will be lost in the load. The circuit models can be cascaded to account for the multiple reflections and frequency effects. The design process for the array including mutual coupling effects is similar to that for the resonant array. However, the variation of the mode voltage along the array must be included in the model [29].

4. WAVEGUIDE PLANAR ARRAY

The waveguide planar array is constructed by joining a number of linear arrays via a feed network. The planar aperture provides the area required to achieve high gain, which is a critical parameter for most designs as it determines the effective range of system operations. The rectangular waveguide exhibits low loss values over a wide range of frequencies (up to the millimeter waveband), which makes the waveguide slot array desirable for high-gain applications. The sidelobe distribution is also important for many applications as high sidelobes may

result in unwanted interference between adjacent installations or false returns off scatterers located in the sidelobe region. For the planar-slot array, the aperture distribution is achieved by controlling the characteristics of the individual radiating elements and the coupling characteristics of the feed network. The ability to accurately control the excitation across the aperture allows the designer to set the radiation pattern sidelobes.

4.1. Planar-Array Far-Field Patterns

The equation to compute the far-field pattern of a planar array located in the $x-y$ plane is

$$S(\theta, \phi) = A(\theta, \phi) \sum_{m=1}^M \sum_{n=1}^N V_{mn} e^{jk(x_{mn} \sin \theta \cos \phi + y_{mn} \sin \theta \sin \phi)} \quad (39)$$

The array elements are assumed to have identical element patterns that are similar to Eq. (2) with the appropriate coordinate transformation to match the element orientation. The array factor is given by the summation term where V_{mn} is the excitation of each element. If the array elements are on a rectangular grid, the equation simplifies to

$$S(\theta, \phi) = A(\theta, \phi) \sum_{m=1}^M \sum_{n=1}^N V_{mn} e^{jk(md_x \sin \theta \cos \phi + nd_y \sin \theta \sin \phi)} \quad (40)$$

This formulation is in the form of a Fourier transform, and with appropriate manipulations fast Fourier transform [30] computer routines are used to reduce computation time greatly. For a rectangular, separable array, the distribution is chosen to be of the form

$$V_{mn} = V_m V_n$$

Now the resulting planar-array equation is the product of the two linear-array distributions. This results in a dramatic reduction in computation time:

$$S(\theta, \phi) = A(\theta, \phi) \sum_{m=1}^M V_m e^{jkm d_x \sin \theta \cos \phi} \sum_{n=1}^M V_n e^{jkn d_y \sin \theta \sin \phi} \quad (41)$$

For arrays with separable distributions, the desired linear-array distributions are selected, and then the products are used to determine the individual element distributions. The cardinal plane patterns of the array match the linear-array patterns, and the intercardinal planes have sidelobes that are the product of the two linear-array distributions. For circular apertures, there are a variety of circular distributions available that are sampled to generate the array distribution [31]. More complex distributions are synthesized for specific applications. The planar-array directivity is computed by using the array far-field pattern in the directivity expression, Eq. (4). The

directivity is reduced by the losses in the antenna system to determine the array gain.

4.2. Resonant Planar-Array Design

A common architecture for a resonant planar array, shown in Fig. 8, uses broadwall offset-shunt slots as the radiating elements. The linear arrays are attached along the sidewalls, and common sidewalls are used to reduce the weight. Different lengths are used for the linear arrays to fit the array within a specified area. Power is fed to the individual linear arrays via a waveguide network beneath the radiating aperture. A compact feed network is formed with a linear array of broadwall coupling slots to distribute power to the radiating waveguides. Angled series-series slots provide a convenient coupling mechanism because the power to each linear array is controlled by adjusting the slot angle. Offset shunt-series slots are also used as coupling elements, but they have the disadvantage that the linear arrays must be offset to maintain the proper feed point and compensate for the staggered offsets of the coupling slot.

The radiating slots and feed network are designed together to provide the desired input match and to achieve the aperture radiating distribution. The design values for the radiating slots and the coupling slots must be chosen together to meet the performance goals as the input impedance and the slot radiation are functions of both the radiating slot values and the coupling values of slots in the feed waveguide. The array spacings to achieve resonance in both the radiating and feed planes are related because the radiating guide width determines the spacing in the feed plane. The spacings and the waveguide dimensions must be chosen as a set to achieve the correct resonant frequency in each plane of the array.

4.2.1. Planar-Array Circuit Models. The lumped-circuit models used for the linear-array design combine with the coupling-slot models to provide a simple model for the planar array. The impedance at resonance of a series-series slot coupling to a linear array of M radiating slots is

Figure 8. Waveguide planar array with offset longitudinal shunt-slot radiators and series-series angle-slot coupling elements.

given by

$$R_n/R_0 = \frac{1}{M_n} \sum_{m=1}^{M(n)} G_{mn}/G_0 \tag{42}$$

The coupling elements form a linear array of N slots in the feed waveguide with an input impedance at resonance of

$$Z_i/Z_0 = \sum_{n=1}^N \frac{1}{M_n} \sum_{m=1}^{M(n)} G_{mn}/G_0 \tag{43}$$

The ratios of the slot conductance and coupling values must be chosen to provide the correct ratios for the radiating-slot voltages. The slot conductance values within each radiating guide are given by

$$G_{mn} = G_{1n} \frac{P_{mn}^r}{P_{1n}^r} \tag{44}$$

and the coupling ratio for each series-series slot is given by

$$M_n = M_1 \frac{\sum_{m=1}^{M(n)} G_{mn}/G_0 \sum_{m=1}^{M(1)} P_{m1}^r}{\sum_{m=1}^{M(1)} G_{m1}/G_0 \sum_{m=1}^{M(n)} P_{mn}^r} \tag{45}$$

The values for the G_{1n} and M_1 must be chosen to create the desired input impedance value. For compactness and improved bandwidth characteristics, it may be desirable to feed the array at the center of the feed waveguide using an additional feed layer with a coupling slot. For a shunt-series coupling element where the waveguide terminated by a short at one-quarter guide wavelength, the input admittance to the array is given by

$$Y_i = \frac{Z'}{\mathcal{M}_0} \tag{46}$$

where Z' is the impedance in the feed waveguide and \mathcal{M}_0 is the input slot coupling ratio. The values for the series-series coupling slots must be chosen to account for the power division between the elements to each side of the input slot.

4.2.2. Mutual-Coupling Effects. As in the linear array, the simple-circuit model neglects effects, such as mutual coupling between the slots, that perturb the performance. The mutual-coupling effects between the radiating elements are handled as described for the linear array with a separate input admittance requirement for each radiating waveguide. The external mutual-coupling effects are generally more significant in the E -plane of the slots than in the H -plane. Additional coupling mechanisms that impact the array performance include coupling-slot interaction with the radiating slots and with the other coupling slots in the feed guide. The radiating slots closest to the coupling slots in each guide are significantly affected by these

interactions, which are modeled by the method of moments [32].

4.2.3. Large Resonant Arrays. The array bandwidth decreases as the size increases because of the increased number of elements in the radiating and feed linear arrays. To avoid the bandwidth reduction for a large array, the array is subdivided into a number of subarrays or modules with shorter radiating and feed arrays. The array power is distributed to the individual modules via a feed network made up of a series of waveguide power dividers. The configurations of the modules are dictated by the required array bandwidth, the available aperture area, and the packaging limitations for the feed network. It is desirable to minimize the modular size to improve the array bandwidth, but this requires more modules and complicates the feed network. Dividing the array into subarrays is fairly straightforward for rectangular arrays. The choice of modular layouts is more complex for arrays with elliptical or irregular boundaries. The available range of coupling values for the slots and the feed network limits the choice of modular configurations. Systems requirements, such as the need to provide both sum and difference patterns, which necessitates dividing the array into equal quadrants, also determine the available configurations.

A typical configuration for a resonant planar array is built up of several modules with offset-shunt radiating slots and angled series-series coupling slots. Offset-shunt series slots are used to couple power from a waveguide corporate feed network made up of reactive H -plane waveguide three-port power dividers. For an array with difference pattern requirements, the power is distributed to the quadrants of the array by a network of waveguide magic-tee four-port power dividers. This architecture provides some inherent mechanical advantages because of the box-like structure of the radiating aperture, and, depending on the array size, is packaged so that the depth of the array is as small as three times the waveguide b dimensions. Numerous other variations of array architecture are also used.

To begin the design of an array of this type, the desired gain, sidelobe performance, and frequency bandwidth must be specified. The size of the array is driven by the array gain. The area is chosen so that the area directivity minus the taper loss, all losses in the aperture and feed networks, and any of the return loss at the array input meets the required gain value with some margin. Because of variations, the required aperture distribution is selected to meet the sidelobe requirements with some margin. The array slot spacings are chosen to meet the frequency requirements and make the most effective use of the available area. The aperture distribution is discretized to give the required value at each slot. Then the array is subdivided into modules whose size is based on the required frequency bandwidth. The design of individual modules is similar to that described previously with the additional complication that now the external mutual coupling includes both the slots within the module and all slots in the other modules.

The feed network is a multiport power-dividing network with an output port for each module. The relative power to each port is calculated by summing the specified powers of the slots in each module. For most applications, a corporate feed structure with equal path lengths to each module is required to meet the bandwidth requirements. A reactive H -plane tee in a rectangular waveguide provides a low-loss, low-profile, power-dividing network. The individual tees are matched, and the power splits are controlled by adjusting inductive-tuning irises at the tee input and the length and position of a septum on the back wall of the tee. The performance of the reactive-feed network is sensitive to the loads placed on the feed by the modules. To reduce this sensitivity and provide broader band performance, matched power dividers are used even though they have higher loss and larger sizes.

4.2.4. Frequency and Power-Handling Effects. As the operating frequency of a resonant array moves away from the design frequency, the input match degrades and the pattern performance suffers. For arrays whose radiating guide and feed waveguides are fed near or at their centers, the amplitude and phase of elements at the ends of the guide diverge from those near the center. For a single module, this broadens the main beam and increases the sidelobe level. For an array of modules, this creates an error across the array with a period equal to the modular spacing, which creates error lobes in the far-field pattern and reduces the array directivity. These effects are modeled by using a circuit model for the modules and feed network.

The amount of power that the array is required to handle also influences the design. The waveguide power-handling capability is reduced as the waveguide b dimension is decreased, so for high-power applications, full-height waveguide should be used. For arrays that must operate at high altitudes, the waveguides are pressurized. Care should be taken to avoid any obstacles that protrude into the guide in the b dimension, and mismatches should be minimized to reduce the standing-wave effect. The amount of power is reduced as it divides through the feed network and subarrays, so the power-handling problem is less severe at the aperture.

4.3. Nonresonant Planar Arrays

The traveling-wave planar array is created by joining a set of linear, traveling-wave arrays with a feed network. The sidewall edge-slot array is frequently chosen, particularly for applications where the array is scanned in the feed plane, because the linear arrays can be packed closely together. The radiating arrays are designed similarly to the linear array, but mutual coupling between the linear arrays must be taken into account. It is generally preferable not to subdivide the array and to end feed the radiating aperture to minimize the power lost to the loads. The feed network can be traveling wave or standing wave depending on the application. A linear array of coupling slots provides a compact feed network for many applications. Where beam squint in the feed plane is not desired, a corporate feed network of waveguide power dividers is used.

4.4. Effects of Manufacturing Variations

Array performance is influenced by how accurately the design is realized in manufacturing. For arrays with stringent sidelobe requirements, the effects of manufacturing deviations from the design values significantly alter the performance, and the deviations must be carefully controlled. The potential impacts of the manufacturing process should be accounted for in the design. Where possible, the design values should be chosen to minimize sensitivity to the variations. The acceptable limits for process variations should be set on the basis of acceptable performance limits; the processes should be chosen for compatibility with these limits. The relative locations of the features and the geometry of the individual features must be controlled. The potential cost impacts of overly tight tolerances must be weighed against the performance impacts. The operating frequency of the array is a major factor in the allowable tolerances and hence the preferred manufacturing technique. Typical manufacturing processes for slot arrays include machined metal assemblies joined either by brazing or bonding, stamped or punched slots, etched slots on metal clad dielectric, molded metallized plastic assemblies, or cast parts.

For slots manufactured by conventional machining techniques, it is more convenient and cost effective to machine the slots with a rounded end that matches the diameter of the endmill rather than create a true rectangular slot. For narrow slots, the main effect of the rounded end is a change in the slot resonant frequency. The effect is modeled and compensated for by assuming that a rounded end slot has the same resonant frequency as a square-ended slot of equal area [14].

For large arrays, errors that are randomly distributed across the array face result primarily in increased average sidelobe level and a decreased array gain. The effects of these errors are estimated by statistical techniques [33,34] or by a Monte Carlo simulation of the array pattern. The variation in the element excitation must be estimated from the tolerances on the element features, and then these values are used to estimate the change in array performance. The sensitivity of the characteristics of the individual slots to a given variation in slot dimensions is determined by using the slot design equations or design curves such as those shown in Fig. 4.

Systematic errors have more significant impacts. A consistent change in the waveguide a dimension shifts the resonant frequency of the standing-wave array and alters the beam-pointing angle in the traveling-wave array. A systematic error in the slot locations creates undesirable sidelobes. In the traveling-wave array, if the slot coupling or the waveguide losses are consistently higher or lower than the design value, the error in the array excitation accumulates along the array because the mode amplitude is increasingly perturbed. If the coupling is significantly lower than the design value, excess power is lost in the load. Periodic errors raise the sidelobe at the position where a grating lobe would occur for an array whose spacing is equal to the spacing of the periodic error. Feed network or other errors that affect large portions of the array have significant impacts on the array sidelobe and

gain performance. An array with a difference pattern requirement is sensitive to asymmetrical errors across the array because any imbalance affects the cancellation that occurs at the difference pattern null.

Acknowledgments

The author wishes to thank W. H. Kummer for his assistance with the manuscript and historical background, R. C. Hansen for providing historical material, G. R. Kulakowski for his assistance with the figures, and the reviewers for their helpful comments.

1. INTRODUCTION

Waveguide components such as waveguides as transmission lines, mode transducers, terminations, discontinuities, attenuators, nonreciprocal devices (isolators and circulators), TR cells, phase shifters, power measuring

devices (bolometers), crystal detectors, junctions devices (the magic “tee”), directional couplers, mixers, periodic structures (disk-loaded slow-wave structures), resonators, filters, diplexers, and multiplexers are extensively employed in industry to produce waveguide subsystems for a wide variety of microwave and millimeter-wave applications. Waveguide components, in general, are constructed from elements of transmission structures and it is therefore essential to understand the theory of electromagnetic waveguides. This article attempts to illustrate the basic considerations by referring to a few of the more important rectangular waveguide components employed in microwave and millimeter-wave systems. It is hoped that the references included at the end of this article will direct the interested reader to sources of more detailed information on particular subjects.

2. WAVEGUIDE AS TRANSMISSION LINES

In this section we will summarize the information for waveguides as transmission lines that is most often needed in waveguide component design. Waveguides have a relatively low loss and a large power-handling capability for a given operating frequency. They are used in a wide variety of applications, including precision instrumentation equipment, specifically, the network analyzer. Waveguides are also useful in some millimeter-wave systems, very-low-loss transmission systems, very-low-loss filters (very-high- Q filters), and high-power transmission (e.g., kW–MW range).

2.1. Rectangular Waveguides

Probably the most widely used elements in high-power and very-low-loss microwave and millimeter-wave filters are the rectangular waveguides (see Fig. 1). Additional details on waveguides and their applications may be found in the literature [1–23].

The waveguide supports TE (transverse electric) and TM (transverse magnetic) modes. TE modes have a magnetic field (H_z) but no electric field (E_z) in the direction of propagation. They have also been referred to as H modes, or modes of magnetic type.

Figure 1. The rectangular waveguide structure.

For TE_{mn} modes, the electromagnetic field components are given by

$$E_x = \frac{jk_0\eta_0 n\pi}{b} A_{mn} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) \quad (1)$$

$$E_y = \frac{jk_0\eta_0 m\pi}{a} A_{mn} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) \quad (2)$$

$$E_z = 0 \quad (3)$$

$$H_x = \frac{j\beta_{mn} m\pi}{a} A_{mn} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) \quad (4)$$

$$H_y = \frac{j\beta_{mn} n\pi}{b} A_{mn} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) \quad (5)$$

$$H_z = k_c^2 A_{mn} \cos\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) \quad (6)$$

Modes that have an electric field (E_z) but no magnetic field (H_z) in the direction of propagation are known as *TM*, and have also been referred to as *E modes* or modes of electric type.

The electromagnetic field components of TM_{mn} modes are given by

$$E_x = \frac{-j\beta_{mn} m\pi}{a} B_{mn} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) \quad (7)$$

$$E_y = \frac{-j\beta_{mn} n\pi}{b} B_{mn} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) \quad (8)$$

$$E_z = k_c B_{mn} \sin\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) \quad (9)$$

$$H_x = \frac{jk_0 n\pi}{b\eta_0} B_{mn} \sin\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) \quad (10)$$

$$H_y = \frac{-jk_0 m\pi}{a\eta_0} B_{mn} \cos\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) \quad (11)$$

$$H_z = 0 \quad (12)$$

where A_{mn} and B_{mn} are amplitude coefficients, and

$$k_0 = \omega\sqrt{\mu_0\epsilon_0} \quad (13)$$

$$\eta_0 = \sqrt{\frac{\mu_0}{\epsilon_0}} \quad (14)$$

$$k_c = \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2} \quad (15)$$

The phase constant of the waveguide is related to λ_g by

$$\beta = \frac{2\pi}{\lambda_g} \quad \text{with} \quad \lambda_g = \frac{\lambda_0}{\sqrt{1 - \left(\frac{\lambda_0}{\lambda_c}\right)^2}} \quad (16)$$

where λ_0 is the free-space wavelength:

$$\lambda_0 = \frac{c}{f} \quad \text{and} \quad \lambda_c = \frac{2\pi}{k_c} \quad (17)$$

Figure 2. Relative cutoff frequencies of waves in a rectangular waveguide.

The modes that enable single-mode operation in the natural state are usually referred to as *dominant* or *fundamental*, while all other modes are known as *high-order* modes. The TE_{10} is the dominant mode of the rectangular waveguide. It has the lowest cutoff frequency of all possible rectangular waveguide modes. Figure 2 shows the line diagram that indicates the cutoff frequencies of a few of the lowest-order modes in a rectangular waveguide for a ratio of width a to height b of 0.5. The properties of standard air-filled rectangular waveguides are summarized in Table 1.

2.1.1. Dominant TE_{10} Mode in Rectangular Waveguides. For TE_{10} modes, the electromagnetic field components are given by

$$E_x = 0 \quad (18)$$

$$E_y = E_{y0} \sin\left(\frac{\pi x}{a}\right) \quad (19)$$

$$E_z = 0 \quad (20)$$

$$H_x = H_{x0} \sin\left(\frac{\pi x}{a}\right) \quad (21)$$

$$H_y = 0 \quad (22)$$

$$H_z = H_{z0} \cos\left(\frac{\pi x}{a}\right) \quad (23)$$

2.1.2. Characteristic Impedance (Z_0) in Waveguides. There are a few commonly used definitions, as follows. The *voltage-current* definition:

$$Z_0 = \frac{V}{I} = \frac{\pi}{2} \frac{b}{a} Z_{TE}$$

The *power-current* definition:

$$Z_0 = \frac{P}{I^2} = \frac{\pi^2}{8} \frac{b}{a} Z_{TE}$$

The *power-voltage* definition:

$$Z_0 = \frac{V^2}{P} = 2 \frac{b}{a} Z_{TE}$$

The modified *power-voltage* definition:

$$Z_0 = \frac{V^2}{P} = \frac{b}{a} Z_{TE}$$

The wave impedance for the TE_{mn} mode is given by

$$Z_{TE} = \frac{E_y}{H_x} = \frac{\omega\mu}{\beta} = \eta_0 \left(\frac{\lambda_g}{\lambda_0} \right)$$

2.2. Ridged Waveguides

Ridged waveguides are commonly used in some communication systems for wideband operation. The cross section of a ridged waveguide is given in Fig. 3. The introduction of a ridge to the waveguide reduces the

Figure 3. The ridged waveguide structure.

cutoff frequency of the fundamental mode more than the cutoff of the first higher-order mode. Thus, the bandwidth of single-mode operation in such a waveguide can be expanded. By suitable selection of the geometry of the ridge, the bandwidth of the ridged waveguide can be controlled. For more information about these lines the reader is referred to the literature [1,5,6,23,24,56,57,59].

2.3. Circular Waveguides

The cross section of a circular waveguide is given in Fig. 4. Like the rectangular waveguide, the circular waveguide

Figure 4. Geometry of a circular waveguide.

Figure 5. Relative cutoff frequencies of waves in a circular waveguide.

supports TE and TM modes. In the circular waveguide the *dominant* mode is the TE₁₁ since it has the lowest cutoff frequency. The circular waveguide is well suited for application in long-distance communication at frequencies between 40 and 110 GHz because it has, if oversized and excited in the TE₀₁ mode, extremely low attenuation. However, the TE₀₁ is not a dominant mode, thus necessitating the incorporation of mode filters. Figure 5 shows the line diagram that indicates the cutoff frequencies of a few of the lowest-order modes in a circular waveguide. The line diagrams shown in Figs. 2 and 5, respectively, in which the mode numbers refer to a particular field structure, are very important because they provide information about the relative frequency range over which only a single mode will propagate in a particular waveguide. For more details, the reader is referred to references the literature [1–5,56,58].

For the TE₁₁ mode, the electromagnetic field components are given by

$$H_z = \left(\frac{pr}{a}\right)BJ_1(\cos \phi + \sin \phi)e^{j(\omega t - \gamma z)} \quad (24)$$

$$E_r = \frac{jf\eta}{2\pi r f_c^2 \sqrt{\mu\epsilon}} \left(\frac{pr}{a}\right)BJ_1(\sin \phi - \cos \phi)e^{j(\omega t - \gamma z)} \quad (25)$$

$$E_\phi = \frac{jf\eta}{f_c} \left(\frac{pr}{a}\right)BJ'_1(\cos \phi - \sin \phi)e^{j(\omega t - \gamma z)} \quad (26)$$

$$H_\phi = \frac{E_r}{Z} \quad (27)$$

$$H_r = -\frac{E_\phi}{Z} \quad (28)$$

where

$$Z = \frac{\eta}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}}, \quad \eta = \sqrt{\frac{\mu}{\epsilon}}, \quad f_c = \frac{p}{2\pi a \sqrt{\mu\epsilon}} \quad (29)$$

and p is the first root of $J'_1(x) = 0$.

2.4. Some Special Waveguide Configurations

2.4.1. Rectangular Dielectric-Loaded Waveguides. The rectangular dielectric-loaded waveguide is basically a form of capacitively loaded rectangular waveguide. Figure 6 shows a cross-sectional view of this waveguide used in some communication systems for wideband operation. As with the ridged waveguide, the usable bandwidth of the dielectric-loaded waveguide is greater than that of an ordinary rectangular waveguide. However, this waveguide

Figure 6. Transmission-line structures for microwave, millimeter, submillimeter, and terahertz frequency applications.

has higher conductor losses and lower power-handling capacity than does an ordinary rectangular waveguide. By suitable selection of geometry of the dielectric slab, the bandwidth of the dielectric-loaded waveguide can be controlled. For more details, the reader is referred to the literature [1,25,26].

2.4.2. E-Plane Circuits (Finlines). A dielectric-loaded waveguide with fins is called a “printed E -plane circuit”. It can also be viewed as a slotline inserted in the E plane of a rectangular waveguide, or as a ridged waveguide, with thin ridges backed by dielectric substrate or all-metal E -plane circuits and finlines (see Fig. 6). The advantages of low insertion loss, simple fabrication, and wide single-mode bandwidth have made this circuit widely utilized in low- and medium-power millimeter-wave applications. The mode of propagation is a hybrid mode consisting of a combination of TE and TM modes. In Ref. 25 the line parameters of these waveguides are determined numerically as well as experimentally for the first time considering the metallization thickness and the influence of the longitudinal slits in the mount groove. A substantial amount of work on these structures has been reported in the literature [26–28].

2.4.3. Dielectric Waveguides. At millimeter-wave frequencies (up to ~ 140 GHz), where precise fabrication of ordinary rectangular waveguides, suspended striplines, and finlines becomes extremely difficult, dielectric waveguide structures offer an alternative approach with the potential for lower losses and relaxed tolerances. There are several different dielectric waveguide structures such as dielectric rod, dielectric slab (image line), trapped image line, insulated image line, or inverted stripline. Cross-sectional views of a dielectric rod waveguide and an image

Figure 7. *H*-plane and *E*-plane waveguide bends.

line are shown in Fig. 6. The dielectric rod waveguide consists of a rectangular dielectric rod surrounded by an infinite air medium. The dominant mode of a dielectric rod waveguide has no cutoff frequency, so its operational bandwidth is unlimited in theory. The image line consists of a rectangular dielectric slab placed on a backing sheet of a perfectly conducting ground plane. This structure behaves like a dielectric rod waveguide that supports hybrid modes. The main drawback of these structures is the radiation loss at junctions, discontinuities, and bends. Also the dielectric/metal adhesives are very lossy, and this reduces the practical, loaded *Q* factor. Because of these difficulties, some further low-cost contenders have been considered for operation at frequencies around and exceeding 100 GHz. A detailed discussion about these structures has been reported in the literature [25,26,29,30].

2.4.4. MMIC Waveguides. Monolithic transmission lines for sub-millimeter-wave and terahertz frequency applications may be realized by considering variants of the early dielectric waveguides. Metal pipe on-wafer waveguides are constructed from dielectric materials and structures that are available in monolithic technology, enabling their use in integrated circuits. A cross-sectional view of this transmission line is shown in Fig. 6. These structures may be used not only as transmission lines but also as filter elements. For more information about these lines the reader is referred to Refs. 31–34.

3. MODE TRANSDUCERS

In order to change the mode, direction, or polarization of wave transmission in microwave and millimeter-wave systems, mode transducers should be used. The most popular mode transformers are coaxial-to-rectangular waveguide transitions, rectangular-waveguide-to-rectangular-waveguide transitions, rectangular-waveguide-to-ridged-waveguide transitions, stepped transformers in rectangular waveguides, impedance transformers in a circular waveguide, stepped dielectric slab transformers, waveguide bends, and waveguide circular polarizers. Figure 7 shows

Figure 8. Waveguide terminations with low VSWR.

Figure 9. Adjustable waveguide load.

the *H*-plane and *E*-plane waveguide bends. For more details about mode transducers, the reader is referred to the literature [3,37,38,56].

4. TERMINATIONS AND ATTENUATORS

The most commonly used waveguide terminations are the matched loads, the standard mismatches, and the adjustable short circuits. The matched loads are of either the stepped or tapered variety. Some of them are shown in Fig. 8. Figure 9 shows the adjustable waveguide load used to provide a variable reactance in waveguide systems. This section presents a brief description of the terminations and attenuators commonly used in microwave systems.

Some of the methods used to control the amplitude of microwave transmission in waveguides will be illustrated in this subsection. These include the resistive card attenuator, and the be either variable of fixed, the rotary-vane attenuator, and the cutoff waveguide attenuator, which are shown in Figs. 10, 11 and 12, respectively. The latter is particularly useful in signal generators, where large attenuation is required. The cutoff attenuator is based on a section of circular waveguide operating at a frequency below cutoff. The attenuation is frequency-independent at frequencies well below cutoff and is not dissipative (reactive). The lowest mode (TE_{11}) suffers the least attenuation, and operation is usually viewed in terms of this mode. For more information about terminations and attenuators, the reader is referred to Ref. 3.

5. WAVEGUIDE RESONATORS AND FILTERS

Resonant structures are used extensively as filter elements in the realization of various bandpass and band-stop filters. At low frequencies, resonant structures are invariably composed of lumped elements. At higher frequencies, however, lumped elements in general cannot be employed because of low *Q* and difficulties in realizing inductances and capacitances at high frequencies. Distributed

Figure 10. Variable resistive card waveguide attenuator.

Figure 11. The rotary-vane waveguide attenuator.

elements, that is, transmission-line and waveguide sections, are widely used to overcome these limitations. The resonant structures commonly used in various bandpass and bandstop filters can be realized in several forms, such as lumped-element resonators, cavity resonators, planar resonators, and dielectric resonators. The choice of structure depends on the mechanical size of the resonator at the resonant frequency, the unloaded Q , and the temperature stability and electrical tunability of the frequency. This section presents a brief description of the waveguide filters commonly used in microwave and millimeter-wave systems. Inductive elements such as posts, transverse strips, and transverse diaphragms (irises) are extensively employed in industry to produce waveguide bandpass filters for a wide variety of applications. However, they are difficult to make cheaply and to put into mass production because of their complicated structure. To solve this problem, E -plane metal insert filters have been proposed by Y. Konishi [40]. The normal construction for E -plane bandpass filters is to place inductive obstacles, typically metal septa, in the E plane of a rectangular waveguide, at spacings close to a half-guide wavelength apart (see Fig. 13a). The size and number of the metal septa are the parameters that vary the filter bandwidth,

while the longitudinal spacing determines the center frequency of the E -plane filter.

A common feature of these filters is that the performance is determined essentially by the metallization pattern of the insert. The most important point, however, is that the insert can be fabricated very accurately by spark erosion or photolithographic metal-etching techniques, which allows low-cost mass fabrication. Finally, the insert is clamped between the two halves of a split block housing, which simplifies assembly and reduces machining cost to a minimum. E -plane filters can offer an unloaded Q factor of about 2000–2500 at X band, and can be used at frequencies up to 140 GHz. The CAD of these filters has received considerable attention in the literature [57].

However, the problem with the use of these filters in many applications (e.g., for diplexers and multiplexers) is that the attainable stopband attenuation and edge steepness may be too low. Several different solutions have been proposed to alleviate the latter problem [39]. Although most of these solutions lead to a higher passband insertion loss, this is at the expense of increased manufacturing complexity. Therefore, new E -plane filter structures are proposed, in order to improve performance in the second stopband. The main characteristics of the new filter structures are the use of a conventional rectangular waveguide housing and the use of a metal insert that when mounted introduces ridges in the resonators. The proposed filter structures relate to microwave filters employing sections of ridged waveguide in which all the waveguide sections are resonant at a single fundamental frequency but are not simultaneously resonant at any higher frequency because of different guide wavelengths in the different filter sections (see Fig. 13b). A detailed description of waveguide resonant structures and waveguide filters may be found in the literature [35,36,39–42,55–59].

6. WAVEGUIDE DIPLEXERS AND MULTIPLEXERS

Point-to-point and point-to-multipoint digital communication systems are a rapidly expanding market. Such systems commonly employ filters and diplexers in microwave and millimeter-wave transceivers as channel separators. Hence there is an increasing demand for low-cost, low-dissipation-loss, low-insertion-loss, low-return-loss (see Fig. 14), and compact filters and diplexers. The designed diplexer offers broadband operation and improved selectivity without introducing any further complexity over that involved in the fabrication of standard E -plane

Figure 12. Below-cutoff waveguide attenuator.

diplexers. Figure 15 shows the cross section of a double-ridge waveguide T junction, the configuration of the designed diplexer, and the simulated *S* parameters of a double-ridge waveguide diplexer.

Waveguide manifold multiplexers have been widely used in wireless applications that require high power-handling capability and low insertion loss in the passband of each channel. *E*-plane integrated quasiplanar printed-circuit technology is a well-established technology for realizing microwave and millimeter-wave circuits and offers a convenient low-cost solution for waveguide manifold multiplexers [56]. Since the waveguide housing dimensions have been standardized in bands, the available bandwidth for a particular system is generally determined as the width of the corresponding microwave or millimeter-wave waveguide band. Conventional *E*-plane filters exhibit a spurious harmonic passband at a frequency roughly 1.4 times their center frequency. For such a filter centered at the lower part of a standardized band, the harmonic behavior is exhibited within the upper part of the same band. Hence, in order to avoid significant crosstalk between the channels at the lower and higher frequency ranges of a band, the available bandwidth for the multiplexer is reduced to the stopband of the lowest frequency filter. Improvement in the stopband performance of an *E*-plane filter may be met by introducing ridges in the resonators of a conventional *E*-plane filter. Such a

configuration, without involving any further complexity in the fabrication process, could shift the spurious harmonic passband of the filter farther away from its centre frequency, out of the waveguide band, increasing at the same time the isolation between the channels. Incorporating ridge waveguide filters in *E*-plane manifold multiplexers can thus maximize the available multiplexer bandwidth to that of the waveguide band. This contribution demonstrates the bandwidth limitation imposed by the poor stopband performance of standard *E*-plane filters on the bandwidth of a multiplexer. A four-channel X-band multiplexer is used as an example. It shows how ridged waveguide filters help to overcome this limitation. Figure 16 shows the layout of Four-channel *E*-plane manifold multiplexer and the performance of the Four-channel multiplexer using a ridged waveguide filter. A detailed description of waveguide diplexers and multiplexers may be found in the literature [43–57].

WAVEGUIDE DIRECTIONAL COUPLERS

RALPH LEVY
R. Levy Associates
La Jolla, California

1. INTRODUCTION

A directional coupler is a four-port circuit having the schematic shown in Fig. 1, where transmission lines 1–4 and 2–3 are mutually coupled by means of some type of cou-

Figure 1. Directional coupler showing port nomenclature and symmetry planes.

pling mechanism or mechanisms indicated by the central cross. An electromagnetic wave incident at port 1 is partly coupled to port 3, and the remaining power is transmitted to port 4. In an ideal directional coupler no energy is coupled to port 2, which is termed the *isolated port*. In this article the transmission lines to be considered are waveguides, but similar theory and design principles may apply to other types of transmission lines, such as coaxial, strip-line, or microstrip lines.

Directional couplers have several applications, such as a device for monitoring the power along the mainline (1–4 in Fig. 1). Since the device is directional, the power at the coupled port 3 will be proportional to the power propagating in the 1–4 direction. Power propagating in the 4–1 direction will be coupled to port 2 and will not be detected by a detector mounted on port 3. This forms the basis of another application, known as a *reflectometer*, where detectors at ports 3 and 2 may be used to measure both the incident and reflected waves on the main 1–4 transmission line. In practice it is simpler to use two directional couplers connected in tandem, one for the incident and one for the reflected wave, since this device, known as a *dual-directional coupler*, is simpler to “match” over a broad frequency bandwidth, avoiding having very well-matched detectors.

A very common type of directional coupler is designed to couple half of the power to port 3 with the remaining half directed to port 4. Here the coupling is 3.01 dB (or 3 dB for conciseness), and such a coupler is also known as a “hybrid coupler” or simply as a “hybrid”. It has many applications in microwave technology, including use as a component of a balanced mixer with detectors mounted on ports 3 and 4. The main signal is applied to port 1 and a local oscillator signal to port 2. Hybrids are used in the design of duplexers or diplexers, and their advantageous phase properties make them ideal as power dividers for balanced amplifiers or as components in feed networks for antenna arrays. The phase property alluded to here refers to the fact that in a well-matched hybrid the phase difference between the main (or through) line and coupled port signals is either 0°, 90°, or 180°, depending on the type of coupler. The proofs of these phase properties are given by fundamental theory from geometric considerations (i.e., the type of network symmetry) and will be discussed further in Section 2.

2. BASIC PROPERTIES OF DIRECTIONAL COUPLERS

Early work in the field of directional couplers with the basic theory together with numerous references is discussed in Refs. 1 and 2. The most fundamental theory states that all reciprocal four-port junctions having a perfect match at all four ports are directional couplers. This simplifies the conceptual design of directional couplers since one need obtain only a matched condition, knowing that there will always be an isolated port. The theorem may be proved by application of the unitary condition to the scattering matrix of the matched four-port [3]

$$SS^* = I \quad (1)$$

where S^* is the complex conjugate transposed matrix and I is the unit matrix. (Since the network is reciprocal, the transposed matrix is identical to the original matrix.)

In all types of couplers considered here there is symmetry about the plane indicated by the horizontal dotted line shown in Fig. 1; thus the coupled waveguides are identical. This condition is by far the most common case, but couplers between nonidentical waveguides have been described in the literature for special rare applications. The symmetric case simplifies the analysis and synthesis (i.e., the design) of directional couplers since the four-port may be split into odd and even mode two-port circuits [1, p. 125]. In the even mode the symmetry plane becomes a magnetic wall or open circuit, and in the odd mode it becomes an electric wall or short circuit.

In the case where there are symmetry planes at both the horizontal and vertical planes indicated by the dotted lines in Fig. 1, then the coupler has complete symmetry and the four ports are indistinguishable. This will be the case for all the couplers to be described here, and almost all waveguide couplers fall into this category. An important property of all such couplers is that the phase difference between the two signals at the direct and coupled ports is always 90° . The proof involves writing down the unitary condition (1) on the scattering matrix—see details presented in [Ref. 1 (pp. 121–122)]. The phase difference is exactly 90° only if the coupler has perfect match and isolation. The deviation from 90° may be estimated using the same scattering matrix theory for a slightly imperfect coupler, and is surprisingly small. In the case of a nominal 3-dB coupler or hybrid, the phase difference between the waves coupled to ports 3 and 4 is given by [1, pp. 122–125]

$$\cos(\theta_3 - \theta_4) = 2 \times 10^{-I/10} \quad (2)$$

where I represents the isolation in decibels. Thus for 30 dB isolation we obtain a phase difference of 89.885° and for 20 dB isolation this becomes 88.854° . We may conclude that there is no need to worry about the phase performance of any symmetric coupler that is well matched and isolated.

3. TYPES OF WAVEGUIDE DIRECTIONAL COUPLERS

The most widely used types of waveguide directional couplers are multiaperture couplers, cross-guide couplers, sidewall and topwall hybrids, and branch-guide couplers.

Some of the very early couplers designed during the 1930s and 1940s are no longer or rarely used; examples are the Bethe hole and Schwinger couplers, and are omitted here. The theory for many couplers as presented in Ref. 1 have been superseded by more accurate theories, including those by the present author who realized that there were deficiencies in the previous theories while preparing the 1966 survey [1].

3.1. Waveguide Multiaperture Couplers

The design initially evolves from Bethe's small-aperture coupling theory [4], whose main result may be applied to the case of a pair of waveguides propagating in the dominant TE_{10} mode with a single aperture, as shown in Fig. 2. The amplitudes of the forward coupled wave A_1 and the backward wave B_1 are given by

$$A_1 = j \frac{2\pi}{ab\lambda_g} [M_x H_x^2 + M_z H_z^2 - P E_y^2] \quad (3)$$

$$B_1 = j \frac{2\pi}{ab\lambda_g} [-M_x H_x^2 + M_z H_z^2 - P E_y^2] \quad (4)$$

where the two identical waveguides have broad and narrow dimensions a and b , respectively; M_x and M_y are the components of the magnetic polarizability of the aperture in the x and y directions; and P is the electric polarizability. The polarizabilities are functions of the aperture shape and size having the dimensions of volume, and expressions for these will be presented. H_x , H_z , and E_y are amplitudes of the magnetic and electric fields evaluated at the center of the aperture, and are given by

$$\begin{aligned} H_x &= -\sin \frac{\pi x}{a} e^{-jy z}; \\ H_z &= j \frac{\lambda_g}{2a} \cos \frac{\pi x}{a} e^{-jy z}; \\ E_y &= \frac{\lambda_g}{\lambda} \sin \frac{\pi x}{a} e^{-jy z} \end{aligned} \quad (5)$$

In the case of narrow-wall coupling as shown in Fig. 2b, at the hole location we have $x = 0$ so that the only field component is H_z . The coupled waves as given by Eqs. (3) and (4) become

$$A_1 = B_1 = \frac{-j\lambda_g M_z}{2a^3 b} \quad (6)$$

Figure 2. (a) Broad-wall coupling aperture; (b) narrow-wall coupling aperture.

Figure 3. Loose coupling theory for a multiaperture coupler.

Now the polarizability M_z possesses only a slow variation with frequency (this will be shown later), and hence the coupling is closely proportional to the guide wavelength λ_g . This implies that the coupling of a narrow-wall coupler, consisting of several apertures spaced at $\lambda_g/4$ intervals to give some directivity, will vary considerably over a moderate to broad bandwidth. The broadwall coupler case is far different since all three components of the field with their varying frequency dependence are present, and by judicious choice of x , the distance from the sidewall, couplers may be designed with flat coupling over very broad bandwidths [1, pp. 136–138]. However, narrow-wall couplers find application when the power is very high since there is no component of the electric field, which is mainly responsible for power breakdown in broad-wall couplers, at the apertures located on the sidewalls.

In order to obtain high directivity in directional couplers consisting of parallel waveguides and also reasonably tight coupling values, several apertures must be used to cancel out the backward waves, specifically, the B_1 terms of Eq. (3). The standard theory given in all textbooks to date [e.g., 1, pp. 140–144] is based on an approximate coupling theory as indicated in Fig. 3. In the forward direction the coupled waves add in phase, and the total coupled wave is given by

$$A = e^{-j(n-1)\phi} \sum a_r \tag{7}$$

where the summation is taken from $r = 1$ to n . Note that errors in sign in Ref. 1 have been corrected, and also here we consider the more general case with the forward and backward coupled waves of each aperture being unequal, but the final results are affected only marginally.

In the case of the backward wave the opposite situation occurs; specifically, the individual waves tend to cancel since they are out of phase by multiples of 180° , at least at midband. The total wave coupled in the backward direction is

$$B = b_1 + b_2 e^{-2j\phi} + b_3 e^{-4j\phi} + \dots + b_n e^{-2(n-1)j\phi} \tag{8}$$

When the array is symmetric, we have $b_1 = b_n$, $b_2 = b_{n-1}$, and so on, and (8) simplifies to give

$$B = [2b_1 \cos(n-1)\phi + 2b_2 \cos(n-2)\phi + \dots + 2b_{n/2} \cos \phi] e^{-(n-1)j\phi} \quad (\text{n even}) \tag{9}$$

$$B = [2b_1 \cos(n-1)\phi + 2b_2 \cos(n-2)\phi + \dots + b_{(n+1)/2}] e^{-(n-1)j\phi} \quad (\text{n odd}) \tag{10}$$

If the apertures are of equal size, $b_i = b_1$, then B in (8) becomes a geometric progression with n terms and a multiplication factor of $e^{-2j\phi}$, which may be summed to give

$$B = \frac{b_1 \sin(n\phi)}{\sin \phi} e^{-(n-1)j\phi} \tag{11}$$

The directivity D is defined as the ratio of this backward wave to the forward wave given by (7). In the case of equal coupling apertures, $a_i = a_1$, and the ratio of (11) to (7) becomes

$$D = \frac{b_1 \sin(n\phi)}{a_1 n \sin \phi} \tag{12}$$

The angle ϕ deviates from 90° by perhaps $\pm 20^\circ$ over a fairly wide bandwidth of about 30% and Eq. (12) varies considerably over this band, having maximums equal to $b_1/(na_1)$ which is of the order $1/n$. Thus, for a 10-aperture coupler, the directivity would be expected to oscillate between infinity and approximately 20 dB, and this is considered to represent a rather poor performance. In practice a tapered distribution of the coupling apertures is used to obtain much better directivity. Similar techniques are employed in the design of multielement antenna arrays to give low sidelobe levels, such as in the well-known Dolph–Chebyshev array. The simplest tapered distribution is the binomial one, where for three apertures the relative amplitudes of the b_i in (9) or (10) are given by the series 1,2,1; for four apertures, 1,3,3,1; for five apertures, 1,4,6,4,1, and so on. However, a much better result is obtained using a Chebyshev amplitude taper, where the amplitude distribution for three apertures is

$$1, 2(1 - c^2), 1 \tag{13}$$

For four apertures, the distribution is

$$1, 3(1 - c^2), 3(1 - c^2), 1 \tag{14}$$

and for five apertures

$$1, 4(1 - c^2), 6(1 - c^2)(1 - c^2/3), 4(1 - c^2), 1 \tag{15}$$

Here $c = \cos \phi_0$, where the design band extends from ϕ_0 to $(\pi - \phi_0)$. Hence the Chebyshev taper is less steep than the corresponding binomial taper and also has much better directivity [1, p. 141–143]. The latter reference also gives a simple formula to calculate the relative couplings of the various apertures in the array [1, Eq. (88), etc.].

When the number of apertures becomes large, it is more convenient to use the concept of superimposed arrays. Here two or more smaller Chebyshev arrays are staggered along the length of the coupler, and are actually superimposed. An example is given in Ref. 1 (p. 144) but is not convenient since the central apertures are unequal and the array distribution is nonmonotonic. A possibly better and certainly well tested set of superimposed arrays is to combine $n = 5$ arrays as follows. We take a Chebyshev array with $\phi_0 = 72^\circ$ and $c_0 = \cos(72^\circ) = 0.309$, and

substituting in the general formula [15] above, the series is 1, 3.618, 5.254, 3.618, 1. Superimposing two such arrays gives

$$\text{Total : } \frac{1 \quad 3.618 \quad 5.254 \quad 3.618 \quad 1}{1 \quad 3.618 \quad 6.254 \quad 7.236 \quad 6.254 \quad 3.618 \quad 1}$$

Rather than continuing this process by adding extra arrays, which causes oscillatory behavior of the central values, it is simpler merely to repeat the central value of 7.236 as many times as required. This is convenient and practical since all apertures have the same size except for three at each end, and such arrays have been found to give excellent performance when applied to the design of multiaperture couplers for operation over complete recommended waveguide operating bandwidths.

The simple theory outlined above is applicable only to the design of couplers having loose coupling values, since the series representation of the coupled waves given by Eqs. (7)–(10) assume very small couplings, and the uncoupled wave is assumed to be unattenuated. In particular, it has been found that the directivity is not well predicted if this technique is used, and the prediction of coupling is often quite poor. A considerably improved method is to form the equivalent circuit of the aperture and then to analyze the coupler using circuit theory, for instance, by multiplication of transfer matrices for the even- and odd-mode subnetworks as described in Ref. 5, with extensions and improvements given in Ref. 6. The concept of the equivalent circuit of a coupling aperture was described much earlier by Oliner [7], but without much in the way of detail for the design of waveguide directional couplers. However, this contribution was key in formulation of the later developments [5,6]. One form of the equivalent circuit of an aperture having all three field components as designated in Eqs. (3) and (4) is given in Ref. 1 (Fig. 4 there) and is derived by substituting the field expressions given in Eq. (5) into Eqs. (3) and (4), leading to the equivalent circuit shown in Fig. 4 (here). The proof is somewhat lengthy, and interested readers will find this detailed in Ref. 5. Another lengthy argument is given there to derive equations for the coupling. These are based on the multi-section quarter-wave transformer circuit [8] or alternatively the equivalent lowpass prototype circuit [9]. An

Figure 4. (a) Equivalent circuit for an aperture; (b) even and odd mode equivalent circuits; $X_x/Z_0 = 4\pi M_x \sin^2(\pi x/a)/(ab\lambda_g)$, $B_z/Y_0 = -\pi\lambda_g M_z \cos^2(\pi x/a)/(a^3b)$, $B_y/Z_0 = 4\pi\lambda_g P_y \sin^2(\pi x/a)/(ab\lambda^2)$.

appropriate prototype is chosen to give a value for the quantity R , which is the product of all the junction VSWRs (i.e., the ratios of the impedances > 1 at each junction) of the prototype. R is also equal to the impedance ratio of the quarter-wave transformer prototype. Defining an angle

$$\psi = \frac{2}{n} \sin^{-1} k \tag{16}$$

where k is the coupling coefficient, then the value of R is

$$R = \left(\frac{1 + \sin \psi}{1 - \sin \psi} \right)^n \tag{17}$$

In these equations n is the number of coupling apertures, equal to the number of step junctions of the prototype, which therefore has $n - 1$ steps.

Rather than using a complete distributed prototype, which, although giving the ultimate in directivity performance, means that all the apertures up to the centerline are different, the superimposed array method may be used, in almost all cases giving an insignificant degradation in directivity. The junction VSWRs V_i are calculated using the method outlined in Ref. 10 (pp. 284–290)

$$\log(V_i) = \frac{Z_i \log(R)}{\Sigma(Z_i)} \tag{18}$$

where Z_i is the i th step impedance of the distributed prototype and the summation is from $i = 1$ to n .

The final step in the theory is to relate the aperture polarizabilities to dimensions, with the correct frequency dependencies. The most commonly used apertures are circular holes, usually with two holes transversely arranged on the broad wall as indicated in Fig. 5, or longitudinal and transverse slots as shown in Fig. 6. Bethe's theory [4] assumes that the apertures are small, and direct application of simple formulas for the electric and magnetic polarizabilities leads to considerable deviations from measured results. The most complete account of the correction factors for large apertures is given in Ref. 6. In addition to the aperture resonance effect and wave attenuation due to finite wall thickness, the fields are averaged over the areas of the apertures. The resulting theory has given agreement of coupling with measurements of the order of 0.2 dB over complete waveguide operating

Figure 5. Common wall of broad-wall coupler using circular apertures.

Figure 6. Common wall of broad-wall coupler using slot apertures.

bandwidths, and such a figure is within errors caused by tolerances.

3.2. Cross-Guide Directional Couplers

These are closely related to multiaperture couplers; the difference is that since the waveguides are crossed as shown in Fig. 7, only one or two sets of coupling apertures are feasible. Hence the coupling is limited to rather loose values, although tight values of the order of 5 dB may be obtained using reduced-height crossed waveguides [11]. Since the narrow coupling slots have negligible electric polarizabilities, using the generalized form of Bethe's coupling equations [Eqs. (3) and (4)], where H_x^2 and H_y^2 are replaced by products of the fields in the two waveguides, the equations for the coupled waves become

$$A_1 = j \frac{2\pi}{ab\lambda_g} [M_1 H_x H_z + M_2 H_z H_x] \tag{19}$$

$$B_1 = j \frac{2\pi}{ab\lambda_g} [-M_1 H_x H_z + M_2 H_z H_x] \tag{20}$$

where M_1 and M_2 are the polarizabilities of the individual slots in the cross or crosses. When these coupling slots have equal dimensions, then $M_1 = M_2$ and (23) gives $B_1 = 0$; thus we obtain perfect directivity. In the case of a

single-cross aperture, the coupling becomes

$$A_1 = j \frac{\pi}{a^2 b} M_1 \sin \frac{2\pi x_0}{a} \tag{21}$$

where the only frequency sensitive term is M_1 . Hence cross-guide couplers have very good coupling flatness over entire waveguide recommended operating bandwidths. The directivity in practice is not as good as implied above (i.e., $B_1 = 0$), since it relies on perfect cancellation of only two coupled waves, one from each slot in the cross. However, the theory has ignored the finite width of the slots that introduces small terms in the coupled waves due to the electric polarizability, as indicated in Eqs. (3) and (4). Much better directivity is obtained with multiaperture couplers where there are many such backward waves.

In the case of two cross slot apertures the theory for loosely coupled waves may be applied, taking the phase difference of the line lengths $2d$ between the two coupled waves into account. This gives a total coupled wave

$$A_1 = j \frac{\pi}{a^2 b} M_1 \sin \frac{2\pi x_0}{a} (1 + e^{-2j\phi}) \tag{22}$$

which has an amplitude of

$$A_1 = \frac{2\pi}{a^2 b} M_1 \sin \frac{2\pi x_0}{a} \sin(\phi); \quad \phi = \frac{2\pi d}{\lambda_g} \tag{23}$$

3.3. Sidewall and Topwall Directional Couplers and Hybrids

The sidewall or short-slot coupler was initially described by Riblet [12], and became the most commonly employed 90° hybrid junction used in the microwave industry. The representation of Fig. 8 shows a view looking down on the broad walls of the waveguides. The coupling slot is the full height of the narrow dimension. An analysis of the coupler uses the even/odd-mode concept, where the reflected and transmitted wave amplitudes for the even mode are Γ_e

Figure 7. Cross-guide directional coupler.

Figure 8. Short-slot or narrow-wall directional coupler.

and T_e and for the odd mode Γ_o and T_o , respectively [1, pp. 125–126]. In the odd-mode case we can see that the match may be very good for an infinitesimally thin common wall thickness since then we have straight waveguides with only minor discontinuities due to a pair of small steps and the end tapers. The design of the coupler then hinges on the analysis of the even-mode circuit, and then forcing the condition for good match and directivity, specifically, that $\Gamma_e = 0$.

This was a rather empirical procedure for many years until the advent of 3D field analysis programs made possible a better understanding of the role of the higher-order modes in the coupling region. It was always somewhat of a mystery why the coupling of the short-slot hybrid could be so flat over relatively broad bandwidths. The author [13,14] has shown that this is due solely to the presence of the evanescent TE_{30} mode, which is cutoff only slightly above the operating band of the coupler. An equivalent circuit of the even-mode two-port is given in Fig. 5 of Ref. 13, which leads to good physical understanding of the operation of this mode. Ref. 14 describes how a central capacitive matching probe is necessary to give good performance in 3-dB hybrids, but for looser coupling values this is not required because of the stronger effect of the TE_{30} mode for shorter slot lengths.

The topwall coupler [15] shown in Fig. 9 has a pair of short slots in the common broad wall, and the E -field patterns of the even and odd modes are given in Fig. 10. Here it is seen that the even mode is fairly trivial, being simply a TE_{10} mode with a central floating strip. The odd-mode circuit is also amenable to straightforward analysis since

it is a commonly used thick stripline TEM line with side-walls.

3.4. Branch-Guide Couplers

A schematic representation is shown in Fig. 11, where the view is of the side walls of the waveguide, and the broad dimensions of the main and coupling branches are all equal. Such couplers are very useful for coupling values in the range 0 dB to about 15 dB, since for looser couplings the branches become too thin (i.e., small b dimensions.) The bandwidths are not as broad as those of multiaperture couplers, but for bandwidths typically half of the recommended waveguide operating ranges they are very useful because in general they are both shorter in length and less expensive to manufacture than multiaperture couplers.

The couplers may be manufactured in two halves split down the centerline of the broad walls. In addition, the spacing between the input and coupled waveguides means that access to the ports may not require special bends, and the flange hole patterns may be machined directly into the blocks constituting the two halves, avoiding the expense of separate brazed flanges.

A number of original approximate theories were used to design branch-guide couplers, but they have been superseded by exact synthesis techniques [16,17]. The even- and odd-mode circuits are shown in Fig. 12 for an ideal branch-guide coupler; thus junction discontinuities are disregarded initially. In both circuits the stubs are half the length of the connecting mainlines. The transfer matrices of the a series stub of characteristic admittance a_i is given by

Figure 9. Topwall directional coupler or hybrid: (a) top view; (b) side view.

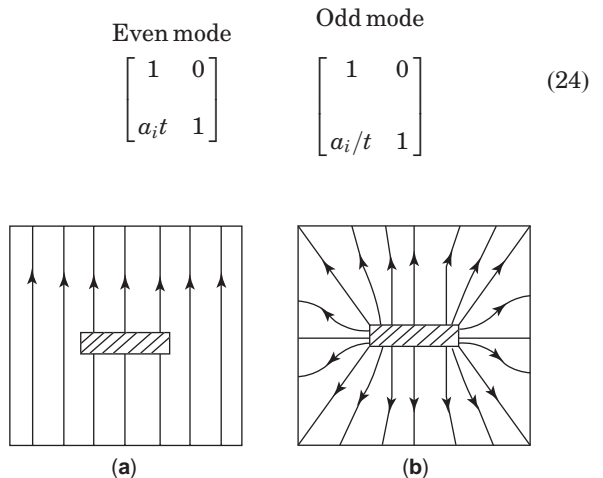

Figure 10. Electric field patterns of the topwall coupler: (a) even mode; (b) odd mode.

Figure 11. Cross section of a branch-guide directional coupler (uniform in the broad dimension).

where t is the Richards variable:

$$t = j \tan \theta \tag{25}$$

The transfer matrix of a connecting line of admittance b_i is

$$\begin{bmatrix} \cos 2\theta & \sin 2\theta/b_i \\ b_i \sin 2\theta & \cos 2\theta \end{bmatrix} = \frac{1}{1-t^2} \begin{bmatrix} 1+t^2 & 2t/b_i \\ 2tb_i & 1+t^2 \end{bmatrix} \tag{26}$$

Note that apart from an unimportant change of sign, Eq. (26) is invariant to the transformation

$$t \rightarrow \frac{1}{t} \tag{27}$$

Since the transfer matrices of the series stub networks of the even- and odd-mode series stubs of (24) are related by this same transformation (27), the overall transfer matrices of the even- and odd-mode networks are similarly related. Hence, if either network is synthesized to give a match between band edges where the electrical lengths of the commensurate stubs are θ_c and $\pi - \theta_c$, then the other network will also be matched over the same passband. This reduces the synthesis problem from that of a four-port to that of a two-port, but the question then arises, as to how the unit elements of the mainlines can be extracted from a transfer function to have twice the length of the series stubs. The answer is related to the fact that both the even- and odd-mode circuits have redundant series stubs; specifically, the nonredundant transfer function is that of

one series stub and $2(n - 1)$ unit elements, which are transmission lines of electrical length θ . It is possible therefore to extract the first series stub such that two unit elements may then be extracted in cascade having equal admittances. Starting from a transfer matrix $[A,B,C,D]$ where the matrix elements are polynomials in t , it can be shown that the admittance of the extracted series stub is

$$a = \frac{A(1)}{C(1)} = \frac{B(1)}{D(1)} \tag{28}$$

This relationship holds for the extraction of the first $n - 1$ series stubs with the associated double-length unit elements, with the final stub given by the remainder matrix.

The final steps in the design process are concerned with the choice of suitable equiripple functions in the t variable, followed by the synthesis. In the original paper [16] the insertion loss function is

$$\frac{1}{|S_{12}|^2} = 1 + \frac{K^2 P_{n-1}^2(x/x_c)}{(1-x^2)} \tag{29}$$

where

$$x = \cos(2\theta), \quad x_c = \cos(2\theta_c) \tag{30}$$

or in terms of t

$$x = \frac{1+t^2}{1-t^2} \tag{31}$$

The function $P_{n-1}(x/x_c)$ gives equiripple performance in the range of x from $-x_c$ to x_c when it takes the following form [16]:

$$P_{n-1} \frac{x}{x_c} = 0.5[1 + (1-x_c^2)^{1/2}]T_{n-1} \frac{x}{x_c} - 0.5[1 - (1-x_c^2)^{1/2}]T_{n-3} \frac{x}{x_c} \tag{32}$$

The original paper [16] includes design tables for Chebyshev couplers having three to eight branches, coupling values from 3 to 20 dB, and for a wide range of bandwidths. From these data it becomes evident that there is a drawback for tight values of coupling of less than 6 dB; namely, the mainline immittances (actually impedances for waveguide branch-guide couplers) become somewhat larger than the desired value of unity. A solution to this problem is to select a different insertion loss function, and this is described in Ref. 17, where the Zolotarev

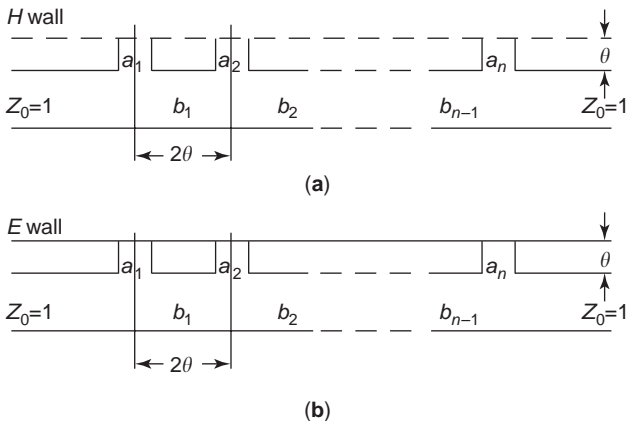

Figure 12. Even (a) and odd (b) modes for the branch-guide coupler.

branch-guide coupler is introduced. The Zolotarev function has a free parameter that controls the lower band edge of the equiripple function, and this has a very significant effect on the internal impedance levels of the coupler, where the mainline impedances are close to unity and the branch-guide impedances have much more favorable values with much less spread of impedances compared with the simple Chebyshev designs. Examples are given in Table 1 of Ref. 17 for 3-dB couplers of five branches indicating the tremendous range of design possibilities. Note that it is not absolutely necessary to work with the complicated formal theory, involving elliptic functions and integrals, to derive the Zolotarev functions in order to obtain these results. The Zolotarev polynomials, which have one large zero above $x = 0$ and the rest of equal ripple, may be easily generated using simple computer optimization.

4. COMPUTER-AIDED DESIGN TECHNIQUES

There are numerous papers describing the design of waveguide couplers of the types described in this article using computer-aided design (CAD), but considering the precision of the latest purely theoretical techniques, CAD may be considered to be mainly unnecessary, at least as a primary design methodology. It tends to be cumbersome, and with standard optimization packages, convergence to a good design may be a very slow process. However, computer analysis programs are useful in checking the accuracy of the theoretical designs. There are several general analysis programs available based either on three-dimensional field theory using the finite-element method or mode matching. Rather than using them to design a complicated multisection waveguide coupler ab initio, it is recommended that they be used in conjunction with analytical theory. For example, in the case of a branch-guide coupler of the type described in Section 3.4, the CAD program may be used to analyze the performance of a theoretical design. The initial design may then be adjusted to compensate for slight discrepancies in the coupling, which are typically up to about 0.3 dB. It has been found that some designs require no adjustments.

In some cases CAD has proved very useful as a design tool. Thus the design of the short-slot hybrid described in Section 3.3 relies on results obtained from 3D field theory. However, even in this case, the field analysis is used as a method for obtaining equivalent circuits for the even mode, which are then used in a circuit theory design approach, not simply and solely as a CAD technique. Similar design approaches may be applied to the design of other single- or multiaperture directional couplers. As an example, in the case of multiaperture couplers (Section 3.1) the field theory could be used to check the equivalent circuits for single apertures, and to investigate any interaction effects between closely spaced apertures.

WAVEGUIDE DISCONTINUITIES

R. SORRENTINO
F. ALIMENTI
University of Perugia
Perugia, Italy

1. INTRODUCTION

Any deviation from uniformity along the longitudinal axis of a waveguide constitutes a discontinuity. Discontinuities

are unavoidably present in any microwave circuit either unintentionally or to the purpose of performing a prescribed function. In the former case one usually tries to minimize the unwanted mismatching due to the presence of the discontinuity, while in the latter case the discontinuity is instrumental in the design of a specific component. Typical example of the former category is a waveguide bend, while a metal diaphragm is representative of the latter.

The electromagnetic (EM) field incident onto a discontinuity is partly reflected and partly transmitted, while reactive energy is stored in the proximity of the discontinuity. If lossy materials are present, some power may be lost and, in case of open structures, some power may be radiated.

The electromagnetic analysis of a discontinuity involves the solution of Maxwell's equations with the appropriate boundary conditions. Analytical techniques for the solution of boundary-value problems in electromagnetics are presented and discussed in a number of classical textbooks such as, for instance, Refs. 1–4. Extensive discussion on waveguide discontinuities and their general properties can be found in Refs. 5 and 6. With the exception of a few simple cases, for which an analytical solution can be found, some sort of approximation, either analytical or numerical, is necessary to express the solution of the electromagnetic problem.

The problem can be attacked using either rigorous or approximate approaches. Rigorous approaches differ from approximate ones in that the exact solution can, in principle, be obtained with any degree of accuracy. On the contrary, the accuracy obtainable with approximate approaches cannot be pushed beyond intrinsic limits.

Although a number of rigorous methods have been developed for the solution of electromagnetic structures and available computational resources are extremely powerful, rigorous solutions are often too heavy for many practical purposes. Approximate solutions, although less accurate, may result more advantageous as they are much simpler to achieve.

Numerical methods for the analysis of waveguide discontinuities and, more generally, for the solution of microwave boundary-value problems have been presented in large amount of papers and books Refs. 7–10.

One of the most powerful and popular methods used to solve waveguide discontinuities is the modal analysis or mode-matching technique Refs. 11–13. Besides being a rigorous approach, it lends itself to a physical interpretation of the electromagnetic field behavior due to the presence of the discontinuity and leads to the so-called microwave network formalism. By virtue of the equivalence between waveguide modes and transmission lines, the electromagnetic description of the discontinuity can be translated in terms of an equivalent network. Observe that the full computation of the electromagnetic field in the structure is more than is usually required. A terminal description of the discontinuity as seen from the waveguides connected to it is all that is necessary. This makes it possible to express a complicated electromagnetic problem in terms of a more familiar circuit theory model.

In Section 2 the description of waveguide discontinuities is introduced on the basis of the modal analysis approach. This leads to the generalized description of the discontinuity as a multiport network using impedance, admittance, or scattering matrix (or other matrix descriptions). General properties of waveguide discontinuities are presented in Section 3, while Section 4 categorizes various classes of waveguide discontinuities. The concept of interacting and isolated discontinuities, which is familiar to the microwave engineer, but has no counterpart in the conventional circuit theory, is illustrated in Section 5 by a specific example.

2. DESCRIPTION OF WAVEGUIDE DISCONTINUITIES

Figure 1a depicts a generic discontinuity with two outputs. The structure consists of a central region bounded by metallic walls, connected to two uniform waveguides. In the present discussion, the structure of Fig. 1a is taken as an example; the extension to more general cases, such as multiple outputs and magnetic walls, is straightforward. Two reference planes, T_1 and T_2 , define the boundary between the discontinuity region and the input and output waveguides. Various types of obstacles, either lossless (perfectly conducting or perfect dielectric materials) or lossy, isotropic or anisotropic may be present in the discontinuity region.

When an electromagnetic field impinges onto the discontinuity from one or both waveguides, part of the associated energy is reflected, part is dissipated within the discontinuity, and part is transmitted to the other waveguide. In case of open discontinuities (see Section 4.5), part of the energy can be radiated into outer space. Reactive energy is stored in the discontinuity region and in the waveguide region close to it.

In most practical cases, rather than a detailed knowledge of the electromagnetic field distribution within the discontinuity, what is required is just a terminal description of the discontinuity. It is worth recalling here that the field distribution in a waveguide results from the superposition of its normal modes. Under normal operating conditions, the dominant mode is the only propagating mode, while all higher-order modes, excited at the discontinuity, are exponentially decaying. The terminal planes are usually, placed far enough from the discontinuity in such a way that only the dominant modes have nonnegligible amplitudes. In such conditions, a terminal description of the discontinuity can be obtained by writing the equations relating the field quantities at the two terminal planes. Such relations may take the form of a 2×2 impedance matrix if the electric fields are expressed in terms of the magnetic fields, or the form of an admittance matrix if the magnetic fields are expressed in terms of the electric fields, and so on. As will be specified below, in fact, electric and magnetic fields can be replaced by equivalent voltage and current amplitudes. In a number of important cases, however, the terminal planes must be placed near the discontinuity region, so that the field distribution cannot be reduced to the only dominant modes. This typically happens when multiple discontinuities are cascaded

Figure 1. Generic, two-port, waveguide discontinuity and its network representations: (a) waveguide discontinuity; (b) multiport description; (c) reduced two-port description.

together at short distances. In higher-order modes interaction takes place between adjacent discontinuities, in such a way that active power may be carried by these higher-order modes. In such cases, a more general description of the discontinuity is needed.

In order to obtain a terminal description of the discontinuity in the general case, it is worth recalling that each waveguide mode can be represented by an equivalent transmission line, where the voltage and current amplitudes are proportional to the modal electric and magnetic field amplitudes, respectively:

$$\mathbf{E}_t^{(i)}(x, y, z) = \sum_m V_m^{(i)}(z) \mathbf{e}_m^{(i)}(x, y) \quad (1)$$

$$\mathbf{H}_t^{(i)}(x, y, z) = \sum_m I_m^{(i)}(z) \mathbf{h}_m^{(i)}(x, y) \quad (2)$$

where z is the longitudinal axis of the waveguide, $\mathbf{E}_t^{(i)}$ and $\mathbf{H}_t^{(i)}$ are the transverse electric and magnetic fields, $V_m^{(i)}$ and $I_m^{(i)}$ are the voltage and current of the transmission line equivalent to the m th mode of the i th waveguide, and $\mathbf{e}_m^{(i)}$ and $\mathbf{h}_m^{(i)}$ are the transverse and magnetic modal vectors, respectively.

Although in principle an infinite series of modes is involved in the electromagnetic field representation, in practice only a finite number of modes need to be taken into account to achieve a prescribed accuracy. As a consequence, the electromagnetic field distribution over each terminal plane is expressed in terms of a finite number of voltage and current amplitudes. Letting N_i be the number of modes taken into account in the field description at the i th terminal plane ($i = 1, 2$), the terminal description of the discontinuity will involve $N_1 + N_2$ voltages and the same number of currents. Because of the linearity of Maxwell's

equations, these quantities are related by a linear set of $N_1 + N_2$ equations. One can easily realize that Maxwell's equations lead to $N_1 + N_2$ equations by the following reasoning. By virtue of the unicity theorem for electromagnetic fields, the entire electromagnetic field distribution in the structure is determined by the knowledge of tangential electric (or magnetic) field at the two terminal planes, thus by the knowledge of the whole set of $N_1 + N_2$ voltages (or currents) over such planes. In other words, from the knowledge of $N_1 + N_2$ voltages (currents), one can compute the $N_1 + N_2$ currents (voltages). This implies that the linear system consists of $N_1 + N_2$ equations relating the $N_1 + N_2$ voltages to the $N_1 + N_2$ currents.

The modal approach lends itself to the so-called microwave network formalism. The discontinuity, rather than in terms of electric and magnetic field distributions, is described in terms of voltages and currents, namely, as a multiport circuit. This is described with the equivalent circuit of Fig. 1b, where each port corresponds to a mode excited at one of the terminal planes of the discontinuity. The system can be put in many different forms. One of the most convenient approach consists of expressing currents in terms of voltages. In matrix form this corresponds to writing

$$[I] = [Y] \cdot [V] \quad (3)$$

where $[I]$ is the vector of the currents, $[V]$ that of the voltages, and $[Y]$ the admittance matrix. For the case of the two-terminal-plane network of Fig. 1a the vector of the currents is

$$[I] = \begin{bmatrix} [I^{(1)}] \\ [I^{(2)}] \end{bmatrix} \quad (4)$$

The subvector of the currents at the i th terminal plane ($i = 1, 2$) is

$$[I^{(i)}] = [I_1^{(i)}, I_2^{(i)}, \dots, I_{N_i}^{(i)}]^T \quad (5)$$

where N_i is the number of modes (or electrical ports) considered at the i th plane. The voltage vector is similar to the current vector, and the admittance matrix is composed by four submatrices as follows:

$$[Y] = \begin{bmatrix} [Y^{(11)}] & [Y^{(12)}] \\ [Y^{(21)}] & [Y^{(22)}] \end{bmatrix} \quad (6)$$

Observe that while the electromagnetic structure has two outputs (or two apertures), the equivalent circuit has $N_1 + N_2$ electric ports.

In most practical cases the terminal planes are chosen far enough from the discontinuity in such a way that higher-order modes have vanished. This is possible whenever the discontinuity is isolated, that is, if there are no other discontinuities close to it. The electromagnetic field at the terminal planes is that of the dominant modes of the respective waveguides, while higher-order modes have died out. In the multiport equivalent circuit description of Fig. 1b, this situation corresponds to terminating the higher-order mode ports with their characteristic admittances. The multiport description reduces to the two-port description of Fig. 1c, where the accessible ports represent the dominant modes of both waveguides.

To compute the 2×2 admittance matrix of Fig. 1c from the $(N_1 + N_2) \times (N_1 + N_2)$ admittance matrix of Fig. 1b, the matching conditions at the higher-order mode ports are added to Eq. (3):

$$I_m^{(i)} = -y_{c,m}^{(i)} V_m^{(i)} \quad (7)$$

In (7) $y_{c,m}^{(i)}$ is the characteristic admittance of the equivalent transmission line, which has been assumed as the wave admittance of the waveguide mode $y_{c,m}^{(i)} = 1/\eta_m^{(i)}$, where

$$\eta_m^{(i)} = \begin{cases} \frac{\omega\mu}{\beta_m^{(i)}}, & \text{TE modes} \\ \frac{\beta_m^{(i)}}{\omega\varepsilon}, & \text{TM modes} \end{cases} \quad (8)$$

with

$$\beta_m^{(i)} = \left[\left(\frac{\omega}{c}\right)^2 - \left(k_{c,m}^{(i)}\right)^2 \right]^{1/2} \quad (9)$$

where c is the light velocity; $\beta_m^{(i)}$, the phase constant; and $k_{c,m}^{(i)}$, the eigenvalue of the m th mode. These equations refer to hollow waveguides or to waveguides totally filled with a homogeneous lossless dielectric. After rearranging and partitioning the admittance matrix (6) according to fundamental (subscript f) and higher-order modes

(subscript h)

$$[Y] = \begin{bmatrix} [Y_{ff}] & [Y_{fh}] \\ [Y_{hf}] & [Y_{hh}] \end{bmatrix} \quad (10)$$

the two-port admittance matrix description $[Y_{2p}]$ of the discontinuity is easily obtained from (7) and (3):

$$[Y_{2p}] = [Y_{ff}] - [Y_{fh}] \cdot ([Y_{hh}] + [Y_c])^{-1} \cdot [Y_{hf}] \quad (11)$$

In this relationship $[Y_c]$ is the diagonal matrix of the higher-order modes' characteristic admittances; it is defined as

$$[Y_c] = \text{diag} [y_{c,2}^{(1)}, \dots, y_{c,N_1}^{(1)}, y_{c,2}^{(2)}, \dots, y_{c,N_2}^{(2)}] \quad (12)$$

Alternative descriptions of the discontinuity can be obtained by either rearranging the discontinuity equations or using different electrical quantities rather than voltages and currents. In the former case, an impedance matrix description is obtained by expressing the voltages in terms of the currents:

$$[V] = [Z] \cdot [I] \quad (13)$$

By expressing the waveguide fields in terms of incident $[a]$ and reflected $[b]$ wavevectors, one can obtain a scattering matrix description of the discontinuity:

$$[b] = [S] \cdot [a] \quad (14)$$

The incident and reflected waves are related to voltage and current amplitudes as follows:

$$a_m^{(i)} = \frac{y_{c,m}^{(i)} V_m^{(i)} + I_m^{(i)}}{2 [y_{c,m}^{(i)}]^{1/2}} \quad (15)$$

$$b_m^{(i)} = \frac{y_{c,m}^{(i)} V_m^{(i)} - I_m^{(i)}}{2 [y_{c,m}^{(i)}]^{1/2}} \quad (16)$$

with $i = 1, 2$ and $m = 1, \dots, N_i$. As is well known from many textbooks, the interrelations among this matrix descriptions are

$$\begin{aligned} [Y_N] &= [Z_N]^{-1} = ([U] + [S])^{-1} \cdot ([U] - [S]) \\ [Z_N] &= [Y_N]^{-1} = ([U] + [S]) \cdot ([U] - [S])^{-1} \\ [S] &= ([Z_N] - [U]) \cdot ([Z_N] + [U])^{-1} \\ &= ([U] + [Y_N])^{-1} \cdot ([U] - [Y_N]) \end{aligned} \quad (17)$$

where $[U]$ is the unit matrix. The normalized (subscript N) admittance and impedance matrix elements are expressed

as

$$Y_{N,mn}^{(ij)} = \frac{Y_{mn}^{(ij)}}{\left[y_{c,m}^{(i)} y_{c,n}^{(j)} \right]^{1/2}} \quad (18)$$

$$Z_{N,mn}^{(ij)} = \frac{Z_{mn}^{(ij)}}{\left[z_{c,m}^{(i)} z_{c,n}^{(j)} \right]^{1/2}} \quad (19)$$

where $z_{c,m}^{(i)} = 1/y_{c,m}^{(i)}$ is the characteristic impedance of the equivalent transmission line.

The use of a lumped or distributed element equivalent circuit model to describe the discontinuity can be advantageous for many practical applications. The circuit model can be easily handled in more conventional engineering terms, and, when properly derived, reflects the physical behavior of the discontinuity. Moreover, it has the advantage of easily providing by mere inspection a description of the behavior of the discontinuity and the way the latter can be used for practical applications (e.g., filters).

From the discussion above it is apparent that a certain degree of arbitrariness is involved in the choice of the reference planes. As a consequence, different equivalent circuits can be assumed, depending on the location of the terminal planes. A proper choice of the reference plane locations can be exploited in some cases in order to reduce the complexity of the equivalent circuit. Observe that this ambiguity is inherent to the distributed nature of waveguide circuits, as opposed to lumped low-frequency circuits, where no ambiguity exists.

An additional ambiguity in the definition of the equivalent circuit models resides in the arbitrariness of the definition of the equivalence between waveguide mode and transmission line. In particular, the characteristic impedance $z_{c,m}^{(i)}$ of the m th transmission line can be changed by a factor of n^2 by transforming the voltages $V_m^{(i)}$ and currents $I_m^{(i)}$ into a new set $V_m'^{(i)}$ and $I_m'^{(i)}$

$$V_m'^{(i)} = n V_m^{(i)} \quad (20)$$

$$I_m'^{(i)} = \frac{1}{n} I_m^{(i)} \quad (21)$$

so that

$$z_{c,m}'^{(i)} = n^2 z_{c,m}^{(i)} \quad (22)$$

It is worth noting that the transformation represented by Eqs. (20) and (21) is such that power is conserved. The new definition is equivalent to the introduction of ideal transformers at the circuit terminals. By an appropriate selection of both the reference planes and the voltage-current definitions, different equivalent circuits with reduced complexity can be derived.

In the presence of multiple or cascaded discontinuities special caution should be employed in the use of equivalent-circuit models. If adjacent discontinuities are cascaded at a short distance, in fact, the reference planes cannot be chosen far enough from the discontinuities to make higher-order modes vanish. In this case, discontinuities

interact through higher-order modes. The models for isolated discontinuities may lead to significant errors. Multiport equivalent networks, including higher-order mode interactions, must be adopted instead. This is illustrated in Section 5 using a specific example.

3. GENERAL PROPERTIES OF WAVEGUIDE DISCONTINUITIES

This section presents a brief description of the general properties of waveguide discontinuities.

3.1. Losslessness

Losses in microwave circuits are due to imperfect dielectric materials (dielectric loss), finite conductivity of the conductors (conductor loss), and, for open structures, radiation (radiation loss). The impedance or admittance matrices of lossy discontinuities possess real as well as imaginary parts that are associated with the real and the reactive power, respectively.

In many practical cases losses may be neglected with good approximation so that the discontinuity behaves as a reactive circuit. The admittance and the impedance matrices are purely imaginary, and the scattering matrix is unitary. The latter property is obtained by expressing the balance between incident and reflected power in terms of wavevectors, (15), (16) as follows:

$$\frac{1}{2} [a]^T \cdot [a]^* = \frac{1}{2} [b]^T \cdot [b]^* \quad (23)$$

Using (14), one obtains the unitarity condition for the scattering matrix of a lossless discontinuity, where the asterisk * stands for complex conjugate:

$$[S]^T \cdot [S]^* = [U] \quad (24)$$

3.2. Reciprocity

As long as Lorentz' reciprocity theorem holds for the region occupied by the discontinuity, the latter behaves as a reciprocal network. This implies that the admittance, impedance, and scattering matrices are symmetric. As a consequence, a reciprocal N -port discontinuity is characterized by $N(N+1)/2$ complex parameters. Such parameters reduce to real parameters for lossless structures. Discontinuities containing anisotropic materials such as ferrite are examples of nonreciprocal circuits characterized by nonsymmetric matrix descriptions.

3.3. Symmetry

The presence of geometric symmetries of a discontinuity can be exploited to reduce the complexity of its analysis, as well as the number of unknown parameters of its equivalent network representation. For example, in the case of a two-port discontinuity, the existence of a central symmetry plane between the two outputs implies a corresponding symmetry of the matrix representations,

provided the terminal planes are chosen symmetrically (e.g., $Y_{11} = Y_{22}$). In such a case, the discontinuity, if reciprocal, is characterized by only two rather than three parameters, as in the general case. For a more detailed discussion on the exploitation of symmetry planes in three- or four-port structures, the reader is referred to Section 3.2 of Ref. 7.

4. CATEGORIZATION OF WAVEGUIDE DISCONTINUITIES

There is no unique way to classify waveguide discontinuities, since a number of different criteria can be adopted. Here we attempt at a categorization of discontinuities with reference to some geometric characteristics that are somewhat related to the corresponding electromagnetic problem. Examples of common discontinuities are shown in Tables 1–5. The examples discussed here are not exhaustive at all, but represent only a small fraction of what can be found in practical applications. The reader is also provided with some representative references taken from the immense amount of technical publications on this topic.

4.1. Uniaxial Junctions

In a uniaxial junction, two waveguides with different cross sections and coincident longitudinal axes are connected together. In the case of rectangular waveguides, examples of such discontinuities are: the *E*-plane (or capacitive) step Refs. 12–14, the *H*-plane (or inductive) step Ref. 15, and the *E*-plane and *H*-plane offsets. These discontinuities are illustrated in Table 1. As long as both waveguides are in

the monomodal regime, the corresponding equivalent networks have two ports. Other examples of uniaxial discontinuities are some particular kind of transitions (see later in the text), specifically, structures designed to transfer the microwave power from one waveguide system to another. In particular, we recall the transition between coaxial cable and a circular waveguide Ref. 16 and that between rectangular and circular waveguides Ref. 17.

4.2. Bifurcations and N-Furcations

One waveguide is joined to two or more waveguides with parallel longitudinal axes. A theoretical model of *N*-furcations has been presented in Ref. 18. In rectangular waveguide, the bifurcation can occur in either the *E* or the *H* plane, as shown in Table 2. The equivalent circuit may contain more than three ports, because the larger waveguide may support the propagation of higher-order modes.

4.3. Obstacles

Metallic or dielectric obstacles can be inserted in a waveguide to achieve specific electrical behaviors. Metallic obstacles may have infinitesimal or finite length along the waveguide axis. In the former case the equivalent circuit can be reduced to a shunt admittance. Typical examples are metal irises and metal posts. They have been widely employed as filter and matching network elements. In the case of rectangular waveguide, depending on the orientation with respect to the electric field of the dominant mode, such obstacles exhibit inductive or capacitive behavior, as shown in Table 3. Observe that irises are supposed to be

infinitesimally thin. A full-wave model of the inductive iris in rectangular waveguide can be found in Ref. 19. More complicated geometries involving circular irises Refs. 20,21, slanting and multiple rectangular irises Refs. 22,23 in rectangular waveguide, as well as irises in coaxial cable Ref. 24 and circular waveguides Refs. 25,26, have been investigated. Electromagnetic models of posts in rectangular waveguide have also been presented Refs. 27–29.

4.4. Multiaxial Junctions

Two or more waveguides with different longitudinal axes are connected together (see Table 4). In the case of uniaxial junctions, the associated boundary-value problem is a two-dimensional one. For multiaxial junctions, on the contrary, the analysis involves the solution of a 3D boundary-value problem Ref. 30. The simplest case of a biaxial junction is the right-angle junction between two rectangular

waveguides. Depending on the plane of such junction, we have the *E*-plane or *H*-plane corner. This type of discontinuity realizes a 90° change of direction in the waveguide axis. To minimize reflections, alternative geometries can be adopted, such as the mitered bends Refs. 31,32 and the circular bends Refs. 33,34.

More complicated multi-axial junctions in rectangular waveguide technology are the *T* junctions in the *E* plane Refs. 35–37, or *H* plane Refs. 38–40. The matching of such a junction has been analyzed in detail in Ref. 41. The so-called magic (hybrid) tee is a well-known rectangular waveguide component where ports are decoupled in pairs Ref. 42. The aperture in the common wall of two rectangular waveguides Refs. 43,44 can also be seen as an example of a four-port multi-axial junction. An example of a

T-junction between rectangular and circular waveguide has been investigated Ref. 45.

The transitions, that is, the junction between two waveguide of different cross sections, can be considered as a particular case of multi-axial junctions. The purpose of these structures is to transfer the microwave power from one waveguide system to the other while minimizing the return loss in a band as wide as possible. As an example, we consider the transition between a coaxial cable and a rectangular waveguide as shown in Fig. 2. In its basic configuration, the center conductor of the coaxial line extends into the waveguide to form an electric probe. One of the two waveguide ends is short-circuited while the other is used as the output. The tuning of the structure is achieved by adjusting the probe penetration and/or the distance between probe and short circuit. Typically, the former is close to the 60% of the waveguide height, while the latter is between $\lambda_g/8$ and $\lambda_g/4$ at the operating frequency Ref. 4, pp. 471–484. If properly tuned, a 10% fractional bandwidth can be achieved for $S_{11} < -30$ dB. At the output side, a uniform waveguide section provides a suitable attenuation of the higher-order modes excited by the probe.

4.5. Open Discontinuities

In the examples presented so far, the discontinuities were completely bounded by metallic walls. An important category of waveguide discontinuities, however, is represented by open discontinuities, where the electromagnetic field can be radiated in outer space. The equivalent circuits of such discontinuities contain resistors that represent the radiation loss. Some examples are illustrated in Table 5.

Table 5. Radiating Discontinuities

Name	Structure	Equivalent Circuit	References/Comments
Open waveguide (with flange)			7 , pp. 193–194
Longitudinal slot			52

A first example is the open-ended waveguide. When the electromagnetic field impinges on such a termination, part of the associated power is reflected and part is radiated in the free space, so that the termination can be considered as an antenna. Such terminations, in fact, are widely used as secondary antennas (feeding antennas) in reflector-type antennas or as elements of an array antenna. The study of the radiation mechanism is rather complicated, and electromagnetic full-wave models are mandatory. The reader is referred to Refs. 46–48 for rectangular waveguide and to Refs. 49 and 50 for coaxial and circular waveguides.

Other radiating discontinuities are obtained by producing apertures in the waveguide walls. The aperture interrupts locally the conduction current flowing on the walls, producing both a distortion in the lines of flux and a displacement current in the aperture. The latter is necessary to maintain the continuity of the total current and constitutes the source of the radiated electromagnetic field. The most common example is the radiating slot in a rectangular waveguide. The longitudinal slot in the broad wall Refs. 51–53, and the slanting slot have been analyzed, Ref. 54, and the transverse slot has been investigated Refs. 55,56. These discontinuities are used to build slotted antennas.

5. ISOLATED AND INTERACTING DISCONTINUITIES

In Section 2 it was pointed out that the reduced equivalent circuit valid for an isolated discontinuity may not be adopted, in general, for adjacent discontinuities, because of the higher-order mode interaction occurring between them. To illustrate this phenomenon, consider as an example the symmetric capacitive step in rectangular waveguide depicted in Fig. 3a. The larger waveguide is the WR75 waveguide operating in the 10–15 GHz frequency range. The equivalent circuit of the step, supposed as isolated, is shown in Fig. 3b. The shunt capacitance represents the reactive energy stored in the proximity of the

Figure 3. Capacitive step in rectangular waveguide: structure (a) and equivalent circuit (b). Geometric dimensions: $a = 19.05$ mm, $b_2 = 9.52$ mm, $b_1 = s b_2$.

Figure 4. S_{11} of a capacitive step in rectangular waveguide for various step ratios $s = b_1/b_2$; comparison between the equivalent circuit and the full-wave mode-matching analysis.

step, due to attenuated higher-order modes excited at the junction between the two waveguides. The step susceptance is sB , where s being the step ratio

$$s = \frac{b_1}{b_2} \tag{25}$$

and B is easily computed by the approximate formula given in Ref. 7, p. 307. The scattering parameter S_{11} of the discontinuity, can be evaluated by elementary network analysis:

$$S_{11} = \frac{(1 - s) - jsB}{(1 + s) + jsB} \tag{26}$$

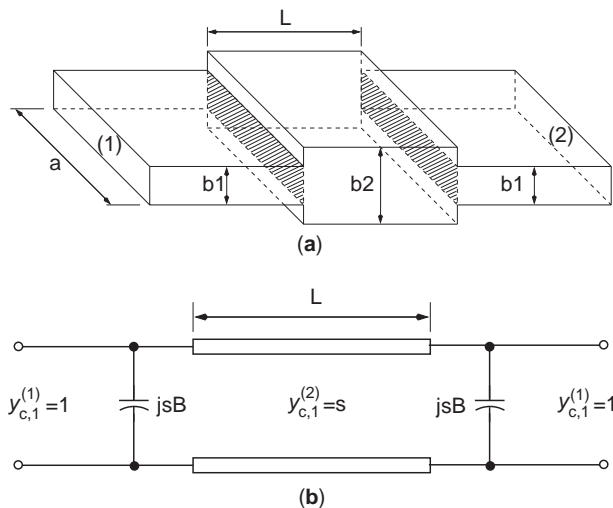

Figure 5. Capacitive double step in rectangular waveguide: structure (a) and equivalent circuit (b). Note that the equivalent circuit is derived under the approximation of isolated discontinuities. Geometrical dimensions: $a = 19.05$ mm, $b_2 = 9.52$ mm, $s = 0.20$, $b_1 = 1.90$ mm.

Figure 6. S_{11} of the double step versus the normalized length L/λ_{c1} of the central waveguide. Comparison between the equivalent circuit and the full-wave mode-matching analysis.

This parameter is shown in Fig. 4 as a function of frequency for different step ratios. For comparison, the scattering parameter computed by the rigorous mode-matching technique is also shown. The approximate formula is shown to be very accurate compared with the computationally more expensive mode-matching method.

Let us now consider two capacitive steps (step ratio $s = b_1/b_2 = 0.2$) cascaded through a uniform waveguide of length L as in Fig. 5a. The cascaded steps have been analyzed both by the equivalent circuit of Fig. 5b and by the mode-matching method. In the former case the higher-order mode interaction between the two steps is totally neglected, while in the latter case, higher-order mode interaction has been fully taken into account. Observe that higher-order modes, although evanescent, carry active power that flows between the two discontinuities. This causes the discrepancy observed between the two models, as illustrated in Fig. 6. In particular, such a figure shows the computed scattering parameter $S_{11} = S_{22}$ as a function of the normalized length L/λ_{c1} at the lower (10-GHz) and upper (15-GHz) ends of the frequency range of the WR75 waveguide; $\lambda_{c1} = 2a = 39$ mm is the cutoff wavelength of the waveguide. It is observed that the equivalent circuit of Fig. 5b, based on the hypotheses of isolated discontinuities, is accurate as long as the normalized distance exceeds $\lambda_{c1}/8$. For lower distances the error increases and becomes unacceptable below $\lambda_{c1}/20$. It can be noted that the error increases with frequency, as a result of the stronger excitation of higher-order modes.

WAVEGUIDE JUNCTIONS

RALPH LEVY
R. Levy Associates
La Jolla, California

1. INTRODUCTION

A waveguide junction comprises two or more waveguides connected by a common metallic region having relatively small volume. The number of such waveguides is denoted by n , and for $n = 2$ we have a simple junction of two

waveguides. In some cases one or more of the waveguides may be a transmission line supporting the TEM mode, such as coaxial line, stripline, or microstrip. When $n=2$, such a junction is known as an *adapter*, and is a very important basic microwave component. Three- and four-port junctions are also very important, and occasionally one sees junctions having $n > 4$, but these are comparatively rare. Frequently several waveguide junctions are connected to form more complex effective n -port junctions that may be used as power dividers, typically in antenna feed networks. In other cases they are combined with other components to realize microwave subassemblies, such as duplexers, multiplexers, and monopulse arrays. In the case of $n=4$ having certain symmetry properties, the junction becomes a 0° or 180° hybrid, which, together with 90° hybrids treated in the article WAVEGUIDE DIRECTIONAL COUPLERS, are the most commonly used four-port waveguide junctions.

In general the junction regions have complex shapes with various types of discontinuities that are describable only in terms of higher-order modes, which frequently and most desirably lead to equivalent-circuit representations. The multiport junction is depicted in Fig. 1, where each port supports a single mode. Note that if a single waveguide supports more than one mode, say, m modes, then it is represented as m distinct "waveguides" with m ports.

An excellent description of n -port junctions (microwave networks) is given in Ref. 1, particularly in Chap. 3, and actually it is probably valid to state that there has been very little fundamental advancement in the state of the art since that work, which dates to the 1940s, at least in a basic sense. The main additions are probably due to the use of effective computer techniques to solve Maxwell's equations for the junction regions, thus deriving scattering matrices. An important general conclusion stated there [1] is that waveguide junctions always have equivalent-circuit representations. Any one junction will have a variety of such equivalent circuits, but usually there is one having the minimum number of circuit elements and possessing simple frequency dependence. Such a "natural" equivalent circuit can often be found by a suitable choice of reference planes, and sometimes also in the choice of terminating impedances of the ports. Further information

Figure 1. Schematic of an n -port waveguide junction.

on this general topic is given in Ref. 2, which also describes some methods for deriving equivalent circuits from numerically derived scattering matrices.

The treatment here is limited to passive reciprocal junctions, where the characteristic impedances of the ports are real. Ports having complex characteristic impedances may be handled using a simple modification [3]. We will be concerned primarily with the various waveguides at distances sufficiently far from the junction such that the dominant modes are the only ones of concern. As mentioned above, equivalent-circuit determination is very useful and important, and will be considered here in general terms.

The basic equations for the voltage and current at a port are

$$V = Ae^{-\gamma z} + Be^{\gamma z} \quad (1)$$

$$I = \frac{Ae^{-\gamma z} - Be^{\gamma z}}{Z_0} \quad (2)$$

where γ is the propagation constant and A and B have dimensions of voltage. At the arbitrary plane where $z=0$, we have $V=A+B$ and $I=(A-B)/Z_0$. If we now renormalize A and B so that $A=aZ_0^{1/2}$ and $B=bZ_0^{1/2}$, then at the plane $z=0$ (1) and (2) become

$$V = Z_0^{1/2}(a+b) \quad (3)$$

$$I = Z_0^{-1/2}(a-b) \quad (4)$$

Hence the net power flow into the port is

$$P = \text{Re}(VI^*) = \text{Re}\{(a+b)(a^* - b^*)\} = |a|^2 - |b|^2 \quad (5)$$

Thus $|a|^2$ and $|b|^2$ have the physical interpretation of incident and reflected powers, where a is the amplitude of the incident wave and b is the reflected wave amplitude. We now define the scattering matrix S according to

$$b_1 = S_{11}a_1 + S_{12}a_2 + \cdots + S_{1n}a_n$$

$$b_2 = S_{21}a_1 + S_{22}a_2 + \cdots + S_{2n}a_n$$

$$\vdots$$

$$b_n = S_{n1}a_1 + S_{n2}a_2 + \cdots + S_{nn}a_n$$

or

$$b = S \cdot a \quad (6)$$

where a and b are column vectors.

In the case of reciprocal networks each scattering matrix element satisfies the condition

$$S_{ij} = S_{ji} \quad i, j = 1, 2, \dots, n \quad (7)$$

or in scattering matrix representation, we have

$$S = S^{\text{tr}} \quad (8)$$

where S^{tr} denotes the transposed S matrix. When the network is lossless, then power conservation considerations lead to the unitary condition

$$S \cdot S^{tr*} = S \cdot S^* = \mathbf{1} \tag{9}$$

where $*$ indicates the complex conjugate matrix, and $\mathbf{1}$ is the unit matrix having entries of unity on the main diagonal and zero elsewhere. Sometimes $\mathbf{1}$ is denoted by I , meaning the identity matrix, but $\mathbf{1}$ is used here to avoid confusion with electric current I . Equation (9) is very important since it leads to a variety of basic and useful general properties for several types of n -port networks. It also leads to simpler expressions for other representations of microwave networks, such as the impedance, admittance, or transfer matrix representations.

2. IMPEDANCE MATRICES

The impedance matrix Z relates the voltages V_i and currents I_i ($i = 1, 2, \dots, n$) via the matrix equation

$$V = Z \cdot I \tag{10}$$

Where V and I consist of column vectors of the voltages V_i and currents I_i , and Z is, of course, an $n \times n$ square matrix having elements Z_{ij} . Using Eqs. (3) and (4) we can now relate the scattering and impedance matrices, and solving for a and b , we find

$$2Z_i^{1/2} a_i = (V_i + Z_i I_i) \tag{11}$$

$$2Z_i^{1/2} b_i = (V_i - Z_i I_i) \tag{12}$$

where Z_i is the real characteristic impedance of the i th port. Here the subscript i has been added to a and b to represent the forward and reflected wave amplitudes at the i th port. These equations may be expressed in matrix format if we define the characteristic impedance matrix of the n ports as

$$Z_0 = \begin{bmatrix} Z_1 & & & \\ & Z_2 & & \\ 0 & & \ddots & 0 \\ & & & Z_n \end{bmatrix} \tag{13}$$

where the positive real characteristic impedances of each port form the main diagonal, with zero entries elsewhere. Now Eqs. (11) and (12) may be expressed in matrix form as

$$a = Z_0^{-1/2} \frac{V + Z_0 \cdot I}{2} \tag{14}$$

$$b = Z_0^{-1/2} \frac{V - Z_0 \cdot I}{2} \tag{15}$$

and substituting for V using (10) we find

$$a = Z_0^{-1/2} \frac{(Z + Z_0)I}{2} \tag{16}$$

$$b = Z_0^{-1/2} \frac{(Z - Z_0)I}{2} \tag{17}$$

Substituting (16) and (17) into (6), we find

$$Z_0^{-1/2} \frac{(Z - Z_0) \cdot I}{2} = S \cdot Z_0^{-1/2} \frac{(Z + Z_0) \cdot I}{2} \tag{18}$$

which after a few cancellations and inverse multiplications gives S in the form

$$S = Z_0^{-1/2} (Z - Z_0) \cdot (Z + Z_0)^{-1} \cdot Z_0^{1/2} \tag{19}$$

which is the desired relationship giving the scattering matrix as a function of the impedance matrix.

It is usually more important to express the impedance matrix Z as a function of S , and this may be derived from Eq. (19) by carrying out the appropriate pre- and postmatrix multiplications, finally giving

$$Z = Z_0^{1/2} (\mathbf{1} - S)^{-1} (\mathbf{1} + S) Z_0^{1/2} \tag{20}$$

where $\mathbf{1}$ is the unit matrix. Note that in the case of a one-port network this equation becomes the familiar relationship

$$\frac{Z}{Z_0} = \frac{1 + S_{11}}{1 - S_{11}} \tag{21}$$

The n -port admittance matrix Y is given by an expression similar to Eq. (20)

$$Y = Y_0^{1/2} (\mathbf{1} + S)^{-1} \cdot (\mathbf{1} - S) \cdot Y_0^{1/2} \tag{22}$$

where Y_0 is, of course, similar to (13), and also $Y_0 = Z_0^{-1}$.

The scattering matrix of an n -port network always exists, but this is not always the case for the impedance and/or admittance matrices; for instance, $(\mathbf{1} + S)$ occasionally becomes a zero matrix or has a zero determinant; then $(\mathbf{1} + S)^{-1}$ is a singular matrix and Z as derived by (20) does not exist. In such a case Y probably exists, and if not, then the network may contain ideal transformers for which Z and Y do not exist.

An interesting special case is one where the scattering matrix is purely imaginary,

$$S = jS_i \tag{23}$$

where S_i is a real matrix. In this case we see that

$$SS^* = S_i^2 = -S^2 = \mathbf{1} \tag{24}$$

Here the unitary condition (9) has been used.

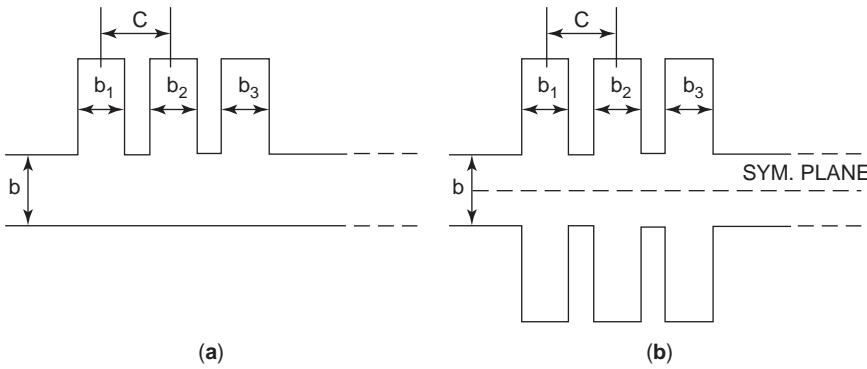

Figure 2. Interacting three- and four-port junctions spaced along a main waveguide to form a resonated stub bandstop filter: (a) asymmetric filter; (b) symmetric filter.

Hence we see that

$$(\mathbf{1} - S)(\mathbf{1} + S) = \mathbf{1} - S^2 = 2 \cdot \mathbf{1}$$

and therefore

$$(\mathbf{1} - S)^{-1} = \frac{\mathbf{1} + S}{2} \quad (25)$$

Consider the case where the port impedances are normalized to unity, that is, $Z_0 = \mathbf{1}$. Equation (20) becomes

$$Z = (\mathbf{1} - S)^{-1} \cdot (\mathbf{1} + S) = \frac{(\mathbf{1} + S)^2}{2} = \frac{1 + 2S + S^2}{2} = S \quad (26)$$

where we have used $S^2 = -\mathbf{1}$ from (24). Hence we have the remarkable result that the normalized impedance matrix of an n -port is identical to its scattering matrix when the latter is purely imaginary. An example of this situation is given in Section 5.2 on a four-port network, namely, a rat-race hybrid junction.

3. TWO-PORT NETWORKS

Numerous examples of two-port junctions of waveguides are given in Ref. 1 (where they are termed *four-terminal networks*) and elsewhere. Examples include inductive and capacitive irises in rectangular waveguides, E - and H -plane steps, and various junctions in circular cross-sectional waveguides. These are not dealt with in this article because the topic is well documented elsewhere as in Ref. 1, and also because the more interesting properties of waveguide junctions occur for three or more ports. A class of two-ports not treated in Ref. 1 is the coaxial-to-waveguide adapter, and readers are referred to the literature on this topic, such as Ref. 4, which also gives other pertinent references.

4. THREE-PORT NETWORKS

One of the most important properties of three-port networks is that it is impossible to obtain a match simultaneously at all three ports. If there were such a junction, it would have a scattering matrix having a zero main

diagonal:

$$S = \begin{bmatrix} 0 & \mathbf{S}_{12} & \mathbf{S}_{13} \\ \mathbf{S}_{12} & 0 & \mathbf{S}_{23} \\ \mathbf{S}_{13} & \mathbf{S}_{23} & 0 \end{bmatrix} \quad (27)$$

If we now apply the unitary condition (9) to this matrix, the following equations result:

$$\mathbf{S}_{12}\mathbf{S}_{12}^* + \mathbf{S}_{13}\mathbf{S}_{13}^* = 1$$

$$\mathbf{S}_{12}\mathbf{S}_{13}^* = 0 \quad \mathbf{S}_{12}\mathbf{S}_{23}^* = 0 \quad \mathbf{S}_{13}\mathbf{S}_{23}^* = 0 \quad (28)$$

From the last three equations (28) we see that two of \mathbf{S}_{12} , \mathbf{S}_{13} , and \mathbf{S}_{23} must be zero. In such case one row of the S matrix (27) will be all zero, which is impossible.

4.1. T Junctions

Among the important three-port networks are E -plane and H -plane T junctions and Y junctions. They received extensive treatment in Ref. 1, and in the case of T junctions more recent papers such as Ref. 5 have confirmed the validity of the early work. T junctions are an important component part of many microwave networks, such as filters with series or shunt stubs, and branch guide couplers. It is important to realize that the equations given for E - and H -plane T junctions in Ref. 1 are not accurate except in a rather restricted range of design parameters, but the information given in the various graphs is very good, as demonstrated in Ref. 5 (Figs. 9 and 10).

There is an important restriction on the validity of the results that is not well described in the literature, and this concerns the effect on the equivalent circuits when two or more T junctions are spaced along a connecting waveguide. This is indicated in the case of E -plane T junctions in Fig. 2a, and Fig. 2b shows a related situation where the junctions are also located across from one another, forming so-called cross-junctions. Considering one such junction of Fig. 2b with the short circuits in the vertical arm removed, we see that it is actually a four-port, but the device has a symmetry plane down the centerline of the main (horizontal) waveguide, and it may be treated as a three-port problem. The branchlines are shown short-circuited in Fig. 2 to form a type of waveguide filter known

as a resonated stub waveguide bandstop filter. When the spacing between the stubs c is sufficiently small, then the junctions interact, especially when the various b dimensions are somewhat large. The effect is observed as a considerable narrowing of the filter stop bandwidth. A discussion of means by which such interaction problems may be solved is given in Ref. 6, but the method has not yet been applied to the interacting stub situation.

Another useful class of T junctions are the E - and H -plane aperture coupled junctions, which are adequately treated in Ref. 1. They find application in E - and H -plane waveguide manifold multiplexers, where the filters are directly connected to the manifold rather than being offset by a length of waveguide, which forms an open T junction.

4.2. E -Plane Bifurcations

Another useful three-port junction treated in Ref. 1 is the E -plane bifurcation. This is shown in one of several possible formats in Fig. 3, which indicates it as a type of Y junction where the output arms are folded to become parallel and adjacent to one another. This is a very compact junction that is useful in the design of waveguide multiplexers. Thus, if bandpass filters tuned to different frequencies and having nonoverlapping passbands are introduced into the two folded output arms of Fig. 3 and their reference planes are correctly located with respect to the input or common port, a diplexer results. Several examples of the technique are given in Ref. 7.

5. FOUR-PORT NETWORKS

The types of four-port networks considered here have just one plane of symmetry; four ports with two such symmetry planes being considered in the article WAVEGUIDE DIRECTIONAL COUPLERS. The single plane of symmetry results in hybrid junctions where for one type of input port (the difference port) a pair of output ports have a phase difference of 180° and the remaining port is isolated. For a second type of input port, actually the isolated port of the previous 180° case, the phase difference is 0° , and this input port is known as the *sum port*. It can be shown that the scattering matrix of an ideal four-port 180° hybrid is given by

$$S = 2^{-1/2} \begin{bmatrix} 0 & 0 & j & j \\ 0 & 0 & j & -j \\ j & j & 0 & 0 \\ j & -j & 0 & 0 \end{bmatrix} \tag{29}$$

Figure 3. E -plane bifurcation.

Figure 4. Magic-T junction.

We see that all ports are matched, ports 1 and 2 are isolated as are ports 3 and 4. The phase difference between S_{13} and S_{14} is zero in accordance with one of the initial conditions, and that between S_{23} and S_{24} is the required 180° . It is easily seen that the scattering matrix of (29) is unitary, satisfying the basic equation (9).

5.1. Magic-T Junctions

The abovementioned conditions hold for the magic-T shown in Fig. 4, where the input port is port 2 to give 180° phase difference between the output signals at ports 3 and 4, and port 1 is isolated. When the input is switched to port 1, output signals at ports 3 and 4 are in phase and port 2 is isolated. The phase properties may be deduced from the fact that with excitation at port 1 the hybrid degenerates to an H -plane three-port, and the electric fields in ports 3 and 4 of Fig. 5a are in phase. With excitation at port 2, the junction appears as an E -plane three-port and then, as indicated in Fig. 5b, the electric fields are in opposite phase in ports 3 and 4. Good match and isolation are ensured by incorporating irises or other obstacles in the common junction.

In practice it is perhaps more common to utilize more compact versions of the magic-T junction where waveguides 3 and 4 are folded to become parallel in either the E or H plane. Such T junctions give more compact physical realizations for diplexers and other sub-assemblies. Further information is given in Ref. 8 (pp. 162-163).

Figure 5. Electric field patterns of (a) H -plane T, (b) E -plane T.

5.2. Waveguide Ring (Rat-Race) Hybrids

A waveguide realization of a ring hybrid junction is shown in Fig. 6, where the plan view shows the narrow dimensions of the waveguide, with the uniform broad dimensions at right angles to the plane of the figure. Hence the ring is a composite of four E -plane T junctions. The characteristic impedance of the ring is lower than that of the input arms by a factor of $2^{1/2}$; specifically, the narrow dimension of the ring waveguide is smaller than that of the input ports. This is the dual of the similar ring hybrids built in TEM lines, such as coaxial, stripline, or microstrip, where the individual T junctions are of the shunt type, and the impedance of the ring is then *higher* than the input ports by the factor $2^{1/2}$. Note that in both cases the dimensions of the ring determining the characteristic impedance decreases, namely, the waveguide height, or the cross section of the inner conductor of the TEM line. The port nomenclature of Fig. 6 is chosen to make the scattering matrix identical to that for the magic-T junction, as given by Eq. (29). The sum port is port 1, and the difference port is port 2. Port 3 is also a sum port, and port 4 is a difference port, as deduced from Eq. (29).

It is now possible to consider the synthesis of the ring hybrid commencing from the scattering matrix (29), knowing that since it is purely imaginary, the impedance matrix is identical, as given by Eq. (26). Actually the rat-race realization shown in Fig. 6 becomes obvious, since a quarter-wavelength waveguide of characteristic impedance Z_0 between ports i and k gives a matrix entry jZ_0 , while if the waveguide is of length $\frac{3}{4}$ wavelength, the matrix entry is $-jZ_0$. A similar result may be obtained for the TEM line ring hybrid where one starts from an admittance matrix given by Eq. (29). The reasoning for this dual-admittance case is somewhat simpler and more familiar since the nodal admittance matrix has a more obvious synthesis in the form of the ring hybrid.

Figure 6. Waveguide rat-race or ring hybrid.

Numerous detailed reports on the various waveguide junctions and associated devices with actual example designs are given in several of the references listed below.

WAVEGUIDE OSCILLATORS

ERIC L. HOLZMAN
Northrop Grumman
Corporation
Baltimore, Maryland

1. INTRODUCTION

Waveguide oscillators are DC-to-RF converters that function primarily as millimeter-wave power sources. Compared to more traditional millimeter-wave sources, such as klystrons, magnetrons, and traveling-wave tubes, these oscillators are lower in cost, and smaller in size, require lower operating voltages, and have higher reliability. A waveguide oscillator comprises two parts: (1) an *active element*, usually a packaged, two-terminal, solid-state device such as an *impact avalanche and transit time (IMPATT) diode* or *Gunn device*, which converts DC to RF power, and (2) a *passive element*, the waveguide circuit, which provides the DC power to the diode, the electromagnetic conditions required to sustain oscillation, a port for output of the RF power, and a stable thermal environment. The active device, mounted in an optimum circuit, determines the *conversion efficiency*, the ratio of RF output power to DC input power, a parameter that

decreases with frequency and is usually less than 20%. The principles governing IMPATT and Gunn device operation are complex and are described by Holzman and Robertson [1]. The key characteristic of these devices is that they exhibit a bias and temperature-dependent negative resistance at microwave frequencies.

Figure 1 shows a simplified internal view of a waveguide oscillator. A coaxial transmission line delivers DC power to the device, which is mounted on the floor of the waveguide in a gap under the coax center conductor. Unlike microwave transistors, IMPATT and Gunn devices will oscillate spontaneously without a feedback circuit when they are DC-biased. The waveguide circuit forms the resonator that tunes the *RF operating point* (output power and frequency) of the device.

The fundamental condition for oscillation is the oscillator equation, which states that the device impedance plus the circuit impedance equals zero ohms

$$Z_{\text{device}}(\text{frequency}, P_{\text{out}}, V_{\text{DC}}, I_{\text{DC}}, T) + Z_{\text{circuit}}(\text{frequency}, \text{geometry}) = 0 \tag{1}$$

where T = temperature. Kurokawa [2] showed that an oscillator’s output power is determined primarily by the resistive portion of the oscillator equation

$$R_{\text{device}}(P_{\text{out}}, V_{\text{DC}}, I_{\text{DC}}, T) = -R_{\text{circuit}}(\text{frequency}, \text{geometry}) \tag{2}$$

and an oscillator’s fundamental frequency of oscillation satisfies the reactive portion of the equation

$$X_{\text{device}}(\text{frequency}, P_{\text{out}}, V_{\text{DC}}, I_{\text{DC}}, T) = -X_{\text{circuit}}(\text{frequency}, \text{geometry}) \tag{3}$$

Since the circuit resistance must be greater than zero, the device must exhibit *negative resistance* to oscillate. A typical device’s resistance is on the order of a few ohms, while

Figure 1. Cross-sectional view of a waveguide oscillator circuit. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

the characteristic impedance of the dominant TE_{10} mode of the rectangular waveguide is a few hundred ohms. The oscillator circuit must be able to transform these widely varying impedances to satisfy Eqs. (2) and (3).

This article draws on material from the book by Holzman and Robertson [1] to discuss three different solid-state waveguide oscillator topologies:

- The single-device oscillator (SDO) is simply a single active device in a waveguide circuit. The frequency and power of an SDO can be tuned mechanically by changing the dimensions of the waveguide circuit or by adjusting the device’s DC bias point.
- A voltage-controlled oscillator (VCO) is an SDO plus an electronically adjustable, reactive tuning element such as a varactor diode placed in the waveguide circuit. The VCO frequency of oscillation can be adjusted with a separate DC voltage over a bandwidth that depends on the varactor’s range of reactance adjustment.
- A waveguide power combiner adds the power output of two or more active devices within a single waveguide circuit.

2. SINGLE-DEVICE OSCILLATORS

Single-device waveguide oscillators are used as bias tunable sources or device evaluation fixtures. Figure 2 shows four commonly used waveguide circuits. Each consists of waveguide/coaxial-line junction, with the coaxial-line center conductor supplying bias to the active device. The center conductor also influences the circuit impedance presented at the device terminals. The coaxial line is sized so that only the TEM-mode propagates, which requires that the sum of the inner and outer conductor diameters be less than $c/\pi f_{\text{max}}$, where c is the speed of light in the

Figure 2. Waveguide oscillator circuits: (a) post gap; (b) top hat; (c) coaxial gap; (d) cross-coupled coaxial. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

coax dielectric and f_{\max} is the maximum frequency of oscillation [3]. The RF-absorbing load material isolates the waveguide circuit from the external environment and presents a well-defined load impedance. It also maintains the coaxial-line center conductor concentric within the bias port.

In general, one of the two waveguide ports delivers the RF output power, while the other waveguide port is terminated in a short circuit, which often is adjustable. The output port may include a reactive tuning element such as an iris or post to further adjust the circuit impedance. The primary differences between the four circuits in Fig. 2 appear in the device mount region. In the post in Fig. 2a, a gap is placed at an arbitrary position above the waveguide floor. The diameter and the position of the gap determine how the propagating and evanescent modes in the waveguide couple to the device. Eisenhart and Khan discuss the behavior of the *post gap* circuit in some detail [4,5]. The *top hat* circuit in Fig. 2b is similar, but the device generally sits on the floor of the waveguide, and a radial disk transforms the circuit admittance Y_{in} to the device's package surface. This circuit is used when the device package becomes relatively large compared to the waveguide, at millimeter-wave frequencies. The circuit in Fig. 2c uses the RF-absorbing load in the bias port of the coaxial line to help tune the device operating point. Figure 2d shows the *Kurokawa* or *cross-coupled* circuit, which recesses the device below the waveguide floor so that the circuit admittance Y_{in} is transformed to the device by a section of coaxial line.

2.1. Waveguide Circuit Analysis

Oscillator circuits can be tuned by purely empirical means. However, to use the circuits in Fig. 2 effectively, an accurate electromagnetic model helps calculate the circuit impedance at the device terminals. Commercially available, generalized, three-dimensional frequency or time-domain simulators certainly can analyze these circuits. However, for speed and optimization, there are specialized, numerically efficient, and accurate, well-validated models for all four circuits [1,6–12]. With these circuit models, one can calculate the circuit admittance Y_{in} (see Fig. 2). Then, with a second transformation, depending on the device mount configuration, one can calculate the circuit impedance at the device package.

Figure 3. Waveguide oscillator circuit equivalent circuit. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

All four circuits in Fig. 2 can be represented by an equivalent circuit of the form shown in Fig. 3. The desired circuit admittance is Y_{in} . Z_{gap} is the impedance presented at the reference plane where the coaxial line enters the waveguide (see, e.g., Fig. 2c), and Z_e is the total impedance presented by the waveguide, with equations for its computation given in Ref. 1. For the post gap circuits shown in Figs. 2a and 2b, Z_{gap} has an impedance of $0\ \Omega$ at the frequency of oscillation. However, the coax line delivers the bias to the device, so a lowpass filter is required in the bias port. Figure 4 shows a standard low–high–low filter. The cascading of three quarter-wave impedance transformers makes Z_{gap} a very low RF impedance as given by the following equation [1]:

$$Z_{\text{gap}} = \frac{1}{Z_L} \left(\frac{Z_{\text{c,lo}}^2}{Z_{\text{c,hi}}} \right)^2 \quad (4)$$

As shown in Fig. 4, dielectric sleeves are wrapped around the low-impedance section inner conductors to maintain their concentricity and to prevent the occurrence of a DC short circuit.

A nonzero Z_{gap} for the coax gap and cross-coupled coaxial circuits provides an extra variable for tuning the oscillator. One can use standard transmission-line equations to transform the load impedance of the RF absorber to the post gap as explained in Ref. 1, which also describes a way to measure the impedance of the absorber.

The equation giving the input admittance in terms of Y_{in} , Z_{gap} and Z_e is

$$Y_{\text{in}} = Y_{11} - Z_{\text{gap}} \frac{Y_{12}Y_{21}}{1 + Z_{\text{gap}}Y_{22}} \quad (5)$$

Figure 4. Low–high–low impedance transformer for applying DC bias and RF short-circuiting the coaxial waveguide bias port. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

where

$$Y_{ii} = Z_{\text{gap}} \frac{1}{Z_e R_i^2} + jB_i, \quad i = 1, 2 \quad (6)$$

$$Y_{21} = Z_{\text{gap}} \frac{1}{Z_e R_1 R_2} + jB_{21} \quad (7)$$

Expressions for the terms in Eqs. (5)–(7) can be found in Ref. 1.

One uses Eq. (5) to compute the circuit admittance, and then transforms it through the device mount to the device terminals. This second calculation is relatively straightforward and involves simple equations. Figure 5 shows the

Figure 5. Coaxial gap oscillator circuit device mount and equivalent circuit. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

post gap circuit (Fig. 2c) in detail. As long as the active device and gap are small relative to a wavelength, we can assume that the electromagnetic field in the gap is uniform, and that the electric field vector is vertical in orientation. One can use radial transmission-line equations to

Figure 6. Device mount and equivalent circuit for the cross-coupled circuit. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

transform the impedance Z_{in} ($1/Y_{in}$) to the device package [3]. Getsinger describes a package lumped inductance and capacitance model that gives the actual semiconductor chip impedance [13]. However, for oscillator design, this additional effort is seldom necessary since package characteristics tend to be repeatable. Further, above 40 GHz Getsinger’s model loses validity as most packages can no longer be modeled with lumped elements.

Figure 6 shows the details of the device mount for the cross-coupled circuit mount. The approach to calculating the circuit admittance at the device package is similar. A series of coaxial line transformations are applied to Z_{in} ($1/Y_{in}$) to obtain Z_p , and then Getsinger’s model in combination with radial line transformations gives Z_{circ} at the device package.

As an evaluation fixture for devices, a properly designed waveguide circuit allows users a wide range of mechanical tuning. They can tune a device to several different operating points. With an accurate electromagnetic model of their waveguide circuit, they can calculate the circuit impedance at the device terminals, and, in combination with the oscillation equations (2) and (3), predict the device impedance curve versus frequency. The device then can be mounted in a different waveguide circuit, and its resistance and reactance curves can be used to predict output power and frequency of oscillation.

2.2. Oscillator Circuit Hardware Design

Waveguide oscillator circuits are fabricated from metals such as copper, which have excellent electrical and thermal properties. Most circuits are nickel- and gold-plated to prevent oxidation. Since nickel is a relatively poor electrical conductor, the overlying gold should be a minimum of several skin depths thick. Figure 7 shows a Gunn oscillator DC bias circuit, and Fig. 8 shows a waveguide circuit housing that has been designed for maximum mechanical adjustment. There are two main parts to the housing: (1) bias port and rectangular waveguide cutout and (2) device port and rectangular waveguide floor. These parts are precision-aligned with metal dowel pins. One should choose a waveguide height that is below the standard to minimize higher-order-mode effects, which tend to create startup problems such as frequency hopping and spurious oscillations [17]. The active device is mounted in the device port. Device port shims are used to recess the device and adjust the circuit admittance. The coaxial-line center conductor slides through the RF-absorbing load to contact the device. For high-power oscillators, the load may have to be lengthened and a bias port filter may be needed to suppress *parametric oscillations* at multiples or fractions of the fundamental frequency [18–21]. A section of empty waveguide is attached to one waveguide port, and an adjustable short circuit is inserted for tuning. A good

Figure 7. Gunn oscillator DC bias circuit schematic. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

Figure 8. Waveguide oscillator circuit assembly. (Reprinted with permission from *Solid-State Microwave Power Oscillator Design* by E. L. Holzman and R. S. Robertson, Artech House Publishers, Norwood, MA, USA, www.artechhouse.com.)

waveguide short circuit, with a well-defined reference plane such as that designed by Eisenhart and Monzello [22], is important, especially if one is analyzing the circuit with a numerical model. At the other waveguide port, one can attach irises for further tuning. These can be etched from standard brass shim stock using a photolithographic print-and-etch process. An isolator at the output is often required to prevent external mismatched loads from tuning the oscillator frequency and output power.

2.3. External Bias Circuit Design

One must exercise caution when applying DC bias to two-terminal device oscillators. Voltage spikes or polarity changes can be catastrophic. A zener diode, shunted across the DC supply terminals, with its positive terminal connected to the negative of the supply, can limit such a polarity change. The zener diode reverse breakdown voltage must exceed the normal maximum DC bias voltage required for the active device, while its forward voltage should be less than one volt. If the polarity of the supply output changes, the zener forward voltage will limit the supply. If a zener diode provides inadequate protection, a voltage regulator may be needed.

Long wire leads to power supplies can behave as resonant circuits at frequencies as high as 100 MHz and cause unwanted bias circuit oscillations. To suppress these oscillations, one can place a capacitor close to the active device; a thin, annular, discoidal capacitor may have to be placed in the bias port coaxial line. It is wise to watch for bias circuit oscillations with voltage and current probes connected to an oscilloscope. Figure 7 shows the DC bias circuit for a Gunn oscillator driven by a regulator. Brackett [14] and Lee and coworkers [15,16] discuss IMPATT biasing in some detail.

2.4. Temperature Effects

An oscillator's power and frequency will change with temperature because the properties of solid-state materials and the circuit housing dimensions are temperature-dependent. If the circuit Q factor is high, thermal expansion of the housing can be the main cause of frequency drift. The differential metal expansion technique can be employed to cancel the changes in circuit size with temperature [17]. Alternatively, one can build the circuit out of a metal such as *invar*, a nickel-steel alloy that has a low thermal expansion coefficient. Even so, if the device is not well heatsunk, the oscillator frequency may exhibit *post-tuning drift* for minutes after the bias is applied. Sometimes the only way to eliminate temperature effects is to attach a heater to the housing.

Temperature effects also arise when an oscillator's DC bias is pulsed on and off. The active device reexperiences the startup phase at the beginning of each pulse. During the pulse, the device's junction temperature increases, causing the oscillator to *chirp* as its frequency drifts monotonically. Shaping of the chirp spectrum sometimes can be used to advantage in radar applications. If one applies a small amount of DC bias during the OFF-state portion of the waveform, chirp bandwidth can be reduced [23,24]. The *preheat bias* does not actually start oscillations, but

because the active device is warmed before the DC pulse turns it on, the temperature gradient is lessened, and so is the frequency drift.

3. VOLTAGE-CONTROLLED OSCILLATORS

A voltage-controlled oscillator (VCO) incorporates some means to vary the oscillation frequency with a separate external DC voltage. Although a variety of voltage control mechanisms exist, *varactor tuning* is the most popular choice for waveguide oscillators.

A VCO's *tuning range* is the frequency range over which the VCO meets its performance requirements such as output power. A typical waveguide VCO tuning bandwidth is about 5%. The *sensitivity* of a VCO is the ratio of the change in frequency to the change in tuning voltage in units of megahertz per volt. The ideal for most VCOs is a linear frequency-tuning voltage characteristic. The parameter *linearity* describes the degree to which the VCO response approximates a straight line

$$L = \frac{S_{\max} - S_{\min}}{S_{\max} + S_{\min}} \quad (8)$$

where S_{\min} and S_{\max} are the minimum and maximum values of sensitivity over the tuning range.

3.1. Varactor Diode Characteristics

One who uses a *varactor diode* to control the frequency of a VCO is simply making use of the bias voltage-varying capacitance of a p-n junction [1]. In the waveguide circuit, the capacitance is a reactance given by

$$X_j = \frac{1}{j\omega C_j} \quad (9)$$

where ω is 2π times the oscillation frequency and C_j is the varactor junction capacitance. To obtain a wide tuning range, a wide range of reactance is needed. Most varactors are packaged, so one must be sure that the package inductance and capacitance do not dominate the junction capacitance. In particular, the inductance of the leads connecting the semiconductor to the inside of the package can resonate with the junction capacitance and cause an excessive amount of current to flow through and potentially destroy the varactor.

The varactor capacitance-voltage slope is roughly proportional to $V_{\text{DC}}^{-0.5}$ [1], a nonlinear characteristic that does not naturally lead to a linear VCO. One technique for *linearizing* a VCO is to use an external bias circuit that is designed to compensate for the nonlinear varactor voltage characteristic. Another technique involves the use of linearizing circuit elements in the waveguide circuit. Last, semiconductor design engineers are always striving to adjust the varactor structure to produce a more linear response.

3.2. Waveguide Circuit Modeling

In a sense, a varactor is just another tuning element in the waveguide oscillator circuit. However, one must account for the varactor and its mounting structure if one is to model the waveguide VCO circuit analytically. Figure 9 shows a waveguide VCO circuit with the active device and varactor mounted under separate posts. For posts spaced apart so that only the dominant mode couples between them, one can create an equivalent circuit like that shown in Fig. 3 for each device and cascade the circuits. However, the two posts often are closely spaced to maximize the coupling between the two devices. Consequently, higher-order, evanescent waveguide modes must be included in the circuit model. Joshi and Cornick [25–27] have developed such a model based on the work of Eisenhart and Khan [4]. The details can also be found in Ref. 1.

3.3. VCO Circuit Design Practice

The amount of frequency tuning that can be achieved with a waveguide varactor-tuned VCO is controlled by the varactor capacitance range and the varactor to active device coupling. A VCO configured as in Fig. 9 has the most frequency tuning when the posts are centered in the waveguide, where the fields and coupling are the strongest. The coupling has a strong dependence on the post dimensions and spacing between posts, parameters that also can be used to linearize the VCO. Robertson and Poelker employed a top hat structure (see Fig. 2b) above their varactor diode and by adjusting the disk diameter achieved excellent linearity [28].

There are three basic steps to follow when designing a varactor VCO:

- Place the active device in a SDO circuit and characterize its impedance–frequency curve.
- Model the varactor as an impedance versus DC bias voltage [1].
- With both devices characterized, place them in a VCO circuit, and use a two-post analytical model to search for circuit dimensions that give the desired VCO tuning range and linearity.

If the active device resistance is constant with frequency in the tuning range (which is likely for tuning ranges of a few percent), design the oscillator so that the circuit resistance is also constant with varactor bias to maintain a constant level of output power with frequency [29].

4. WAVEGUIDE OSCILLATOR POWER COMBINERS

Power combining of several devices becomes necessary when higher-power devices are not available. Power combining can be accomplished at the device level, at the circuit level, or in free space. *Power combining efficiency*, the net power P_T at the combiner output divided by the sum of the powers of the individual devices P_O , is given by [1]

$$\eta_c = \frac{P_T}{NP_O} \quad (10)$$

where N is the number of devices being combined. The combining efficiency of a well-designed combiner should exceed 90%.

Two-terminal devices are usually power combined in resonant waveguide cavities, although both oscillators and amplifiers can be combined in resonant circuits. Resonant combiners have a number of excellent features, including very high efficiency. They also provide good heatsinking, since devices are mounted in the metal housing. The active devices tend to lock to each other in frequency, which leads to stable operation and compensates for device-to-device impedance variations. Further, resonant combiners can operate as high as 300 GHz, and they are compact in size. Some of their disadvantages include narrow bandwidth, limitations on the number of devices that can be combined without exciting unwanted cavity modes and electrical tuning complexity.

One advantage that a power combiner has over a SDO is that its performance will degrade in a gradual manner as active devices fail. Sarkar and Agrawal have performed an analytical study of gradual degradation due to device failure [30]. They derived an expression for the power *degradation* of the combiner by assuming that only a small number of the devices in the combiner fail and all devices are performing identically

$$GD = 10 \log_{10} \left(1 - \frac{F}{N} \right) \quad (11)$$

where F is the number of failed devices and N is the total number of devices. Equation (11) is optimistic. Holzman and Robertson remark that when IMPATT and Gunn devices fail, they mostly become short circuits rather than open circuits [1]. Short-circuited (shorted) devices cause a significant imbalance in the impedances presented to the other devices. A loss of 3 dB in output power is typical for a single shorted device, and the missing power often ends up in the shorted device's bias port load.

4.1. Rectangular Waveguide Cavity Combiners

Kurokawa and Magalhaes designed the first resonant cavity combiner in 1971 using rectangular waveguide [31]. The circuit, shown in Fig. 10, comprises a multitude of coaxial-waveguide junctions. Each active device is recessed at the end of a coax transmission line, below the floor of the waveguide. Pairs of devices are placed in transverse planes spaced down the waveguide cavity at half-guide wavelength intervals such that each device couples to a maximum in the magnetic field. For an SDO circuit, typically only one mode is resonant. But, as the cavity is lengthened to accommodate more devices, more cavity modes become resonant within the operational frequency range. Because the spacing between devices is selected for the resonant mode of interest only, the other resonant modes will be excited only weakly, although any energy coupled into these modes will degrade the combiner efficiency. In addition, as the cavity is lengthened, its tuning bandwidth decreases because the circuit impedance of

devices farthest from the short circuit becomes more sensitive to frequency. To get optimum efficiency from a combiner, one should characterize a large number of active devices in a single-device evaluation circuit and select only those with similar characteristics.

One way to increase the output power of the combiner without increasing the length of the waveguide cavity is to increase the density of devices. The circuit in Fig. 11 has double the combiner density with two devices closely straddling each magnetic field maximum [32]. Figure 12 shows another way to increase device density by mounting three devices in each transverse plane of the combiner cavity [33]. In this combiner, the active devices near the cavity wall couple to the magnetic field, while a coaxial probe couples the center device to the TE₁₀₁-mode electric field maximum. The probe is connected to the bias port of one of the other devices with a wire.

4.2. Cylindrical Cavity Resonant Combiners

The cylindrical cavity resonant combiner is based on the circular waveguide cavity. The main benefit of this combiner, depicted in Fig. 13, is that a large number of devices can be combined with only the dominant, TM₀₁₀-mode resonant in the frequency band of operation. As shown in the figure, the devices are placed around the edge of the

cavity, where the magnetic field reaches its maximum level. A coax probe, placed in the center of the combiner, is the output. Both the coax TEM mode and cavity TM_{010} mode have similar axial field distributions, which enables good coupling between the devices and output. A mechanically adjustable tuning rod optimizes the combiner efficiency. The maximum number of devices that can fit

within a dominant mode combiner depends on the combiner’s *radius*, which is given by the formula for the resonant frequency of the TM_{010} mode [1]

$$r = \frac{c}{2\pi f_0} 2.4049 \tag{12}$$

where f_0 is the operational frequency of the combiner and c is the speed of light. The *height* h of the cavity is chosen so that the next higher-order mode, the TE_{111} mode (for $r > h$), resonates at a frequency outside the operational band. The resonant frequency of this mode is

$$f_{r,111} = \frac{c}{2\pi} \sqrt{\left(\frac{1.8412}{r}\right)^2 + \left(\frac{\pi}{h}\right)^2} \tag{13}$$

The cavity field is axially symmetric, so the magnetic field is constant with angle (see Fig. 13). Thus, the devices can be spaced as closely as physically and thermally possible. The dissipated heat can be better distributed by alternately reversing the locations of the device and absorber in adjacent locations [34]. Accurate models of cylindrical combiner structures have been developed using field matching [35,36]. Generalized, commercially available three-dimensional numerical electromagnetics software can be used also.

Cylindrical cavities are highly efficient with measured efficiencies sometimes exceeding 100%, implying that devices operate more efficiently in the combiner environment than as SDOs [37]. For a given cavity size, measured data show that the combining efficiency increases with device density. However, at *millimeter-wave frequencies*, the cylindrical cavity is less efficient, because the cavity size must be reduced to avoid higher-order modes. Unfortunately, the packaged devices do not decrease in size with higher operating frequency, so fewer devices can be combined. Further, the output coaxial probe dimensions must be very small for single-mode operation. The rectangular cavity may be a better choice at higher frequencies, because the number of unwanted modes increases comparatively slowly as its length increases.

One solution to the higher-order moding problem is the *window output* cylindrical combiner of Fukui and Nogi shown in Fig. 14 [38]. This combiner can be operated in axially varying modes with devices nonuniformly spaced, and it does not require a coaxial probe output. Another solution is to use an oversized combiner operating in a

higher-order cavity mode such as the TM_{0n0} ($n > 1$) or TM_{m10} ($m > 0$) mode. However, the unwanted modes must be suppressed without affecting the desired mode. TM_{020} -mode cavities have performed well [39–41], and even higher-order mode cavities have been designed and built [42,43].

5. CONCLUSION

Waveguide oscillators have lost favor as GaAs and InP microwave integrated circuit (MMIC) amplifier technology has advanced into the millimeter-wave frequency range. High-power diode multipliers have also encroached on the domain of Gunn and IMPATTs. Even with the good analytical models available today, waveguide oscillators are not easy to mass-produce, so they find use primarily as custom sources operating in the highest millimeter-wave frequency bands. The one exception is the cylindrical cavity combiner, which is employed as low as 10 GHz because of its capability to combine many devices with the highest possible efficiency.

WAVEGUIDES

ANDRÉ VANDER VORST
 Université Catholique de
 Louvain
 Louvain-la-Neuve, Belgium

In the electromagnetic spectrum, microwaves are the waves with wavelengths comparable to ordinary laboratory

dimensions. Furthermore, smooth surfaces of good conductors form very perfect reflectors for them. As a consequence, an electromagnetic wave in a reflecting pipe is reflected back and forth from wall to wall, so that it can travel to large distances with small attenuation. Hence we have “waveguides” as transmission lines, dealing with electromagnetic fields inside of hollow regions, rather than outside wires for more conventional electric applications, or waves in free space as in optics, and the propagating electromagnetic field is confined to the finite region of the guide by reflecting walls. The present article essentially reviews the basic theory and the different geometries used in the various applications of such hollow waveguides.

1. FUNDAMENTALS

1.1. Historical Evolution

J. C. Maxwell established the fundamentals of electromagnetic theory around 1880. In 1883, F. G. Fitzgerald suggested sources for electromagnetic emission. In 1888, H. Hertz proved that the concept of propagation was included in Maxwell's theory. At the same time, O. Lodge demonstrated the existence of maxima and minima on transmission lines. A group of experimental scientists was formed—the Hertzians—while J. C. Bose was experimenting with millimeter waves in India. In 1894, Lodge demonstrated radiation from circular hollow pipes—waveguides—as well as the effect of irises and resonant cavities, and illustrated the highpass properties of the device. Bose developed a semiconductor detector, rectangular waveguides and horns, at 60 GHz [1–5]. In 1893, Heaviside considered various possibilities for waves along wire lines from a theoretical standpoint and concluded that guided waves needed “two leads as a pair of parallel lines; or if but one is to be used, there is the earth, or something equivalent, to make another” [6]. J. J. Thompson gave a theoretical analysis of electric oscillations within a conducting cylindrical cavity of finite length. He found that there were permissible normal modes that were a function of the radius of the cylinder [7]. Shortly thereafter, J. Larmor similarly investigated the theory of resonant structures such as coaxial metallic cylinders and a single dielectric cylinder [8].

In 1897, Rayleigh showed that waves could indeed propagate within a hollow metallic cylinder [9]. He found that such waves existed only in a set of well-defined normal modes, with waves of two types: one with a longitudinal component of electric intensity only, while the other had a longitudinal component of magnetic intensity only. Both types had transverse components of both electric and magnetic intensity. He found that a fundamental limitation on the existence of such waves was that the frequency must exceed a lower limit—cutoff frequency—depending on mode number and the cross-sectional dimensions of the cylinder. He published the complete solutions in the case of rectangular and circular cross section, yielding all possible solutions.

Hertzian links, feeders, detectors, and even radioastronomy with an attempt by Lodge were on the horizon. In

fact, none of this happened, probably because of both the success of the long waves used by Marconi and the difficulty in generating microwaves. Lodge got interested in paranormal phenomena, and Bose in plant growth and biological effects of electromagnetic fields. Microwave electronics fell out of favor.

Almost 40 years later, G. C. Southworth, working with Schelkunoff, of Bell Telephone Laboratories (BTL), and W. L. Barrow, working with Chu, Stratton, and others, of the Massachusetts Institute of Technology (MIT), rediscovered the concept, each working independently for almost 5 years with no knowledge of the other. The question they investigated was the practical possibility of using waveguides for the transmission of microwave power. This work culminated in almost simultaneous presentations in 1936, when they claimed that they had discovered that electromagnetic waves would propagate in hollow tubes and had experimentally demonstrated the practicality of this phenomenon. They had become aware of each other's work about one month prior to the announcements, after publication of the programs for the meetings at which the presentations were to be made (3).

From the beginning, the most obvious application of waveguide had been as a communications medium. It had been determined by both Schelkunoff and Mead independently in 1933 that an axially symmetric electric wave in circular waveguide would have an attenuation factor that decreased with increased frequency [3]. This unique characteristic was believed to offer a great potential for wide-band multichannel systems, and for many years to come the development of such a system was a major focus of activity within the waveguide group at BTL. The use of a waveguide as a long transmission line, however, did not prove to be practical and Southworth himself concluded in 1939 that microwave radio with highly directive antennas was preferable, coming to the conclusion that the hollow cylindrical conductor would be valued as a new circuit element, a new type of toll cable.

The years from 1936 to 1940 saw great activity in microwave electronics, but hardly with important practical applications. The great impetus to its further development came with the application to radar in World War II. Generally, the development of experimental radar into an operational system is attributed to R. Watson-Watt, having convinced politicians to install a range of radar protection on the British coast. At the end of the summer of 1938, 5 stations were protecting London. In July 1940, 50 stations were operational. The efficiency of the system was determinant on the evolution of the war in Europe. During the war, the famous MIT Radiation Laboratory was the place where British and U.S. scientists and technicians worked together, developing microwave technology and electronics as well as the basic theory. The series of 28 books published after the war summarized the tremendous amount of high-quality work accomplished at that time [2,10].

Since then, waveguides have been very common in microwaves, especially in the centimeter and millimeter wave ranges, mostly because of their losses, lower than in coaxial cables. Another reason is that the waveguide forms a closed transmission line, which is an advantage in certain environments, in particular in the presence of

interferences or adverse tropospheric conditions. The tendency to go to higher frequencies has introduced particular configurations of loaded waveguides, essentially the fin line structure (see FINLINES).

For a few decades now most commercial applications have been based on planar transmission lines, especially in the lower frequency range, such as the microstrip, the most common planar line, although stripline came first. More recently, other configurations like slotlines and coplanar waveguides have become popular, because of their good properties at higher frequencies, namely, in the 30–60 GHz range. Planar technology developed with respect to waveguides for essentially two reasons. One is economical; producing a planar circuit is cheap, which compensates for the cost of research and development. The other is that planar technology easily combines with semiconductors, leading to microwaves monolithic integrated circuits (MMIC), while the combination waveguide-semiconductor has always been rather laborious, because of the significant differences in configuration as well as in impedance level.

1.2. Basic Theory

1.2.1. Electromagnetic Field in a Waveguide. Electromagnetic fields within any region of space are determined by solving Maxwell's equations in a coordinate system appropriate to the region. Such regions may be termed as either uniform or non-uniform. Uniform regions are characterized by the fact that cross sections transverse to a given symmetry, or propagation, direction are everywhere identical with one another in both size and shape. Examples of uniform regions are provided by regions cylindrical about the symmetry direction and having planar cross sections with, for example, rectangular or circular peripheries [2,4,5,10–12].

A waveguide is a metallic structure of arbitrary but constant cross section that extends in the direction of propagation of a wave and confines the wave energy within it. It is bounded by a conductor of high conductivity, filled with a dielectric of low loss, with arbitrary cross section. It may have more than one bounding surface, as the coaxial line, which consists of the annular space between two concentric circular cylindrical conductors. In practice the two most common cases are the rectangular and the circular guide. Hollow waveguide cross sections are limited by metallic boundaries. In the basic theory, those metallic boundaries are supposed to be made of perfect electric conductors. At microwaves, the actual losses in actual conductors are very small and are usually evaluated by a perturbation theory.

Within the enclosed region the electromagnetic field may be represented as the superposition of an infinite number of standard functions that form a mathematically complete set. The mathematical representation of the electromagnetic field within a uniform region is in the form of a superposition of an infinite number of modes or wave types. The electric and magnetic field components of each mode are factorable into form functions depending only on the cross-sectional coordinates transverse to the direction of propagation, and into amplitude functions depending

only on the coordinate in the propagation direction. The transverse functional form of each mode depends on the cross-sectional shape of the region and, save for the amplitude factor, is identical at every cross section. As a result the amplitudes of a mode completely characterize the mode at every cross section. The variation of each amplitude along the propagation direction is given implicitly as a solution of a one-dimensional wave or transmission-line equation. According to the mode in question the wave amplitudes may be either propagating or attenuating along the transmission line.

1.2.2. Transverse Electromagnetic, Transverse Magnetic, and Transverse Electric Modes. In physics, waves are usually classified according to two criteria. One is the geometric form of the wavefront, which describes the surface of constant phase, most generally planar, cylindrical, or spherical, more rarely elliptical or other. The second criterion is that the wave is said to be uniform or nonuniform, depending on whether the field has a constant amplitude in each point of the wavefront or not. As examples, the wave emitted from a point source is a uniform spherical wave while the wave propagating in a coaxial cable is a nonuniform plane wave. The term “pure mode,” or simply “mode,” refers to a wave whose field structure remains the same along the entire path of propagation. Different modes will, in general, have different field structures and different velocities of propagation. In uniform hollow waveguides, the waves, more often called the *modes*, are usually classified according to their properties with respect to the propagation direction and whether they have longitudinal components or not. A wave with longitudinal components for neither the electric nor the magnetic field is called a transverse electromagnetic (TEM) wave. It has only four field components. A wave with no longitudinal magnetic field component while having a longitudinal electric field component is called a transverse magnetic (TM) wave, and a wave with no longitudinal electric field component while having a longitudinal magnetic field component is called a transverse electric (TE) wave. TM and TE waves, or modes, each have five field components.

For a TEM mode to propagate on a guiding structure, at least two conductors are needed. The equations to be satisfied by a TEM mode *in the transverse plane* of such a structure are indeed identical to those of statics where two conductors at least are necessary, to impose a potential difference as a boundary condition. Hence a TEM mode cannot propagate on or in a hollow one-conductor waveguide, while it can propagate on or in a two-conductor waveguide of any cross section and any geometry, for instance, a coaxial cable or waveguide. A TEM mode has no cutoff frequency: because of the two or more conductors it can propagate down to zero frequency.

In a waveguide, an infinite number of TE and of TM modes can propagate. In the usual one-conductor waveguide, those two classes of modes cannot propagate down to zero frequency, since only one conductor is available. All the TE and the TM modes have a cutoff frequency below which they cannot propagate: the waveguide has a high-pass characteristic. The cutoff frequencies depend on the

dimensions of the waveguide and of the homogeneous medium filling the waveguide. In a waveguide with two or more conductors, like the coaxial cable or waveguide, the TEM, TE, and TM modes can propagate. The number of propagating modes is determined by the frequency: all the modes with a cutoff frequency lower than the generator frequency propagate while the others do not. If a waveguide is excited with a signal whose frequency is lower than the cutoff frequency, then instead of propagating, this signal is attenuated exponentially with distance. This phenomenon of attenuation in a nonabsorbing medium that occurs in a waveguide below cutoff is similar to the phenomenon of total reflection in optics, in which light is reflected going from an optically denser to an optically rarer medium. In the rarer medium there is an attenuated wave of the type discussed here. With a slightly absorbing medium inside the waveguide, the cutoff is no longer as sharp as it is in the nonabsorbing case. The attenuation is small in the range of frequency above cutoff, and rapidly becomes large when going to lower frequencies.

The mode with the lowest cutoff frequency is called the *dominant mode*. In general, most waveguides are operating at a frequency such that only the dominant mode propagates. In that case, the electromagnetic field is characterized by the amplitudes of this dominant mode. The amplitudes that measure the transverse electric and magnetic field intensities of this dominant mode are defined as voltage and current, respectively, as on appropriate transmission line. The knowledge of the wave impedance and propagation constant, that is, propagating, of the transmission line then permits one to describe the propagation of the dominant mode in familiar impedance terms.

When cross-sectional discontinuities are present in the waveguide, they require more boundary conditions to be satisfied than those characterizing the dominant mode, which are imposed by the longitudinal metallic walls. Mode voltages and currents are introduced as measures of the amplitudes of the transverse electric and magnetic field intensities of each of the higher-order modes. Each of these is represented by a transmission line, having however a reactive wave impedance and a real propagation constant, that is, attenuating. In this manner the complete description of the electromagnetic field in a waveguide may be represented in terms of the behavior of the voltages and currents on a infinite number of transmission lines.

1.2.3. Orthogonality Properties and Expansion of the Fields in Normal Modes. Solutions of the wave equation always have certain properties of orthogonality, which are particularly important when expanding a general solution as a sum of solutions for the various modes and when considering problems of energy. Several general theorems have been proved independently of the particular geometry of the cross section. The main orthogonality theorems are the following:

1. The integral over the cross section of the scalar product of either the transverse electric fields or the transverse magnetic fields of two different modes is zero.

2. The integral over the cross section of the product of either the longitudinal electric field components or the longitudinal magnetic field components of two different modes is zero.
3. The integral over the cross section of the longitudinal component of the vector product of the transverse electric field of one mode with the transverse magnetic field of another mode is zero.

These theorems hold when the two modes are both TE or both TM, as well as when the two modes are of opposite types. Several other theorems can be derived, relating to the integrals of squares of components of the electric and the magnetic fields, or of products of components with their conjugates.

Maxwell's equations within an one-conductor waveguide with perfectly reflecting walls have an infinite number of possible solutions, representing various normal modes, some TE and some TM. Furthermore, corresponding to each of these modes with propagation along the $+z$ direction, there is a possible wave propagated along $-z$. Each mode has a cutoff frequency, such that a disturbance in that mode at a frequency below cutoff is rapidly attenuated, whereas at a frequency higher than cutoff it is propagated.

The last problem to be considered is that of the most general field that can exist in the waveguide. Maxwell's equations, as well as the boundary conditions are linear. Hence, all the solutions that have been found can be superposed, with appropriate coefficients, to form another solution for the equations submitted to the boundary conditions. It can be proved that the most general solution, subject to the boundary conditions and to the additional condition that the guide contains no volume charge or current except what arises from Ohm's law in the imperfect dielectric filling it, can be represented by such a superposition. As usual when dealing with problems of expansion in orthogonal functions, the magnitude of the functions are normalized by determining their magnitudes so that their squares integrate to some convenient value, and by multiplying these normalized functions by an additional coefficient to secure an arbitrary value for the function. The complete field is obtained by superposing all possible fields, with waves traveling along the $-z$ direction as well as along $+z$ (2).

A quite general approach to waveguide theory is obtained by elevating Maxwell's equations into a dyadic form. This yields the concept of dyadic Green functions in electromagnetic theory. Vector wave functions can then be established for waveguides of specific cross sections [12,13].

2. THEORY

2.1. Electromagnetic Fields in a Waveguide

2.1.1. TEM Mode. TEM waves have longitudinal field components neither for the electric nor for the magnetic field. Hence they are fully determined by four components only, two for the transverse electric field and two for the

transverse magnetic field. Along a guiding structure, TEM waves can propagate only if at least two conductors are available, as is the case in a coaxial cable or waveguide. It can be shown indeed that those fields satisfy in the transverse plane the same equations as those of statics. To demonstrate the statement the vectors and operators appearing in Maxwell's equations are decomposed into their transverse and longitudinal components, which leads to decomposed equations [14]. These show that in the absence of the longitudinal components the purely transverse electric and magnetic fields do satisfy the equations of statics in the transverse plane. Furthermore, since neither electric nor magnetic variable field can exist in a perfect electric conductor, boundary conditions to be satisfied at the walls are also identical to those of statics. Hence two conductors at least are necessary for a TEM wave to propagate on a guiding structure: in a coaxial waveguide a TEM wave can propagate, while it cannot in a one-conductor hollow waveguide.

2.1.2. TE and TEM Modes. Only uniform waveguides are considered, where the cross section is identical along the propagation direction and limited by conducting walls surrounding a homogeneous and isotropic medium, usually with small losses. The propagation is interior to the guide. The walls are first supposed to be lossless. They can be either perfect electric or perfect magnetic, which can be used for the ease of calculation in some special cases. In practice, however, there are numerous materials that are very good electric conductors, although not perfect, which is not the case for magnetic conductors. Small losses in the walls will be evaluated later, using a perturbation method. Internal volume charge and current density are assumed to be zero. Steady-state sinusoidal solutions are calculated. Maxwell's equations are solved in the frequency domain and fields are represented by phasors (complex vectors).

Maxwell's equations are written as

$$\begin{aligned}\nabla \times \bar{\mathbf{E}} &= -j\omega\mu\bar{\mathbf{H}} \quad \text{or} \quad \nabla \times \bar{\mathbf{E}} = -jk\zeta\bar{\mathbf{H}} \\ \nabla \times \bar{\mathbf{H}} &= (j\omega\epsilon + \sigma)\bar{\mathbf{E}} \quad \text{or} \quad \nabla \times \bar{\mathbf{H}} = jk\eta\bar{\mathbf{E}} \\ \nabla \cdot \bar{\mathbf{E}} &= 0 \\ \nabla \cdot \bar{\mathbf{H}} &= 0\end{aligned}\tag{1}$$

by defining

$$\begin{aligned}jk &\triangleq \sqrt{j\omega\mu(\sigma + j\omega\epsilon)} \quad (\text{m}^{-1}) \\ \frac{\eta \triangleq 1}{\zeta} &\triangleq \sqrt{\frac{\sigma + j\omega\epsilon}{j\omega\mu}} \quad (\text{S})\end{aligned}\tag{2}$$

2.1.3. Transverse and Longitudinal Components for TE and TM Modes. Rewriting the first two equations of

Eq. (1) in detail yields

$$\begin{aligned}\frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} &= -jk\zeta H_x \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} = jk\eta E_x \\ \frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x} &= -jk\zeta H_y \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} = jk\eta E_y \\ \frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} &= -jk\zeta H_z \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} = jk\eta E_z\end{aligned}\quad (3)$$

Looking for a solution propagating in the $+z$ direction, the classical transmission line formalism yields a z dependence $e^{-\gamma z}$. Hence derivatives with respect to z are replaced by multiplications by $-\gamma$. TE and TM modes are most easily investigated by obtaining an equation for each of the longitudinal components separately. Extracting, for example, E_z from the last equation after replacing H_x and H_y by their values from the first two equations yields

$$E_z = \frac{1}{j^2 k^2} \left[\gamma \left(\frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} \right) + \frac{\partial^2 E_z}{\partial x^2} + \frac{\partial^2 E_z}{\partial y^2} \right] \quad (4)$$

Usually the third Maxwell's equation yields

$$E_z = -\frac{1}{k^2} \left(\gamma^2 E_z + \frac{\partial^2 E_z}{\partial x^2} + \frac{\partial^2 E_z}{\partial y^2} \right) \quad (5)$$

or

$$[\nabla_t^2 + (k^2 + \gamma^2)]E_z = 0 \quad (6)$$

A similar equation can be obtained for any other component, and in particular for H_z . Defining

$$p^2 \triangleq \gamma^2 + k^2 \quad (7)$$

yields

$$(\nabla_t^2 + p^2)(E_z \text{ or } H_z) = 0 \quad (8)$$

the scalar eigenvalue Helmholtz equation. The eigenvalues are p^2 , defined by Eq. (7). To each eigenvalue there corresponds at least one eigenfunction, solution of the equation. If there is more than one eigenfunction, the solutions are said to be degenerate. This is the case, for instance, in a square waveguide for the solutions which have as the only difference the orientation of the electromagnetic field with respect to the two sides of the waveguide.

Equations similar to Eq. (8) can be obtained also for E_x and H_x , and for E_y and H_y , respectively. The fact, however, that the longitudinal components of electric and magnetic fields are not coupled—which is not the case when the medium filling the guide is inhomogeneous or anisotropic—makes solutions easy to calculate when the boundary conditions do not introduce a coupling between the two longitudinal components. It will be shown that this is the case for uniform waveguides filled with homogeneous and isotropic medium.

2.2. Waveguide Modes

The absence of coupling between the two longitudinal components in Eq. (8) yields separate solutions for modes with no H_z called *TM modes* (also sometimes called *E modes* because of nonzero E_z) and modes with no E_z called *TE modes* (also sometimes called *H modes* because of nonzero H_z). The general solution can be any linear combination of any TE and TM modes [2]. The separation of solutions for uniform, homogeneous, and isotropic waveguides in two classes, TE and TM modes, respectively, is particularly useful because, once solutions have been obtained either for TE or for TM modes, all the transverse components can be calculated from the longitudinal components. The appropriate rearrangement of Eq. (3) yields as an example

$$E_x = \frac{k}{p^2} \left(\frac{1}{j\eta} \frac{\partial H_z}{\partial y} - \frac{\gamma}{k} \frac{\partial E_z}{\partial x} \right) \quad (9)$$

and the relation between the transverse and longitudinal components can be rewritten as [14]

$$\begin{aligned}\bar{\mathbf{E}}_t &= \frac{1}{p^2} (-\gamma \nabla_t E_z + jk\zeta \bar{\mathbf{a}}_z \times \nabla_t H_z) \\ \bar{\mathbf{H}}_t &= \frac{1}{p^2} (-\gamma \nabla_t H_z - jk\eta \bar{\mathbf{a}}_z \times \nabla_t E_z)\end{aligned}\quad (10)$$

In summary, one has the general relations:

TE modes (H)	TM modes (E)
$(\nabla_t^2 + p^2)H_z = 0$	$(\nabla_t^2 + p^2)E_z = 0$
$\bar{\mathbf{H}}_t = -\left(\frac{\gamma}{p^2}\right)\nabla_t H_z$	$\bar{\mathbf{E}}_t = -\left(\frac{\gamma}{p^2}\right)\nabla_t E_z$
$\bar{\mathbf{E}}_t = \left(\frac{jk\zeta}{p^2}\right)\bar{\mathbf{a}}_z \times \nabla_t H_z$	$\bar{\mathbf{H}}_t = -\left(\frac{jk\eta}{p^2}\right)\bar{\mathbf{a}}_z \times \nabla_t E_z$

(11)

For both types of modes, boundary conditions are the vanishing of the tangential electric field at perfect electric walls and magnetic field at perfect magnetic walls, respectively.

2.2.1. Equivalent Transmission Lines. The previously obtained equations contain partial derivatives. An equivalence can be found between the expressions relating the transverse components and transmission line equations. Separating indeed the transverse and longitudinal variables by defining

$$\begin{aligned}\bar{\mathbf{E}}_t &\triangleq V(z)\bar{\mathbf{e}}_t(\bar{\mathbf{r}}_t) \\ \bar{\mathbf{H}}_t &\triangleq I(z)\bar{\mathbf{h}}_t(\bar{\mathbf{r}}_t)\end{aligned}\quad (12)$$

one observes that the vectors $\bar{\mathbf{e}}_t$ and $\bar{\mathbf{h}}_t$ are transverse but do not vary in z , while $V(z)$ and $I(z)$ are amplitude coefficients as a function of the coordinate z . It should be noted that at the right side of both equations each of the two terms of the products are only defined with respect to a complex arbitrary constant that may multiply one term

and divide the other: only their products are defined. Looking after an equivalence with transmission line equations, one has

$$\begin{aligned} V(z) &= V_+ e^{-\gamma z} + V_- e^{+\gamma z} \\ I(z) &= Y_0 (V_+ e^{-\gamma z} - V_- e^{+\gamma z}) \end{aligned} \quad (13)$$

where Y_0 is the characteristic admittance of the transmission line. The parameters Z_0 and γ are now to be calculated, in view of determining the parameters of the line: Z -series impedance in Ω/m , and Y shunt admittance in S/m . Those are different for TE and TM modes, respectively.

Investigating first the *TM modes*, the first Maxwell's equation shows that the transverse curl of \bar{e}_t is zero. Hence the transverse field derives in the transverse plane from a complex scalar *electric potential*:

$$\bar{e}_t = -\nabla_t \phi \quad (14)$$

This potential is proportional to E_z . Considering only one traveling wave, and introducing Eq. (12) into Eq. (10) yields

$$Y_0 \bar{h}_t = \left(\frac{jk\eta}{\gamma} \right) \bar{a}_z \times \bar{e}_t \quad (15)$$

Defining

$$Y_0 \triangleq \left(\frac{jk\eta}{\gamma} \right) K \quad (\text{S}) \quad (16)$$

where K is an arbitrary complex constant, depending on the complex constants unwritten in Eq. (12) to be determined, yields

$$\bar{h}_t = \left(\frac{1}{K} \right) \bar{a}_z \times \bar{e}_t \quad (17)$$

from which can be deduced

$$E_z = \frac{p^2}{jk\eta K} I(z) \phi \quad (18)$$

Hence, the potential is proportional to E_z and satisfies the same equation:

$$(\nabla_t^2 + p^2) \phi = 0 \quad (19)$$

When the wall is a perfect electric conductor, the longitudinal electric field vanishes at the wall, and so does the potential. There is a particular case, however—the potential may be a nonzero constant when p^2 is zero. This is the case for the TEM mode, which may exist if the guide has more than one conductor; the TEM mode is a special case of a TM mode. The parameters Z and Y of the equivalent transmission line *for the transverse components* can be

calculated using

$$Z = \frac{\gamma}{Y_0} \quad \text{and} \quad Y = \gamma Y_0 \quad (20)$$

which yields (Fig. 1)

$$Z = \frac{\gamma^2}{jk\eta K} (\Omega/\text{m}); \quad Y = jk\eta K \quad (\text{S}/\text{m}) \quad (21)$$

or:

$$Z = \frac{p^2 - k^2}{(\sigma + j\omega\epsilon)K} = \frac{p^2}{P(\sigma + j\omega\epsilon)K} + \frac{j\omega\mu}{K} \quad (22)$$

$$Y = (\sigma + j\omega\epsilon)K$$

It is observed that, if there are no losses in the medium filling the guide, the equivalent circuit has a highpass characteristic with a cutoff frequency given by:

$$\frac{\mu\omega_c}{K} = \frac{p^2}{\epsilon K \omega_c} \quad \text{from which} \quad \omega_c = pc \quad (23)$$

where c is the phase velocity in the medium supposed to be infinite.

Proceeding similarly for the *TE modes*, it can be shown that \bar{h}_t now depends upon a complex scalar *magnetic potential*, that the wave admittance also contains an arbitrary complex constant to be determined, that the potential is proportional to H_z , and that it satisfies the same equation as before:

$$(\nabla_t^2 + p^2) \Psi = 0 \quad (24)$$

The boundary conditions to be satisfied on perfect electric walls impose the normal derivative of the magnetic potential to vanish. The parameters of the equivalent transmission line are

$$\begin{aligned} Z &= \frac{\gamma}{Y_0} = \frac{jk\zeta}{K} = \frac{j\omega\mu}{K} \\ Y &= \frac{\gamma^2 K}{jk\zeta} = \frac{p^2 - k^2}{ik\zeta} K = \frac{p^2 K}{j\omega\mu} + (\sigma + j\omega\epsilon)K \end{aligned} \quad (25)$$

which are represented in Fig. 2. The equivalent circuit also exhibits a highpass characteristic, and the cutoff frequency is given by the same expression as for TM modes.

The equivalent circuits in Figs. 1 and 2 are not dual. This is because magnetic losses have not been introduced for the medium. The circuits would be dual if those losses were introduced. It can be seen that the equivalent circuits for the transverse components of TE and TM modes, respectively, are dual in the absence of any loss in the medium.

2.2.2. Eigenvalues, Power, and Impedance Level. Equations (19) and (24) are eigenvalue equations. They only have solutions—eigenfunctions—for an infinite number of

Figure 1. Equivalent circuit of TM modes, illustrating series impedance and parallel admittance.

discrete values of the eigenvalues p^2 . To each eigenvalue correspond one, or more in the case of degeneracy, eigenfunctions that determine the spatial distributions of the transverse fields. Those spatial distributions are called the *modes* of the waveguide. Equation (7) describes the dispersion characteristic of each mode: it expresses the variation of the propagation constant as a function of frequency and of the parameters of the medium. Certain properties of the eigenvalues can be demonstrated using Green's theorems [5]. In particular they are equal to the ratio of integrals over the cross section of the square of the absolute values of the gradient of the potential and of the potential, respectively, for TE as well as for TM modes:

$$p^2 = p^{*2} = \frac{\int_A |\nabla_t \theta|^2 da}{\int_A |\theta|^2 da} \quad \theta = \phi \text{ or } \Psi \quad (26)$$

Hence the eigenvalues

1. Are real and positive, even in the presence of losses in the medium
2. Do not depend on the properties of the medium filling the guide, as long as the medium is homogeneous and isotropic
3. Depend entirely on the geometry of the cross section of the guide

There is an interest in expressing the complex power traveling along the guide identically to the classical expression of lumped circuit theory $VI^*/2$. Calculating the complex power S in the $+z$ direction by using Poynting's vector integrated over the cross section A yields the classical expression:

$$S = \frac{1}{2} VI^* \quad (27)$$

provided one imposes

$$K^* \triangleq \int_A |\bar{e}_t|^2 da \quad (28)$$

This shows that to obtain Eq. (27) the unknown complex constant K must be real. It also shows that the value of K remains unknown, because no more equations can be used to specify the value of this constant; for TE and TM modes

Figure 2. Equivalent circuit of TE modes, illustrating series impedance and parallel admittance.

the impedance of the equivalent transmission is not uniquely specified, and its level is arbitrary. This is why, when calculating the three expressions of power for TE and TM modes

$$\frac{V}{I}; \quad \frac{2S}{|I|^2}; \quad \frac{|V|^2}{2S} \quad (29)$$

identical values are not found [15]. The TEM mode is the only field configuration for which the concept of characteristic impedance is rigorously valid, and the three expressions in Eq. (29) yield the same value. Unfortunately, in most references the existence of the unknown constant for TE and TM modes is not stated explicitly. From this point on, it will be put equal to 1. This has consequences:

1. Equation (28) with $K^* = 1$ can be used as a normalization condition for the fields.
2. Equation (26) reduces to

$$p^2 \int_A |\theta|^2 da = 1 \quad (30)$$

which will be used to determine the integration constants when integrating the Helmholtz equation.

TE and TM modes, as well as the TEM mode in a more-than-one-conductor waveguide, have been shown to be the solutions of waves propagating in a waveguide. To actually exist in the guide, however, an adequate excitation transducer must be available. Its geometry has to be compatible with the geometry of the electromagnetic configuration of the launched modes, as will be demonstrated later.

2.2.3. Dispersion Diagram, Active and Reactive Power. Equation (7), defining the eigenvalues, can be written as

$$\gamma^2 = p^2 - \left(\frac{\omega}{c}\right)^2 \quad (31)$$

in the absence of losses in the medium filling the guide. It relates the propagation constant to the frequency. The propagation constant vanishes at the cutoff frequency, which determines the cutoff wavelength:

$$\omega_c = pc; \quad \lambda_c \frac{c}{f_c} = \frac{2\pi}{p} \quad (32)$$

Variations of γ^2 and $\gamma = \alpha + j\beta$ are represented in Fig. 3. At frequencies below cutoff the propagation constant is real. There is attenuation and the value of the attenuation constant is

$$\alpha = \sqrt{p^2 - \omega^2 \mu \epsilon} \tag{33}$$

At zero frequency the value of the attenuation constant is p and the curve $\alpha - \omega$ is an ellipse. At frequencies above cutoff the propagation constant is imaginary. There is propagation; the value of the propagation constant is

$$\beta = \sqrt{\omega^2 \mu \epsilon - p^2} \tag{34}$$

and the curve $\beta - \omega$ is hyperbolic with the straight line $\beta = \omega/c$ as an asymptote for any value of p . At high frequencies indeed the wavelength decreases, the electric distance between the walls increases, and the propagation approaches free-space propagation. At frequencies of operation the waveguide modes are dispersive and the dispersion increases when the frequency decreases down to the cutoff frequency. The mode having the lowest cutoff frequency, hence the smallest eigenvalue p , is called the *dominant mode*. It is most common to operate at a frequency located between the lowest cutoff frequency and the cutoff frequency of the next higher-order mode, so that only one mode propagates, the dominant one. To optimize this fre-

quency range, sometimes called the *bandwidth*, appropriate waveguide dimensions are chosen, in particular for the rectangular waveguide.

From Eq. (34) one determines the guide wavelength, the phase velocity, and the group velocity for each mode:

$$\lambda_g \triangleq \frac{2\pi}{\beta} = \frac{2\pi}{\sqrt{\left(\frac{\omega}{c}\right)^2 - p^2}} = \frac{1}{\sqrt{\left(\frac{1}{\lambda_0}\right)^2 - \left(\frac{p}{2\pi}\right)^2}} \tag{35}$$

$$v_{ph} = \frac{\omega}{\beta} = \frac{c\lambda_g}{\lambda_0}$$

$$v_g = \frac{\partial\omega}{\partial\beta} = \frac{c^2\beta}{\omega} = \frac{c\lambda_0}{\lambda_g}$$

It is observed that, for each mode, the product of the phase velocity and of the group velocity is equal to the constant c^2 . For only one traveling wave, the complex power of Eq. (27) can be written

$$S = P + jQ = \frac{1}{2} |V +|^2 Y_0^* e^{-2\alpha z} \tag{36}$$

with

$$P = \frac{1}{2} |V +|^2 e^{-2\alpha z} \text{Re } Y_0 \quad Q = - \left(\frac{1}{2}\right) |V +|^2 e^{-2\alpha z} \text{Im } Y_0 \tag{37}$$

where the admittance Y_0 is complex and is equal to

$$\text{For TM modes: } Y_{0E} = jk\eta/\gamma = \frac{\sigma + j\omega\epsilon}{\alpha + j\beta}$$

$$\text{For TE modes: } Y_{0H} = \gamma/jk\zeta = \frac{\sigma + j\beta}{j\omega\mu}$$

For no losses in the medium, these expressions reduce to the following:

1. For $\omega > \omega_c$: Real power is transmitted. There is no energy storage.
2. For $\omega < \omega_c$: Power is purely imaginary. No real power is transmitted and there is energy storage. The energy is capacitive for TM (E) modes and inductive for TE (H) modes: TM modes below cutoff store electric energy while TE modes below cutoff store magnetic energy. Hence, capacitors and inductors are designed at centimeter and millimeter wavelength by creating a limited region of space along the waveguide that concentrates the appropriate modes below cutoff. A resonant circuit is similarly designed around a frequency where the stored electric and magnetic energies of modes below cutoff compensate. Those regions of stored energy are centered on obstacles of the appropriate geometry, creating supplementary boundary conditions to be satisfied by higher-order modes, which are below cutoff.

Metallic waveguides can transport a significant power. Its value depends on the medium filling the guide, surface

Figure 3. Dispersion diagram of typical modes, illustrating cut-off frequencies.

quality, humidity, pressure, possible temperature elevation, and frequency. If the guide is filled with dry air, the electric field may not go beyond 3 MV/m, which corresponds to a power range of 10 MW at 4 GHz and 100 kW at 40 GHz. Discontinuities and irregularities in the waveguide may impose a security factor of 4 or more. Furthermore, losses in copper walls are of the order of 0.03 dB/m at 4 GHz and 0.75 dB/m at 40 GHz (5).

2.2.4. Wall Losses. The losses in a metallic waveguide wall can be calculated by considering the metal wall as a perturbation of the perfectly conducting wall and using skin effect formulation. The formulation is valid as long as the skin depth is small compared with a distance around the periphery in which the magnetic field of the lossless guide changes considerably. Hence the formulation is not valid near corners unless that magnetic field is zero at the corner and may not be valid for modes of very high order, which, however, are seldom of great interest in practice. A number of results are given in 4 for rectangular and circular metal-walled guides, as well as for coaxial lines and other lines which are not of the guide type.

2.3. Specific Geometries

2.3.1. Rectangular Waveguide. The guide with a rectangular cross section has an inside horizontal width a (coordinate x) and vertical height b (coordinate y) with $a > b$. The identical eigenvalue Eq. (19) for TM modes and Eq. (24) for TE modes are solved by separation of variables and the potentials are the Cartesian eigenfunctions sine and cosine. The general solution for the potentials is

$$\text{Potential} = C(\cos ux \text{ or } \sin ux)(\cos vy \text{ or } \sin vy)$$

where C is an integration constant to be determined and u and v are constituents of the eigenvalue:

$$p^2 = u^2 + v^2 \neq 0 \quad (38)$$

Investigating first the TM modes, imposing the electric potential to vanish in $x=0$, a and in $y=0$, b yields the general solution

$$\phi_{mn} = C_{Emn} \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \quad (39)$$

where the product mn has to be different from zero, because of the sine functions. To each mn combination there corresponds a mode TM_{mn} . The integration constant C_{Emn} is determined by

$$p_{mn}^2 = u^2 + v^2 = \left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 \quad (40)$$

and

$$p_{mn}^2 \int_A |\phi_{mn}|^2 da = 1 \quad (41)$$

from which

$$C_{Emn} = \frac{2}{p_{mn}\sqrt{ab}} \quad (42)$$

The transverse components are calculated using Eq. (14):

$$\begin{aligned} \bar{e}_{t,mn} &= -C_{mn} \left(\bar{a}_x \frac{m\pi}{a} \cos \frac{m\pi}{a} x \sin \frac{n\pi}{b} y \right. \\ &\quad \left. + \bar{a}_y \frac{n\pi}{b} \sin \frac{m\pi}{a} x \cos \frac{n\pi}{b} y \right) \\ \bar{h}_{t,mn} &= C_{mn} \left(\bar{a}_x \frac{n\pi}{b} \sin \frac{m\pi}{a} x \cos \frac{n\pi}{b} y \right. \\ &\quad \left. - \bar{a}_y \frac{m\pi}{a} \cos \frac{m\pi}{a} x \sin \frac{n\pi}{b} y \right) \end{aligned} \quad (43)$$

As for TE modes, the boundary conditions impose the normal derivatives of the magnetic potential to vanish at the walls, which yields cosine solutions

$$\Psi_{mn} = C_{H,mn} \cos \frac{m\pi x}{a} \cos \frac{n\pi y}{b} \quad (44)$$

where the sum $m+n$ has to be different from zero. To each mn combination corresponds a mode called TE_{mn} . The integration constant $C_{H,mn}$ is determined by the same equations as for TM modes, which yields

$$C_{H,mn} = \frac{2}{p_{mn}\sqrt{ab}} \quad (45)$$

when m and n are different from zero and

$$C_{H,mn} = \frac{\sqrt{2}}{p_{mn}\sqrt{ab}} \quad (46)$$

when m or n is zero. The transverse components are

$$\begin{aligned} \bar{e}_{t,mn} &= C_{mn} \left(\bar{a}_x \frac{n\pi}{b} \cos \frac{m\pi}{a} x \sin \frac{n\pi}{b} y \right. \\ &\quad \left. - \bar{a}_y \frac{m\pi}{a} \sin \frac{m\pi}{a} x \cos \frac{n\pi}{b} y \right) \\ \bar{h}_{t,mn} &= C_{mn} \left(\bar{a}_x \frac{m\pi}{a} \sin \frac{m\pi}{a} x \cos \frac{n\pi}{b} y \right. \\ &\quad \left. + \bar{a}_y \frac{n\pi}{b} \cos \frac{m\pi}{a} x \sin \frac{n\pi}{b} y \right) \end{aligned} \quad (47)$$

The smallest eigenvalue is obtained when the integer n related to the smallest dimension b is zero. Hence the dominant mode is the TE_{10} . For a lossless medium, its

Figure 4. Fields and wall currents of dominant mode in rectangular waveguide, showing current source and sink.

parameters are

$$\begin{aligned} \Psi_{10} &= C_{10} \cos \frac{\pi x}{a} \\ C_{10} &= \frac{\sqrt{2a/b}}{\pi} \\ p_{10} &= \frac{\pi}{a} \\ \omega_{c10} &= \frac{\pi c}{a} \\ \lambda_{c10} &= 2a \\ \beta_{10} &= \left[\left(\frac{\omega}{c} \right)^2 - \left(\frac{\pi}{a} \right)^2 \right]^{1/2} \text{ at } \omega > \omega_c \\ \lambda_{g10} &= \left[\left(\frac{1}{\lambda_0} \right)^2 - \left(\frac{1}{2a} \right)^2 \right]^{-1/2} = \lambda_0 \left[1 - \left(\frac{\lambda_0}{2a} \right)^2 \right]^{-1/2} \end{aligned} \tag{48}$$

The fields of a traveling wave of the dominant mode have only three components:

$$\begin{aligned} \vec{E}_t &= -\bar{a}_y C_{10} V_+ \frac{\pi}{a} \sin \frac{\pi x}{a} e^{-j\beta_{10}z} \\ \vec{H}_t &= \bar{a}_x C_{10} V_+ \frac{\pi \beta_{10}}{\omega \mu} \sin \frac{\pi x}{a} e^{-j\beta_{10}z} \\ H_z &= C_{10} V_+ \left(\frac{\pi}{a} \right)^2 \frac{1}{j\omega \mu} \cos \frac{\pi x}{a} e^{-j\beta_{10}z} \end{aligned} \tag{49}$$

The transverse fields are in phase in time and in space, while H_z is out of phase with them, both in time and in space. Figure 4 represents the fields and surface current of the dominant mode along one-half guide wavelength. Hence the dominant mode is linearly polarized in the electric field. Calculating the cutoff frequencies of the first higher-order modes, it can be seen that to improve the bandwidth the height b must be chosen smaller than half the width a .

Calculating the three power expressions Eq. (29) for the dominant mode, normalized with respect to the factor $(b/a)Z_0$, respectively yields the values 1.57, 1.23, and 2.00, which shows that the differences are significant. Hence matching for instance a rectangular to a circular waveguide may offer serious difficulties. It seems that the square root of the product of 1.57 by 2.00 leads to the most convenient result for the power, although the reason is not certain [16]. The mode impedances and the parameters of interest for all the modes can be calculated according to the general theory developed earlier. Mode configurations can be found in a number of references [4,10,17,18].

Equation (40) shows that the eigenvalues, hence the cutoff frequencies, depend on the dimensions of both sides of the cross section of the guide. Furthermore, the height b must be smaller than $a/2$ to optimize the frequency range in which only the dominant mode propagates. For these reasons rectangular waveguides have specified dimensions [17] and corresponding normalized frequency bands have been defined. The most common bands are the following:

L	1.12–1.70 GHz
S	2.6–3.95 GHz
C	3.94–5.99 GHz
X	8.2–12.4 GHz
Ku	12.4–18.8 GHz
K	18.0–26.5 GHz
Ka	(or Q) 26.5–40 GHz
O	40–70 GHz
V	50–75 GHz
W	75–110 GHz

2.3.2. Ridge Waveguide. A waveguide that has the cross section as shown in Fig. 5 is called a *ridge waveguide*; it has a central ridge added either to the top or bottom or both of a rectangular section. Its interesting

Figure 5. Cross section of a ridge waveguide.

electromagnetic property is that the cutoff frequency is lowered because of the capacitance effect at the center and could in principle be made as low as desired by decreasing the gap width sufficiently. Of course, the impedance of the guide also decreases as the gap is made smaller. Because of the increased effective length of the periphery, the attenuation is larger than in a usual rectangular waveguide. One of the important applications is as a nonuniform transmission system for matching purposes, obtained by varying the depth of ridge as one progresses along the guide [18].

Calculation of cutoff frequencies is rather easy if one remembers that, at cutoff, there is no variation in the z direction, so that waves reflect from sidewall to sidewall in a transverse direction at or below cutoff. Thus, at cutoff, the ridge waveguide can be considered as a short-circuited parallel-plane waveguide with infinite width in the z direction. The case of the dominant mode, like all the modes with no variation in the y direction, is particularly easy to calculate. Starting in the x direction from the vertical sidewall, which is a short circuit at the end of the transverse equivalent transmission line, one first has a parallel-plate waveguide per unit length in the z direction, then a capacitance because of the abrupt change in height, then again a parallel-plate waveguide with reduced height up to the middle of the cross section. There the impedance is either infinity or zero, depending on whether the mode is odd or even as a function of the electric field. The second half of the cross section is identical to the first half just described. The transverse resonance frequency, hence the cutoff frequency of the mode, can easily be calculated in terms of transmission-line parameters, as well as wavelength and impedance [19]. For the double-ridge waveguide, the impedance is twice that of the simple-ridge waveguide. Fundamental sources are Refs. 20 and 21.

2.3.3. Circular Waveguide. The circular waveguide has a circular cross section of radius a . The eigenvalue Eq. (19) for TM modes and Eq. (24) for TE modes are written in polar form for the transverse coordinates and solved again by separation of variables $r\phi$. The potentials are the polar eigenfunctions sine and cosine. The general solution for the potentials is

$$\theta = [A_m J_m(pr) + B_m y_m(pr)](\cos m\phi + \alpha \sin m\phi) \quad (50)$$

where m is an integer, possibly equal to zero, when the guide is of circular symmetry, which ensures a periodic solution in the polar angle, and where J_m and Y_m are the

Bessel functions of first and second kinds, respectively. The functions Y_m are sometimes called *Weber* or *Neumann functions*. They are singular at the origin $r = 0$. They have hence to be excluded from the solutions for a hollow guide. They have, however, to be included in the solutions for a coaxial cable or guide, and the general solution in that case will include a linear combination of both functions J and Y . In the case of the one-conductor circular waveguide, the general solution reduces to

$$\theta(r, \phi) = C_m J_m(pr)(\cos m\phi + \alpha \sin m\phi) \quad (51)$$

The choice of the cosine or sine function depends only on the polarization of the field, and all the modes are spatially degenerate. An elliptical polarization will be obtained by linearly combining the two orthogonal polarizations. In the following, only the cosine variation will be considered.

For *TM modes* the scalar potential must be zero at the wall:

$$J_m(p_e a) = 0 \quad (52)$$

which determines the eigenvalues p_{emn} from the arguments $em_n = p_{em}na$ for which the J_m functions vanish and yield:

$$\phi_m = C_{em} J_m(p_e r) \cos m\phi \quad (53)$$

where the first index m is the order of the function J_m and the second n relates to the order of the zeros with increasing argument.

For *TE modes* the normal derivative of the potential must vanish at the wall

$$J'_m(p_h a) = 0 \quad (54)$$

which determines the eigenvalues p_{hmn} from the arguments $hmn = p_{hm}na$ for which the J_m functions are extremum, and yields

$$\Psi_m = C_{hm} J_m(p_h r) \cos m\phi \quad (55)$$

where the first index m still is the order of the function J_m and the second n relates to the order of the extreme with increasing argument. There is a degeneracy that is typical of the circular waveguide—the TE_{0n} modes have the same eigenvalue as the TM_{1n} modes since a property of the Bessel functions is

$$J'_0(pr) = -J_1(pr) \quad (56)$$

For TM and for TE modes, the field configurations can be calculated from the general theory and the normalization conditions. The following results are obtained. TE

modes

$$\begin{aligned} \Psi_{mn} &= C_{hmn} J_m(p_{hmn}r) \cos m\phi \\ J'_m(h_{mn}) &= 0 \\ C_{hmn} &= \frac{1}{h_{mn} \sqrt{\pi} \sqrt{1 - (m/h_{mn})^2} J_m(h_{mn})} \\ &\text{multiplied by } \sqrt{2} \text{ if } m \neq 0; \text{ by } 1 \text{ if } m = 0 \\ \bar{h}_t &= C_{hmn} \left[-\bar{a}_r p_{hmn} J'_m(p_{hmn}r) \cos m\phi \right. \\ &\quad \left. + a_\phi \frac{m}{r} J_m(p_{hmn}r) \sin m\phi \right] \\ \bar{e}_t &= C_{hmn} \left[\bar{a}_r \frac{m}{r} J_m(p_{hmn}r) \sin m\phi \right. \\ &\quad \left. + \bar{a}_\phi p_{hmn} J'_m(p_{hmn}r) \cos m\phi \right] \end{aligned}$$

TM modes

$$\begin{aligned} \phi_{mn} &= C_{emn} J_m(p_{emn}r) \cos m\phi \\ J_m(e_{mn}) &= 0 \\ C_{emn} &= \frac{1}{e_{mn} \sqrt{\pi} J'_m(e_{mn})} \\ &\text{multiplied by } \sqrt{2} \text{ if } m \neq 0; \text{ by } 1 \text{ if } m = 0 \\ \bar{e}_t &= C_{emn} \left[-\bar{a}_r p_{emn} J'_m(p_{emn}r) \cos m\phi \right. \\ &\quad \left. + a_\phi \frac{m}{r} J_m(p_{emn}r) \sin m\phi \right] \\ \bar{h}_t &= C_{emn} \left[-\bar{a}_r \frac{m}{r} J_m(p_{emn}r) \sin m\phi \right. \\ &\quad \left. - \bar{a}_\phi p_{emn} J'_m(p_{emn}r) \cos m\phi \right] \end{aligned}$$

Comparing the successive order of zeros and extrema of Bessel functions shows that the *dominant mode* is the TE₁₁ mode. Its eigenvalue corresponds to the first maximum of the function J_1 and has the following characteristics:

$$\begin{aligned} p_{h11} &\cong \frac{1.84}{a} \\ \Psi_{11} &= C_{h11} J_1(p_{h11}r) \cos \phi \\ \omega_{h11} &= p_{h11}c \cong \frac{1.84c}{a} \\ \lambda_c &\cong \frac{2\pi}{1.84a} \end{aligned} \tag{57}$$

It is apparent that the wavelength at the cutoff frequency of the dominant mode is of the order of the guide circumference, while being larger than $2a$. Hence, the cutoff frequency of a circular waveguide of radius a is lower than that of a rectangular waveguide of width a . The transverse

fields of the dominant mode are

$$\begin{aligned} \bar{h}_t &= -\bar{a}_r C J'_1(pr) \cos \phi + \bar{a}_\phi \frac{C}{r} J_1(pr) \sin \phi \\ \bar{e}_t &= \bar{a}_r \frac{C}{r} J_1(pr) \sin \phi + \bar{a}_\phi C J'_1(pr) \cos \phi \end{aligned} \tag{58}$$

The TE_{0n} modes exhibit the interesting property of having losses that decrease when the frequency increases. As an example, the TE₀₁ mode has the following characteristics:

$$\begin{aligned} \Psi_{01} &= C J_0(p_{h01}r) \text{ with } p_{h01} \cong \frac{3.83}{a} \\ \bar{h}_t &= \bar{a}_r C p_{h01} J_1(pr); \bar{e}_t = -\bar{a}_\phi C p_{h01} J_1(pr) \end{aligned} \tag{59}$$

Hence the transverse fields vanish at the wall and induce no wall losses. The only wall losses are due to the field longitudinal component. Calculating the proportionality between the H_z component of a TE mode and the scalar potential yields

$$H_z = \frac{p^2}{jk\zeta} kV(z)\Psi \tag{60}$$

which shows that when the medium is lossless H_z is inversely proportional to the frequency. Hence losses decrease with increasing frequency. A number of mode configurations can be found in Refs. 4,10,17, and 18.

2.3.4. Coaxial Waveguide. Coaxial lines are among the most commonly used of all transmission lines, largely because of the convenient construction and the nearly perfect shielding between fields inside and outside of the line. They are commonly used up to 10–20 GHz. The range of impedances that may be obtained most conveniently in the TEM mode is about 30–100 Ω. Above 15 GHz and up to ~30 GHz the most common coaxial lines are rigid. In addition to the TEM mode, higher-order TE/TM-mode solutions can also exist. They are usually cutoff and are important essentially as reactive effects near junctions of the line, although they occasionally may enter as additional propagating modes in the transmission system. Higher-order TE and TM modes are calculated as indicated for the circular waveguide and the general solution is Eq. (50), where Bessel functions of both the first and second kind are to be used. The transcendental equations are more complicated than for the one-conductor circular guide. The solutions determine the values of the cutoff frequency, for any mode type and any particular sizes. Solution of the transcendental equations is obtained by graphical methods or by consulting published tables. More information is found in Refs. 10 and 18.

There are a number of normalized connectors for coaxial cables and waveguides. They are characterized by a maximum admissible standing wave ratio, due to very severe tolerances. In a rigid coaxial guide with no dielectric, the inside conductor is maintained in position by using special techniques [22].

The usual frequency limitation for using coaxial cable at microwaves is its specific attenuation, which is the sum of copper and dielectric losses. Analytical expressions are found for instance in Ref. 23. The specific attenuation of a good coaxial cable is of the order of 1 dB/m. When calculating the attenuation, the voltage breakdown, and the maximum power as a function of the ratio of the outside to the inside radii of an air-filled coaxial line, it appears that there is a minimum for the attenuation and a maximum for the voltage breakdown and for the maximum power in the approximate range of 30–80 Ω for the characteristic impedance, which explains why most coaxial lines and cables have an impedance of 50 or 75 Ω .

2.3.5. Elliptical Waveguide. An elliptical waveguide is a uniform region in which the transverse cross section is of elliptical form [24]. The rectangular coordinates xy of the cross section are related to the coordinates of the confocal ellipse and confocal hyperbola. The boundary ellipse is defined by the coordinate as a function of which the major and minor axes as well as the eccentricity and the focal distance can be expressed. Mode functions for TE and TM modes are derived from Mathieu functions, eigenfunctions of Helmholtz equation in elliptical coordinates [25]. When the eccentricity decreases, the elliptical boundary reduces to a circular one and the Mathieu functions degenerate into circular functions. Correspondingly, the confocal coordinates become the polar coordinates.

The field components can be calculated for each mode according to the general theory. The cutoff frequencies are expressed in terms of the roots of the functions, determined by the boundary conditions, and the semifocal distance. An alternative expression in terms of the eccentricity of the boundary ellipse is obtained by use of the elliptic integral formula for the length of the boundary ellipse. Computation of power flow and attenuation in elliptical guides involves numerical integration of the Mathieu functions over the guide cross section. Some mode patterns are shown in Ref. 10.

2.4. Radial Waveguide

2.4.1. Cylindrical Cross Section. The transverse cross section of a radial waveguide with cylindrical cross section is a complete cylindrical surface of a given height. The classical circular cylindrical coordinate system is appropriate to a region of this type. Radial waveguides are encountered in many of the resonant cavities used in microwave oscillator tubes, filters, and so on. Free space can be regarded as a radial waveguide of infinite height. The transverse electromagnetic field in radial waveguides cannot be represented, in general, as a superposition of transverse vector modes; there exists only a scalar representation that, for no H_z field, is expressible in terms of TM modes and, for no E_z field, in terms of TE-type modes [10].

In a radial waveguide the concept of guide wavelength loses its customary significance because of the nonperiodic nature of the field variation in the transmission direction. Consequently the usual relation between guide wavelength and cutoff wavelength is no longer valid. The cutoff wavelength however is still useful as an indication

of the propagating or nonpropagating character of a mode. The radial waveguide is a two-conductor system and supports a TEM mode. TE and TM modes are calculated according to the general theory (10).

2.4.2. Cylindrical Sector Cross Section. In this case the transverse cross section has a given aperture, limited by vertical metallic planes. Such devices have been used for quite some time as specific radar antennas. They have a wall formed by one conductor only, hence no TEM mode can propagate. Furthermore, there is no periodic symmetry in the horizontal plane, which alters the solutions with respect to the cylindrical situation. TE and TM modes are calculated according to the general theory [10].

2.5. Spherical Waveguide

Free space can be considered as a nonuniform transmission region or spherical waveguide. The cross sections transverse to the radial transmission direction are complete spherical surfaces. In practice many spherical cavities may be conveniently regarded as terminated spherical guides. The dominant mode is spherical TEM. TE and TM modes are based on the eigenfunctions in the spherical coordinate system, that is, the associated Legendre functions, or Legendre polynomials [15]. The corresponding fields are calculated for both types of mode [10]. The r dependence of the mode fields is determined by the spherical transmission-line behavior of the mode voltage and current. As for the modes in radial waveguide, the concepts of cutoff wavelength and guide wavelength lose their customary significance in a spherical waveguide because of the lack of spatial periodicity along the transmission direction. The cutoff wavelength of both TE and TM modes is, however, indicative of the regions wherein these modes are propagating or nonpropagating. For regions such that the wavelength is smaller than a given cutoff wavelength the mode fields decay spatially like $1/r$ and hence may be termed propagating; conversely, for wavelength larger than the cutoff wavelength the mode fields decay faster than $1/r$ and may, therefore, be termed *nonpropagating*.

2.6. Conical Waveguide

Conical waveguides are of a two-conductor type. The transmission direction is along the radius r and the cross sections transverse thereto are spherical surfaces bounded by the two cones. The conical waveguide is seen to bear the same relation to a spherical waveguide that a coaxial waveguide bears to a circular guide. Examples of conical guides are provided by tapered sections in coaxial guide, conical antennas [15], and others. Because of the two conductors, the conical waveguide propagates a TEM mode. The r dependence of this dominant mode voltage and current is determined by the spherical transmission-line equations, which reduce in this case to uniform transmission-line equations. The attenuation constant of this mode is given in Ref. 10, as well as some expressions related to TE and TM modes.

3. ADVANCED TOPICS

3.1. Periodic Waveguides

Periodic waveguides are periodically loaded waveguides. Hence, strictly speaking, they should not be considered in this article. The importance they have had, the fact that they are “empty” except for a periodic loading by infinitely thin obstacles, in most cases capacitive, and the beauty of their electromagnetic properties certainly deserves some attention [26].

Periodic waveguides have been used in the microwave-tube family as traveling-wave amplifiers and backward-wave oscillators, as microwave and video filters, and as linear particle accelerators. Most of the mathematics and point of view in studying such structures is the same as that used in analyzing the vibrations of a periodically weighted string or in studying the propagation of light or electrons through a crystal lattice [27]. The basic theorem is from Floquet [28]. The theorem applies to a second-order linear differential equation with periodic coefficients and is quite general [5]. It says that a solution of the equation differs from the solution one period away by only a complex factor. Applied to a periodically loaded transmission line it may be translated as follows [26]. For a given mode of propagation at a given steady-state frequency the fields at one cross section differ from those one period away only by a complex constant. The theorem is valid whether the structure contains loss or not so long as it is periodic.

The study reveals that periodic transmission lines have the following characteristics:

1. There are passbands and stopbands, which is to say certain frequencies can propagate down the structure with little or no attenuation, whereas other frequencies are attenuated at a rapid rate. These frequencies occur in bands.
2. There is no unique phase velocity. At any frequency for a given mode of propagation there is found to be an infinite number of discrete velocities characterizing the mode.
3. The fields may be analyzed in a Fourier series, often called *space harmonics* or *Hartree harmonics*, each component of the series having a different phase velocity but all having the same group velocity. Typically, there will be many components with phase velocities less than the velocity of light, yielding slow waves.
4. Structures can be treated from both the field and the circuit standpoint, each approach being useful in certain problems.

To understand what causes passbands and stopbands, assume that circular infinitely thin irises are placed periodically in a circular waveguide propagating the TM_{10} mode. This is the structure used in the linear electron accelerator. At each obstacle there will be transmission and reflection. An observer stationed in the plane of an iris will see that there are certain frequencies for which the reflections from the successive obstacles returning to her/

Figure 6. Dispersion diagram ($\omega - \beta$) for iris-loaded waveguide, with dashed line for unloaded waveguide.

him add in phase. These frequencies will be nearly equal to the frequencies for which the one-way phase shift between obstacles in the unperturbed guide is any multiple of π . These frequencies are the centers of the stopbands. At other frequencies the accumulated reflections from an infinite length of guide add up to zero, and transmission occurs. Those frequencies make up the passbands. Figure 6 shows an $\omega - \beta$ diagram for this structure. The dashed line represents the $\omega - \beta$ line for the waveguide without obstacles. Electric field representations illustrate the situation in more detail.

Two important theorems on lossless periodic transmission lines have been derived [26]. One is that the time-average electrical stored energy per period is equal to the time-average magnetic stored energy per period in the passbands. The other is that the time-average power flow in the passbands is equal to the group velocity times the time-average electrical and magnetic stored energy per period divided by the period.

3.2. Oversize Waveguides

As has already been mentioned, the TE_{0n} and in particular the TE_{01} modes in circular waveguides have received a good deal of attention for possible long-distance propagation of energy, especially at millimeter waves. The reason is that the amplitude of the fields at the wall decrease when frequency increases, and current and conductor losses approach zero at very high frequency. Attenuations as low as 1.3 dB/km have been attained. Since electric field lines are circular, modes of this class are often described as *circular electric modes* [18]. A major problem arises because the mode is not the dominant one. Such guides are known as *oversize guides*. For the TE_{01} mode, there are four other propagating modes, with cutoff frequency below the TE_{01} cutoff. Furthermore, since the frequency is well above cutoff, many other modes are in the propagating range. This raises several practical problems; for instance, the desired mode must be excited with reasonable purity, and, coupling from the desired mode to undesired

modes must be avoided. A general solution is to devise mode filters that discriminate against the undesired modes but cause negligible attenuation to the desired one [18].

Suggestions have been advanced also for using a large-size rectangular waveguide, whose transverse dimensions are just less than $\lambda \times 2\lambda$, to increase the CW power-handling capability. Trapped-mode resonance effects in such a system have been investigated experimentally, and it has been shown how to suppress them [29].

3.3. Mode Excitation

The general theory shows that an infinity of TE and TM modes may exist in a hollow waveguide. Furthermore, in a more-than-one-conductor waveguide a TEM mode may also exist. This possible TEM mode has a zero cutoff frequency while the TE and TM modes each have a specific cutoff frequency. Each of those modes will attenuate below cutoff, storing energy as has been seen, and propagate above cutoff. The modes however are only the possible solutions of the equations, submitted to the boundary conditions. As mentioned earlier, modes will actually exist in the waveguide only if they are properly excited, which requires an adequate transducer at the generator end of the waveguide. To adequately detect the power transmitted by those modes, such a transducer is also necessary at the detector end of the waveguide. For the sake of completeness, it should be mentioned that irregularities or non-uniformities in the waveguide may also excite other modes, causing what is called *mode conversion*. This may be an advantage or a disadvantage, depending on the application. This subject is, however, outside the scope of this article.

Equation (12) and the associated boundary conditions may yield the amplitudes of the fields, under specific excitation conditions. As already stated, a linear combination of all the modes, with adequate coefficients, is the general solution of Maxwell's equations for the waveguide [2]. If for a given excitation specific mode coefficients are found to be zero because the corresponding modes do not satisfy the boundary conditions of the excitation, those modes will not be excited and will not actually exist in the guide. Using Eq. (12) and adding the expressions of the longitudinal components [Eqs. (18) and (60)] for both directions of propagation yields the system:

$$\begin{aligned}\bar{\mathbf{E}}_t &= \sum_i (V_{+i}e^{-\gamma_i z} + V_{-i}e^{\gamma_i z})\bar{\mathbf{e}}_{t,i} \\ \bar{\mathbf{H}}_t &= \sum_i Y_{0i}(V_{+i}e^{-\gamma_i z} - v_{-i}e^{\gamma_i z})\bar{\mathbf{h}}_{t,i} \\ E_z &= \sum_i \frac{p_i^2}{jk\eta} Y_{0i}(V_{+i}e^{-\gamma_i z} - V_{-i}e^{\gamma_i z})\phi_i \\ H_z &= \sum_i \frac{p_i^2}{jk\zeta} (V_{+i}e^{-\gamma_i z} + V_{-i}e^{\gamma_i z})\psi_i\end{aligned}\quad (61)$$

The sums are on the indices m and n for TE as well as for TM modes. All the modes are considered, propagating and attenuating. The coefficients V are calculated from the

boundary conditions. To obtain a unique solution in a given volume the tangential electric field must be imposed on part of the bounding surface and the tangential magnetic field on the remaining part of the surface. In a waveguide with lossless conducting walls the tangential electric field is known to be zero on the walls. Hence it is sufficient to impose two conditions in reference planes; for instance, \mathbf{E}_{tan} in $z=0$ and \mathbf{H}_{tan} in $z=L$, or \mathbf{E}_{tan} and \mathbf{H}_{tan} in $z=0$, and so on. Use is then made of orthogonality conditions obtained from Green's theorems (see Green's function methods). As an example, if \mathbf{E}_{tan} is specified in $z=0$ and \mathbf{H}_{tan} in $z=L$, the following system is obtained:

$$\begin{aligned}V_{+j} &= (e^{\gamma_j L} + e^{-\gamma_j L})^{-1} \left[e^{\gamma_j L} \int_A \bar{\mathbf{E}}_{\text{tan}} \cdot \bar{\mathbf{e}}_{t,j}^* da + Z_{0j} \int_A \bar{\mathbf{H}}_{\text{tan}} \cdot \bar{\mathbf{h}}_{t,j}^* da \right] \\ V_{-j} &= (e^{\gamma_j L} + e^{-\gamma_j L})^{-1} \left[e^{-\gamma_j L} \int_A \bar{\mathbf{E}}_{\text{tan}} \cdot \bar{\mathbf{e}}_{t,j}^* da - Z_{0j} \int_A \bar{\mathbf{H}}_{\text{tan}} \cdot \bar{\mathbf{h}}_{t,j}^* da \right]\end{aligned}\quad (62)$$

If \mathbf{E}_{tan} and \mathbf{H}_{tan} are specified in $z=0$, for instance, by specifying a current sheet \mathbf{K} in part of the plane $z=0$, which could be a transverse electron pencil in that plane, and terming 1 the negative z region and 2 the positive z region yields as source conditions:

$$\bar{\mathbf{a}}_z \times (\bar{\mathbf{H}}_{t,1} - \bar{\mathbf{H}}_{t,2}) = \bar{\mathbf{K}}_t \quad \text{and} \quad \bar{\mathbf{E}}_{t,1} = \bar{\mathbf{E}}_{t,2}\quad (63)$$

Suppose that matching at both ends of the guide finally yields

$$V_{-j}^{(1)} = V_{+j}^{(2)} = \frac{Z_{0j}}{2} \int_A \bar{\mathbf{e}}_{t,j}^* \cdot \bar{\mathbf{K}}_t da\quad (64)$$

Hence, specifying \mathbf{K} yields the coefficients of the excited modes. Equation (64) clearly shows as an example that the modes for which the transverse fields are perpendicular to the current source are not excited.

4. SPECIFIC RECENT DEVELOPMENTS

4.1. Theory

A new causal power-normalized waveguide equivalent-circuit theory has been established very recently (as of 2003). Unlike its predecessors, it results in network parameters usable in both the frequency and time domains in a broad class of waveguides. Enforcing simultaneity of the voltages, currents, and fields and a power normalization fixes all the parameters of the new theory within a single normalization factor, including both the amplitude and phase of the characteristic impedance of the waveguide. Enforcing simultaneity also ensures that the network parameters of passive devices are causal [30]. On the other hand, an efficient finite-element method has been developed for

waveguide analysis. It uses Hermitian polynomials to interpolate the axial field component (E_z or H_z) and some of its derivatives at the nodal points, rather than the field components, as in the Lagrangian interpolation case, with significant advantages: (1) a significant reduction of the matrix order needed to compute the eigenvalues and eigenfunctions, (2) smooth axial components and continuous transverse field components, and (3) low-cost refinement of the mesh near nonconvex corners of the waveguide [31]. Furthermore, it has been shown that the upper and lower bounds of the cutoff frequencies of TE and TM modes in many waveguides bounded by metallic lossless walls and that may be hollow or comprise one or more inner conductor, can be computed using two independent methods. The methods are applicable whenever the cross section of the waveguide can be split up into several regions bounded by lines having a fixed coordinate and includes several cases of particular interest. The theory is illustrated with a rectangular coaxial line [32].

Mode coupling in waveguiding structures has been revisited using the theory of Morse critical points from catastrophe theory. The traditional coupled-mode formalism has a clear analytical connection with functional properties of the characteristic determinant in the vicinity of these points. Numerical results have been obtained for a variety of waveguiding structures like printed-circuit transmission lines, planar slab waveguides, and shielded microstriplike lines [33]. It has then been shown that two distinct regimes of modal behavior exist in the vicinity of the mode-coupling region, resulting from the presence of frequency branchpoints of the dispersion function. These branchpoint singularities are intimately associated with the Morse critical points [34]. Overmoded waveguides, with waveguide diameter large in terms of wavelength, have been a subject of interest for many years. These waveguides have been analyzed, when coated with a lossy material, particularly for their attenuation properties as a function of coating material, layer thickness, and frequency. It has been shown that, when the coating material is not too lossy, the low-order modes are highly attenuated even with a thin layer of coating. Hence, this coated waveguide may serve as a mode suppressor of the low-order modes, which can be particularly useful for reducing the radar cross section of a cavity structure such as a jet engine inlet [35,36].

On the other hand, how waveguide modes can transform into surface waves has been investigated. An asymptotic form of the characteristic equation that describes wave propagation at near-infrared wavelengths in small core hollow circular waveguides has been developed. Analytic solutions for the transverse and axial propagation constants have been obtained. They show that the TE_{11} and TM_{01} modes transfer to surface waves as the guide radius is increased to values much greater than at cutoff [37].

Twists may be required in oversized waveguide used for low-loss transmission at the higher microwave and millimeter-wave frequencies. The unwanted mode conversion in such twists has been calculated from numerical integration of the coupled mode equations, considering simultaneous coupling of the five lowest-order modes coupled in

a twist. Twists with tapered or linearly varying rates of twist have been shown to be superior in medium- or broad-band applications to those with uniform twist rate, such as those normally made commercially for single-mode waveguide [38].

An important problem is the determination of the input impedance of a probe when inserted into a waveguide [12]. A method-of-moments formulation based on a nonuniform surface current approximation and on the use of an impressed electric field arising from a semifinite rectangular waveguide Green function has been used to calculate the input impedance of a coaxial probe in a semifinite waveguide. The probe surface current was shown to vary significantly with probe angle [39]. Furthermore, the probe field distribution and mutual coupling between two probes arbitrarily located in a rectangular waveguide have been studied by means of dyadic Green's function, field transformation, and reaction concept. The waveguide is semi-infinite. Lengths, feeding points, and orientations of the two probes in the waveguide are arbitrary [40]. General formulas of the mutual impedance between probes have been established for a circular waveguide as well [41].

Nonuniform waveguides have been studied for some time with application to antennas and tapers. Furthermore, irregularities in waveguide walls are important to investigate as well. For typical tolerances the reflection coefficients are very small ($<10^{-3}$), but the results are important in precise six-port measurements. First-order results have been derived for the reflection coefficient of a waveguide with slightly uneven walls. Specific analytical and numerical results have been given for rectangular waveguides and coaxial transmission lines [42].

Finally, the expected properties of high- T_c superconductor waveguides have recently been evaluated. It has been shown that these devices would offer the potential of 100 GHz bandwidth for transmission over long distance with low attenuation, with a wider dynamic range than optical systems. The potential applications in local area networks have been investigated [43].

4.2. Arbitrary Cross Section

The treatment of waveguides with arbitrary cross section is a challenging task to solve on the computer, in particular when looking for speed and simplicity. A surface integral equation approach has been used where the E field is transformed into a matrix equation using the method of moments. The salient features of this method are speed, simplicity, and the absence of any spurious modes while treating waveguides of arbitrary cross section. It leads to the calculation of cutoff wavenumbers for a variety of cross sections and of modes [44].

On the other hand, it has been shown that the fields associated with the TM_{01} mode of an elliptical waveguide are qualitatively different from those that have appeared in the standard literature since the early 1950s. The method used was to solve the wave equation by numerical integration, using an iterative technique to obtain the relevant eigenvalues [45]. Cutoff frequencies of eccentric circular-elliptical metallic waveguides have also been

calculated [46]. A perturbation method has been used to obtain the attenuation constant and Q factor of several TEM, TE, and TM modes in confocal annular elliptic waveguides and resonators. Comparisons between the first higher-order mode in a confocal annular elliptic waveguide and a coaxial waveguide with the same cutoff frequency and cross-sectional propagating area reveals a lower attenuation in elliptical geometry. The Q factor has been found to be 20–40% higher in elliptical geometry than in a coaxial resonator with the same volume and resonant frequency [47].

Approximate analytical expressions have been derived by a perturbation technique for the cutoff wavenumbers and the corresponding modes in annular-cross-sectional waveguides having inner conductors of small radius. Waveguides with circular and rectangular outer boundary have been considered [48].

The mode analysis for parabolic waveguides has been performed. The approach is simple. It is based on one-dimensional analytic continuation. It yields exact values for parabolic cylinder functions. The difficulty in obtaining accurate values for these functions has long been an impediment to mode analysis for parabolic waveguides [49].

When looking at toroidal waveguides, it can be shown that the explicit solution of Maxwell's equations cannot be given. For small curvature the field equations can, however, be solved by means of an analytical approximation method. A perturbation method has provided eigenvalues and eigenfunctions containing first-order correction terms for the full spectrum of all modes including the degenerate ones [50].

A general analysis for the modal characterization of multiconnected uniform, hollow, conducting waveguides has been performed. It is relevant to waveguides with an outer conductor for which analytical Green functions are known and inner conductors described by integral equations. The TEM mode space is analyzed, and singularities of the integral equations are studied for determining the higher-order modes. Spurious solutions arise as a result of the structure of the integral equations for multiconnected waveguides; criteria to discard such modes are presented [51].

4.3. Ridged Waveguide

Ridged waveguides have found many applications in microwave and millimeter-wave devices. Their advantages include large single-mode broadband operation, large dominant cutoff wavelength, and low impedance characteristics. A magnetic field integral equation approach has been developed for the analysis and design of ridged waveguides. It has been pointed out that bandwidth estimates in previous works were erroneous because of the neglect of the TE_{11} mode. Design curves on cutoff frequency, bandwidth, attenuation, and waveguide impedance have been provided [52,53]. On the other hand, a coupled-integral equations technique has been used to determine the cutoff frequencies of all TE and TM modes of a ridged rectangular waveguide. The technique analyzes both symmetric and asymmetric situations. Basis functions, which include the edge conditions and mirror images in the waveguide walls, are used in the moment method solution of the integral equations [54]. Generalized rectangular and circu-

lar ridge waveguides have been analyzed using the mode-matching method, yielding the characteristic impedance, attenuation, and power-handling capability of several types of rectangular and circular ridge waveguides [55].

4.4. Grooved Waveguide

High-power devices such as gyrotrons have necessitated the development of specific structures, in particular grooved waveguides and, more specifically, axially multiple-grooved waveguides. A method has been developed to calculate the TE mode fields and cutoff frequencies of an axially multigrooved rectangular waveguide. The method has been extended to a rectangular waveguide with multiple grooves cut into two of its broad wall parallel surfaces [56]. The development of the gyrotron has also brought more attention to the corrugated waveguide, dielectric-loaded or not, in particular nonperiodic configurations. The Floquet theorem is used to express the field distribution in the vacuum region, while an eigenfunction expansion is employed in each dielectric region, with the appropriate boundary conditions applied at the interfaces, leading to an infinite number of equations. The system is solved numerically by truncation [57]. It should also be mentioned that radiation from the open end of a corrugated hybrid-mode circular waveguide has excellent properties, such as low sidelobes, cross-polarization levels, axial beam symmetry, and low attenuation. The general characteristics of electromagnetic scattering from a circular waveguide with rectangular corrugations have been calculated, in terms of frequency and waveguide geometry. Dyadic Green functions and Fourier transforms were used to get the field in terms of modal currents induced on the corrugation openings [58]. The grooved waveguide is considered for use at millimeter wavelengths as an alternative to classical waveguides such as the H guide and the rectangular guide. It is low loss, with low-dimensional tolerance and the ability to handle higher power capacities at high frequencies. Most of these properties are attributed to the open endedness of the guide, which reduces wall losses. The grooves in the guide trap the fields locally and prevent radiation from leaking out along the open parts of the guide. Multimodal analysis of an open rectangular groove waveguide is available for both TE and TM modes [59].

1. BASIC INFORMATION

1.1. Definition of Wavelength for a Monochromatic Source

Wavelength meters are instruments designed to measure the wavelength of an electromagnetic wave. Electromagnetic waves are the classic way to represent modifications of the space surrounding a moving electrically charged body. Time-varying electric and magnetic fields are produced and can be sensed. Wavelength is a well-established parameter when considering a monochromatic (single-frequency) plane wave propagating in vacuum. It is the distance between two planes, measured along the direction of propagation of energy, where the phase and its derivatives have the same values. For the purpose of electromagnetic

wave propagation, vacuum is a homogeneous, linear, isotropic, and nondispersive medium. This implies that the reaction of the medium to the electromagnetic wave's presence is instantaneous and does not depend on the location of the observation or on the amplitude and direction of propagation of the wave.

Nonconducting materials, like gases, ceramics, or polymers, are called dielectrics. They have electric charges, but the charges are not allowed to move freely within the medium. When an electromagnetic wave moves through such a medium, it stimulates the charges to oscillate around their equilibrium positions. These oscillating charges radiate an electromagnetic field that adds up to the impinging field. The resulting field is the field propagating in the medium. The reaction of the medium will then change the conditions of propagation when compared with those of vacuum. In general, a real medium is non-homogeneous, nonlinear, nonisotropic, and dispersive. This implies that the reaction will be dependent on location in the medium and the amplitude and direction of propagation of the field, that it will not be instantaneous, and that some of the wave energy will be transferred to other spectrum bands (harmonic generation). In a first approximation, it is useful to reduce the complexity of the medium reaction to something close to that of the vacuum, taking only into account a reduction of the propagation speed associated with the summing action. The speed of the wave in a perfect dielectric material is less than that in vacuum, and the ratio of the speed value in vacuum to the speed value in the medium is the index of refraction. It is then possible to reconsider the propagation of infinite plane waves and use the same definition for the wavelength. As the speed of propagation is less in the medium than in vacuum, the distance between the planes will be less, which implies that the wavelength in the material is less than that for vacuum. Consequently, the wavelength value is dependent on the medium in which the wave is propagating.

1.2. Wavelength or Frequency?

Wavelength is measured along the space (position) axis. However, if we measure the field associated with a monochromatic electromagnetic wave at a fixed position, we observe that this field oscillates regularly with time. The rate of this oscillation per unit of time is the frequency. The frequency is then measured along the time axis. The wavelength (λ) times the frequency (ν) is equal to the speed of light in the medium (v).

The two measurements, wavelength and frequency, are dual quantities. They reveal two aspects of the same physical interaction. The wavelength is related to the "wave" aspect of electromagnetic energy, whereas the frequency is related to the "corpuscular" aspect, the photon or quantum of energy. The wavelength is helpful for evaluating the probability of finding photons, which are the unit of exchange of electromagnetic energy with the surroundings during an interaction. The energy E of each photon is $E = h\nu$, where h is the Planck constant. The frequency ν is not dependent on the medium of propagation. The measurement of frequency is preferred by signal

engineers, whereas wavelength is the preferred choice for opticians.

1.3. Spectral Distribution

Another important aspect of wavelength measurement is the distribution of optical energy as a function of the wavelength. When a pure monochromatic wave is considered, there is no problem with the definition of wavelength because all the energy is concentrated on a single value. However, this is not realistic. Such a distribution would be generated by a noise-free source that evidently does not exist. This brings up a point related to the spectral distribution of the electromagnetic energy for which wavelength has to be measured.

Generally speaking, the energy emitted by a source is distributed over a given range of wavelengths or frequencies. This is called the *spectral distribution* of the source. If the spectral distribution is a symmetrically decreasing function around a central wavelength value, this value is defined as the nominal wavelength. If the distribution is not symmetrical and/or reveals many intense peaks, the wavelength definition is more complex. Giving a specific value of nominal wavelength is then somewhat arbitrary and must be justified by stating the prevailing conditions for the selection. In the next section, wavelength (or frequency) definitions will be given more in detail.

Particular cases that will require specifications are modulated and pulsed sources. According to the Fourier analysis of such signals, a periodically modulated source will produce a number of sidelobes, each being the replica of the unmodulated original source, whereas a pulse has a broad spectrum whose width is related to the reciprocal of its time duration.

1.4. Instruments Used for Wavelength Measurement

In the subsequent sections, we describe different instruments performing wavelength measurements. First, we present a brief overview of the principle of operation of the two most commonly used instruments, which are the spectrometer-based and the interferometer-based wavelength meters.

If the source has a broad spectrum, spectrometers are the instruments commonly used. The spectrum of the source is first analyzed using a dispersive element such as a prism or a grating. The intensity and central wavelength are then recorded by an appropriate detector for a number of dispersive element settings. This method results in a spectral analysis from which a nominal wavelength can be identified if the instrument has been previously calibrated.

As wavelength is defined in the space-domain, its accurate measurement will be done essentially through interferometric phenomena. Let us first consider a monochromatic source. The source signal is first split into space, allowing the various parts to travel different trajectories and recombine to produce interference patterns. Calibrated measurement of the periodicity revealed in the pattern gives an indication on the wavelength. We will later describe in detail the principle of operation of the

most commonly used type of interferometers used to measure wavelengths: Michelson, Fizeau, and Fabry–Perot interferometers.

Before we proceed with the description of the different wavelength meters encountered in research laboratories and in the industry, Section 2 gives some information regarding basic electromagnetic wave theory as well as useful wavelength-measurement definitions.

2. BASIC ELECTROMAGNETIC WAVE THEORY AND USEFUL WAVELENGTH-MEASUREMENT DEFINITIONS

2.1. Theoretical Background

The resolution of Maxwell's equations in vacuum gives rise to plane electromagnetic waves. Such waves are characterized by an electric field (units of volts per meter) and a magnetic field (units of amperes per meter), mutually oriented in perpendicular directions, which are themselves perpendicular to the direction of propagation of the plane wave, given by the direction of the Poynting vector (units of watts per square meter). The latter is defined as the cross-product between the electric and magnetic fields. The modulus of the Poynting vector represents the instantaneous intensity of the light beam. As both fields are perpendicular to the direction of propagation, such waves are called transverse electromagnetic (TEM) waves. Practical collimated laser beams are often well described by plane waves.

2.2. Fluctuating Electric Field

We define a Cartesian component of the electric field labeled $E^{(r)}(\mathbf{r}, t)$, which is a real field variable at a point represented by a position vector \mathbf{r} , at a time t . For any real light beam $E^{(r)}(\mathbf{r}, t)$, will be a fluctuating function of time. For example, laser fields exhibit intensity noise as well as phase noise.

In order to simplify the present analysis, we do not use the real field variable $E^{(r)}(\mathbf{r}, t)$. We rather consider its corresponding analytic signal $E(\mathbf{r}, t)$, which has only spectral components for the positive frequency part of the spectrum. This complex field is defined as

$$E(\mathbf{r}, t) = \frac{1}{2} E^{(r)}(\mathbf{r}, t) + j \frac{1}{2} \mathcal{H}\{E^{(r)}(\mathbf{r}, t)\} \quad (1)$$

where $\mathcal{H}\{E^{(r)}(\mathbf{r}, t)\}$ denotes the Hilbert transform of the real field.

The field intensity at the position \mathbf{r} and at time t is defined as

$$I(\mathbf{r}, t) = E^*(\mathbf{r}, t)E(\mathbf{r}, t) \quad (2)$$

The field intensity gives the beam power distribution over the beam shape.

We are usually concerned with stationary fields, in which case the statistical properties are independent of the origin of time. Such a field could be characterized by

the correlations of the field at two space-time points,

$$\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = \langle E^*(\mathbf{r}_1, t)E(\mathbf{r}_2, t + \tau) \rangle \quad (3)$$

where $\langle \rangle$ denotes an ensemble average. As the field is stationary, this ensemble average does not depend on t . This function is also called the mutual coherence function [1, Ch. 4]. When evaluated at the same position, it gives the autocorrelation function of the field $\Gamma(\mathbf{r}, \mathbf{r}, \tau)$ at position \mathbf{r} . Moreover, it follows that the autocorrelation function evaluated for a zero delay gives the ensemble average of the field intensity at position \mathbf{r} ,

$$\Gamma(\mathbf{r}, \mathbf{r}, 0) = \langle I(\mathbf{r}, t) \rangle \quad (4)$$

The intensity is constant over time for stationary fields.

According to the generalized Wiener-Khintchine theorem, the cross-spectral density is defined as the Fourier transform of the mutual coherence function,

$$W(\mathbf{r}_1, \mathbf{r}_2, \nu) = \mathcal{F}\{\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)\} \quad (5)$$

The spectral density, also called the spectrum of the light beam at position \mathbf{r} , is then the Fourier transform of its autocorrelation function,

$$W(\mathbf{r}, \mathbf{r}, \nu) = \mathcal{F}\{\Gamma(\mathbf{r}, \mathbf{r}, \tau)\} \quad (6)$$

So the spread of the spectral density is directly related to the decorrelation time. Short decorrelation time gives rise to broad spectrum and vice versa. On proper normalization, the field spectral density could be related to the measured power spectrum.

Usually, the spectral density of the field has important components only over a frequency range much narrower than the frequencies of interest. This case is called quasimonochromatic light. For such situations, the spectral density of the field is often characterized by two global parameters: one giving the position of the spectrum and the other one estimating its width.

2.3. Parameter Definitions

The center frequency could be defined in many ways. We could use the median frequency ν_m , which is the frequency for which half the power of the signal is distributed on each side, so

$$\int_0^{\nu_m} W(\mathbf{r}, \mathbf{r}, \nu) d\nu = \int_{\nu_m}^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu \quad (7)$$

A common way of specifying the position of the spectrum is the most probable frequency ν_{mp} , which is the frequency at which the spectral density of the field is maximum. Finally, the usual frequency value used and measured is the mean frequency, which is

$$\bar{\nu} = \frac{\int_0^{\infty} \nu W(\mathbf{r}, \mathbf{r}, \nu) d\nu}{\int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu} \quad (8)$$

The other parameter is the linewidth of the spectral density of the field. We could define the half-power bandwidth $\Delta\nu_{hp}$ as the symmetrical range around the median frequency containing half the power of the light,

$$\int_{\nu_m - \Delta\nu_{hp}/2}^{\nu_m + \Delta\nu_{hp}/2} W(\mathbf{r}, \mathbf{r}, \nu) d\nu = \frac{1}{2} \int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu \quad (9)$$

The root mean square (rms) width of the spectrum is also often encountered,

$$\Delta\nu_{rms}^2 = \frac{\int_0^{\infty} (\nu - \bar{\nu})^2 W(\mathbf{r}, \mathbf{r}, \nu) d\nu}{\int_0^{\infty} W(\mathbf{r}, \mathbf{r}, \nu) d\nu} \quad (10)$$

Usually, we use a more experimentally convenient definition, which is the full width at half maximum (FWHM) width. This width gives the frequency range over which the spectral density exceeds half its maximum value,

$$\Delta\nu = \nu_2 - \nu_1, \quad W(\mathbf{r}, \mathbf{r}, \nu_{1,2}) = \frac{1}{2} W(\mathbf{r}, \mathbf{r}, \nu_{mp}) \quad (11)$$

For quasimonochromatic light, the effective width of its power spectrum is much smaller than the mean frequency,

$$\frac{\Delta\nu}{\bar{\nu}} \ll 1 \quad (12)$$

All these definitions also apply to wavelength and to wave-number ($\sigma = \nu/\nu$).

2.4. Interference

Let us introduce the concept of interference through a simple experiment. Consider a light beam incident on an opaque screen having two distinct pinholes at positions r_1 and r_2 . The light emerging from these pinholes is observed on a second screen distant from the first one. The electric field at a position \mathbf{r} on the second screen is the sum of two components,

$$E_s(\mathbf{r}, t) = K_1 E(\mathbf{r}_1, t - t_1) + K_2 E(\mathbf{r}_2, t - t_2) \quad (13)$$

where K_1 and K_2 are constant factors and t_1 and t_2 are the propagation delays from the pinholes,

$$t_1 = |\mathbf{r}_1 - \mathbf{r}|/c \quad \text{and} \quad t_2 = |\mathbf{r}_2 - \mathbf{r}|/c \quad (14)$$

The average intensity observed on the second screen is

$$\begin{aligned} \langle I_s(\mathbf{r}, t) \rangle &= |K_1|^2 \langle I(\mathbf{r}_1, t - t_1) \rangle + |K_2|^2 \langle I(\mathbf{r}_2, t - t_2) \rangle \\ &\quad + 2 \operatorname{Re}[K_1^* K_2 \Gamma(\mathbf{r}_1, \mathbf{r}_2, t_1 - t_2)] \end{aligned} \quad (15)$$

This intensity differs from the sum of the intensities of the distinct components. A supplementary term develops, which takes into account the ‘‘correlation’’ between the two beams. This phenomenon is called interference.

For quasimonochromatic beams, the mutual coherence function could be expressed as

$$\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = g(\mathbf{r}_1, \mathbf{r}_2, \tau) e^{j2\pi\bar{\nu}\tau} \tag{16}$$

where $g(\mathbf{r}_1, \mathbf{r}_2, \tau)$ is a slowly varying function of τ , because its bandwidth is much smaller than the mean frequency of the field. In this case, the observed intensity on the second screen is

$$\begin{aligned} \langle I_s(\mathbf{r}, t) \rangle &= |K_1|^2 \langle I(\mathbf{r}_1, t - t_1) \rangle + |K_2|^2 \langle I(\mathbf{r}_2, t - t_2) \rangle \\ &+ 2|K_1 K_2| |g(\mathbf{r}_1, \mathbf{r}_2, t_1 - t_2)| \cos[2\pi\bar{\nu}(t_1 - t_2)] \\ &+ \angle(K_1^* K_2) + \angle g(\mathbf{r}_1, \mathbf{r}_2, t_1 - t_2) \end{aligned} \tag{17}$$

where \angle is defined as the angle. Thus, as we move along the second screen, the intensity varies sinusoidally at the spatial frequency $\bar{\nu}/c$. This variation is the interference fringe pattern. Fringe contrast is measured through their visibility, defined as

$$V(\mathbf{r}) = \frac{\langle I_s(\mathbf{r}, t) \rangle_{\max} - \langle I_s(\mathbf{r}, t) \rangle_{\min}}{\langle I_s(\mathbf{r}, t) \rangle_{\max} + \langle I_s(\mathbf{r}, t) \rangle_{\min}} \tag{18}$$

where the extreme values are evaluated in the neighborhood of the position \mathbf{r} .

When the mutual coherence function vanishes, the visibility is 0. This represents complete incoherence. The other extreme case is called complete coherence. In this case,

$$|\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| = \sqrt{\langle I(\mathbf{r}_1, t) \rangle \langle I(\mathbf{r}_2, t) \rangle} \tag{19}$$

which corresponds to the following visibility:

$$V(\mathbf{r}) = \frac{2|K_1 K_2| \sqrt{\langle I(\mathbf{r}_1, t) \rangle \langle I(\mathbf{r}_2, t) \rangle}}{|K_1|^2 \langle I(\mathbf{r}_1, t) \rangle + |K_2|^2 \langle I(\mathbf{r}_2, t) \rangle} \tag{20}$$

The visibility is 1 if the intensities associated with each beam are equal. Otherwise, perfect contrast is not achieved for complete coherence. In the general case, we experiment partial coherence, so the resulting visibility does not reach 1.

3. SPECTROMETER-BASED WAVELENGTH METERS

In this section, we describe instruments based on spectrometers using prism or diffraction gratings. We discuss their performances and limitations and explain their use as wavelength meters.

3.1. Basic Properties of Spectrometers

3.1.1. Spectrographs or Monochromators?. The difference between the two types of instruments is related to the detection of diffracted/dispersed light: in a spectrograph, a photographic plate or a charge-coupled device (CCD) array is placed in the output focal plane and records the entire spectrum. In a monochromator, a slit and a

Figure 1. Rayleigh criterion for the definition of the spectral resolving power: two lines are resolved when the intensity profile corresponding to λ_1 has its maximum in coincidence with the minimum of the intensity profile corresponding to λ_2 . The interval $\Delta\lambda$ between two resolved wavelengths is the resolution limit.

photodetector are used so that only a portion of the output spectrum is recorded. It is therefore necessary to move the detection system in the output focal plane, or to rotate the dispersive/diffractive element, to obtain the complete spectrum. Both instruments are often referred to as spectrometers in the literature.

3.1.2. Spectral Resolving Power and Rayleigh's Criterion.

The spectral resolving power R is defined by

$$R = \frac{\lambda}{\Delta\lambda} = \frac{\nu}{\Delta\nu} \tag{21}$$

where $\Delta\lambda = \lambda_1 - \lambda_2$ is the smallest separation between two wavelengths λ_1 and λ_2 that the instrument is able to resolve. According to Rayleigh's criterion, illustrated in Fig. 1, two lines are resolved when the intensity profile corresponding to λ_1 has its maximum in coincidence with the minimum of the intensity profile corresponding to λ_2 . The interval $\Delta\lambda$ between two resolved wavelengths, known as the resolution limit, can also be expressed in terms of frequency $\Delta\nu$ or wavenumber $\Delta\sigma$.

The achievable resolving power of a spectrometer is in direct relation with the slit width and its linear dispersion $dx/d\lambda$, which is given by

$$\frac{dx}{d\lambda} = f \frac{d\theta}{d\lambda} \tag{22}$$

where f is the lens focal length and $d\theta/d\lambda$ the angular dispersion. If the entrance slit width is ε_1 , the slit image in the focal plane of the focusing lens will be

$$\varepsilon_2 = \frac{f_2}{f_1} \varepsilon_1 \tag{23}$$

where f_1 and f_2 are, respectively, the focal length of the collimating and focusing lenses of the spectrometer. If we want to be able to resolve two lines at λ_1 and λ_2 , the

separation of their image

$$\Delta x = f_2 \frac{d\theta}{d\lambda} \Delta\lambda = \frac{dx}{d\lambda} \Delta\lambda \quad (24)$$

must be greater than $2\epsilon_2$. It is therefore possible to increase the resolving power by decreasing the input slit width (at the expense of decreasing the amount of light to be detected). However, it will be limited because of diffraction because of the finite aperture a of the dispersive element. When the collimated beam is incident on the prism or grating, it experiences Fraunhofer diffraction resulting in an intensity distribution in $\sin^2(\gamma)(\sin(\pi\gamma)/\pi\gamma)$ with γ the diffraction angle. The central lobe of the distribution has a width equal to $2\lambda/a$ and contains 90% of the incident intensity. The distance between the two maxima in the output plane will be $f_2\lambda/a$, so that the condition for resolving λ_1 and λ_2 becomes

$$\Delta x \geq f_2 \frac{\lambda}{a} \quad \text{or} \quad \frac{\lambda}{\Delta\lambda} \leq a \frac{d\theta}{d\lambda} \quad (25)$$

giving the corresponding resolving power. One must notice that the spectral resolving power is limited by diffraction effects because of the finite aperture a (determined by the size of the prism or diffraction grating) and not by the entrance slit width. When taking into account the entrance finite slit width ϵ_1 , the condition is

$$\Delta x \geq \left(f_2 \frac{\lambda}{a} + \epsilon_1 \frac{f_2}{f_1} \right) \quad \text{or} \quad \Delta\lambda \geq \left(\frac{\lambda}{a} + \frac{\epsilon_1}{f_1} \right) \left(\frac{d\theta}{d\lambda} \right)^{-1} \quad (26)$$

However, there is a lower limit for ϵ_1 [2] resulting in a practical resolving power

$$R = \frac{\lambda}{d\lambda} = \frac{1}{3} a \frac{d\theta}{d\lambda} \quad (27)$$

3.1.3. Free Spectral Range. In the case of a spectrometer, the free spectral range is the wavelength region where the instrument has a one-valued relation between the wavelength and the position $x(\lambda)$ in the focal plane of the focusing lens. For prism spectrometers, it corresponds to the whole wavelength range of the instrument, whereas for grating spectrometers it is related to the diffraction order m .

3.2. Prism Spectrometers

3.2.1. Principle of Operation. A typical arrangement for a prism spectrometer is given in Fig. 2. The entrance slit S illuminated by the light source is placed in the focal plane of a collimating lens L_c . The prism P diffracts the incident collimated beam with an angle dependent on the wavelength. As shown in Fig. 3(a), the angle θ , relative to the incident direction, depends on the prism angle α , the angle of incidence of the beam θ_1 , and the refractive index of the prism material $n(\lambda)$. A focusing lens L_f is used after the prism to image the entrance slit so that the position $x(\lambda)$ of

Figure 2. Typical configuration for a prism spectrometer: the light source illuminates the entrance slit S , which is placed in the focal plane of a collimating lens L_c . The prism P diffracts the incident collimated beam and a focusing lens L_f images the entrance slit so that the position $x(\lambda)$ of the focal point in the x plane is wavelength dependent.

the focal point in the x plane is a function of λ . A wavelength scan can be done either by rotating the prism while keeping the output slit fixed, or the contrary.

3.2.2. Angular and Linear Dispersion. When the prism is used at the minimum deviation [Fig. 3(a)], we have

$$\frac{1}{2} \sin(\theta + \alpha) = n \sin(\alpha/2) \quad (28)$$

Then, it is possible to derive the angular dispersion $d\theta/d\lambda$ by first evaluating $d\theta/dn$. We have

$$\frac{d\theta}{dn} = \frac{2 \sin(\alpha/2)}{\cos[(\theta + \alpha)/2]} = \frac{2 \sin(\alpha/2)}{\sqrt{1 - n^2 \sin^2(\alpha/2)}} \quad (29)$$

The angular dispersion is given by

$$\frac{d\theta}{d\lambda} = \frac{2 \sin(\alpha/2)}{\sqrt{1 - n^2 \sin^2(\alpha/2)}} \frac{dn}{d\lambda} \quad (30)$$

We see that dispersion increases with the prism angle α (and so does the size of the prism) but does not depend on the prism size. Therefore, small prisms can be used for small laser beams while keeping the same angular dispersion. However, the prism must be chosen large enough to prevent diffraction problems and to achieve a large

Figure 3. (a) Illustration of a diffraction prism used at minimum deviation: the beam exits the prism with an angle θ verifying the equation $\frac{1}{2} \sin(\theta + \alpha) = n \sin(\alpha/2)$, where α is the prism angle and n is its refractive index. (b) The limiting aperture of the prism a depends on the height of the prism d and on the incident angle θ_1 following the equation $a = d \cos \theta_1 = b[(\cos \theta_1)/2 \sin(\alpha/2)]$.

spectral resolving power. An equilateral prism with $\alpha = 60^\circ$ is usually chosen as the best compromise. In that case

$$\frac{d\theta}{d\lambda} = \frac{1}{\sqrt{1 - (n/2)^2}} \frac{dn}{d\lambda} \quad (31)$$

For values of n around 1.4 to 1.6, the angular dispersion reduces to

$$\frac{d\theta}{d\lambda} \cong n \frac{dn}{d\lambda} \quad (32)$$

The linear dispersion $dx/d\lambda$ depends directly on the prism material dispersion $dn/d\lambda$ and on the focal length f of L_f . It is given by

$$\frac{dx}{d\lambda} = f \frac{d\theta}{d\lambda} \quad (33)$$

3.2.3. Spectral Transmission and Dispersion of Prism Materials. The transparent spectral range for fused silica prisms is 180 nm to 3000 nm. For shorter wavelengths (VUV region), lithium or calcium fluoride can be used, whereas for longer wavelengths, CaF_2 , KBr, or NaCl are transparent up to 30 μm .

The spectral dispersion $dn/d\lambda$ increases greatly near a region of absorption, making glass (e.g., BK7) an attractive material in the visible and near-ultraviolet regions, whereas quartz is more interesting for the ultraviolet region.

3.2.4. Performance and Limitations. If the collimating and focusing lenses L_c and L_f are not achromatic, their focal length will decrease with wavelength. This effect can be compensated by tilting the image plane so that it matches the focal point for every wavelength. If the plane is tilted by an angle φ , the linear dispersion will be increased by a factor $1/\cos \varphi$.

The resolving power is

$$R = \frac{1}{3} a \frac{d\theta}{d\lambda} \quad (34)$$

where the limiting aperture of the prism a is given by [see Fig. 3(b)]

$$a = d \cos \theta_1 = b \frac{\cos \theta_1}{2 \sin(\alpha/2)} \quad (35)$$

with d the height of the input face of the prism and b the length of its base. At minimum deviation, we have

$$n \sin(\alpha/2) = \sin \theta_1 \quad (36)$$

so that

$$\frac{\lambda}{d\lambda} = b \frac{dn}{d\lambda} \quad (37)$$

is only limited by the size of the prism base and the dispersion. For example, if the prism material has a dispersion $dn/d\lambda$ of 500 cm^{-1} at 633 nm and the prism has a base $b = 50 \text{ mm}$, then $R \leq \frac{1}{3} \times 2500$. A spectrometer with such a prism is then able to resolve two lines separated by $\Delta\lambda = 0.75 \text{ nm}$ at 633 nm.

A prism spectrometer is interesting because it allows an unambiguous determination of wavelengths because of the nature of the equation $x(\lambda)$. Its cost can be low when using a small prism and it is simple to make and to adjust. However, as its spectral resolution is limited, it is mainly used for wavelengths scans over large spectral regions as a preliminary survey work.

3.3. Grating Spectrometers

3.3.1. Principle of Operation. Many configurations have been demonstrated for grating spectrometers. One possibility is to use an arrangement similar to the prism spectrometer (Fig. 2) and replace the prism by a diffraction grating used in transmission. Another way is to use the diffraction grating in reflection. Plane diffraction gratings can be used in a Littrow mounting [Fig. 4(a)] or in the Ebert mounting with a concave mirror [Fig. 4(b)]. A variation of the Ebert mounting is the Czerny–Turner mounting, where two adjacent concave mirrors are used. Many configurations have also been demonstrated using concave diffraction gratings [3].

The input light is first collimated by a lens or a concave mirror. It is then diffracted by the grating that separates the different wavelengths. The refracted light is focused in the detection plane. If an aperture is used, its width determines the wavelength resolution of the spectrometer.

In every case, the diffraction grating acts as a wavelength-selective reflector, by reflecting light into well-defined directions for each incident wavelength. The different reflected beams correspond to the orders of the grating. The general equation for the grating is

$$d(\sin \alpha \pm \sin \beta) = m\lambda \quad (38)$$

Figure 4. (a) Grating spectrometer using a Littrow-mounted grating: the light exiting the input slit is first reflected by the prism and diffracted by the grating. The diffracted light is imaged on the output plane. Note that the slit and the prism are placed in a different plane from the grating so that the light reflected by the grating does not pass twice in the prism. (b) Grating spectrometer using the Ebert mounting configuration: the light exiting the slit is collimated by a concave mirror, diffracted by the grating and imaged in the output plane after a second reflection on the concave mirror.

Figure 5. (a) The diffraction of a beam by a diffraction grating follows the equation $d(\sin \alpha \pm \sin \beta) = m\lambda$, where d is the groove dimension, α and β are the incidence and reflection angles relative to the grating normal, m is the grating order, and λ is the wavelength. (b) Intensity distribution of the reflected beam for $N = 10$. The amplitude of the wave reflected in the direction β results from the interference of the beams reflected by all the grooves illuminated. The corresponding intensity is $I = R_g I_0 \sin^2(N\varphi/2) / \sin^2(\varphi/2)$.

where d is the groove dimension, α and β are the incidence and reflection angles relative to the grating normal, m is the grating order, and λ the wavelength [see Fig. 5(a)]. The amplitude of the wave reflected in the detection β is the superposition of the amplitudes reflected by all the grooves illuminated.

The corresponding intensity is

$$I = R_g I_0 \frac{\sin^2(N\varphi/2)}{\sin^2(\varphi/2)} \quad (39)$$

where R_g is the reflectivity of the grating, I_0 the intensity of the incident wave on each groove, N the number of grooves illuminated, and

$$\varphi = \frac{2\pi}{\lambda} d(\sin \alpha \pm \sin \beta) \quad (40)$$

is the phase difference between two adjacent grooves. Figure 5(b) shows I as a function of φ for $N = 10$. Each maximum occurs when $\varphi = 2k\pi$. In terms of β , the line profile has a base half width of

$$\Delta\beta = \frac{\lambda}{Nd \cos \beta} \quad (41)$$

We can evaluate the angular dispersion from the grating equation to obtain

$$\frac{d\beta}{d\lambda} = \frac{m}{d \cos \beta} = \frac{\sin \alpha \pm \sin \beta}{\lambda \cos \beta} \quad (42)$$

which only depends on α and β and not on the number of grooves. The angular dispersion is reduced to

$$2 \tan \alpha / \lambda \quad (43)$$

in the case of a Littrow-mounted grating ($\alpha = \beta$).

3.4. Possible Monochromator Configurations

A double monochromator is a combination of two single monochromators placed in cascade. This configuration

improves the dynamic range, but the wavelength span is reduced and the losses are increased, degrading the sensitivity. Another possible configuration is the double-pass monochromator, which provides the dynamic range of a double monochromator while keeping the sensitivity and compactness of a single one.

3.4.1. Performance and Limitations. The resolving power R can be expressed from

$$\Delta\lambda = \Delta\beta \left(\frac{d\beta}{d\lambda} \right)^{-1} \quad (44)$$

so that

$$R = \frac{Nd(\sin \alpha \pm \sin \beta)}{\lambda} = mN \quad (45)$$

R depends on the number of illuminated grooves N and on the diffraction order m used. If the finite slit width and diffraction effects are considered, we have:

$$R = \frac{1}{3} mN \quad (46)$$

R is limited physically by the dimensions of the grating. It is advantageous to use a high-order m , but the grating reflectivity might decrease drastically. For example, a $5 \text{ cm} \times 5 \text{ cm}$ grating with 1200 grooves/mm used to first order has a practical resolving power of 2×10^4 . When used at 1550 nm, it is capable of resolving $\Delta\lambda = 0.075 \text{ nm}$.

The main disadvantage of grating spectrometers is the possible ambiguity in interpreting the output spectrum as the different orders will overlap for different wavelengths. A solution consists in using wavelength-selective filters in order to isolate one particular order of diffraction. However, the resolving power is much better than that obtained with a prism spectrometer. It can be increased by using a double-pass configuration where the beam is diffracted once by the grating, then passes into an aperture and diffracted again before being detected.

3.4.2. Wavelength Measurement Using Spectrometers. Both prism and grating spectrometers can be used as wavelength meters. To do so, it is necessary to tune the instrument over the unknown light-source spectrum. Another important aspect is to perform an accurate calibration for the wavelength determination.

One possibility for tuning monochromators is to rotate either the prism or the grating, which causes a different wavelength to be focused on the output slit, placed in front of a detector. Another possibility is to keep the prism or grating fixed and move the slit and photodetector in the output plane. In both cases, the prism or grating angle or the slit-photodetector movement must be controlled precisely and in a repeatable way to allow accurate tuning from measurement to measurement [4].

In the case of spectrographs (no moving parts), the spectrum is recorded at once using a photodetector array, and it is only necessary to know the wavelength calibration along the photodetector array. In order to make sure that the wavelength is correctly assigned, a calibration procedure is required for spectrometers as they do not have an internal wavelength reference. It is necessary to have external reference sources such as spectral lamps or lasers stabilized to atomic or molecular absorption lines. For an accurate calibration, the use of several wavelength references (at least three) is recommended and they should be distributed over the whole spectral range of the instrument. Some commercial instruments now include internal references based on the use of molecular resonances, such as acetylene, to perform internal calibrations (see Table 1).

4. INTERFEROMETER-BASED WAVELENGTH METERS

This section describes wavelength meters using interference phenomenon, including Michelson, Fizeau, and Fabry-Perot interferometers.

4.1. Classification of Interferometers

Optical interferometers can be used to perform a wide variety of precision measurements such as measurement of length, studies of surface structure, measurement of temperature, pressure, and particle velocities. Those measurements are based on the interference phenomena produced by light waves. Wavelength measurement can also be realized with very high precision. In fact, interferometers are the most accurate instruments for measuring the wavelength of an optical source.

Interferometers can be classified as two-beam interferometers or multiple-beam interferometers according to the number of interfering beams. The most common type of two-beam interferometers used to measure wavelength are the Michelson and Fizeau interferometers. The Fabry-Perot interferometer is the most usual type of multiple-beam interferometers.

Wavelength meters based on interference phenomena can be subdivided in two categories; dynamic and static

wavelength meters. The former relies on the displacement of an element. It is the most accurate type of instrument, but it can only perform wavelength measurement on continuous wave (CW) sources. On the other hand, static wavelength meters have no moving parts and can be used to measure wavelength of CW or pulsed sources.

4.2. Michelson-Based Wavelength Meters

The principle of operation of the Michelson interferometer is presented in Fig. 6. The incident beam is first divided by a 50-50 beam splitter that can be either a partially reflecting metal mirror or dielectric film on a transparent substrate. The two beams are next recombined by the same beam splitter on a detector (or a screen). As the second beam passes only one time through the beam splitter, a compensating plate may be used in the second arm to equalize the optical path followed by the two beams, but is not always necessary for small collimated beams.

If the mirror M_2 is moved by Δx , the intensity of the interference pattern on the detector changes sinusoidally. A complete cycle is observed when the optical path difference between the two arms of the interferometer corresponds to one wavelength of the incident light beam. Thus, when a mirror displacement of $\lambda/2$ is performed, a complete cycle is observed.

The wavelength of the incident light beam can be deduced if the interference maxima frequency is measured when the mirror M_2 is displaced at constant speed

$$\lambda = \frac{2v_m}{f} \quad (47)$$

Figure 6. Principle of operation of a Michelson interferometer. An incident beam is divided by a 50–50 beam splitter. The two beams are next recombined by the same beam splitter on a detector. If the mirror M_2 is moved, the intensity of the interference pattern on the detector changes sinusoidally. The wavelength of the incident light beam is deduced if the interference maxima frequency is measured when the mirror M_2 is displaced at constant speed.

where v_m is the displacement speed of moving mirror M_2 and f is the frequency of apparition of interference maxima.

The main problem with the previously described Michelson-based wavelength meter resides in the determination and the accuracy of the displacement speed of the moving mirror. For that reason, Michelson interferometers are rarely used in that configuration unless low accuracy ($\sim 1 \times 10^{-4}$) is sufficient.

The most common type of Michelson-based wavelength meter uses a two-beam interferometry process [5]. In that configuration, a two-beam scanning Michelson interferometer compares the number of fringes obtained by both a reference laser, for which the wavelength is known very accurately, and an unknown laser. Absolute wavelength measurement or CW sources can then be performed. For the two beams, the optical path d is changed by the same and known amount. A typical optical configuration for that type of interferometer is presented in Fig. 7.

With this type of wavelength meter, the wavelength of the unknown laser can be determined by the following relation:

$$\lambda_U = \frac{N_R n_U \lambda_R}{N_U n_R} \quad (48)$$

where N_R and N_U are the number of fringes counted on the reference and input photodetectors (corresponding to the reference and unknown laser), n_R and n_U are the refractive index of the media at the reference and unknown wavelengths, and λ_R is the wavelength of the reference laser. From that equation, it is clear that all parameters in Eq. (48) must be known very accurately. The maximum relative uncertainty of the unknown wavelength λ_U is the sum of the relative uncertainty of each relevant parameter, which are the wavelength reference, number of fringes, the ratio of the refractive indexes, beam misalignment, and wave-front distortion [2, Ch. 4].

The measurement accuracy can be greatly enhanced by improving the wavelength reference's own accuracy.

Figure 7. Commercially available two-beam scanning Michelson-based wavemeter™ (courtesy of Burleigh).

Wavelength references found in current laboratory instruments are relatively simple He–Ne gas lasers with about 10^{-7} absolute accuracy. A more accurate I_2 -stabilized He–Ne laser is often used in laboratory installations where size is of minor concern but is somewhat difficult to implement in a portable instrument. Those type of lasers are calibrated with an uncertainty smaller than 10^{-10} . Recently, some progress has been made in replacing He–Ne lasers at 633 nm by semiconductor lasers, providing a more compact and reliable source for the reference laser [6].

Other sources of error for wavelength determination come from the number of fringes seen by the input and reference detectors. One way to improve the accuracy is to count as many fringes as possible; this can be done by increasing the retroreflector mirror displacement. Unfortunately, this also increases the size of the instrument that, for a commercial instrument, is not suitable. Usually, this technique is implemented in a laboratory environment where space is not a concern. The maximum retroreflector mirror displacement is limited by the coherence length l_c of the reference and unknown laser sources. After a displacement corresponding to one coherence length, no interference pattern can be observed [7]. The coherence length is related to the spectral width of the source and is given by

$$l_c = c/\Delta\nu \quad (49)$$

where c is the speed of light in vacuum and $\Delta\nu$ is the spectral width of the source. From that relation, it is clear that the frequency of a source emitting in a very narrow band of frequency can be determined with greater precision than a broad-band source.

Another way to improve the wavelength-measurement accuracy without increasing the path displacement of the retroreflector mirror is to determine a fractional order number of interference fringes. Techniques such as phase-locking an oscillator to an exact multiple of the frequency of the ac signal from the reference laser [8] or using a vernier method in which the counting cycle starts and stops when the two signals coincide [9] have been proposed. With these techniques, fringe fractions can be determined with an uncertainty of $\frac{1}{500}$ of a fringe [10]. Moreover, vibrations during the measurement must be reduced to a minimum in order to eliminate the frequency jitter on the fringe signal [11].

To eliminate the dispersion of air, the wavelength meter is often operated in a vacuum chamber. If the instrument is operated in air, the index of refraction depends on the wavelength, the total air pressure, the partial pressures of H_2O and CO_2 , and the temperature. All those parameters must be controlled and/or recorded with great precision. Moreover, the ratio of the refractive indices depends on the wavelength difference $\Delta\lambda = \lambda_R - \lambda_U$. The relative uncertainty on the index of refraction depends on the wavelength range. Typically for visible wavelengths, the uncertainty ranges from 10^{-11} ($\Delta\lambda = 1$ nm) to 5×10^{-9} ($\Delta\lambda = 200$ nm).

There are other sources of systematic errors that can influence the achievable accuracy of a two-beam scanning Michelson-based wavelength meter. One of them is the

misalignment of the two beams that causes them to travel slightly different path lengths. As an example, if the two beams are slightly tilted against each other by 10^{-4} rad, the systematic relative error becomes 5×10^{-9} . In the wavelength meter proposed in Fig. 7, the corner cube retroreflector guarantees that the incoming light beam is reflected exactly parallel to its incident direction regardless of a slight misalignment.

Finally, the quality of the optical components can also limit the measurement accuracy. With a surface quality of $\lambda/10$, wavefront distortions are already visible in the interference pattern [2]. Moreover, to minimize diffraction effects particularly important in the infrared region, a large beam diameter should be used. The uncertainty because of diffraction is inversely proportional to the square of the beam diameter [11].

4.2.1. Laboratory and Commercial Instrument. In a laboratory experiment, Ishikawa, Ito, and Morinaga demonstrated a wavelength meter with an accuracy of 4×10^{-10} [10]. In that experiment, the main limitation was caused by a slight optical misalignment between the two beams. An improved version of that wavelength meter was later designed [11]. That time the wavelength uncertainty was evaluated at 7×10^{-11} and was limited by the accuracy of the I_2 -stabilized He–Ne laser.

For the most accurate currently available commercial instrument (Burleigh WA-1500), the wavelength of the unknown laser source can usually be determined to an accuracy of 10^{-7} . In that case, the accuracy is limited by the reference laser, which is a He–Ne gas laser stabilized on its gain curve. Temperature and pressure sensors are used to evaluate the index of refraction of air as the interferometer is not evacuated. Figure 8 presents a picture of that instrument.

4.2.2. Multiwavelength Measurement. One of the disadvantages of the previously described wavelength meter is that it can only perform a single wavelength measurement. However, the previous configuration can be modified to perform multiwavelength measurements. This task is particularly suited to dense-wavelength division multiplexing (DWDM) communication systems. The fringe pattern produced by the unknown laser can be sampled at regular intervals corresponding to the period of the reference-laser interference pattern. A Fourier transform on those data yields the complete spectrum. The resolution or the minimum frequency spacing $\Delta\lambda$ that can be measured by the instrument is directly related to the number of counted fringes [12].

$$\frac{\lambda}{\Delta\lambda} = 2N \quad (50)$$

As for the accuracy, the resolution can be improved by counting as many fringes as possible; this can be done by increasing the retroreflector mirror displacement.

A motionless Michelson interferometer with a fixed path difference Δs can also be used to measure the wavelength of pulsed sources [13]. In such a wavelength meter,

Figure 8. Front view of the Burleigh WA-1500 Michelson-based wavemeter (courtesy of Burleigh).

the incident signal enters the interferometer polarized at 45° . A phase difference $\Delta\phi = \pi/2$ is next introduced between the two polarized components. The interference signal at the exit of the interferometer is recorded separately for both polarizations. From the two interference signals obtained, it is possible to deduce the wavenumber $\sigma = 1/\lambda$ modulo $1/\Delta s$ as all wave numbers $\sigma_m = \sigma_0 + m/\Delta s$ ($m = 1, 2, 3, \dots$) give the same interference signals. If similar interferometers having a path difference in geometric ratios are used, the wavenumber can be deduced without ambiguity. As such an instrument measures the wavenumber, it is called a *sigmometer*.

4.3. Fizeau-Based Wavelength Meters

Fizeau interferometers can be used to perform wavelength measurement [14]. Those static wavelength meters have no moving parts and can measure the wavelength of CW and pulsed sources.

Fizeau interferometers consist of two plates inclined to form a wedge of angle α (see Fig. 9). When plane monochromatic light is incident on that type of interferometer, reflected light forms a series of uniformly spaced interference fringes for which the intensity will vary as

$$I(x) = \frac{1}{2} \left[1 + \cos\left(\frac{2\pi x}{\Lambda} + \phi\right) \right] \quad (51)$$

where $\Lambda = \lambda/(2\alpha)$, x is the distance along the detector array, and ϕ is the phase at $x = 0$. The fringes produced are imaged on a detector array. With a typical interferometer plate spacing of 1 mm and a wedge of 3 min, an accurate measurement of the fringe period can give a wavelength measurement accuracy of 10^{-4} . Moreover, if the phase of

the interference pattern on the detector array is determined accurately [15], the accuracy can go as high as 10^{-7} .

Such an accurate measurement can only be accomplished if the wedge angle and spacing are previously calibrated. Also, the fringe pattern on the detector must approximate as much as possible the sinusoidal pattern of Eq. (51). This is done by ensuring that the incident light has plane-wave fronts. This is accomplished by spatially

Figure 9. Principle of operation of a Fizeau-based wavelength meter. Fizeau interferometers consist of two plates inclined to form a wedge of angle α . When plane monochromatic light is incident on that type of interferometer, reflected light forms a series of uniformly spaced interference fringes for which the intensity will vary. The fringes produced are imaged on a detector array. The fringe period is computed and gives a wavelength measurement.

Figure 10. Front view of the New Focus Fizeau-based wavelength (courtesy of New Focus).

filtering the incident light and by using interferometer plates with excellent flatness. Dispersion effects must also be taken into account for very accurate wavelength measurement. The advantage of the Fizeau wavelength meter is its simple, compact, and robust design. However, the accuracy of such a wavelength meter is usually less than a scanning Michelson-based wavelength meter.

Figure 10 presents a commercially available Fizeau-based wavelength meter. It is worth mentioning that this instrument contains a thin fused silica etalon, a precision input aperture, and a silicon CCD array. As a result of the type of detector array used, this instrument can perform wavelength measurement from 400 nm to 1000 nm. The accuracy of the instrument is 10^{-5} . The instrument is wavelength calibrated at the factory using five different stabilized lasers. The calibration process allows for effective determination of the etalon thickness and to linearize the detector array signal. All the components are housed in a thermally isolated enclosure. The index of refraction of air is mathematically compensated for temperature and pressure variations.

4.4. Fabry–Perot-Based Wavelength Meters

Scanning Fabry–Perot interferometers can be used to perform wavelength measurement, although those instruments are usually used as optical spectrum analyzers. Figure 11 depicts the principle of operation of a Fabry–Perot interferometer. This type of interferometer is made of two highly reflecting mirrors (flat or concave) uniformly spaced by air or a dielectric material [16].

When coherent light is injected on one side of the interferometer, an interference phenomenon is created by the multiple reflections inside the cavity. For that reason, Fabry–Perot interferometers are called multiple-beam interferometers. The interference is constructive and a stationary wave is built when the distance between the two mirrors corresponds to an integer multiple of half wavelengths of the input beam. This condition is given by

$$L = \frac{m\lambda}{2n} \quad (52)$$

Figure 11. Principle of operation of a Fabry–Perot interferometer. This type of interferometer is made of two highly reflecting mirrors (flat or concave) uniformly spaced by air or a dielectric material. When coherent light is injected on one side of the interferometer, an interference phenomenon is created by the multiple reflections inside the cavity.

where L is the distance between the mirrors, m is an integer, and n is the refractive index of the material inside the cavity. When the condition in Eq. (52) is respected, light transmission through the interferometer is maximum. The frequency spacing between the transmission peaks is called the free spectral range (FSR) and is determined by the spacing between the mirrors and by the refractive index of the material inside the cavity. The FSR (in hertz) is given by

$$\text{FSR} = \frac{c}{2nL} \quad (53)$$

The transmission coefficient of an ideal Fabry–Perot interferometer is described by an Airy function [16]

$$\tau(\lambda) = \frac{I_t}{I_0} = \left[1 + \frac{4R}{(1-R)^2} \sin^2 \left(\frac{2\pi nL \cos(\theta)}{\lambda} \right) \right]^{-1} \quad (54)$$

where I_t and I_0 are the input and transmitted intensities, R and T are the mirror reflection and transmission intensity coefficients, and θ is the angle (relative to the mirror plane inside the cavity) of the input beam (usually the input beam is perpendicular to the mirrors, and this angle is 0). Figure 12 presents the transmission of an ideal Fabry–Perot interferometer for various mirror reflectivities at $\theta = 0^\circ$.

From Fig. 12, we see that another parameter, the finesse (F), gives information about the spectral width of each transmission peak. This parameter depends on the mirror reflectivities, optical quality, and alignment. The finesse is defined by

$$F = \frac{\text{FSR}}{\Delta\nu} \quad (55)$$

where $\Delta\nu$ is the full width at half maximum of the transmission peaks. If the finesse is much larger than 1 (which is usually the case), F can be approximated by

$$F = \frac{\pi R^{1/2}}{1-R} \quad (56)$$

Let us now return to the principle of operation of a scanning Fabry–Perot interferometer. If two signals are incident on the interferometer, and if the distance L between

Figure 12. Transmission of an ideal Fabry–Perot interferometer for different mirror reflectivities ($\theta = 0^\circ$, $L = 1.5$ mm, $n = 1$, FSR = 99.9 GHz).

the two mirrors is changed, the interference patterns of both signals appear one after the other. For a given FSR, a high finesse allows the resolution of very closely spaced signals. The resolution is given by [12]

$$\frac{\lambda}{\Delta\lambda} = mF \quad (57)$$

where m is the mode number. The resolution can be increased if a high-order mode is used. This can be done by using a large distance L between the mirrors. In that case, the FSR is reduced; this means that the spectral range is also reduced. Depending on the application, tradeoffs have to be made. As we mentioned previously, that type of instrument is mainly used to perform high-resolution optical spectrum analysis over a relatively narrow spectral range.

However, by counting the fringes obtained by one reference and one unknown laser while the mirrors are scanned over a relatively long displacement, and by using a coincidence technique similar to the vernier technique, wavelength measurement with an accuracy of 1×10^{-7} can be obtained [17]. Also, by carefully calibrating the position of the mirrors against wavelength, and by carefully controlling parameters such as temperature, pressure and alignment, the instrument could be turned into a wavelength meter. Today, Fabry–Perot based wavelength meters are widely used for measuring the wavelength of pulsed lasers. In that case, a plane-mirror Fabry–Perot interferometer is operated in a static configuration (etalons). Such etalons, when illuminating with diverging light, produce a characteristic bull’s-eye fringe pattern corresponding to different angles of incidence. A CCD camera positioned across the fringe pattern is then used along with a computer to reconstruct the interferometer spectrum. The fringes of a Fabry–Perot etalon are

unequally spaced; for that reason, Fizeau etalons, which produce equally spaced fringes, can be used instead of the Fabry–Perot etalon. However, Fabry–Perot etalons have better shaped fringes. Let us also mention that high-accuracy (1 ppm) wavelength measurement of pulsed laser sources can also be performed using two different fixed Fabry–Perot etalons and a reference laser for continuous calibration. In that case, the interference patterns generated by both etalons are recorded by two CCD cameras. The patterns are finally analyzed in a computer and the wavelength is deduced.

5. APPLICATIONS AND ADVANCED TOPICS

5.1. Applications

5.1.1. Scientific Measurements. With the now generalized use of the laser as a scientific investigative tool, wavelength meters have established a firm presence in research and industrial environments. Laser-based measurement techniques reach well beyond the optics field into general physics, chemistry, biology, and engineering. The extremely coherent signal emitted from a laser, whether semiconductor, solid-state, gas, or dye-based, is ideal for probing materials in order to determine their composition or properties, measure dimensions or distances accurately, and much more. In such measurements, the laser wavelength must generally be known precisely, and often the parameter of interest can actually be transformed into a reading of wavelength or wavelength offset. This is where the accuracy of modern wavelength meters as instruments plays a vital role. Wavelength meters in general can also be used for spectral analysis, which expands even further their applicability.

Optical spectroscopy, in its various forms, is useful in a vast number of applications, because it deals with the precise measurement of atomic and molecular absorption or emission features. These features reveal fundamental characteristics of virtually any material, e.g., metals, gases, organic tissue, and crystals [18]. Possible wavelength ranges go from visible to infrared, which will guide the choice of a particular tunable laser, for example, semiconductor or dye [19], and of a particular wavelength meter. In a basic measurement, the frequency of an absorption feature is readily obtained by tuning the laser to it and measuring its wavelength with a wavelength meter. Simple spectral analysis can then be achieved by scanning the laser wavelength through the absorption feature and recording the amplitude versus wavelength for each step, as depicted in Fig. 13.

A different application of spectroscopy is the light detection and ranging (LIDAR), used for monitoring aerosols in the atmosphere. A pulsed (nanosecond timescale) laser signal is sent to a target zone, from which backscattered light is captured. Detailed optical frequency/spectrum measurement of this signal yields information about the target atmosphere. As this is a pulsed application, the typical scanned Michelson interferometer is not suitable and instruments with faster response times using Fabry–Perot or Fizeau interferometers are likely to be used. Calibrated with a reference He–Ne laser, such an instrument

Figure 13. Use of the wavelength meter in a simple absorption spectroscopy experiment. Simple spectral analysis can be achieved by scanning the laser wavelength through the absorption feature and recording the amplitude versus wavelength for each step.

gives information about the absolute wavelength and spectral properties of the backscattered light, which in turn give information about the scattering medium properties.

5.1.2. DWDM Optical Communication. The laser has also enabled an area of significance for electrical engineering, that of optical communication, where wavelength meters find widespread use. After years of steady growth with single-wavelength systems at $0.8\ \mu\text{m}$, then $1.3\ \mu\text{m}$, the advent of the erbium-doped fiber amplifier (EDFA) has enabled a massive deployment of systems in the low-loss region at $1.5\ \mu\text{m}$ [20]. Accurate knowledge of the wavelength is generally not required in a single-wavelength system. However, technology advances coupled to the ever-increasing demand for bandwidth fueled by the Internet explosion have recently led to industrial implementation of dense-wavelength division multiplexing (DWDM). In such systems, up to tens of optical channels are transmitted on a single fiber with frequency spacing currently as low as 100 GHz (about 0.8 nm at $1.55\ \mu\text{m}$). Typical bit rates for individual channels in current high-capacity transport applications are 2.488 Gbit/s (Sonet OC-48) and 9.952 Gbit/s (Sonet OC-192). (Sonet is a multiplexing format and is the acronym for Synchronous Optical Network.)

The 100 GHz standard channel spacing has been endorsed globally through a recommendation of the International Telecommunication Union (ITU). This recommendation actually defines precisely each channel frequency to be used: at this time, 40 channels from $\nu = 192\ 100\ \text{GHz}$ to $\nu = 196\ 100\ \text{GHz}$ applying to the individual transmitters and receivers. Corresponding vacuum wavelengths can be computed with $\lambda = c/\nu$, where $c = 299\ 792\ 458\ \text{m/s}$, the speed of light. Each frequency (or wavelength) value is in essence absolute: no particular technique for obtaining it is specified. This allows various equipment manufacturers and users worldwide to work with a common set of specifications, easing interoperability while employing potentially different technologies. The frequency tolerance around the absolute value is not standardized rigidly and is evolving as manufacturers and users refine their designs. Current observed tolerances are in the $\pm 10\ \text{GHz}$ to $\pm 20\ \text{GHz}$ range for a 100 GHz channel spacing.

As every transmitter and receiver must be designed, constructed, verified, and maintained in accordance with such tolerances, the need for accurate and easy wavelength measurements is clear. DWDM transmitters

typically use distributed feedback (DFB) semiconductor lasers [21], which present a significant frequency dependence on operational parameters like temperature and current. As typical coefficients are $10\ \text{GHz}/^\circ\text{C}$ and $1.5\ \text{GHz}/\text{mA}$, and given the tight-frequency tolerance required, it follows that transmitter emission wavelengths need to be calibrated in terms of temperature and current. These parameters also influence markedly the laser's output power, a critical parameter that must also be mapped out.

Wavelength meters as instruments now find widespread industrial use in optical telecommunication manufacturers production facilities at various instances. At the DFB fabrication and testing stage, they are used for selecting a laser operating point (temperature and current within an acceptable range) resulting in a wavelength situated within a desired channel tolerance, this at a predefined power level. Devices for which such a setpoint cannot be found are rejected. At the transmitter subsystem assembly stage, they are used for setting up and verifying the laser initial operating conditions, always ensuring an output wavelength within prescribed tolerances. At the DWDM transmission system setup stage, they are used for final verification of the multiple channel wavelengths. Meters based on FFT techniques providing a multiwavelength function are particularly useful at this point because their spectral analysis capability provides a quick view of the entire transmitted signal. See the HP 86120B instrument in Table 1.

DWDM systems must be designed for very high reliability over many years, and laser frequency aging must be taken into account in order to guarantee that transmitter wavelengths will remain within the specified tolerances. Frequency stabilization external to the laser itself is then required and various schemes have been developed [22–24]. The basic approach is to compare the emitted wavelength with some active (reference laser) or passive (reference filter) wavelength standard, determine if the transmitter wavelength is adequate, and take corrective action if not. This will counteract the effect of laser wavelength aging and maintain a precise emission frequency over long periods of time. In a way, this comparison with a wavelength reference implements the wavelength meter function, although it does not necessarily return a reading of the wavelength itself. Of course, one possibility is to monitor the transmitter output with an actual wavelength meter instrument, and instruct a controller unit to slightly modify the laser operating conditions over time so as to maintain a prescribed wavelength. As represented in Fig. 14, a multiwavelength meter allows this concept to be extended simultaneously to every channel in the system [25].

DWDM receivers generally use demultiplexing filters with well-defined transmission responses that must be measured precisely. As in the electrical-domain, a simple way to achieve this measurement is to send the signal from a broad-band noise source through the filter and look at the transmitted shape on an Optical Spectrum Analyzer (OSA). For the $1.55\ \mu\text{m}$ communication band, an easily available noise source is the amplified spontaneous emission (ASE) found at the output of an EDFA [20]. The OSA, typically a grating-based monochromator-type instrument,

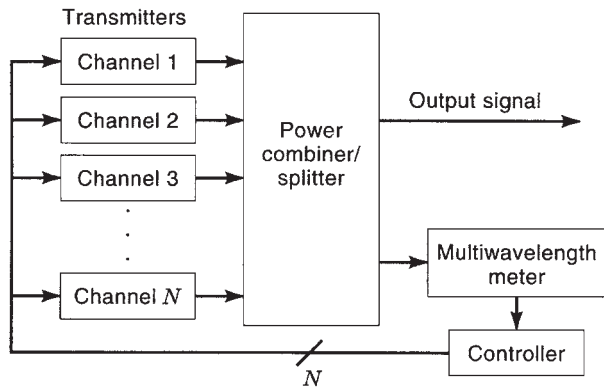

Figure 14. Use of a multiwavelength meter to control simultaneously the frequency of multiple laser transmitters in a DWDM communication system.

can measure wavelengths with less accuracy than a typical interferometer-based wavelength meter but offers more advanced spectral analysis capability. Again, wavelength meters with FFT-based spectral analysis capability can be used advantageously depending on the application. However, for precise transmission versus wavelength measurements, one can revert to the fundamental spectroscopic technique of scanning the wavelength of a tunable laser (typically a laboratory instrument based on an external-cavity laser design [19, Ch. 8], recording simultaneously the transmitted power and the wavelength with, respectively, a power meter and a wavelength meter, exactly as depicted in Fig. 13.

5.2. Advanced Topics

Let us now address some foreseen or desirable avenues for improvements of the wavelength meter instrument, as well as discuss the current state-of-the-art in wavelength measurement. In stand-alone instruments, one may wish to improve the resolution and accuracy of present units, in order to enable yet more precise measurements of all kinds. Improving the resolution means being able to sense a smaller wavelength change, and for the Michelson interferometer this requires a longer mirror travel. Although this can be achieved easily in a laboratory interferometer setup, it is harder to realize in an actual instrument because of size, reliability, and cost constraints. For example, a wavelength ratio uncertainty of 7×10^{-11} has been demonstrated in a laboratory configuration presenting a 60 cm mirror travel in vacuum and a 30 mm beam size [11]. Mechanically scanned interferometers tend also to have slow update rates, which will likely be slowed down further by longer travels. Simultaneous improvements in resolution and measurement speed appear difficult, although compromises toward either parameter can certainly be achieved.

Improving the measurement accuracy rests first on improving the wavelength reference's own accuracy. Semiconductor lasers stabilized to atomic or molecular features are a foreseen development in future instruments, featuring reduced size, increased reliability, and an improvement in reference accuracy to the 10^{-10} level [23,24]. Given an improved reference wavelength, one can then

refine the interferometer's intrinsic design. This implies a minimization and a precise characterization of the sources of error inherent in the design, its tolerance to misalignment, and the ultimate effect on the wavelength reading. Again, in the case of a commercial instrument, cost and reliability issues must be addressed at the same time as these refinements.

For the DWDM field, improvement paths may be oriented slightly differently, because the resolution and accuracy of commercial wavelength meters are basically sufficient for the needs of current and near-future systems. Emphasis should then be put on realizing wavelength meters that are smaller, cheaper, and more robust, particularly by developing solid-state designs with no moving parts. Resolution and accuracy may well be traded off for these considerations, depending on the particular application. Such developments might result in the ability to integrate an accurate wavelength meter function (as well as spectrum analysis) into optical transmission subsystems. Various possibilities for solid-state wavelength meters have been investigated [25,26].

Finally, let us touch on absolute wavelength measurement. Here, the term *absolute* means that the measurement must be related directly to the universal reference for frequency and time, the cesium primary standard. The SI unit of time, that is, the second, is defined with respect to a microwave transition from the ground state of cesium, around 9.192 GHz. Cesium primary standards, or "atomic clocks," exist as standalone instruments, but the most accurate and stable ones are fairly complex installations found at various national laboratories around the world. Their output usually consists of an RF signal in the 10 MHz range. One approach for absolute optical frequency measurement is to synthesize from the cesium reference, through frequency multiplication and heterodyning, phase-locked signals at progressively higher frequencies until the unknown wavelength has been reached [24, Ch. 5] This unknown wavelength can of course be measured with less accuracy prior to the absolute measurement with the help of a standard laboratory wavelength/optical frequency meter. The final determination of frequency is done by measuring a specific RF or microwave transfer frequency at a particular point in the chain. Such an absolute optical frequency measurement can then be transformed into an absolute vacuum wavelength measurement through the basic relation $\lambda_0 = c_0/v$. This was enabled by the 1983 redefinition of a meter by the Bureau International des Poids et Mesures (BIPM) [27], which effectively defined the speed of light in vacuum as $c_0 = 299,792,458$ m/s exactly. Measurement accuracies of 10^{-12} have been obtained in the visible range and also at the well-established $3.39 \mu\text{m}$ and $10 \mu\text{m}$ wavelengths of metrological He-Ne and CO_2 lasers. This is to be compared with the 10^{-7} basic accuracy of the most accurate currently available commercial instrument, the Burleigh WA-1500 depicted in Fig. 8.

Optical comb generation [28], that is the generation of precisely controlled optical sidebands at RF or microwave intervals from a precise reference wavelength, can also be used for creating signals in the vicinity of the unknown signal. This technique has recently been employed for

measuring accurately a series of molecular resonances of acetylene in the 1.5- μm communication band [29]. An accuracy in the 10^{-9} range was achieved.

6. CONCLUSION

Wavelength measurement is a fundamental and versatile function in many aspects of science and technology, as optical waves are prevalent in our everyday lives, in the scientific laboratory and in technology-based commercial ventures. As we have seen, wavelength measurement can take various shapes depending on the particular application, and it calls on diverse aspects of optics and both electrical and mechanical engineering.

One can use calibrated spectrometers based on prisms or gratings, or for better precision, Michelson, Fizeau, or Fabry-Perot interferometers. Each type of instrument presents advantages and limitations, so specific applications will dictate the choice of a particular configuration. Refined laboratory setups built for absolute measurements demand very accurate modeling and optical/mechanical design as well as construction, but size, complexity, and cost constraints are relaxed. Stand-alone laboratory instruments for scientific applications must be engineered so that a suitable level of performance is packaged in an easy to operate, robust, and cost-effective instrument. Finally, further improvements in the design of wavelength meters is leading the way toward the integration of this function into more and more compact subsystems, where size and cost are paramount.

WAVELET TRANSFORMS

STANLEY R. DEANS
 JOHN J. HEINE
 DEEPAK GANGADHARAN
 WEI QIAN
 MARIA KALLERGI
 LAURENCE P. CLARKE
 University of South Florida

Functions that oscillate over time are often called waves. If the function is such that it oscillates only in a localized region and goes to zero outside the region it may be called

a wavelet. Thus we say wavelets are localized waves. This is analogous to many processes in nature. Consider a soundwave that starts out at zero, builds to some maximum, and then dies out to zero. If the duration of the sound is a few seconds, we say the scale for the process is on the order of seconds. Whenever examining some physical object, scale plays an important role. For example, when looking at another human at a scale of about a meter, you see the whole individual, but if you examine the same individual at a scale of about a centimeter, you can see details such as whorled ridges that form the fingerprint.

The fundamental role of the wavelet transform is to facilitate the analysis of signals or images according to scale. Wavelets are functions with some special mathematical properties that serve as a tool for efficiently dividing data into a sequence of frequency components without losing all information about position. This can be thought of in terms of viewing an object through different size windows. If a large window is used, we see gross features, and if a small window is used we only see small detail features. There are many similarities between wavelet analysis and classic windowed Fourier analysis. The goal in the latter is to determine the local frequency content of a signal by using sine and cosine functions multiplied by a sliding window. The wavelet analysis makes use of translations and dilations of an oscillating wavelet, called the *mother wavelet*, to characterize both spatial and frequency contents of a signal. The properties of this analyzing wavelet are very different from those of sines and cosines. These differences make it possible to approximate a signal contained in a finite region or a signal with sharp changes with a few coefficients, something not possible with classic Fourier methods.

Many of the principles that are the foundation for wavelet analysis emerged independently in mathematics, physics, geophysics, and engineering. In most cases, the concepts came from the motivation to solve some problem that related to resolution or scale. During the last decade, wavelets have been used with great success in a very wide variety of areas, including image compression, coding, signal processing, numerical analysis, turbulence, acoustics, seismology, and medical imaging.

There are some basic mathematical concepts that must be understood prior to a full explanation of the two types of wavelet transforms, the continuous transform and the discrete transform. Section 1 on basic concepts from linear algebra and Fourier analysis can be skipped by those who have already reached that level of mathematical sophistication.

1. BASIC CONCEPTS

1.1. Basis

One of the most fundamental ideas associated with many areas of mathematics is the concept of a *basis*. A simple illustration serves to get the idea across. Suppose we have a curve (waveform or signal) that looks somewhat complicated, as in Fig. 1. (In practice, this could be a voltage that varies in time.) How could you explain to someone who could not see the curve just what it looks like? One pos-

Figure 1. A complicated curve.

sible way is to think of the complicated curve as being made up of the sum of several simple curves. The complicated curve is selected so that it is exactly the sum of two simple curves shown in Fig. 2. The simple curves are known as sine curves. These fundamental curves can be described in terms of how many times they go through a complete cycle. Note that the low-frequency curve goes through one cycle and the higher frequency curve goes through three cycles. Also note that the low-frequency curve has two times the amplitude of the high-frequency curve. You could tell someone exactly how to reproduce the more complicated curve by giving the information about frequency and amplitude for the two basic curves. For those familiar with formulas for sine curves, the complicated curve is given by $y = 2 \sin(2\pi x) + \sin(6\pi x)$.

Technical Definitions: Motion that repeats in equal intervals of time is called periodic. The *period* is the time required for one complete cycle or oscillation. The *frequency* is the repetition rate of a periodic process, which is the number of cycles that occur over a given interval of time. If the period is given in seconds, the frequency is in hertz, abbreviated Hz. In Fig. 2, if the x axis represents time (in seconds), the frequencies are 1 Hz and 3 Hz for the two curves.

Figure 2. Two simple curves. The curve in Fig. 1 is the sum of these two curves.

The concept of a basis comes from an extension of the approach used to produce the curve in Fig. 1 from the sum of the curves in Fig. 2. If the basis is selected so that it is complete, an arbitrary curve can be replaced by a sum of basic curves. When this is done for periodic functions using sine or cosine curves with different frequencies and amplitudes, it is called a Fourier series decomposition. If the original function is not periodic and can be defined over the entire x axis such that its area is finite, a Fourier transform is used.

The important concept here is that there is a formal way to represent a function or waveform as a sum of basic parts. Fourier analysis corresponds to the language used, and a prescription for calculating the coefficients in the sum exists, which corresponds to finding the amplitudes in Fig. 2. You might think of this as a sort of mathematical prism. The prism breaks light into various colors in much the same way the Fourier analysis breaks the complicated waveform into component parts.

When considering all sorts of waveforms, an obvious question emerges. Under just what conditions is Fourier analysis the appropriate mathematical language to use to decompose the waveform? The complete answer to this question is the subject of the enormous literature on Fourier series and Fourier transforms. There are some simple answers that will suffice for our purposes. The sum in a typical Fourier series problem is an infinite sum. This means an infinite number of coefficients must be computed to represent the function. It seems we have made the problem more complicated! It turns out that in many physical situations only a few coefficients are needed to give an adequate description of the waveform. The coefficients associated with the high-frequency sines and cosines approach zero as the frequency increases. You can think about it this way: The large coefficients correspond to the case where there is a fair match between the original function and the basic sine or cosine. If the original waveform changes slowly relative to the high-frequency oscillations, there is a poor match, and consequently the coefficients are very small. More will be said about this in the sections that follow.

1.2. Orthogonality

Another concept that is essential is that of *orthogonality*. Recall from elementary geometry, if two line segments are perpendicular, we say they are orthogonal. If we make vectors out of line segments by giving them properties of magnitude and direction, we can determine whether they are orthogonal by computing their *scalar* product. This is sometimes called the *dot* or *inner* product. If the scalar product is zero, they are orthogonal. Another way to think about this is that orthogonal vectors do not have any components in common, or they contain completely independent information. The same type of thing can be defined for functions; however, the rule for doing the scalar product is different. It involves doing an integral of the product of two functions. The coefficients in a Fourier series expansion can be found by computing scalar products of the original waveform multiplied by sine and cosine functions with different frequencies. The important point is that the

building blocks, the sines and cosines of different frequencies, are orthogonal and complete. An important consequence is that the frequency content of the waveform can be determined in an unambiguous way. Also, an orthogonal transformation allows perfect reconstruction of the original waveform and eliminates redundancy. Generally, orthogonal transformations are more efficient and easier to use.

1.3. Sampling and the Fast Fourier Transform

In nature, many waveforms are continuous functions of time. If we want to work with these signals using digital computers, it is necessary to find a discrete representation. This means we have to *sample* the continuous function. There is an extremely important theorem known as the *Shannon sampling theorem* that is invoked in these situations. Proofs are given in most standard texts on Fourier analysis, for example, Bracewell [1] and Brigham [2]. The theorem states that a continuous signal can be represented completely by and reconstructed perfectly from a set of measurements (samples) of its amplitude made at equally spaced times. The time interval between samples must be equal to or less than one-half the period of the highest frequency present in the signal. For example, for a typical voice signal, the frequency range is from 0 Hz to 4,000 Hz. This signal must be sampled 8,000 times per second in order to describe it perfectly. In practice, the idea of perfect reconstruction must be compromised. When the amplitude is sampled with real physical apparatus, there must be some sort of round off. In speech transmission, an error of 1% is often sufficient for practical purposes.

Another development that helped usher in the digital communication revolution is the *Fast Fourier Transform* (FFT). For n sampled points, this reduces the number of computations from n^2 to $n \log n$. This is especially important for large values of n . A very interesting discussion of the FFT is given by Heideman, Johnson, and Burrus [3].

1.4. Time- and Frequency-Domains

When we look at the signal in the time-domain, we have full information about the amplitude of the signal at any time. When we do the Fourier decomposition, we have full information about the frequency content of the signal, but the time information is not apparent. The inverse transform yields the time information, but then the frequency spectrum is not apparent. Another way to think about this is to observe that a very sharp signal in the time-domain is flat in the frequency-domain. Inspection of the frequency spectrum does not tell when the sharp signal occurred in time. Some time-domain and frequency-domain transform pairs are shown in Fig. 3. The important point is that signals localized in time are spread in frequency and those spread in time are localized in frequency.

2. CLASSIFICATION OF SIGNALS

It is useful to give a broad classification of signals as *stationary*, *quasistationary*, and *nonstationary*. A signal is

Figure 3. Signals concentrated in one domain are spread in the other domain.

stationary if its statistical properties are invariant over the time duration of the signal. For these signals, the probability of unexpected events is known in advance. If there are transient events (such as blips or discontinuities) in the signal that cannot be predicted, even with knowledge of the past, the signal is *nonstationary*. Consider viewing the signal through a window of some width; that is, look at a section of the signal. A signal is called *quasistationary* if the signal is stationary at the scale of the window.

The ideal tool for studying stationary signals is Fourier analysis. The study of nonstationary signals requires other techniques. One of these is the use of wavelets. An important technique for the study of quasistationary signals came before wavelets and will be discussed first.

The desire to maintain information about time when doing Fourier decompositions leads to the short-time Fourier transform (STFT), sometimes called the windowed Fourier transform. The idea is to select a window with fixed width and slide it along the signal. The Fourier decomposition is done for several short times of the signal rather than for the entire signal all at once. By a proper choice of the window, it is possible to maintain both time and frequency information; thus, this transformation is known as a time–frequency decomposition. When the window is a Gaussian, the transform is known as a Gabor transform in honor of early work done by Dennis Gabor [4]. Difficulties in connection with this approach involve both orthogonality and invertibility. An introduction to the STFT and the wavelet transform is given by Rioul and Vetterli [5]. The close connection with wavelets is illustrated in Fig. 4. Note that the main difference is that the functional form of the wavelet does not change, hence the name *mother wavelet*. The choices for the mother wavelet are virtually unlimited, which is in sharp contrast to Fourier analysis where the basis functions are sines and cosines.

Figure 4. Comparison of STFT and wavelets. On the left, select the window and allow different frequency sinusoids to fill the window. On the right, select the mother wavelet, then translate and dilate the wavelet. The second wavelet is expanded and shifted to the left. The third wavelet is compressed and shifted to the right.

The mother wavelet is allowed to undergo translations and dilations. It is the various translations and dilations of the mother wavelet that form the basis functions for the wavelet transform. This stretching or compressing of the wavelet changes the size of the window and allows the analysis of signals at different scales. This is in some sense like a microscope; the wide stretched-out wavelets are used to give a broad approximate image of the signal, whereas the smaller and smaller compressed wavelets can zoom in on finer and finer details.

3. TIME-FREQUENCY RESOLUTION

We have already seen that sharp signals in the time-domain correspond to flatness in the frequency-domain. If the window for the STFT is selected as in the third row of Fig. 3, then the tiles that represent the essential concentration in the time–frequency plane are squares as indicated on the left in Fig. 5. For a window fixed at one position along the time axis, going up vertically corresponds to higher and higher frequency sinusoidal curves contained within the window. The corresponding tiles for the wavelet transform are shown on the right in Fig. 5. Here the wavelet that is stretched out over the time axis (low frequency) has a narrow concentration in the frequency-domain. As the wavelet is compressed (higher frequencies, smaller time window) the concentration in the frequency-domain is less and less concentrated. Think about this in terms of the curves in Fig. 3 where small time windows correspond to broad frequency windows. This helps in understanding how scale plays such an important role in the wavelet transform.

Figure 5. Left: Time and frequency resolution for STFT. Right: Time and frequency resolution for WT. The tiles indicate the region of concentration in the time–frequency plane for a basis function. As an illustration, if the tile labeled (b) corresponds to (b) in Fig. 4, then tile (c) could correspond to (c) in Fig. 4. The corresponding comparison for wavelets is for tiles labeled (d) and (f) with (d) and (f) in Fig. 4.

4. SOME HISTORY

There are many avenues that can be followed in trying to trace the history of wavelets. Barbara Burke Hubbard [6] has a quote in her beautiful discussion of wavelets by Yves Meyer. He says: “I have found at least 15 distinct roots of the theory, some going back to the 1930s.” Seven of these sources in pure mathematics are discussed in some detail in the translation of some of Meyer’s [7] lecture notes. The reader with some background in harmonic analysis will find this discussion covering 70 years of mathematics fascinating: the Haar basis (1909), the Franklin orthonormal system (1927), Littlewood–Paley theory (1930), Calderón–Zygmund theory (1960–1978), and the work of Strömberg (1980). In addition to the lecture notes by Meyer, references for this background include Haar [8], Franklin [9], Hernández and Weiss [10], Edwards and Gaudry [11] for Littlewood–Paley theory, Stein [12] for Calderón–Zygmund theory, and Strömberg [13].

This work done by mathematicians is now understood as part of the history of wavelets. The term “atomic decompositions” was used in place of the term wavelets. During this period from 1910 to 1980, mathematicians from the University of Chicago (location of Zygmund and Calderón) were leaders in harmonic analysis, but apparently they did not interact very much with the experts in physics and signal processing.

In physics, the ideas underlying wavelets are present in Nobel laureate Kenneth Wilson’s [14] work on the renormalization group. A review of some of Wilson’s work and other uses of wavelets in physics is given by Guy Battle [15,16]. Wavelet concepts also appear in the study of coherent states in quantum mechanics. This work dates from the early 1960s by Glauber [17] and Aslaksen and Klauder [18,19].

In parallel with advances in mathematics and physics, there were important ideas fundamental to wavelets being

developed in signal and image processing. This work was mostly in the context of discrete-time signals. As is often the case in applied science, much of this work was driven by the need to solve a problem. We have already mentioned the work by Gabor who introduced concepts very close to wavelets in speech and signal processing. A technique called subband coding was proposed by Croisier, Esteban, and Galand [20] for speech and image compression. This work and related work by Esteban and Galand [21] and Crochiere, Webber, and Flanagan [22] made use of special filters known as quadrature mirror filters (QMF). This led to important work in perfect reconstruction filter banks discussed in detail by Vetterli and Kovačević [23]. Other important relevant work was the development of pyramidal algorithms in image processing by Burt and Adelson [24], where images are approximated proceeding from a coarse to fine resolution. This idea is similar to the multiresolution framework currently used in connection with the discrete wavelet transform.

The important point of all of this is that the foundations of wavelet transforms were implicit in several areas of science, but those working in the various areas were not communicating outside their own field. The grand unification came as a surprise to many and is certainly one reason why this subject has become so popular. Several people made important contributions to this unification. Yves Meyer, in the foreword to the book by Hernández and Weiss [10], gives special tribute to Alex Grossmann and Stéphane Mallat.

In the early 1980s, Jean Morlet, a geophysicist with the French oil company Elf-Aquitaine, coined the name wavelet in connection with analysis of data in oil prospecting (see Morlet et al. [25]). Morlet’s early work was based on extensions of the Gabor transform coupled with the fundamental idea of holding the number of oscillations in the window constant while varying the width of the window.

Morlet developed empirical methods for decomposing a signal into wavelets and then reconstructing the original signal, but it was not clear how general the numerical techniques were. Morlet was referred to Alex Grossmann who had extensive experience in Fourier analysis as utilized in quantum mechanics. It took them about two years to determine that the inversion was exact, and not an approximation (Grossmann and Morlet [26]).

During 1985–1986, Stéphane Mallat [27,28], an expert in computer vision, signal processing, and applied mathematics, discovered some important connections among: (1) the quadrature mirror filters, (2) the pyramid algorithms, and (3) the orthonormal wavelet bases of Strömberg Meyer, building on the work by Mallat, constructed wavelets that are continuously differentiable, but they do not have compact support. (A function with compact support vanishes outside a finite interval.) A full discussion of these Meyer wavelets is given by Ingrid Daubechies [29], where she points out that Meyer actually found this basis while trying to prove the nonexistence of such nice wavelet bases. It requires a considerable amount of work to calculate the wavelet coefficients for the Meyer wavelets, and Daubechies wanted to construct wavelets that would be easier to use. She had worked with Grossmann in France on her Ph.D. research in physics, and she knew about Mallat and Meyer’s work before it was published. She demanded orthogonality, compact support, and some degree of smoothness (wavelets with vanishing moments). These constraints are so much in conflict that most people doubted such a task could be accomplished. After some very intense work, she had the construction by the end of March 1987. (See the revealing quote on page 47 of Hubbard [6]). This work is elegant, and the Daubechies wavelets have become the cornerstone of wavelet applications throughout the world. The first publication on her construction is in Ref. 30. Other relevant descriptions are in Refs. 29 and 31.

This concludes an all too brief history of a topic that has roots reaching into the core of pure and applied mathematics, physics, geophysics, computer science, and engineering. The reader with interest in these matters will find the informal discussion by Ingrid Daubechies [32] both enjoyable and enlightening. In that discussion, she does not cite specific references, but all of the characters in the story are identified in the bibliography or reading list for this article or in the books by Vetterli and Kovačević [23] and Daubechies [29].

5. THE CONTINUOUS WAVELET TRANSFORM

Families of continuous wavelets are found by shifting and scaling a “mother” wavelet $\psi(x)$

$$\psi_{a,b} = \frac{1}{\sqrt{a}} \psi\left(\frac{x-b}{a}\right), \quad a, b \in \mathbb{R}, \quad a \neq 0 \quad (1)$$

The parameter a is the scale parameter, b is the shift parameter, and \mathbb{R} is the set of real numbers. One possible

identification for ψ is the Mexican hat function,

$$\psi(x) = \frac{2}{\sqrt{3}} \pi^{-1/4} (1-x^2)e^{-1/2x^2}$$

This function is the second derivative of a Gaussian $e^{-1/2x^2}$. The normalization is such that its square integrated over the real line is unity, $L^2(\mathbb{R})$ norm equal to 1. This is the function used for illustration on the right side of Fig. 4. The reason for the name comes from the image generated by a rotation around its axis of symmetry [29]. Observe that for large a , the basis function $\psi_{a,b}$ is a stretched-out version of ψ and small a gives a contracted version.

If the basis functions are required to satisfy a completeness condition, then it is necessary for the wavelet to satisfy an “admissibility” condition [23]

$$C_\psi = \int_{-\infty}^{\infty} \frac{|\hat{\psi}(\xi)|^2}{\xi} d\xi < \infty$$

where $\hat{\psi}$ is the Fourier transform of ψ ,

$$\hat{\psi}(\xi) = \int_{-\infty}^{\infty} \psi(x)e^{-ix\xi} dx$$

This means that for practical cases we must require (Let $\xi \rightarrow 0$ in the formula for the Fourier transform):

$$\int_{-\infty}^{\infty} \psi(x) dx = \hat{\psi}(0) = 0$$

Thus, the wavelet function cannot be a symmetric positive “bump” function like a Gaussian, but must wiggle around the x axis like a wave. The zero of the Fourier transform at the origin and the decay of the spectrum $\hat{\psi}$ at high frequencies implies that the wavelet has a bandpass behavior.

The continuous wavelet transform of a function $f(x)$ is defined by

$$\tilde{f}(a, b) = \langle \psi_{a,b}, f \rangle = \int_{-\infty}^{\infty} \psi_{a,b}(x)f(x) dx \quad (2)$$

for a *real* set of basis functions. The function f is recovered from the transformed function \tilde{f} by the inversion formula

$$f(x) = \frac{1}{C_\psi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{da db}{a^2} \tilde{f}(a, b) \psi_{a,b}(x) \quad (3)$$

For a proof, see Chapter 5 of Ref. 23. This last formula says that $f(x)$ can be written as a superposition of shifted and dilated wavelets.

The continuous wavelet transform has an energy conservation property that is similar to Parseval’s formula for the Fourier transform. The function $f(x)$ and its continuous wavelet transform $\tilde{f}(a, b)$ satisfy

$$\int_{-\infty}^{\infty} |f(x)|^2 dx = \frac{1}{C_\psi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{da db}{a^2} |\tilde{f}(a, b)|^2 \quad (4)$$

The wavelet transform has localization properties. There is a sharp time localization at high frequencies, in marked contrast with Fourier transforms. For example, the

wavelet transform of a delta function centered at x_0 is

$$\frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} \psi\left(\frac{x-b}{a}\right) \delta(x-x_0) dx = \frac{1}{\sqrt{a}} \psi\left(\frac{x_0-b}{a}\right)$$

For a given scale factor a , the transform is equal to a scaled and normalized wavelet centered at the location of the delta function.

6. DISCRETE WAVELET TRANSFORM

The wavelet transform has to be discretized for most applications. One way to approach this is to attempt to directly discretize the continuous wavelet transform and find a discrete version of the reconstruction formula given in Eq. (3). In effect, this means replace $\psi_{a,b}$ by $\psi_{m,n}$ with $m, n \in \mathbb{Z}$, where \mathbb{Z} is the set of integers. The appropriate replacements for a and b are [23,29]

$$a = a_0^m, \quad b = nb_0 a_0^m, \quad a_0 > 1, \quad b_0 > 0$$

When this is done, it turns out that in the discrete parameter case there is no direct generalization of Eq. (3); however, for certain ψ and appropriate a_0 and b_0 $\tilde{\psi}_{m,n}$ exist, such that

$$f = \sum_{m,n} \langle \psi_{m,n}, f \rangle \tilde{\psi}_{m,n}$$

This leads to the introduction of *frames* and *dual frames*. These represent an alternative to orthonormal bases in a Hilbert space (see Heil and Walnut [33]). This approach will not be pursued here. We refer the reader to standard references [10,23,29,33].

The approach presented here leads to the construction of orthonormal wavelet expansions for discrete sets of data. We *do not* start with a continuous wavelet and attempt to find a discrete counterpart. We make full use of multiresolution, the idea of looking at something at various scales or resolutions.

6.1. Multiresolution Analysis

In this approach, another function ϕ plays a fundamental role along with the wavelet function ψ . The simplest possible system that illustrates most of the fundamental properties of these functions is the Haar scaling function and Haar wavelet. In this case, the scaling function is the box function illustrated in Fig. 6(a) and the corresponding wavelet is shown in Fig. 6(b). We refer to these two functions as the *level 0* functions. The fundamental idea is to construct other scaling functions and wavelets from dilations and translations of the level 0 functions. Some of these are shown in Fig. 6. Note that scaling by $x \rightarrow 2x$ corresponds to a contraction, and scaling by $x \rightarrow \frac{1}{2}x$ gives an expansion. There are two scaling functions and two wavelet functions at level -1, with support on an interval of length $\frac{1}{2}$,

$$\phi(2x), \quad \phi(2x - 1), \quad \psi(2x), \quad \psi(2x - 1)$$

Figure 6. Scaling function ϕ and wavelet function ψ for the Haar system: (a) $\phi(x)$, (b) $\psi(x)$, level 0, basic; (c) $\phi(x - 1)$, (d) $\psi(x - 1)$, level 0, translated; (e) $\phi(\frac{1}{2}x)$, (f) $\psi(\frac{1}{2}x)$, level 1, basic; and (g) $\phi(2x)$, (h) $\psi(2x)$, level -1, basic.

Complete families of scaling functions and the wavelets are obtained by appropriate translations and dilations. The functions $\phi(x)$ and $\psi(x)$ are the functions at level 0. The move from $\psi(x)$ to $\psi(2x)$ is a dilation operation, whereas the shift from 0 to 1 is a translation operation. Starting from ϕ and ψ , the functions are shifted and compressed. The next level down (level -2) contains

$$\begin{aligned} &\phi(4x), \quad \phi(4x - 1), \quad \phi(4x - 2), \quad \phi(4x - 3); \\ &\psi(4x), \quad \psi(4x - 1), \quad \psi(4x - 2), \quad \psi(4x - 3) \end{aligned}$$

Each of these functions is supported on an interval of length $\frac{1}{4}$. A continuation of this process gives infinite families of functions,

$$\begin{aligned} \phi_{j,k}(x) &= 2^{-j/2} \phi(2^{-j}x - k); \\ \psi_{j,k}(x) &= 2^{-j/2} \psi(2^{-j}x - k) \end{aligned} \tag{5}$$

with $j, k \in \mathbb{Z}$. For the range of values ($j \leq 0$) and ($0 \leq k < 2^{-j}$), these functions form a basis over the interval $[0, 1]$.

Important Remark: The Haar system is used for illustration purposes because it is simple and easy to understand. The important point is that all of this holds for other scaling functions and wavelets that have increasing degrees of smoothness. Some of these will be discussed and illustrated later.

Suppose we designate the space spanned by functions of the form $\phi(x - k), k \in \mathbb{Z}$, by V_0 and the space spanned by functions of the form $\phi(2x - k), k \in \mathbb{Z}$, by V_{-1} . Clearly, the function $\phi(x)$ can be written as

$$\phi(x) = \phi(2x) + \phi(2x - 1)$$

As functions in V_0 can be written as a linear combination of functions in V_{-1} , we have the condition

$$V_0 \subset V_{-1}$$

This argument can be extended in either direction, for example

$$\phi\left(\frac{1}{2}x\right) = \phi(x) + \phi(x - 1), \quad V_1 \subset V_0$$

An example of the projection of a function onto V_0 and V_1 is shown in Fig. 7. By continuing this process, the nesting of the closed subspaces V_j follows,

$$\begin{aligned} \leftarrow \text{coarser} \dots V_2 \subset V_1 \subset V_0 \subset V_{-1} \\ \subset V_{-2} \subset \dots \text{finer} \rightarrow \end{aligned} \tag{6}$$

The nesting order is selected so that the spaces show less detail as the index increases. For example, in Fig. 7 the projection onto V_1 can be considered as a blurred version of the projection onto V_0 . This is an agreement with the choice made by Daubechies [29]. A caution for the reader is in order on this; about half of the wavelet literature uses the opposite convention, coupled with a change of $-j$ to $+j$ in Eq. (5). Properties of the V_j are summarized by the following definition of an orthogonal multiresolution analysis.

A *multiresolution analysis* of $L^2(\mathbb{R})$ consists of a sequence of closed subspaces V_j , for all $j \in \mathbb{Z}$, such that

- (M1) $V_j \subset V_{j-1}$
- (M2) $\overline{\bigcup_j V_j} = L^2(\mathbb{R})$ and $\bigcap_j V_j = \{0\}$
- (M3) $f(x) \in V_j \Leftrightarrow f(2x) \in V_{j-1}$
- (M4) $f(x) \in V_0 \Leftrightarrow f(x - k) \in V_0$ for all $k \in \mathbb{Z}$
- (M5) A function $\phi \in V_0$ exists, so that $\phi(x - k), k \in \mathbb{Z}$ form an orthonormal basis for V_0 .

Several remarks are in order in regard to this definition. In (M2), the bar over the union is to indicate *closure*. The closure of a set is obtained by including all functions that can be obtained as limits of sequences in the set. This terminology could be replaced by saying that the union is dense in L^2 . Condition (M5) is often relaxed by assuming that the set of functions $\phi(x - k)$ is a *Reisz basis* for V_0 . For a full treatment of this approach, see Refs. 10 and 34.

Now let us observe that, although we have the condition $V_0 \subset V_{-1}$, the basis functions in V_0 are not orthogonal to the basis functions in V_{-1} ,

$$\int \phi(x)\phi(2x) dx \neq 0 \quad \text{and} \quad \int \phi(x)\phi(2x - 1) dx \neq 0$$

Figure 7. A function $y=f(x)$ (dots) projected onto V_0 (top), projected onto V_1 (bottom).

The integrals are over all x where the functions do not vanish. For the Haar case illustrated earlier, this would be over the interval $[0, 1]$. There is a clever way to fix this. Note that we can write

$$\phi(2x) = \frac{1}{2} [\phi(x) + \psi(x)] \quad \text{and}$$

$$\phi(2x - 1) = \frac{1}{2} [\phi(x) - \psi(x)]$$

If we designate the space spanned by the wavelets $2^{-j/2}\psi(2^{-j}x - k), j, k \in \mathbb{Z}$, by W_j , it follows that the direct sum of subspaces gives

$$V_{-1} = V_0 \oplus W_0$$

Moreover, it is easy to check that basis functions in V_0 are orthogonal to basis functions in W_0 . This idea can be extended in either direction

$$V_{-2} = V_{-1} \oplus W_{-1} \quad \text{and} \quad V_0 = V_1 \oplus W_1$$

The space W_j is said to be the *orthogonal complement* of V_j in V_{j-1} . In general, we have

$$V_{j-1} = V_j \oplus W_j, \quad W_j \perp W_{j'}, \quad \text{if } j \neq j' \tag{7}$$

If we designate the projection of $f(x)$ onto V_m by $P_m f$ and the projection of $f(x)$ onto W_m by $Q_m f$, then Eq. (7) implies that

$$P_{j-1} f = P_j f + Q_j f \tag{8}$$

If $j = 1, P_0 f = P_1 f + Q_1 f$. Projections $P_0 f$ and $P_1 f$ are shown in Fig. 7. The projection $Q_1 f$ contains the difference or

Figure 8. The detail information for the function from Fig. 7 in W_1 .

detail information, illustrated in Fig. 8. Note that this does indeed represent Haar wavelets at level 1.

To see how the general decomposition emerges, consider

$$V_0 = V_1 \oplus W_1 = V_2 \oplus W_2 \oplus W_1 = V_3 \oplus W_3 \oplus W_2 \oplus W_1$$

This could be extended as far as desired. The general formula is

$$V_j = V_j \oplus \bigoplus_{k=0}^{J-j-1} W_{J-k} \tag{9}$$

where all subspaces on the right are orthogonal, which means that any function can be represented as a sum of detail parts plus a smoothed version of the original function. This is often expressed by saying that the function is resolved into a low-frequency part plus a sum of high-frequency parts. To see this, think of Fourier transforms. The broad part in V_j has a Fourier transform concentrated at the origin in the Fourier domain, hence low frequencies. The parts in W_j have Fourier transforms that must vanish at the origin because the area of the wavelet is 0, hence high-frequency parts.

By use of (M2) and Eq. (9), it follows that

$$L^2(\mathbb{R}) = \bigoplus_{j \in \mathbb{Z}} W_j \tag{10}$$

(Note that $V_j \rightarrow \{0\}$ as $j \rightarrow \infty$.) The collection $\{\psi_{j,k}; j, k \in \mathbb{Z}\}$ is an orthonormal basis for $L^2(\mathbb{R})$. The spaces W_j also have the scaling property (M3), so the job is to find a $\psi \in W_0$, such that the $\psi(x - k)$ form an orthonormal basis for W_0 .

6.2. Orthonormal Wavelets with Compact Support

Before we embark on the task of determining other acceptable scaling and wavelet functions, it may be useful to examine the Haar system more closely. Keep in mind that what we are doing applies to any functions ϕ and ψ that satisfy the multiresolution analysis and decomposition, Eq. (9).

First, we observe that the scaling function $\phi_{j,k}$ from Eq. (5) satisfies an orthogonality condition at the same scale,

$$\langle \phi_{j,k}, \phi_{j,k'} \rangle \equiv \int_{\mathbb{R}} \phi_{j,k} \phi_{j,k'} dx = \delta_{kk'} \tag{11}$$

Here $\delta_{kk'}$ is the Kronecker delta defined to be 1 if $k = k'$ and 0 if $k \neq k'$. The wavelets are orthogonal at the same scale

and across scales,

$$\langle \psi_{j,k}, \psi_{j',k'} \rangle = \delta_{jj'} \delta_{kk'} \tag{12}$$

The wavelets and scaling functions also satisfy

$$\langle \phi_{j,k}, \psi_{j',k'} \rangle = 0 \tag{13}$$

We focus our attention on the containment $V_0 \subset V_{-1}$ and $W_0 \subset V_{-1}$ for the Haar system,

$$\phi(x) = \phi(2x) + \phi(2x - 1) \quad \psi(x) = \phi(2x) - \phi(2x - 1)$$

This is a special case of general expansions for ϕ or ψ where

$$\begin{aligned} \phi(x) &= \sum_{k \in \mathbb{Z}} c_k \phi(2x - k) \\ \psi(x) &= \sum_{k \in \mathbb{Z}} d_k \phi(2x - k) \end{aligned} \tag{14}$$

For the Haar system, there are only two coefficients needed; namely, $c_0 = c_1 = 1$. The d coefficients are found from these. We will see later that the condition is $d_k = (-1)^k c_{1-k}$. One way to obtain the coefficients for more general functions ϕ and ψ is to place constraints on the coefficients c_k in the expansion of the scaling function. The method here follows the pioneer work on this by Ingrid Daubechies [30].

The expansion for $\phi(x)$ in Eq. (14) is called a *dilation equation*. If only a finite number of the coefficients are nonzero, then ϕ must vanish outside a finite interval. This gives the property of *compact support*. Suppose the nonzero coefficients are c_m, c_{m+1}, \dots, c_n . If the original function ϕ has support on the interval $[a, b]$, then $\phi(2x)$ has support on the interval $[a/2, b/2]$. The shifted function $\phi(2x - k)$ has support on $[a + k/2, b + k/2]$. As the index k goes from m to n , we have

$$\phi(x) = \sum_{k=m}^n c_k \phi(2x - k) \tag{15}$$

The support on the left side is related to the support on the right side by

$$[a, b] = \left[\frac{a+m}{2}, \frac{b+n}{2} \right]$$

This requirement yields $a = m$ and $b = n$, hence the support is on $[m, n]$.

Example: Suppose $\phi(x)$ is the level 0 Haar box function, and let the sum go from 0 to n . If this function is substituted and used on the right side of Eq. (15), then the function on the left has support on $[0, 1 + n/2]$. If this function is now substituted on the right side the function on the left has support on $[0, 1 + 3n/4]$. If this procedure is continued, the limiting case is just the interval $[0, n]$.

A *consistency condition* can be established by integrating the dilation equation. This is easy and the details that involve a change of variables ($t = 2x - k$) are left for the reader,

$$\begin{aligned} \int_{-\infty}^{\infty} \phi(x) dx &= \int_{-\infty}^{\infty} \sum_k c_k \phi(2x - k) dx \\ &= \cdots = \frac{1}{2} \sum_k c_k \int_{-\infty}^{\infty} \phi(t) dt \end{aligned}$$

As the integral of the scaling function is assumed to be finite, there is a requirement that

$$\sum_k c_k = 2 \quad (16)$$

A convenient choice for the normalization on ϕ is such that

$$\int_{-\infty}^{\infty} \phi(x) dx = 1$$

Caution: Some authors use a slightly different convention for the constants. The other popular choice is to use $c_n = \sqrt{2}h_n$, where h_n corresponds to the notation used by Daubechies [29].

The *orthogonality* condition in Eq. (11) leads to another important relation. The reader may wish to see Alpert [35] for details.

$$\begin{aligned} \delta_{kl} &= \int_{-\infty}^{\infty} \phi(x - k)\phi(x - l) dx \\ &= \int_{-\infty}^{\infty} \sum_m c_m \phi[2(x - k) - m] \\ &\quad \times \sum_n c_n \phi[2(x - l) - n] dx \\ &= \frac{1}{2} \sum_{m,n} c_m c_n \delta_{2k+m, 2l+n} \\ &= \frac{1}{2} \sum_m c_m c_{2k-2l+m} \end{aligned}$$

As the sum is over all $m \in \mathbb{Z}$, we can make the change of index $m \rightarrow m + 2l$. This leads to the desired orthogonality condition

$$\sum_{m \in \mathbb{Z}} c_{2k+m} c_{2l+m} = 2\delta_{kl} \quad (17)$$

This equation ensures the orthogonality of the translates of the scaling function.

The coefficients d_k must be selected so that an orthogonality condition holds for the translates of the wavelet function $\psi(x)$. It is easy to show that this works for

$$d_k = (-1)^k c_{1-k} \quad (18)$$

The calculation makes use of Eqs. (14) and (17)

$$\begin{aligned} &\int_{-\infty}^{\infty} \psi(x - k)\psi(x - l) dx \\ &= \sum_{m,n} \int_{-\infty}^{\infty} d_m \phi[2(x - k) - m] d_n \phi[2(x - l) - n] dx \\ &= \frac{1}{2} \sum_m d_{2k+m} d_{2l+m} \\ &= \frac{1}{2} \sum_m (-1)^{2k+m} c_{1-2k-m} (-1)^{2l+m} c_{1-2l-m} \\ &= \frac{1}{2} \sum_m c_{1-2k-m} c_{1-2k-l} \\ &= \delta_{kl} \end{aligned}$$

Also, the choice made in Eq. (18) is adequate to establish the orthogonality

$$\int_{-\infty}^{\infty} \phi(x - k)\psi(x - l) dx = 0$$

This is left as an exercise; observe that you do not have to make use of Eq. (17).

The key conditions thus far are Eqs. (16), (17), and (18). These are not adequate for a unique determination of the coefficients that lead to the family of Daubechies that extend the Haar system in a natural way. The next condition relates to *approximation*.

The idea is to approximate polynomials of degree $j = 0, 1, \dots, N - 1$ as linear combinations of translates of the scaling function in V_0 . Thus, we look for coefficients α , such that

$$x^j = \sum_{k \in \mathbb{Z}} \alpha_{j,k}^N \phi(x - k), \quad (j = 0, 1, \dots, N)$$

By orthogonality

$$\alpha_{j,k}^N = \int_{-\infty}^{\infty} x^j \phi(x - k) dx$$

The scaling function depends on N and is often written as $N\phi$. Here, we suppress the N and just use ϕ . Recall that only two coefficients are needed for the Haar scaling function. In this case, polynomials of degree $N = 0$ can be represented with no error by scaling functions in V_0 for many situations as smoother scaling function is desired. We are looking for the conditions that must hold when we allow more than two coefficients, and require that polynomials of higher degree be represented exactly by functions in V_0 .

The space V_0 is orthogonal to W_0 ; consequently, for $j = 0, \dots, N - 1$,

$$\int_{-\infty}^{\infty} x^j \psi(x) dx = 0$$

Now, use Eq. (14) along with the trick (identity)

$$x^j = \left(\frac{2x - k + k}{2}\right)^j$$

which yields

$$\int_{-\infty}^{\infty} \sum_k \left(\frac{2x - k + k}{2}\right)^j d_k \phi(2x - k) dx = 0$$

The general binomial expansion

$$(a + b)^j = \sum_{r=0}^j \binom{j}{r} a^{j-r} b^r, \quad \binom{j}{r} = \frac{j!}{r!(j-r)!}$$

can be applied to give

$$2^{-j} \sum_{r=0}^j \binom{j}{r} \sum_k k^{j-r} d_k \int_{-\infty}^{\infty} (2x - k)^r \phi(2x - k) dx = 0$$

The change of variables $2x - k \rightarrow x$ leads to

$$2^{-j-1} \sum_{r=0}^j \binom{j}{r} \sum_k k^{j-r} d_k \int_{-\infty}^{\infty} x^r \phi(x) dx = 0$$

The integral over x cannot be zero because, by assumption, x^r can be written as a linear combination of translates of ϕ for $r = 0, \dots, N - 1$. It follows that we must require

$$\sum_{r=0}^j \binom{j}{r} \sum_k k^{j-r} d_k = 0$$

hold for individual values of j from 0 to $N - 1$. If you write this out for $j = 0$, then for $j = 1$ and $j = 2$, you see that the condition is

$$\sum_k k^j d_k = 0, \quad (j = 0, \dots, N - 1)$$

This is usually written in terms of the c_j coefficients from Eq. (18) with a slight modification. The index is usually shifted so the nonzero coefficients range from 0 to $2N - 1$ for the Daubechies coefficients [29]. This is accomplished by using the connection

$$d_k = (-1)^k c_{2N-1-k}$$

Then, the approximation condition becomes

$$\sum_{k=0}^{2N-1} (-1)^k k^j c_{2N-1-k} = 0, \quad (j = 0, \dots, N - 1) \quad (19)$$

Examples. The key equations are Eqs. (17)–(19). There are two coefficients for $N = 1$ that satisfy the conditions

$$c_0^2 + c_1^2 = 2, \quad c_0 - c_1 = 0$$

with region of support $[0, 1]$. These are the familiar Harr coefficients $c_0 = c_1 = 1$. For $N = 2$ we have four coefficients, known as the D4 coefficients. They satisfy orthogonality conditions

$$c_0^2 + c_1^2 + c_2^2 + c_3^2 = 2 \quad \text{and} \quad c_0 c_2 + c_1 c_3 = 0$$

and approximation conditions (for $j = 0$ and $j = 1$)

$$c_3 - c_2 + c_1 - c_0 = 0 \quad \text{and} \quad 0c_3 - 1c_2 + 2c_1 - 3c_0 = 0$$

The solution is unique up to a left–right reversal ($c_0 \leftrightarrow c_3, c_1 \leftrightarrow c_2$)

$$c_0 = (1 + \sqrt{3})/4 \quad c_1 = (3 + \sqrt{3})/4 \\ c_2 = (3 - \sqrt{3})/4 \quad c_3 = (1 - \sqrt{3})/4$$

Note that Eq. (16) is also satisfied by these D4 coefficients. Keep in mind that if the other popular normalization condition is used $c_n = \sqrt{2}h_n$, then each of these coefficients must be divided by $\sqrt{2}$. When this is done, then the sum of the squares is 1 rather than 2.

The region of support for the D4 scaling function and the wavelet function is $[0, 3]$. The graphs of these are shown in Fig. 9 across the top. The graphs for $N = 6$ (D12) are shown across the bottom. Here, the region of support is $[0, 11]$. Note that as the number of coefficients increases, the graphs get smoother and the region of support increases. Tables of coefficients for various values of N are given by Daubechies [29].

The functions in Fig. 9 are interesting, but knowing what these functions look like is absolutely unnecessary for implementation of the wavelet transform. The coefficients are all you need, coupled with an algorithm. An example is given in Section 7, and a method for obtaining Fig. 9 is indicated.

6.2.1. Other Wavelets. We have only touched the surface by indicating how to find the family of Daubechies wavelets. If the orthogonality and approximation conditions are modified, other sets of coefficients follow. For example, if you impose conditions of vanishing moments on ϕ as well as ψ , then the resulting wavelets are known as *coiflets*, after a suggestion by Ronald R. Coifman of Yale University. For more information on these, see Refs. 29, 36, and 37. Another example is provided by *biorthogonal wavelets*. The filter coefficients for the reconstruction are not the same as those for the decomposition, and there are two dual wavelet bases associated with two different multiresolution ladders. This leads to symmetric wavelets that are an advantage for some applications. Important references on these are by Cohen and Daubechies [38], Cohen, Daubechies, and Feauveau [39], and Vetterli and Herley [40].

6.2.2. Fourier Space Methods. Very powerful methods for finding wavelet coefficients are provided by Fourier techniques. These techniques can be used to find the family of Daubechies wavelets; also, they form a foundation for finding wavelets with other important properties.

Figure 9. D4 scaling function (top left), D4 wavelet (top right), D12 scaling function (bottom left), and D12 wavelet (bottom right).

Here, we only indicate how this can be started and then refer the reader to some excellent references where this approach is utilized.

Start with the dilation equation for the scaling function

$$\phi(x) = \sum_k c_k \phi(2x - k)$$

The Fourier transform of this equation is

$$\hat{\phi}(\xi) = \sum_k c_k \int_{-\infty}^{\infty} \phi(2x - k) e^{-i\xi x} dx$$

The change of variables $t = 2x - k$ gives

$$\hat{\phi}(\xi) = \frac{1}{2} \sum_k c_k e^{-ik\xi/2} \int_{-\infty}^{\infty} \phi(t) e^{-i\xi t/2} dt$$

Observe that the integral is just $\hat{\phi}(\xi/2)$, which yields

$$\hat{\phi}(\xi) = m_0\left(\frac{\xi}{2}\right) \hat{\phi}\left(\frac{\xi}{2}\right)$$

where, in keeping with the notation of Daubechies [29], we define

$$m_0(\xi) \equiv \frac{1}{2} \sum_k c_k e^{-ik\xi}$$

Note that $m_0(0) = 1$ follows from

$$m_0(0) = \frac{1}{2} \sum_k c_k e^0 = \frac{1}{2} \sum_k c_k = 1$$

If we make the replacement $\xi \rightarrow \xi/2$, then

$$\hat{\phi}\left(\frac{\xi}{2}\right) = m_0\left(\frac{\xi}{4}\right) \hat{\phi}\left(\frac{\xi}{4}\right)$$

and

$$\hat{\phi}(\xi) = m_0\left(\frac{\xi}{2}\right) m_0\left(\frac{\xi}{4}\right) \hat{\phi}\left(\frac{\xi}{4}\right) = \left[\prod_{j=1}^2 m_0\left(\frac{\xi}{2^j}\right) \right] \hat{\phi}\left(\frac{\xi}{2^2}\right)$$

Clearly, this procedure can be continued to give

$$\hat{\phi}(\xi) = \left[\prod_{j=1}^N m_0\left(\frac{\xi}{2^j}\right) \right] \hat{\phi}\left(\frac{\xi}{2^N}\right)$$

As $N \rightarrow \infty$, $\hat{\phi}(\xi/2^N) \rightarrow \hat{\phi}(0) = 1$, because the area under the scaling function is normalized to 1. This means that as $N \rightarrow \infty$, the infinite product goes to the Fourier transform of the scaling function,

$$\hat{\phi}(\xi) = \prod_{j=1}^{\infty} m_0\left(\frac{\xi}{2^j}\right)$$

Example. Let us investigate how this works for the box function, the scaling function for the Haar case. If $c_0 = c_1 = 1$, then

$$m_0\left(\frac{\xi}{2}\right) = \frac{1}{2} (1 + e^{-i\xi/2})$$

and

$$\begin{aligned} m_0\left(\frac{\xi}{2}\right)m_0\left(\frac{\xi}{4}\right) &= \frac{1}{2^2} (1 + e^{-i\xi/2})(1 + e^{i\xi/4}) \\ &= \frac{1}{2^2} (1 + e^{-i\xi/4} + e^{-2i\xi/4} + e^{-3i\xi/4}) \end{aligned}$$

The part in parenthesis on the right is just the sum of $2^2 = 4$ terms of a geometric series, where the first term is 1 and the ratio term r is $e^{-i\xi/4}$. The sum of n terms is given by $(1 - r^n)/(1 - r)$. Thus

$$m_0\left(\frac{\xi}{2}\right)m_0\left(\frac{\xi}{4}\right) = \frac{1}{2^2} \frac{1 - e^{i\xi}}{1 - e^{-i\xi/4}}$$

In the general case, where there are 2^j terms, the result is

$$m_0\left(\frac{\xi}{2}\right) \dots m_0\left(\frac{\xi}{2^j}\right) = \frac{1}{2^j} \frac{1 - e^{i\xi}}{1 - e^{-\xi/2^j}}$$

Now let $2^{-j} = x$, then

$$2^j(1 - e^{-i\xi/2^j}) = \frac{1 - \cos x\xi}{x} + i \frac{\sin x\xi}{x}$$

In the limit as $j \rightarrow \infty$ and $x \rightarrow 0$, we get $i\xi$. It follows that

$$\prod_{j=1}^{\infty} m_0\left(\frac{\xi}{2^j}\right) = \frac{1 - e^{-i\xi}}{i\xi}$$

This is just the Fourier transform of ϕ where ϕ is the box function,

$$\hat{\phi}(\xi) = \int_{-\infty}^{\infty} \phi(x)e^{-i\xi x} dx = \int_0^1 e^{-\xi x} dx = \frac{1 - e^{-i\xi}}{i\xi}$$

just as expected.

A rich resource of information about wavelets comes from using Fourier techniques. The books by Hernández and Weiss [10], Vetterli and Kovačević [23], Strang and Nguyen [41], and Daubechies [29] are excellent sources.

7. MECHANICS OF DOING THE TRANSFORM

This example of how the wavelet transform can be implemented using matrices will be of value to those who wish to acquire an intuitive understanding about how the transform works. This is for illustration only, because in practice, efficient code may not be written in matrix form.

This example is for the simplest case, the Haar; however, the extension to smoother cases is easy, and we will indicate how easy following this example. The following operations are illustrated:

1. Generate the wavelet coefficients with downsampling.
2. Show how this is a dual-filter operation with a shrinking matrix and signal.
3. Mechanics of the reconstruction, the inverse transform.

There is a pyramidal structure to the procedure. At each level, the detail information is stored, whereas the smooth information may be transformed at the next higher scale. One way to indicate this is shown in Fig. 10, where we have carried the transform through three stages.

Let the transpose of the original signal vector for an eight-point transform be designated by

$$[16, 32, 64, 16, 6, 32, 16, 8]$$

The full smoothing operator (the lowpass part) with $c_0 = c_1 = 1$ is given by

$$S = \frac{1}{2} \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

The shift on the last row is to take into account edge effects, and is essential to ensure that the inversion is exact. The highpass operator associated with the detail is given

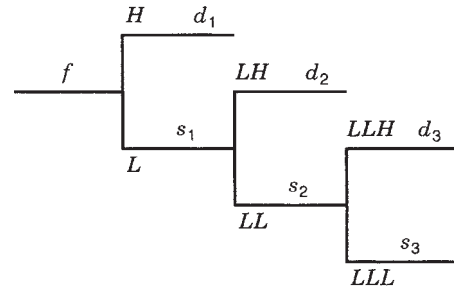

Figure 10. Pyramidal decomposition of a signal. The low- and highpass parts are indicated by L and H . The corresponding smooth and detail parts are designated by s and d with subscripts indicating the level.

by

$$H = \frac{1}{2} \begin{pmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & -1 \\ -1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

Now we calculate the detail and smooth coefficients that lie in W_1 and V_1 , respectively

$$\begin{aligned} d_1 = Hf \downarrow &= [-8, -16, 24, 4, -12, 8, 4, -4] \\ \downarrow &= [-8, 24, -12, 4] \end{aligned}$$

and

$$\begin{aligned} s_1 = S_f \downarrow &= [24, 48, 40, 12, 20, 24, 12, 12] \\ \downarrow &= [24, 40, 20, 12] \end{aligned}$$

The use of the down arrow is to indicate downsampling. Every other value is discarded. You might think information has been lost by doing this, but note that you started with eight independent values in the signal and after downsampling you still have eight independent values, four detail and four smooth coefficients. These can be used to recover the original values. The next step is to contract the matrices S and H ,

$$S = \frac{1}{2} \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \end{pmatrix}$$

$$H = \frac{1}{2} \begin{pmatrix} 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 \\ -1 & 0 & 0 & 1 \end{pmatrix}$$

The coefficients for W_2 and V_2 follow by applying these new contracted matrices to the s_1 vector,

$$\begin{aligned} d_2 = Hs_1 \downarrow &= [-8, 10, 4, -6] \downarrow = [-8, 4] \\ s_2 = Ss_1 \downarrow &= [32, 30, 16, 16] \downarrow = [32, 16] \end{aligned}$$

Once again, we contract S and H ,

$$S = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \quad H = \frac{1}{2} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$$

The last two coefficients are found as before

$$d_3 = Hs_2 \downarrow = [8, -8] \downarrow = [8], \quad s_3 = Ss_2 \downarrow = [24, 24] \downarrow = [24]$$

This completes the eight-point transform. The eight points in the signal vector have been transformed by the Haar wavelet transform to eight points,

$$d_1 = [-8, 24, -12, 4] \quad d_2 = [-8, 4] \quad d_3 = [8] \quad s_3 = [24]$$

The inverse transform must start with the wavelet coefficients and end with the original signal coefficients. This is done by a clever reversal of the directions in Fig. 10, with a sum used to go from two branches on the right to one on the left, at a vertex where three lines meet. Here is how it works. Use the transpose of S and H without the factor of $\frac{1}{2}$ at each step and insert zeros where there were discarded values. This upsampling is indicated by the up arrow.

$$S^\dagger = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \quad H^\dagger = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$$

$$S^\dagger s_3 \uparrow = S^\dagger \begin{pmatrix} 24 \\ 0 \end{pmatrix} = \begin{pmatrix} 24 \\ 24 \end{pmatrix} \quad H^\dagger d_3 \uparrow = H^\dagger \begin{pmatrix} 8 \\ 0 \end{pmatrix} = \begin{pmatrix} 8 \\ -8 \end{pmatrix}$$

The s_2 signal is recovered by addition

$$\begin{pmatrix} 24 \\ 24 \end{pmatrix} + \begin{pmatrix} 8 \\ -8 \end{pmatrix} = \begin{pmatrix} 32 \\ 16 \end{pmatrix}$$

At the next step, we have

$$S^\dagger = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix} \quad H^\dagger = \begin{pmatrix} 1 & 0 & 0 & -1 \\ -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & -1 & 1 \end{pmatrix}$$

$$S^\dagger s_2 \uparrow = S^\dagger \begin{pmatrix} 32 \\ 0 \\ 16 \\ 0 \end{pmatrix} = \begin{pmatrix} 32 \\ 32 \\ 16 \\ 16 \end{pmatrix}$$

$$H^\dagger d_2 \uparrow = H^\dagger \begin{pmatrix} -8 \\ 0 \\ 4 \\ 0 \end{pmatrix} = \begin{pmatrix} -8 \\ 8 \\ 4 \\ -4 \end{pmatrix}$$

Again, by addition we recover the s_1 signal,

$$\begin{pmatrix} 32 \\ 32 \\ 16 \\ 16 \end{pmatrix} + \begin{pmatrix} -8 \\ 8 \\ 4 \\ -4 \end{pmatrix} = \begin{pmatrix} 24 \\ 40 \\ 20 \\ 12 \end{pmatrix}$$

In the final step we are back to the full matrices

$$S^\dagger = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}$$

$$H^\dagger = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & -1 \\ -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 \end{pmatrix}$$

The upsampling gives

$$S^\dagger s_1 \uparrow = S^\dagger \begin{pmatrix} 24 \\ 0 \\ 40 \\ 0 \\ 20 \\ 0 \\ 12 \\ 0 \end{pmatrix} = \begin{pmatrix} 24 \\ 24 \\ 40 \\ 40 \\ 20 \\ 20 \\ 12 \\ 12 \end{pmatrix} = H^\dagger d_1$$

$$\uparrow = H^\dagger \begin{pmatrix} -8 \\ 0 \\ 24 \\ 0 \\ -12 \\ 0 \\ 4 \\ 0 \end{pmatrix} = \begin{pmatrix} -8 \\ 8 \\ 24 \\ -24 \\ -12 \\ 12 \\ 4 \\ -4 \end{pmatrix}$$

The original signal vector is recovered by addition

$$f = \begin{pmatrix} 24 \\ 24 \\ 40 \\ 40 \\ 20 \\ 20 \\ 12 \\ 12 \end{pmatrix} + \begin{pmatrix} -8 \\ 8 \\ 24 \\ -24 \\ -12 \\ 12 \\ 4 \\ -4 \end{pmatrix} = \begin{pmatrix} 16 \\ 32 \\ 64 \\ 16 \\ 8 \\ 32 \\ 16 \\ 8 \end{pmatrix}$$

This concludes the Haar example; however, some additional things should be observed. It is possible to combine the matrix multiplication and the up- and downsampling. For a discussion of this, see Strang and Nguyen [41]. Also, one can combine the operations of finding the d and s parts along with the downsampling. A practical example of this is contained in Ref. 42, section 13.10, for the Daubechies D4 wavelet with four coefficients. In addition to Ref. 42, other sources of code for efficient implementation of the forward and inverse wavelet transform include Bruce and Gao [43] and Cody [44,45]. Also, see Section 10. Finally, note that if we start with

$$d_1 = [0, 0, 0, 0] \quad d_2 = [0, 0] \quad d_3 = [1] \quad s_3 = [0]$$

and apply the inverse transform, we get back the wavelet function

$$[1, 1, 1, 1, -1, -1, -1, -1]$$

This is one way to obtain the wavelets illustrated in Fig. 9. We simply run a unit vector, made up of 0's except for a 1 in a single location through the inverse transform.

8. OCTAVE BAND TREE STRUCTURE

The type of division of the spectrum for the tree structure of Fig. 10 is known as a *dyadic* or *octave* band. The part labeled s is the lowpass part and the part labeled d is the highpass part. At each level of the tree, the lower half of the spectrum is split into two equal bands. In Fourier space, this can be represented by Fig. 11. For an extensive discussion of tree structures and the corresponding frequency band splits, see Akansu and Haddad [46]. Another

Figure 11. Relation of positive part of frequency spectrum to ideal high- and lowpass parts from Fig. 10.

important type of tree structure for wavelet analysis is that used in connection with wavelet packets and best basis algorithms pioneered by Coifman and Wickerhauser [47,48] and Wickerhauser [49]. In this type of tree, there is an option along both the highpass and lowpass branches to send the signal through more highpass and lowpass filters. This is part of an important and extensive area of wavelet theory known as *adaptive wavelet transform methods*. For a full discussion, we refer the reader to Refs. 47–49 and the Reading List.

An extension of the octave band tree structure to 2-D was suggested by Burt and Adelson [24]. The technique goes by the name of the *Laplacian pyramid*. The multi-resolution analysis can be extended to 2-D for functions $f(x, y)$, for details see Daubechies [29]. We define a scaling function of two variables and three wavelets. These come from tensor products of horizontal and vertical 1-D wavelets. Here, superscripts s, h, v , and d refer to smooth, horizontal, vertical, and diagonal, respectively.

$$\Phi^s(x, y) = \phi(x)\phi(y) \quad L(x)L(y)$$

$$\Psi^h(x, y) = \phi(x)\psi(y) \quad L(x)H(y)$$

$$\Psi^v(x, y) = \psi(x)\phi(y) \quad H(x)L(y)$$

$$\Psi^d(x, y) = \psi(x)\psi(y) \quad H(x)H(y)$$

This leads to a decomposition at levels 1 and 2 illustrated by Fig. 12. At level 2, the smooth part from level 1 is further divided to produce the parts in the upper left corner. To go to level 3, the upper left smooth-smooth part would be further broken down as in going from level 1 to level 2. This can go on as far as is practical. In an image, horizontal edges show prominently in the Ψ^h part, vertical edges in the Ψ^v part, and diagonal edges in the Ψ^d part. See Fig. 13 and the discussion and images in Chapter 10 of Ref. 29.

9. SOME INTERESTING APPLICATIONS

The range of fields, both pure and applied, where wavelets have had an impact is wide. The disciplines include mathematics, physics, geophysics, fluid dynamics, engineering,

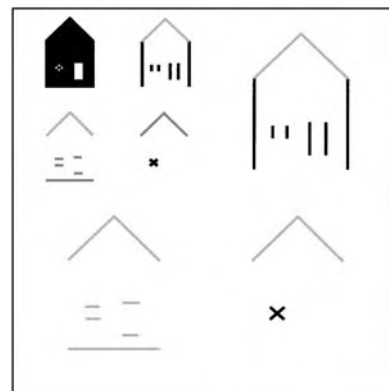

2 $L(x)L(y)$ $L(x)L(y)$	2 $L(x)L(y)$ $H(x)L(y)$	1 $H(x)L(y)$
2 $L(x)L(y)$ $L(x)H(y)$	2 $L(x)L(y)$ $H(x)H(y)$	
1 $L(x)H(y)$		1 $H(x)H(y)$

Figure 12. Decomposition of the 2-D transform into two levels. To go to the next level the lowpass part in the upper left is further broken down just as going from level 1 to level 2.

computer science, and medicine. The broad list of topics include Fourier analysis, approximation theory, numerical analysis, functional analysis, operator theory, group representations, fractals, turbulence, signal processing, image processing, medical imaging, various types of

(a)

(b)

compressions, speech and audio, image, and video. In this section, we give a brief introduction to some of these applications and provide the reader with references to current literature for further study.

9.1. Compression

In many cases, a digitized image contains more information than is needed to convey the message the image carries. In these cases, we want to remove some of the information in the original image without degrading the quality too much; this is called *lossy compression*. This modified image can be stored more economically and can be transmitted more rapidly, using less bandwidth over a communications channel. Wavelets have been used for these kinds of problems with striking success. We illustrate this in Fig. 14. The original image is upper left. To obtain the image upper right, we performed a wavelet transform of the original image, kept 25% of the coefficients with the largest magnitude, replaced the other 75% with zeros, then did the inverse transform. The resulting image is clearly degraded, but not significantly. On the lower left, we did the same thing with 6.25% of the coefficients, and on the lower right with only 1.56%.

There is an enormous amount of literature on compression. Here we suggest only a few recent articles. These contain guidance to earlier work. Uses of wavelet transform maxima in signal and image processing are described by Mallat and Zhong [50] and Mallat [51]. Some new ideas on optimal compression are discussed by Hsiao, Jawerth,

Lucier, and Yu [52] and DeVore, Jawerth, and Lucier [53]. See Ref. 23 for a general discussion of video compression, and speech and audio compression. Acoustic signal compression with wavelet packets and a comparison of compression methods are given by Wickerhauser [54,55], and some general theorems on optimal bases for data compression are developed by Donoho [56].

9.2. Turbulence

Wavelet analysis has provided a new means for examining the structure of turbulent flow. They are especially useful when it is important to obtain some information about the spatial structure of the flow. Some of the pioneer work in this area along with a comparison of older methods is in the review by Marie Farge [57]. Also, see the paper on wavelets and turbulence by Farge, Kevlahan, Perrier, and Goirand [58] for a discussion of the main applications of wavelets and wavelet packets to analyze, model, and compute turbulent flows. Wavelet spectra of buoyant atmospheric turbulence are analyzed by Mayer, Hudgins, and Friehe [59], and an experimental study of inhomogeneous turbulence in the lower troposphere using wavelet analysis is discussed by Druilhet et al. [60]. Wickerhauser et al. [61] compare methods for compression of a two-dimensional turbulent flow and find that the wavelet packet representation is superior to the local cosine representation.

Figure 14. Boat figure to illustrate compression: (a) original, (b) use largest 25%, (c) use largest 6.25%, (d) use largest 1.56%. The degradation can be seen as fewer and fewer coefficients are used to reconstruct the boat.

9.3. Fractals

The wavelet transform is valuable for the efficient representation of scale-invariant signals. Fractal geometry is being used more and more to describe processes that do not fit naturally into traditional Euclidean geometry. Many fractals of interest have structure that is *similar* on different scales. These properties of wavelets and fractals lead to important foundations for scale-invariant signal models. The discrete wavelet transform algorithm is a key component for practical processing of scale-invariant signals and for estimating fractal dimensions. Signal processing with fractals using wavelets is an emerging area, one that is exciting with much work remaining to be done. An important resource in this field is the book by Wornell [62]. The local self-similarity aspect of fractals and the analysis through wavelet transforms is discussed by Holschneider [34], Chapter 4. These two references and the brief review by Hazewinkel [63] provide guidance to the rich literature in this field.

9.4. Medicine and Biology

Wavelets are playing an important role in many areas of medicine and biology. A review of one-dimensional processing in bioacoustics, electrocardiography (ECG), and electroencephalography (EEG) is given by Unser and Aldroubi [64]. This article also contains a brief review of biomedical image processing. Applications of importance include: *noise reduction* in magnetic resonance images [65] using methods systematized by Donoho and Johnstone [66,67] and DeVore and Lucier [68], *image enhancement and segmentation* in digital mammography to accentuate and detect image features that are clinically relevant [69–71], and *image restoration* to restore degradation because of photon scattering and collimator photon penetration with the gamma camera [72]. A general strategy for extraction of microcalcification clusters in digitized mammograms making use of wavelets is outlined by DeVore, Lucier, and Yang [73], and a multiresolution statistical method for the identification of normal mammograms with respect to microcalcifications has been developed [74]; the key to the method is the recognition of the statistical properties of the various levels of the wavelet decomposition. In *computer-assisted tomography* (CT) the Radon transform [75] is fundamental to the algorithms for reconstruction from projections. Several authors have successfully combined wavelet methods with Radon methods to obtain improved algorithms for certain areas of CT (see Refs. 64 and 76 and citations therein). Other medical applications are to *magnetic resonance imaging* (MRI) [77] and functional neuroimaging using *positron emission tomography* (PET) and *functional MRI* (fMRI). A review is given by Unser and Aldroubi [64].

9.5. Others

There are several other areas of application where the wavelet transform plays a key role. We have added a reading list at the end of the bibliography. A quick survey of this list will provide guidance to good starting points for various applications.

10. WAVELETS ON THE INTERNET

An increasing amount of wavelet resources are available on the Internet. Preprints of academic papers are available on the Internet long before they appear in print. Many researchers maintain Internet sites where they post their papers, software, and tutorial guides. In fact the World Wide Web (Web), the graphical interface of the Internet, was created by Tim Berners-Lee while he was at the CERN particle physics laboratory in Geneva. The particle physics community has pioneered in the use of the Internet and the Web in the exchange of ideas, abstracts, and papers since 1991.

A similar effort has been made by Wim Sweldens who founded the *Wavelet Digest* in 1992. The *Wavelet Digest* is a free monthly newsletter, edited by Sweldens, available to subscribers by e-mail. One can browse through past issues of the digest at the Wavelet Digest home page (<http://www.wavelet.org/wavelet/index.html>). The *Wavelet Digest* carries announcements of papers, books, conferences, and seminars in the field of wavelets. It is also a forum for subscribers to ask questions they have about wavelets. Given the wide reach of the *Wavelet Digest*, someone is likely to have an answer for almost any question.

The Collection of Computer Science Bibliographies at the Department of Computer Science of the University of Karlsruhe, Germany has a *Bibliographies on Wavelets* (<http://iinwww.ira.uka.de/bibliography/Theory/Wavelets/>). This is a fairly comprehensive collection of references, although many of them are not available on the Web.

The MathSoft Wavelet Resources page (<http://www.mathsoft.com/wavelets.html>) has a list of links to preprints and papers available on the Web.

Most wavelet pages on the Web have links to other wavelet resources on the Web. The wavelet page maintained by Andreas Uhl at the Department of Mathematics at the University of Salzburg, Austria (<http://www.mat.sbg.ac.at/~uhl/wav.html>) has a useful list of links to wavelet pages, and the Amara Graps wavelet page (<http://www.amara.com/current/wavelet.html>) has a comprehensive list of wavelet links. Also, the Amara Graps page provides a list of wavelet software available on the Internet along with a brief description of each software listed.

The WaveLab software for Matlab written by David Donoho, Iain Johnstone, Jonathan Buckheit, and Shaobing Chen at the Stanford University Statistics Department along with Jeffrey Scargle at NASA-Ames Research Center is available at (<http://stat.stanford.edu/~wave-lab/>). This site includes Macintosh, Unix, and PC versions of the software, including instructions on how to download and install the software.

MathWorks, the creators of Matlab, have introduced the Wavelet Toolbox. The Wavelet Toolbox is written by Michael Misiti, Yves Misiti, Georges Oppenheim, and Jean-Michel Poggi, who are all members of “Laboratoire de Mathématiques,” Orsay-Paris 11 University, France. The book *Wavelets and Filter Banks*, by Gilbert Strang and Truong Nguyen [41], comes with the Toolbox. The

exercises and examples in the book complement the Wavelet Toolbox. The Toolbox has both graphical user interface (GUI) and command line routines. Information on the toolbox can be found at the Matlab Wavelet Toolbox site (<http://www.mathworks.com/products/wavelettbx.shtml>).

An example of a wavelet application in the real world can be found at the Federal Bureau of Investigation (FBI) fingerprint image compression standard website (<http://www.c3.lanl.gov/~brislawn/FBI/FBI.html>). The FBI selected a wavelet standard for digitized fingerprints, and this site gives some of the reasons behind the choice.

Another interesting site on the Web is the Jelena Kovačević Bell Labs Wavelet Group page that includes a link to wavelet related Java applets (http://cm.bell-labs.com/who/jelena/Wavelet/w_applets.html).

This list is far from comprehensive. The interested reader can find wavelet-related links at these sites or by searching on any of the Internet search engines. There are some things one must keep in mind while browsing the Web. Not all information on the Web has been screened by any rigorous peerreview process. One must check the provenance of the information on the Web. Also note that Web addresses are not permanent. The author of a page may graduate or change jobs and the site could be removed. The Internet is a useful resource for any serious researcher. One cannot only get a lot of useful information on the Web, but one can contact other researchers to exchange ideas, data, and programs.

Wavelets have been found to be useful in many scientific and engineering applications, including signal processing, communication, video and image compression, medical imaging, and scientific visualization. The concept of wavelets can be viewed as a synthesis of ideas that originated during the last several decades in engineering, physics, and pure mathematics. Although wavelets are a rather simple mathematical tool with a great variety of possible applications, the subject of wavelets is often introduced at a high level of mathematical sophistication. The goal of this article is to develop a basic understanding of wavelets, their origin, and their relation to scaling functions, using the theory of multiresolution analysis.

1. HISTORICAL PERSPECTIVE [1–14]

Prior to the 1930s, the main tools of mathematics for solving scientific and engineering problems traced back to Joseph Fourier (1807) with his theory of frequency analysis. He proposed that any 2π -periodic function $f(t)$ can be represented by a linear combination of cosines and sines:

$$f(t) = a_0 + \sum_{k=1}^{\infty} (a_k \cos kt + b_k \sin kt) \tag{1}$$

The coefficients a_0 , a_k , and b_k are the *Fourier coefficients* of the series and are given by

$$a_0 = \frac{1}{2\pi} \int_0^{2\pi} f(t) dt \tag{2a}$$

$$a_k = \frac{1}{2\pi} \int_0^{2\pi} f(t) \cos kt dt \tag{2b}$$

$$b_k = \frac{1}{2\pi} \int_0^{2\pi} f(t) \sin kt dt \tag{2c}$$

After 1807, mathematicians gradually were led from the notion of frequency analysis to the notion of scale analysis—that is, analyzing $f(t)$ by creating a mathematical structure that varies in scale. A. Haar, in his thesis (1909), was the first to mention using wavelets. An important property of the wavelets he used is that they have compact support, which means that the function vanishes outside a finite interval. Unfortunately, Haar wavelets are not continuously differentiable, which limits their application.

From the 1930s to the 1960s, several groups, working independently, researched the representation of functions using scale-varying basis functions. By using one such function, the *Haar basis function*, Paul Levy investigated Brownian motion and thereby laid the foundation for the modern theory of random processes. He found that the Haar basis function is superior to the Fourier basis functions for studying small and complicated details in Brownian motion.

Also during the 1930s, research was done by Littlewood, Paley, and Stein on computing the *energy* of a function $f(t)$:

$$\text{energy} = \frac{1}{2} \int_0^{2\pi} |f(t)|^2 dt \tag{3}$$

Their computation produced different results when the energy was concentrated around a few points and when it was distributed over a larger interval. This observation disturbed many scientists, because it indicated that energy might not be conserved. Later on, they discovered a function that can both vary in scale and conserve energy at the same time, when computing the functional energy. David Marr applied this work in developing an efficient algorithm for numerical image processing using wavelets in the early 1980s.

Between 1960 and 1980, the mathematicians Guido Weiss and Ronald Coifman studied the simplest elements of a function space, called *atoms*, with the goals of finding the atoms for a common function and finding the *construction rules* that allow the reconstruction of all the elements of the function space using these atoms. In 1980, Grossman and Morlet recast the study of quantum physics in the context of wavelets using the concept of frames. Morlet introduced the term “wavelet” as an abbreviation of “wavelet of constant shape.” These new insights into using wavelets provided a totally new way of thinking about physical reality.

In the summer of 1985, Stephane Mallat applied wavelets to his work in digital signal processing. He discovered a relationship between quadrature mirror filters, the pyramid algorithm, and orthonormal wavelet bases. Inspired by these results, Y. Meyer constructed the first nontrivial wavelets. Unlike the Haar wavelets, the Meyer wavelets are continuously differentiable; however, they do not have compact support. In the early 1990s, Ingrid Daubechies used Mallat’s work to construct a set of orthonormal wavelet basis functions that are perhaps the most elegant, and have become the cornerstone of wavelet applications today.

The development of wavelets is an emerging field comprising ideas from many different fields. The foundations

of wavelet theory have been completed, and current research is in the refinement stage. The refinement involves generalizations and extensions of wavelets, such as extending wavelet packet techniques.

The future of wavelets depends on the possibility of applications. Wavelets have so far been limited in practical applications by their lack of compact support.

2. FOURIER ANALYSIS

Time-series data have traditionally been analyzed in either the time- or the frequency-domain. Fourier analysis is quite useful in identifying frequency components of a signal, but it cannot describe when those frequency components occurred, because it lacks time resolution. This is particularly important for signals with time-varying frequency content, as in human speech and video images.

The Fourier transform is characterized by the ability to analyze a signal in the time-domain for its frequency content. The transform works by first translating a function in the time-domain into a function in the frequency-domain. The signal can then be analyzed for its frequency content, because the Fourier coefficients of the transformed function represent the contribution of each sine and cosine function at each frequency. An Inverse transform does the opposite by transforming data from the frequency-domain into the time-domain. Although the time-series data can have infinitely many sample points, in practice one deals with a finite time interval using a sampling mechanism. The discrete Fourier transform (DFT) estimates the Fourier transform of a function from a finite number of its sampled points. The sampled points are supposed to be typical of what the signal looks like at all other times. The DFT has symmetry properties almost exactly the same as the continuous Fourier transform. To approximate a function by samples, and to approximate the Fourier integral by the DFT, requires multiplication by a matrix that involves on the order of n^2 arithmetic operations. However, if the samples are uniformly spaced, then the Fourier matrix can be factored into a product of just a few sparse matrices, and the resulting factors can be applied to a vector in a total on the order of $n \log n$ arithmetic operations. This technique is the so-called fast Fourier transform (FFT).

3. WAVELET VERSUS FOURIER TRANSFORM

The FFT and the discrete wavelet transform (DWT) are both linear operations that generate a data structure containing $\log_2 n$ segments of various lengths, usually filling it and transforming it into a different data vector of length 2^n .

The mathematical properties of the matrices involved in the transforms are similar as well. The inverse transform matrix for both the FFT and the DWT is the transpose of the original. As a result, both transforms can be viewed as a rotation in function space to a different domain [1]. For the FFT, this new domain contains basis

functions that are sines and cosines. For the wavelet transform, this new domain contains more complicated basis functions called wavelets, mother wavelets, or analyzing wavelets.

The two transforms have another similarity. The basis functions are localized in frequency, making mathematical tools such as power spectra (how much power is contained in a frequency interval) and scalegrams useful at picking out frequencies and calculating power distributions.

The most interesting dissimilarity between these two kinds of transforms is that individual wavelet functions are localized in space. Fourier sine and cosine functions are not. This localization in space, along with wavelets' localization in frequency, makes many functions and operators using wavelets *sparse* when transformed into the wavelet domain. This sparseness, in turn, makes wavelets useful for a number of applications such as data compression, feature detection in images, and noise removal from time series.

One way to see the time–frequency resolution difference between the two transforms is to look at the basis-function coverage of the time–frequency plane [7,14]. Figure 1 shows a windowed Fourier transform, where the window is simply a square wave. The square-wave window truncates the sine or cosine function to particular width. As a single window is used for all frequencies in the WFT, the resolution of the analysis is the same at all locations in the time–frequency plane. An advantage of wavelet transforms is that the windows vary. In order to isolate signal discontinuities, one would like to have some very short basis functions. At the same time, in order to obtain detailed frequency analysis, one would like to have some very long basis functions. A way to achieve this is to have short high-frequency basis functions and long low-frequency ones. This happy medium is exactly what you get with wavelet transforms. Figure 2 shows the coverage in the time–frequency plane with one wavelet function, the Daubechies wavelet.

Figure 1. Fourier basis functions, time–frequency tiles, and coverage of the frequency plane [1].

Figure 2. Daubechies wavelet basis functions, time–frequency tiles, and coverage of the frequency plane [1].

4. WAVELET ANALYSIS

Wavelets are a class of functions used to localize a given function in both space and scaling. The basic construction of wavelets is based on the family of *mother wavelets* ϕ , consisting of almost any function defined in a finite interval. *Daughter wavelets* are then formed by translation (b) and scaled contraction (a). An individual wavelet can be defined by

$$\phi_{[a,b]}(t) = |a|^{-1/2} \phi\left(\frac{t-b}{a}\right) \quad (4)$$

An example of a typical wavelet is $a = 2^{-j}$ and $b = ak$:

$$\phi_{[j,k]}(t) = 2^{j/2} \phi(2^j t - k) \quad (5)$$

More precisely, it can be written as a linear combination of scaling functions $\phi(2^j t - k)$, which are 2^{-j} -scaled and $k/2^j$ -translated version of $\phi(t)$, as follows:

$$\phi_{[j,k]}(t) = \sum_{k=-\infty}^{\infty} p_k \phi(2^j t - k) \quad (6)$$

This is often referred to as the two-scale function for the scaling functions, and the sequence $\{p_k\}$ is called the two-scale sequence of ϕ .

Given a scaling function ϕ , the basic assumption of multi-resolution analysis is that another function ψ exists, called a wavelet, such that ϕ forms a basis for the reconstruction of ψ , analogously to the relation for a scaling function. The reconstruction of the wavelet can be expressed as follows:

$$\psi_{[j,k]}(t) = \sum_{k=-\infty}^{\infty} q_k \phi(2^j t - k) \quad (7)$$

The two-scale relations in Eqs. (6) and (7) together are called the reconstruction relations. As both $\phi(2x)$ and

$\phi(2x - 1)$ are in the subspace of the analyzing function, Eqs. (6) and (7) can be combined to form the *reconstruction relations*:

$$\phi(2t - l) = \sum_{k=-\infty}^{\infty} [a_{l-2k} \phi(t - k) + b_{l-2k} \psi(t - k)] \quad (8)$$

Although many classes of wavelets exist, there are two main typical classes:

1. The wavelets defined on the real line, such as the Haar wavelet, the Daubechies wavelet, and B-spline wavelets in general. Linear, quadratic, and cubic wavelets have been studied.
2. Multiwavelets, or wavelet-like functions defined on finite intervals, such as Legendre wavelets and flat-let wavelets.

The interested reader is referred to Refs. 11–14.

4.1. Haar Wavelet

The Haar scaling function and Haar wavelet are a very simple example to illustrate many nice properties of scaling functions and wavelets, and are of practical use as well. The Haar scaling function is defined by

$$\phi(t) = \begin{cases} 1 & \text{for } 0 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

The two-scale relation can be expressed in a summation as shown below:

$$\phi_2^H(t) = \sum_{k=0}^2 p_k \phi(2t - k) \quad (10a)$$

or

$$\phi(t) = \phi(2t) + \phi(2t - 1) \quad (10b)$$

The Haar wavelet corresponding to the Haar scaling function is given by

$$\psi(t) = \begin{cases} 1 & \text{for } 0 \leq x \leq \frac{1}{2} \\ -1 & \text{for } \frac{1}{2} \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

We can easily construct the two-scale relation for the Haar wavelet as

$$\psi(2t) = \phi(2t) - \phi(2t - 1) \quad (12)$$

The two-scale relations in Eq. (10b) express $\phi(t)$ in terms of $\phi(2t)$ and $\phi(2t - 1)$, whereas the two-scale relations in Eq. (12) for Haar wavelets express $\psi(t)$ in terms of $\phi(2t)$ and $\phi(2t - 1)$. The reconstruction relations can be

written in the matrix form

$$\begin{bmatrix} \phi(t) \\ \psi(t) \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} \phi(2t) \\ \phi(2t-1) \end{bmatrix} \tag{13}$$

The decomposition relations are easily derived by just inverting the reconstruction relations as follows:

$$\begin{bmatrix} \phi(2t) \\ \pi(2t-1) \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} \end{bmatrix} \begin{bmatrix} \phi(t) \\ \psi(t) \end{bmatrix} \tag{14}$$

4.2. Daubechies Wavelets

Another example of wavelets defined on the real line is Daubechies wavelets. The Daubechies scaling function ϕ_3^D is defined by the following relation:

$$\phi_3^D(t) = \sum_{k=0}^3 p_k \phi(2t-k) \tag{15}$$

where two-scale sequence $\{p_k\}$ are

$$\{p_1, p_2, p_3, p_4\} = \left\{ \frac{1+\sqrt{3}}{4}, \frac{3+\sqrt{3}}{4}, \frac{3-\sqrt{3}}{4}, \frac{1-\sqrt{3}}{4} \right\} \tag{16}$$

In general, the two-scale sequence for any scaling functions has the property

$$\sum_k p_{2k} = \sum_k p_{2k+1} = 1 \tag{17}$$

There is no closed form for ϕ_3^D ; however, one can use numerical computation to draw the graph of ϕ_3^D [1,2].

The Haar wavelet is the simplest one. It has found many applications. However, it has the drawback of discontinuity. It consists entirely of rectangular functions and cannot reproduce even linear functions smoothly in finite series for practical use. On the other hand, B-spline wavelets have higher continuity than Haar wavelets. They are more suitable for representing any continuous function. However, the complications of calculating its wavelet decomposition and reconstruction relation coefficients have limited its usefulness.

5. SUBBAND CODING [7,12–15]

One of the main applications of subband coding is compression. A key concept in signal analysis is that of *localization* in time and frequency. Another important intuitive concept is that of *multiresolution*, or the idea that one can consider a signal at different levels of resolution. These notions are particularly evident in image processing and computer vision, where coarse versions of images are often used as a first approximation in computational algorithms. In signal processing, a low-pass and subsampled

version is often a good coarse approximation for many real-life signals. This intuitive paradigm leads to the mathematical framework for wavelet constructions [12]. The wavelet decomposition is a successive approximation method that adds more and more projections onto *detail* spaces, or spaces spanned by wavelets and their shifts at different scales.

In addition, this multiresolution approximation is well suited to many applications. That is true in cases where successive approximation is useful, for example, in browsing through image databases, as is done for instance on the World-Wide Web. Rather than downloading each full image, which would be time-consuming, one only needs to download a coarse version, which can be done relatively fast. Then, one can fetch the rest, if the image seems of interest. Similarly, for communication applications, multiresolution approximation leads to transmission methods where a coarse version of a signal is better protected against transmission errors than the detailed information. The assumption is that the coarse version is probably more useful than the detail.

There are many techniques for image coding. Subband coding is the most successful today. Pyramid coding is effective for high bit rate compression, and transform coding based on the discrete cosine transform has become the JPEG standard. Subband coding using wavelets (the tree-structured filter-bank approach) avoids blocking at medium bit rates, because its basis functions have variable length. It uses an adapted basis (the transformation depends on the signal). Long basis functions represent flat background (low frequency), and short basis functions represent regions with texture. This feature is good for image enhancement, image edge detection, image classification, videoconferencing, video on demand, tissue and cancer cell detection [16], and so on. And because of its adapted basis functions, one can also develop a set of algorithms for adaptive filtering systems [7].

6. WAVELET APPLICATIONS

This section discusses the applications of wavelets in digital communication systems and in image and video compression. We will present a brief description of how wavelets can be used (1) to improve communication efficiency in digital communication systems, and (2) to remove redundant information (e.g., spatial redundancy, spectral redundancy, and temporal redundancy) in image and video compression for an FBI fingerprint application. Other applications in computer and human vision and for denoising noisy data are also described.

6.1. Wavelets in Digital Communications

The channel coding that follows source coding is designed to reintroduce—in a controlled manner—a prescribed level of redundancy into the source-coded streams to mitigate the anticipated effects of the channel, and best performance is achieved when the redundancy is tailored to the specific characteristics of the channel. Although channel coding and modulation applications have received comparatively little attention to date, wavelet theory has an

important complementary role to play in this aspect of the communications problem. Wavelet representation can be exploited to develop systems for reliable transmission over specific channels such as satellite or mobile wireless channels or a combination of both. The problem of multiple-user communication over a wireless channel is of greatest interest in practice. A wireless communication channel is subject to mutual interference among users and fading because of time-varying multipath propagation. To combat the interference and fading effects, a popular multirate modulation technique, referred to as *spread-spectrum code-division multiplexing access* (SS CDMA) has been used widely in the industry [17–22]. This subsection focuses on the use of wavelets for SS CDMA digital communication systems. In addition, a brief description of fractal modulation using wavelets is described.

6.1.1. Single-Scale Covert Communication Waveform.

The idea of wavelet-based SS CDMA was proposed in Ref. 18. The proposed algorithm is summarized below:

- k information bits are grouped together to form an M -ary set of sequences, where

$$M = 2^k \tag{18}$$

- A pseudonoise (PN) code selects a sequence (out of 2^k sequences) for each input information bit generated by the inverse discrete wavelet transform (IDWT).
- The coded data are sent as binary phase-shift keying (BPSK).
- The receiver reverses the above steps; that is, it performs BPSK demodulation, DWT, and data extraction.

Note that only one of 2^J wavelet coefficients is used for BPSK data and the remaining coefficients are unused, where J denotes the number of stages in the wavelet transform. If we let L be the length of the filterband of the DWT, then the processing gain equals the composite impulse response length, that is,

$$G = (2^J - 1)(L - 1) - 1 \tag{19}$$

This wavelet-based SS technique is equivalent to a single-scale covert communication waveform.

6.1.2. Multiple-Scale Covert Communications Waveform. A multiple-scale covert waveform employing a wavelet-transform-domain SS was proposed in Ref. 19. This technique is summarized as follows:

- Encode the data into an M -ary alphabet.
- Apply the PN code to the encoded data.
- Serial-to-parallel demultiplex the resultant into scale streams.
- Represent the SS chips as wavelet coefficients.
- Create a waveform by IDWT.

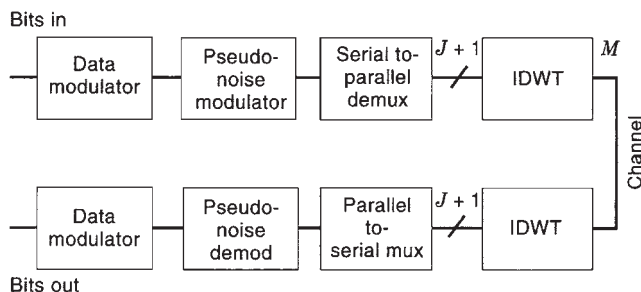

Figure 3. An illustration of a multiple-scale covert communications system using wavelet transforms [4, p. RO-72].

- Receiver reverses the above steps.
- Figure 3 [20, p. RO-72] illustrates the multiple-scale SS system.

6.1.3. Wavelets for Code-Division Multiplexing Access.

The above waveforms are suitable for multiple users where each user has the same waveform algorithm with fixed system parameters and independent PN drivers for the pseudorandom parameters. The design of a CDMA using wavelets has been addressed in Ref. 21, which concerns itself with the three key issues:

- *Channel Capacity.* The number of supportable users per unit bandwidth at a fixed bit error rate (BER) and bit signal-to-noise ratio (SNR), E_b/N_0
- *Near-Far Problem.* The effect of large interference because of a nearby user (this problem is discussed in another article in this encyclopedia)
- *Implementation.* Computational complexity

Regarding the channel capacity, the use of wavelets will lower the required bit SNR. This means that the multiple-access (MA) noise decreases on using a proper wavelet transform. As the wavelet transform is chosen to allow the user to operate at smaller bandwidth, one can impose tighter bandpass filtering at the transmitter. This means improved bandwidth efficiency. In addition to these features, modulation using wavelets occupies all available degrees of freedom in amplitude and phase.

Concerning the near-far problem, the Gaussian character of wavelet-based waveform makes the interference noiselike at all levels, and the near-far effects are perfectly predictable based on power levels.

Finally, the construction of a wavelet-based signal uses a finite number of subsequences, which allows the transmitter to be implemented with only load operations.

Sub-subsections 6.1.3.1. and 6.1.3.2. briefly explains the use of the single-scale and multiple-scale waveforms in CDMA, respectively.

6.1.3.1. Single-Scale CDMA. According to the sub-subsection 6.1.1., the single-scale CDMA waveform is generated using the following algorithm:

- For each input k information bits, we send one of the M complex-valued sequences a_n , where the index n denotes the n th of the M sequences, and M is given in Eq. (18).
- M complex-valued sequences are derived from the M -ary wavelet coefficient matrix. Note that these sequences have approximately Gaussian distribution.
- The set of sequences changes pseudorandomly for each transmission.

If we let the transform length N be k times the alphabet size M ,

$$N = kM \tag{20}$$

and the chip pulse with duration T be $P(t)$, then the signal model for the single-scale CDMA can be written as

$$S(t) = \sum_{n=1}^{N(M-1)} a_n P(t - nT) \tag{21}$$

For unfiltered BPSK or quaternary PSK (QPSK), the pulse shape is square. For filter BPSK/QPSK or wavelet use, the pulse shape is equivalent to the truncated approximation of a sinc pulse, defined as follows:

$$\text{sinc}(t) = \frac{\sin t}{t} \tag{22}$$

It should be noted here that the multiple user waveforms described above possess the following properties:

- Common structure with independent pseudorandom drivers
- Statistical orthogonality

Let us define U as the number of supportable users, G as the processing gain given by Eq. (19), $(E_b/N_0)_{\text{nom}}$ as the nominal bit SNR without MA noise, $(E_b/N_0)_{\text{act}}$ as the actual bit SNR with MA noise and intersymbol interference, and

$$\alpha = \frac{(E_b/N_0)_{\text{act}}}{(E_b/N_0)_{\text{nom}}} \tag{23}$$

The total number of supportable users for unfiltered QPSK is found to be [21]

$$U = \frac{3(1 - \alpha^{-1})G}{4(E_b/N_0)_{\text{nom}}} + 1 \tag{24}$$

whereas for filtered QPSK and a wavelet-based waveform it is

$$U = \frac{(1 - \alpha^{-1})G}{(E_b/N_0)_{\text{nom}}} + 1 \tag{25}$$

A plot of Eqs. (24) and (25) is shown in Fig. 4 [20, p. RO-90] for a QPSK signal with 16-ary simplex. This figure shows

Figure 4. Supportable number of users per unit bandwidth as a function of bit SNR for various QPSK waveforms [4, p. RO-90].

that the wavelet SS can support more users than the filtered QPSK.

6.1.3.2. Multiple-Scale CDMA. According to the subsection 6.1.2., the multiple-scale CDMA waveform uses the wavelet transform domain structure shown in Fig. 3. In this figure, each user signal is driven by an independent PN modulator. The resulting signals will be statistically orthogonal (as good as the PN sequence orthogonality). The performance of the multiple-scale CDMA is as good as that of the single-scale, that is, it has the same channel capacity, BER, interference tolerance, and so on. However, the computational complexity for multiple-scale CDMA is less than for single-scale CDMA. Multiple-scale systems can acquire the signal without a training sequence [20,21], and they can be used for low probability of interception (LPI) and low probability of detection (LPD) networks.

6.1.4. Fractal Modulation. There are some noisy channels whose key characteristic is that the channel is open for some finite but unknown time interval, during which it has some finite but unknown bandwidth. Such models are useful for a range of wireless and secure communications applications, as well as for broadcast applications in which information is being transmitted to receivers whose front ends have different bandwidths and processing capabilities. A wavelet-based modulation model, referred to as *fractal modulation*, which makes efficient use of iterated multirate filter banks, has been shown to provide a novel diversity strategy for communication over such channels [23]. The essence of this scale diversity involves dividing the available transmit spectrum into multiple adjacent octave-spaced bands, and modulating periodic extensions of the symbol stream into these bands at corresponding rates. That is, the information stream is present on all time scales, providing a novel and efficient form of diversity for such applications.

6.2. FBI Fingerprint Compression

Between 1924 and today, the U.S. Federal Bureau of Investigation has collected about 30 million sets of fingerprints [24]. The archive consists mainly of inked impressions on paper cards. Facsimile scans of the impressions are distributed among law enforcement agencies, but the digitization quality is often low. Because a number of jurisdictions are experimenting with digital storage of the prints, incompatibilities between data formats have recently become a problem. This problem led to a demand in the criminal justice community for a digitization and compression standard. In 1993, the FBI's Criminal Justice Information Services Division developed standards for fingerprint digitization and compression in cooperation with the National Institute of Standards and Technology, Los Alamos National Laboratory, commercial vendors, and criminal justice agencies [25].

Let us put the problem of storing the data of digital fingerprints in perspective. Fingerprint images are digitized at a resolution of 500 pixels/in (200 pixels/cm) with 256 levels of gray-scale information per pixel. A single fingerprint is about 700,000 pixels and needs about 0.6 Mbyte of storage. A pair of hands, then, requires about 6 Mbytes of storage. So digitizing the FBI's current archive would result in about 200 terabytes of data. Obviously, data compression is important to bring these numbers down. The data compression standard *wavelet/scalar quantization* (WSQ) implements a hand-tuned custom wavelet basis developed after extensive testing on a collection of fingerprints. The best compression ratio achieved with these wavelets is 26 : 1.

6.3. Computer and Human Vision

In the early 1980s, David Marr began work at MIT's Artificial Intelligence Laboratory on artificial vision for robots. He is an expert on the human visual system, and his goal was to learn why the first attempts to construct a robot capable of understanding its surroundings were unsuccessful. Marr believed that it was important to establish scientific foundations for vision, and that while doing so, one must limit the scope of investigation by excluding everything that depends on training, culture, and so on, and focus on the mechanical or involuntary aspects of vision. This low-level vision is the part that enables us to re-create the three-dimensional organization of the physical world around us from the excitations that stimulate the retina. Marr asked these questions:

- How is it possible to determine the contours of objects from variations in their light intensity?
- How is it possible to sense depth?
- How is motion sensed?

He then developed working algorithmic solutions to answer each of these questions. Marr's theory was that the human visual system has a complicated hierarchical structure that involves several layers of processing. At each processing level, the retinal system provides a visual representation that scales progressively in a geometrical manner. His arguments hinged on the detection of inten-

sity changes. He theorized that intensity changes occur at different scales in an image, so that their optimal detection requires the use of operators of different sizes. He also theorized that sudden intensity changes produce a peak or trough in the first derivative of the image. These two hypotheses require that a vision filter have two characteristics: it should be a differential operator, and it should be capable of being tuned to act at any desired scale. Marr's operator is referred to today as a Marr wavelet.

6.4. Denoising Noisy Data

In diverse fields, from planetary science to molecular spectroscopy, scientists are faced with the problem of recovering a true signal from incomplete, indirect, or noisy data. Can wavelets help solve this problem? The answer is certainly yes, through a technique, called *wavelet shrinkage and thresholding*, that David Donoho of Stanford University has worked on for a number of years [26]. The technique works in the following way. When you decompose a dataset using wavelets, you use filters that act as *averaging* filters, and others that produce *details*. Some of the resulting wavelet coefficients correspond to details in the dataset. If the details are small, they might be omitted without substantially affecting the main features of the dataset. The idea of *thresholding*, then, is to set to zero all coefficients that are less than a particular threshold. The remaining coefficients are used in an inverse wavelet transformation to reconstruct the dataset.

7. REMARKS

There are many applications waiting for wavelet techniques to improve their usefulness beside those mentioned above. Examples are speech compression in mobile communication and digital answering machines; audio compression in digital broadcasting, HDTV, VSAT, storage devices, multimedia, high-fidelity audio, and music; and ECG heart waveform monitoring systems and archives for cardiologists.

In signal processing, wavelets make it possible to recover weak signals from noise. This has proven useful especially in the processing of X ray and magnetic resonance images in medical applications. Images processed in this way can be cleaned up without blurring or muddling the details [16].

In Internet communications, wavelets have been used to compress images to a greater extent than is generally possible with other methods. In some cases, a wavelet-compressed image can be as small as about 25% of the size of similar-quality images using the more familiar JPEG method. Thus, for example, a photograph that requires 200 kbyte and takes a minute to download in JPEG format might require only 50 kbyte and take 15 s to download in wavelet-compressed format.

Wavelet compression works by analyzing an image and converting it into a set of mathematical expressions that can then be decoded by the receiver. Wavelet compression is not yet widely used on the Web. The most common compressed image formats remain the GIF, used mainly for drawings, and JPEG, used mainly for photographs.

1. INTRODUCTION

Almost all signals received from transducers, sensors, radio/television antennas, and other broadcast equipment are always extremely small and are mostly in the microvolt range. Faithful amplification of these feeble signals is essential to activate any device or equipment, whether it is a cellphone or a sophisticated robotic navigator such as the Mars Pathfinder. An amplifier is expected to produce a *faithfully magnified* version of the input signal. It is easy to visualize an *audio amplifier* because the frequency range over which speech signals encountered are in the approximate range of 100–10,000 Hz. However, a *high-fidelity amplifier* may help amplify signals not only in the 100–10,000 Hz range, but also in the lower-frequency range, such as those that are between 35 and 300 Hz (bass) range. In addition, such amplifiers are helpful in the higher frequency ranges as well. The treble control acts to amplify signals beyond the 10,000 Hz range and may be up to 20,000 Hz. Therefore, *bandwidth* provides a measure over which the amplifier is capable of reproducing a magnified version of the input signal faithfully. Bandwidth values for some selected electronic signals are given in Table 1.

It is evident from Table 1 that when one encounters signals in the kilo-, mega-, and gigahertz ranges, it is essential that there be acute need for *wideband* amplifiers. It is recognized that the *gain* A_V of an amplifier is defined as

$$A_V = \frac{V_{\text{out}}}{V_{\text{in}}}$$

Table 1. Bandwidth Values for Selected Electronic Signals

Electrocardiograms	< 100 Hz
Audio signals	20–20,000 Hz
AM radiowaves	550–1600 kHz
FM radiowaves	88–100 MHz
Microwave and satellite signals	1–50 GHz

WIDEBAND AMPLIFIERS

MYSORE NARAYANAN
Miami University
Oxford, Ohio

1. INTRODUCTION

Almost all signals received from transducers, sensors, radio/television antennas, and other broadcast equipment are always extremely small and are mostly in the microvolt range. Faithful amplification of these feeble signals is essential to activate any device or equipment, whether it is a cellphone or a sophisticated robotic navigator such as the Mars Pathfinder. An amplifier is expected to produce a *faithfully magnified* version of the input signal. It is easy to visualize an *audio amplifier* because the frequency range over which speech signals encountered are in the approximate range of 100–10,000 Hz. However, a *high-fidelity amplifier* may help amplify signals not only in the 100–10,000 Hz range, but also in the lower-frequency range, such as those that are between 35 and 300 Hz (bass) range. In addition, such amplifiers are helpful in the higher frequency ranges as well. The treble control acts to amplify signals beyond the 10,000 Hz range and may be up to 20,000 Hz. Therefore, *bandwidth* provides a measure over which the amplifier is capable of reproducing a magnified version of the input signal faithfully. Bandwidth values for some selected electronic signals are given in Table 1.

It is evident from Table 1 that when one encounters signals in the kilo-, mega-, and gigahertz ranges, it is essential that there be acute need for *wideband* amplifiers. It is recognized that the *gain* A_V of an amplifier is defined as

$$A_V = \frac{V_{\text{out}}}{V_{\text{in}}}$$

Table 1. Bandwidth Values for Selected Electronic Signals

Electrocardiograms	< 100 Hz
Audio signals	20–20,000 Hz
AM radiowaves	550–1600 kHz
FM radiowaves	88–100 MHz
Microwave and satellite signals	1–50 GHz

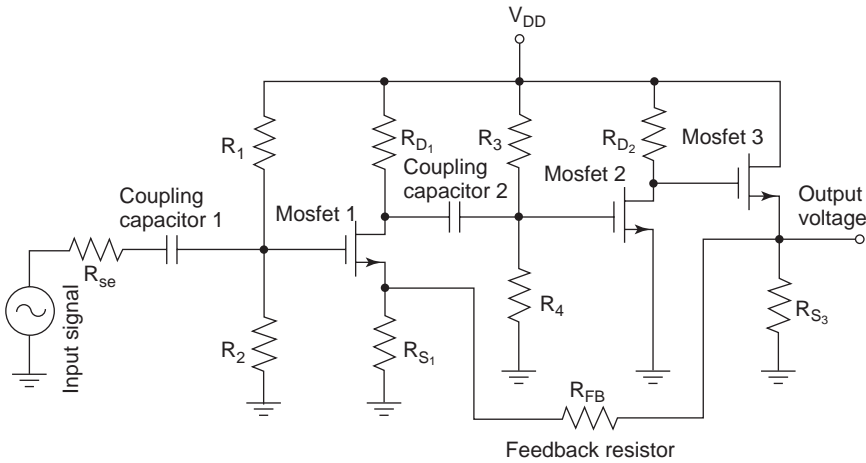

Figure 1. An example of a multistage amplifier.

Assuming that the amplifier utilizes a MOSFET (metal oxide semiconductor field-effect transistor) one can mathematically prove that

$$A_V = -g_m Z_L$$

where g_m is known as the *transconductance* or *mutual conductance* and Z_L is known as the load impedance connected at the *drain* of the transistor. Assuming an “inductance-free” RC load, it is possible to determine that the *uncompensated* bandwidth will be equal to $1/RC$. In other words, if one utilizes a common-source amplifier with a $150\ \Omega$ resistance and a one picofarad (10^{-12} Farad) capacitor would yield a frequency that is approximately 1,000,000,000 Hz. or *one gigahertz*.

When inductances are also utilized, it is possible to develop mathematical equations to govern special designs such as the *shunt peaking amplifier* or the *series peaking amplifier*. A complete discussion of *wideband amplifier* design can be found in many standard textbooks. The text *Highly Linear Integrated Wideband Amplifiers* by Henrik Sjöland of Lund University, Sweden has been completely devoted to the design and analysis techniques for frequencies from audiofrequencies to radiofrequencies.

Consider mathematically analyzing a multistage amplifier, symbolically shown in Fig. 1. The circuit is designed with three MOSFETs with two coupling capacitors. The exact values of the components are not included, because they may widely differ, depending on the design criteria. It should be observed that the input signal is fed to the gate of the first MOSFET via a coupling capacitor. The gate bias is derived from a potential divider circuit, consisting of two resistors. The first stage is designed as a common-source configuration. The output of the first stage is obtained from the drain of the first MOSFET and fed to the gate of the second MOSFET, via a second coupling capacitor. The third and final stage is a source follower and the final output is obtained at the source of the third MOSFET. This output signal is fed back to the source of the first MOSFET via a *feedback resistor*. This type of feedback helps increase the bandwidth of an amplifier. While analyzing such multistage amplifiers, one may conclude that the effect of inductive reactances are small; however, it should be recognized that the two coupling

capacitances incorporated in the circuit may have a pronounced effect on the gain and bandwidth calculations. This is because capacitive reactance is inversely proportional to the frequency. In other words, as the frequency increases, the capacitive reactance decreases because

$$X_C = \frac{1}{j(2\pi f C)}$$

Therefore, it is not advisable to use a grounded *bypass* capacitor, when high frequencies are being dealt with. This may result in signal currents being inadvertently diverted to ground instead of being transmitted through the circuit to the output. It can be seen from the equation above that bypass capacitors offer low reactances to signal currents at higher frequencies. However, the bypass capacitors offer high reactances to signals at lower frequencies, and therefore diversion of signal currents to ground do not pose a major problem, while encountering low-frequency signals.

The frequency plot of an amplifier is represented in Fig. 2. A measure of the magnitude of the output voltage is plotted against a range of frequencies (for a given constant input voltage). The frequency is normally plotted on a logarithmic scale along the x axis (abscissa). The output is plotted on the y axis (ordinate), and the unit is normally

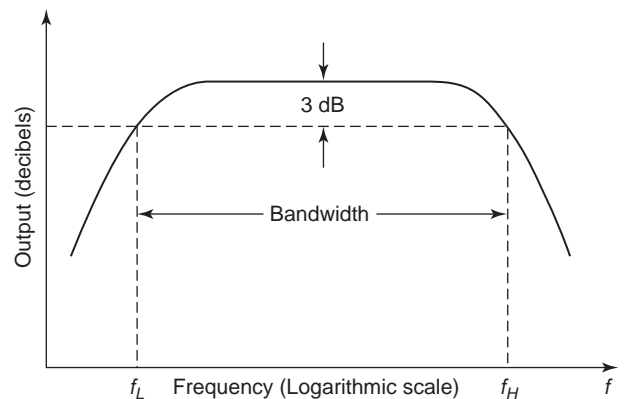

Figure 2. Frequency response characteristics of an amplifier.

decibels (dB):

$$\begin{aligned} \text{dB} &= 20 \log_{10} \frac{\text{voltage}_{\text{out}}}{\text{voltage}_{\text{in}}} \\ &= 10 \log_{10} \frac{\text{power}_{\text{out}}}{\text{power}_{\text{in}}} \end{aligned}$$

Consider the case when $\text{POWER}_{\text{OUT}} = (\frac{1}{2})\text{POWER}_{\text{IN}}$

$$\begin{aligned} \text{dB} &= 10 \log_{10} \left\{ \left(\frac{1}{2} \right) \frac{\text{power}_{\text{in}}}{\text{power}_{\text{in}}} \right\} \\ &= 10 \log_{10} \left\{ \frac{1}{2} \right\} \\ &= -3.0103 \end{aligned}$$

Therefore, design engineers focus at the point where the gain falls by 3 dB. The frequencies at which this occurs are called *half-power frequencies*. If the power is halved, the voltage level is decreased by its square root, because $P = (V^2/R)$. Taking the square root of $\frac{1}{2}$, it is seen that $\sqrt{(\frac{1}{2})} = 0.707$. If the maximum voltage level in the amplifier characteristic is identified as V , then the frequencies at which voltage levels have dropped to $0.707V$ can be identified as f_L and f_H . *Bandwidth* is defined as the range of frequencies that lies between f_L and f_H or in other words, as the frequency range over which the amplifier gain remains almost constant within 29.3% of its maximum value [3 dB level or $(1 - 0.707) = 0.293$].

2. PRINCIPLES OF FEEDBACK

For a simple amplifier, shown symbolically in Fig. 3a, the *voltage gain* is defined as the ratio of output voltage to input voltage. This is written as $A = V_{\text{out}}/V_{\text{in}}$. Addition of a feedback of magnitude F , as shown in Fig. 3b, will result in a modified value for the voltage gain G given by the equation

$$G = \left(\frac{A}{1 + AF} \right)$$

The term AF , called the *feedback factor*, can be either positive or negative. Effectively, Fig. 3c can “replace” Fig. 3b. A study of the variation of G with positive feedback is shown in Fig. 4a. Positive feedback boosts the gain toward infinity. However, positive feedback also greatly increases distortion levels in the output, and therefore it is not viewed as advantageous. Although mathematically the gain approaches infinity, oscillations set in. Therefore, positive feedback is not used in many circuit applications. Positive feedback is also called *regenerative* feedback. Feedback oscillators utilize this principle of positive feedback while designing frequency-selective circuits for audio amplifiers. Harry Nyquist of Bell Telephone Laboratories is credited with this development. His 1932 paper on *regenerative theory* provides more detailed mathematical analysis of positive-feedback circuits. A very simple numerical example may be used to illustrate the significance

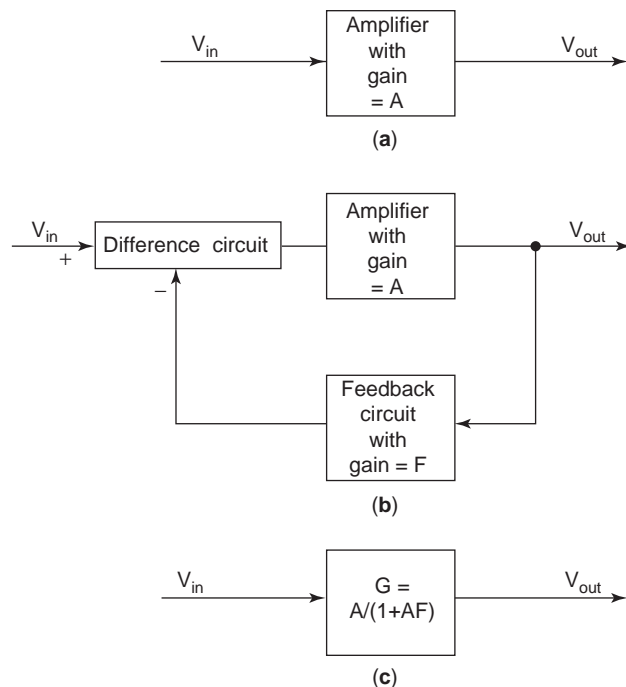

Figure 3. (a) Amplifier without feedback. (b) Amplifier with negative feedback. (c) Simplified version of Fig. 3(b).

Figure 4. Gain with (a) positive and (b) negative feedback.

of the formula

$$G = \left(\frac{A}{1 + AF} \right)$$

Assume that the *midband gain* A_{MB} of a given amplifier is given as 500. This may be mathematically expressed as

$$A = \frac{(500)}{[1 + j(f/10 \text{ kHz})]}$$

where 10 kHz indicates the bandwidth.

If this is used with a negative-feedback configuration with a *feedback factor* $F = 0.01$, one can easily calculate the gain G for the negative-feedback amplifier as

$$G = \frac{500}{[1 + 500(0.01)]} = 83.33$$

The gain has fallen from the original value of 500 to 83.33.

The bandwidth with negative feedback is given by the formula

$$\begin{aligned} \text{BW}_{\text{neg FB}} &= \text{BW}(1 + AF) \\ &= 10[1 + 500(0.01)] = 60 \text{ kHz} \end{aligned}$$

It is seen that the gain has fallen by a factor of 6 but the bandwidth has improved by a factor of 6.

3. NEGATIVE FEEDBACK

As shown in Fig. 4b, negative feedback reduces the overall gain of an amplifier; hence the term, *degenerative* feedback. Here, a portion of the amplifier output is fed back to the input in such way that it opposes the input. Now it is possible to reexamine the frequency response characteristics with and without negative feedback. It is possible to prove that the bandwidth of the amplifier can be increased with negative feedback. This is the greatest advantage of negative-feedback amplifiers. In addition to extended bandwidth, negative feedback provides stabilized amplifier gain and reduced noise or distortion levels. Further, these types of negative-feedback amplifiers are very stable. It is possible to prove that series voltage feedback increases the input impedance of the circuit. The input impedance can be reduced by incorporating a parallel current feedback. Negative feedback also helps in reducing the circuit noise. In other words, signal-to-noise ratio is greatly improved.

4. SERIES AND SHUNT CONFIGURATIONS

The feedback signal can be obtained from the output voltage or output current. Further, this derived voltage or current can be incorporated into the input circuit in either a parallel or series configuration. Thus, it is possible to design four different types of feedback networks, and these are shown in Figs. 5a–d. It should be recognized that the

transfer function F in each case would be different. For a voltage–voltage feedback configuration, the feedback network takes the output voltage, and a fraction of this voltage is fed back to the input voltage. For a negative feedback circuit the *new* input voltage will actually be $V_{\text{in}} - V_{\text{F}}$ as shown in Figs. 5a and 5b. For a current–current feedback configuration, the feedback network takes the output current, and a fraction of this current is fed back to the input current. The corresponding input current for the ideal amplifier will now be $I_{\text{in}} - I_{\text{F}}$.

5. SIGNAL-TO-NOISE RATIO

While designing wideband amplifiers, it is extremely important to maintain the signal quality, faithfully. The characteristic identified as *signal-to-noise ratio* (SNR) is very helpful in determining the quality features of any amplifier. Consider the input signal of an amplifier expressed as

$$V_{\text{input}} = V_{\text{signal}} + V_{\text{noise}}$$

Here, the input consists of a pure signal that is of interest, but, in addition it has been corrupted with an unwanted component identified as V_{noise} . Circuit configurations may contribute toward electronic noise; however, the presence of harmonics and other extraneous signals such as the 60-Hz. “hum” from the power source may be considered undesirable. White noise, nonlinear distortion, and radio-frequency pickup also contribute toward unacceptable amplifier performance characteristics.

Signal-to-noise ratio is defined as

$$\text{SNR} = \frac{V_{\text{signal}}}{V_{\text{noise}}}$$

Even if one were to neglect the noise contained in the input, it should be recognized that the amplifier itself, introduces its own noise component. Now, one can rewrite the preceding equation as

$$[\text{SNR}]_{\text{open-loop amplifier}} = \frac{A[V_{\text{signal}}]}{V_{\text{noise,amp}}}$$

In this equation A represents the open-loop gain of the amplifier (without feedback) and $V_{\text{noise, amp}}$ is the unwanted noise introduced by the amplifier. Recall that the noise level of the input signal, which was identified simply as V_{noise} , has been ignored, indicating that the amplifier received high-quality input signal, *free* of any significant noise. If feedback F is now applied, it can be mathematically proved that

$$[\text{SNR}]_{\text{feedback amplifier}} = \frac{A[V_{\text{signal}}]}{V_{\text{noise,amp}}} (1 + AF)$$

It is easily seen that the SNR of the negative feedback amplifier is better than the SNR of the open-loop amplifier. It has improved by a factor of $(1 + AF)$.

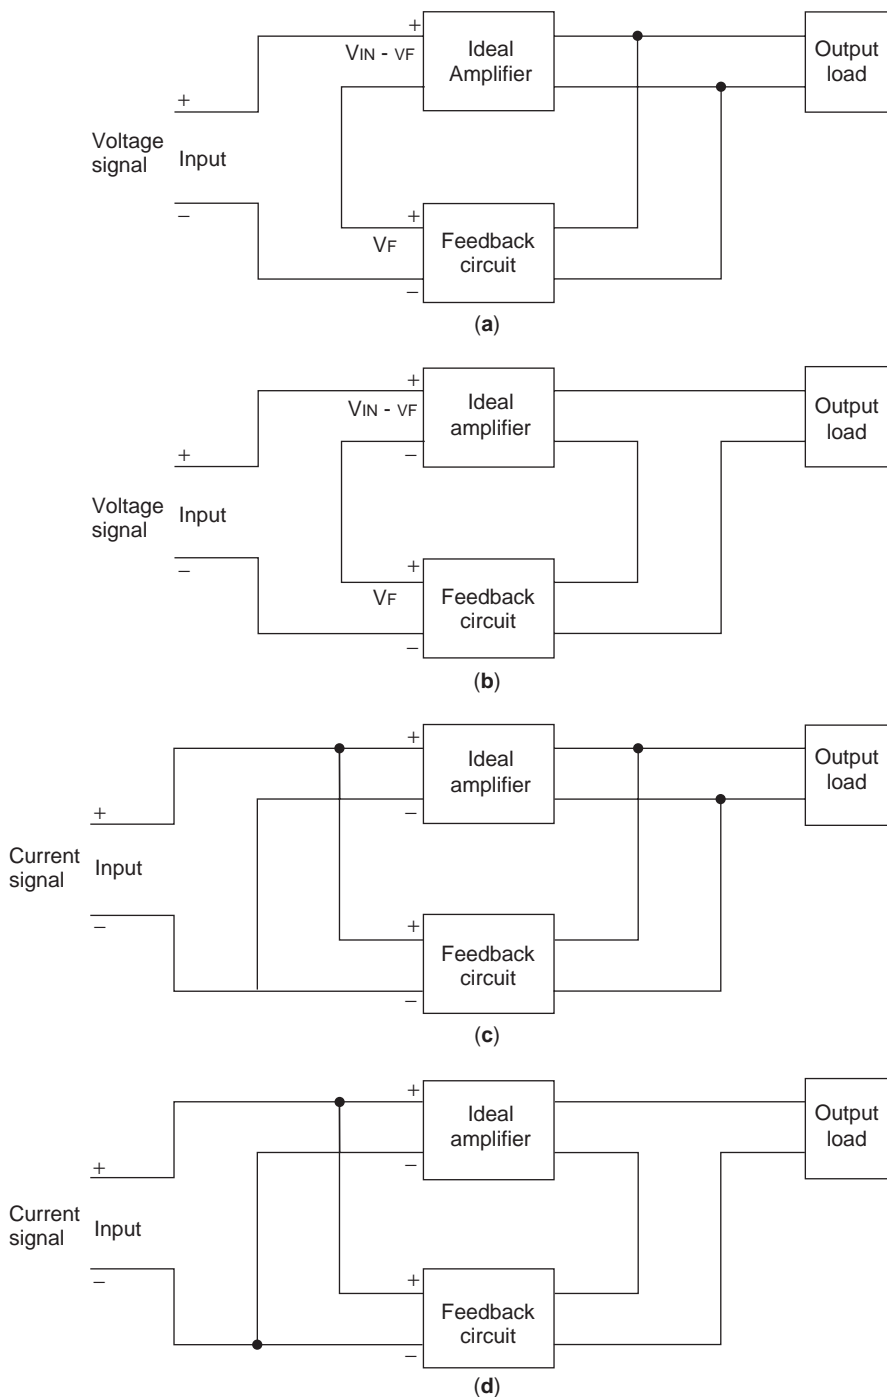

Figure 5. (a) Series–shunt amplifier (also called *voltage amplifier*); (b) series–series amplifier (also called *transadmittance amplifier*); (c) shunt–shunt amplifier (also called *transimpedance amplifier*); (d) shunt–series amplifier (also called *current amplifier*).

Similarly, one can prove that negative feedback helps greatly in reducing distortion:

$$\begin{aligned} & \% \text{ distortion with negative feedback} \\ &= \frac{\% \text{ distortion without negative feedback}}{(1 + AF)} \end{aligned}$$

Negative feedback *may* change to positive feedback at a certain frequency. This may occur as a result of the influence of certain types of reactive elements such as parasitic

capacitive circuit parameters. Oscillations will set in if care is not exercised while designing the wideband amplifier circuit.

6. MILLER EFFECT

While designing amplifiers, engineers may assume that the internal capacitances that exist in the transistor are very small compared to the external capacitances. But in reality, capacitances do exist between base and emitter

(C_{BE}) as well as between base and collector (C_{BC}). It can be mathematically shown that the total input capacitance

$$C_{in} = C_{BE} + (1 + A)(C_{BC})$$

In other words, the total input capacitance is the parallel combination of C_{BE} and $(1 + A) C_{BC}$. The base–collector capacitance has been amplified by a factor of $(1 + A)$. This is called the *Miller effect*.

As mentioned earlier, as the frequency increases, the value of the total input impedance reduces and thereby the frequency response characteristics are affected. The Miller effect has a pronounced effect with common-emitter amplifiers because they introduce a 180° phase shift between the input and the output. For example, the values of C_{BE} and C_{BC} may be small, say, 6 and 5 pF, for example. But when this transistor is used in an amplifier with a gain of 99, the total input capacitance will be large enough to affect the frequency output characteristics of the amplifier. This is because

$$\begin{aligned} C_{in} &= C_{BE} + (1 + A_V)(C_{BC}) \\ &= 6 + (1 + 99)(5) = 506 \text{ pF} \end{aligned}$$

It is recalled that at low frequencies the coupling capacitor and the emitter bypass capacitors offer high impedances, and therefore portions of signal voltage may be lost. The Miller effect is an extremely important concept that is utilized heavily while discussing feedback. Equations for calculating Miller *input impedance* and Miller *output impedance* can be developed, and are given here:

$$\begin{aligned} Z_{in,Miller} &= \frac{Z_{feedback}}{(1 - G)} \\ Z_{out,Miller} &= \frac{(G)Z_{feedback}}{(G - 1)} \end{aligned}$$

7. CASCODE AMPLIFIER STAGE

The drain–gate capacitance in a MOSFET or CMOS is normally designated as C_{gd} . The effect of this capacitance is actually magnified by a factor $(1 + A_V)$, according to the Miller effect, as described above. The *cascode amplifier stage* eliminates the *Miller effect* by isolating this capacitor. Figure 6 illustrates a cascode amplifier stage. Here, CMOS 2 converts the input voltage to an output current. CMOS 1 subsequently transfers this current to the load resistor at the output. It should be observed that the output is at the drain of CMOS 1 and the input is at the gate of CMOS 2. There is no *direct* capacitance across CMOS 2 gate and CMOS 1 drain. With this type of “capacitance isolation” it is possible to design circuits whose time constants are in the nanosecond range. It is possible to produce substantial improvement in bandwidth, with cascode amplifiers. Cascode stages are often used in combination with other methods that utilize inductive coils.

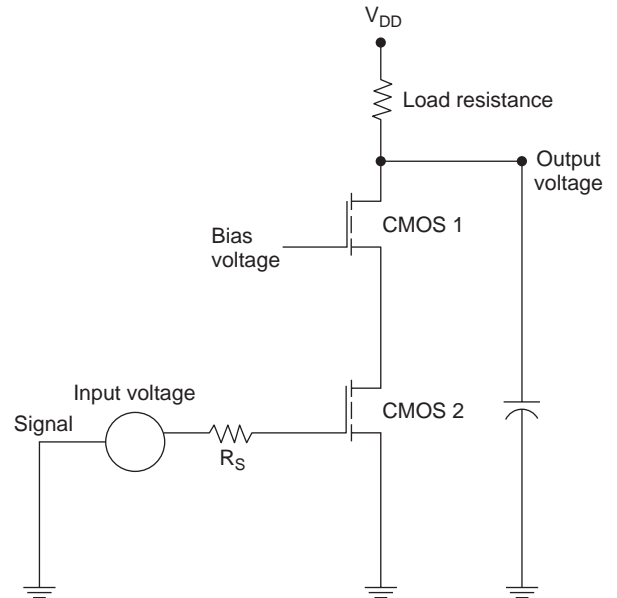

Figure 6. Cascode amplifier stage.

8. BANDWIDTH ENHANCEMENT

Bandwidth, of course, depends on the transistor *cutoff frequency* f_c . Recognizing that $(C_{gs} + C_{gd}) \approx C_{gs}$, then

$$\omega_C = 2\pi f_C \approx \frac{g_m}{C_{gs}}$$

This principle is utilized in the design of certain types of circuit designs. Bandwidth enhancement with *cutoff frequency doublers* can be accomplished by several circuit configurations such as the *Darlington pair* (Fig. 7). A circuit called the *differential pair doubler* is shown in Fig. 8. Another circuit, called the *Battjes doubler*, is also available; however, this does not exactly provide a doubling of the cutoff frequency. With these circuits it is often possible to accomplish a 50% increase in bandwidth, under certain specified conditions. A Bode plot is created using frequency on the x axis (logarithmic scale) and decibels on the y axis (linear scale, because decibels are already obtained from a logarithmic expression). Such a plot provides engineers with a visual picture of bandwidth enhancement, and this is shown in Figs. 9a and 9b. An amplifier without any feedback component has a gain of 100 dB within the frequency range 1–10 Hz. However, at this *breakpoint* frequency, the gain falls off at the rate of 20 dB/decade. With negative feedback incorporated into this amplifier, it can be seen that the new breakpoint frequency can be as high as 100 kHz. This, of course, is accomplished with a sacrifice in gain. Gain has fallen from the original 100 dB to a mere 20 dB, but increase in bandwidth has been accomplished.

9. SENSITIVITY AND GAIN STABILITY

Sensitivity, by definition, compares the fractional change of a dependent variable to the fractional change of an

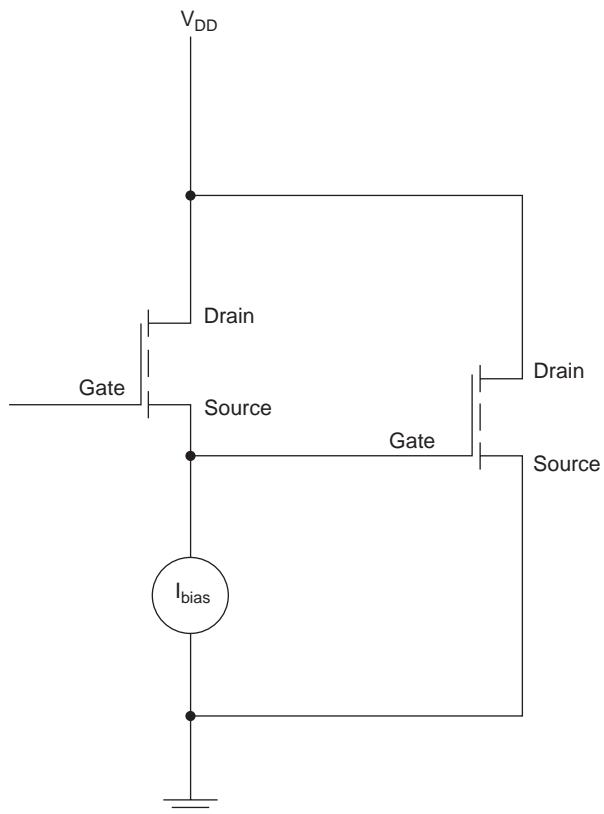

Figure 7. Darlington pair doubler.

independent variable. According to this definition, the sensitivity of V_{out} with respect to the gain A of the amplifier can be mathematically expressed as

$$\frac{(\partial V_{out})/(V_{out})}{(\partial A)/(A)}$$

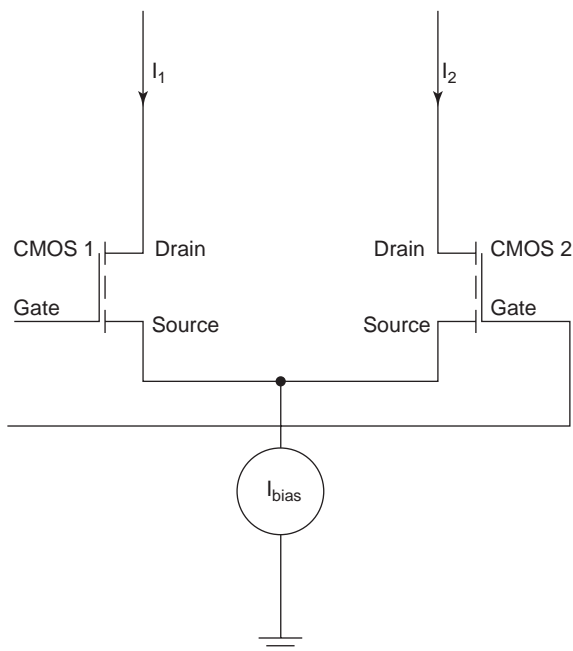

Figure 8. Differential pair doubler.

Figure 9. Bode plots with (a) open-loop and (b) closed-loop configurations.

With a closed-loop negative-feedback system it is possible to prove that the sensitivity of G with respect to A is

$$S_{G,A} = \frac{1}{(1 + AF)}$$

It can be observed that the overall gain reaches high stability as the denominator $(1 + AF)$ increases. Further examination of the closed-loop negative-feedback circuit equation indicates that the overall amplifier gain depends mainly on the feedback factor F . This is because

$$G = \frac{A}{1 + AF}$$

By choosing to design a high-gain amplifier with large feedback, it is possible to make $AF > 1$. Then, the equation above becomes

$$G \approx \frac{A}{AF} \approx \frac{1}{F}$$

indicating that the overall gain G is dependent only on the feedback, F and is insensitive to changes in A . This obviously is an extremely important feature of negative feedback.

With a closed-loop negative feedback system it is possible to prove that the gain sensitivity with respect to changes in feedback as

$$S_{G,F} = \frac{-AF}{(1 + AF)}$$

Again, if $AF > 1$, then $|S_{G,F}| = 1$.

Stability for most feedback amplifiers is usually calculated by determining the frequency at which the phase of AF equals $\pm 180^\circ$. Once this is obtained, the magnitude of AF can be easily calculated.

If the magnitude of the absolute value of AF is plotted on the y axis against radian frequency ω along the x axis, one can determine when $|AF|$ reaches unity. The amplifier circuit is then said to be marginally stable. At this instant, if θ is the phase shift, then one can define phase margin (PM) as

$$PM = 180 + \theta$$

The phase margin is therefore defined as a measure of the additional phase lag that is permitted before it reaches -180° . This is shown in Fig. 10. From the discussion above, it can be seen that phase margin also provides a measure of the stability of the amplifier. Addition of appropriate circuit elements in the feedback loop can help in stabilizing an unstable amplifier. A very common method used with operational amplifiers is called the *dominant pole compensation* method.

10. COILS

The coils realizable on a chip have enabled engineers to be very creative in their approach. Specifically designed coils may occupy only a very small area on a given circuit board. (e.g., approximately $50,000 \mu\text{m}^2$). Judiciously incorporating such inductances along with *bridging capacitances* can provide bandwidths in the gigahertz range. A circuit using coils is shown in Fig. 11. The input is

Figure 10. The example shown here records a phase margin of approximately 70° .

supplied to the gate of a single CMOS. The drain of the CMOS is connected to the DC supply via a series combination of two *coupled* coils and a small resistor. The output is taken from the midpoint junction of the coupled coils. Coupling coefficients are relatively small, of the order of 0.3 or 0.5. Each coil may have an inductance in the nanohenry range. The *bridging capacitor*, whose value is extremely small, may not be a separate circuit component. It may enter the circuit configuration as a result of the layout of the inductors on the board. Such circuits can provide a bandwidth improvement of the order of magnitude equal to $2\sqrt{2}$.

Since the early 1990s, world-class MMIC (monolithic microwave integrated circuit) design engineers have focused on the development of state-of-the-art millimeter-wave MMICs for digital radio applications. Bandpass cascode cell distributed amplifiers operating in the frequency range as high as 40 GHz have provided scientists and engineers with powerful tools to work with. Devices having extremely high performance utilizing the PHEMT (pseudomorphic high-electron-mobility transistor) process have enabled design engineers to work in frequency ranges from X band (8 GHz) to W band (110 GHz). Scientists have chosen mixed-topology configurations to obtain benefits of a bandpass topology circuit design keeping the drain line almost free of unnecessary circuit components. The basic idea is to judiciously incorporate a bandpass gate line with a lowpass drain line.

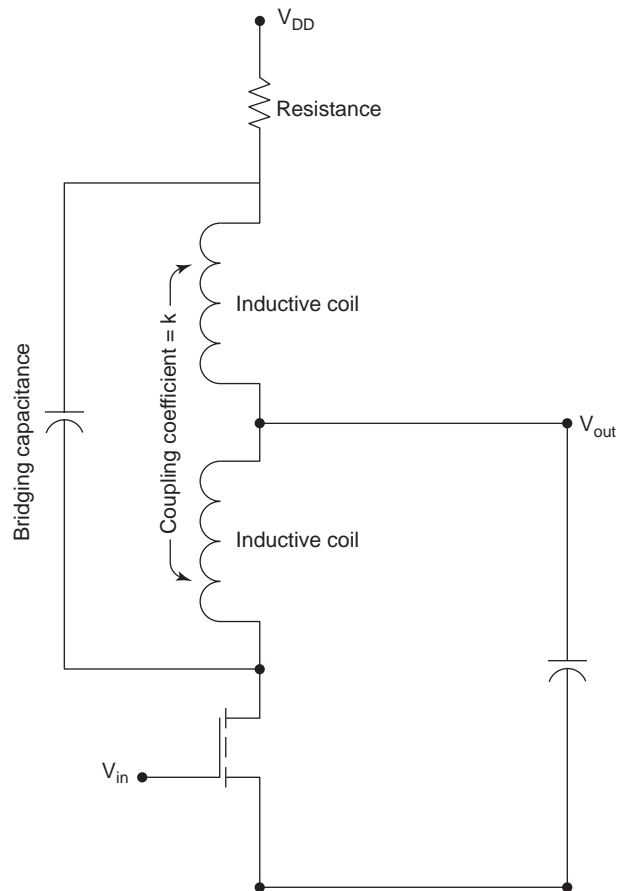

Figure 11. Amplifier with inductively coupled coils.

11. EPILOGUE

More recent developments in broadband communications systems have forced the development of circuit components that are more suited and more appropriate for broadband applications. In addition, the development of broadband communication systems has led the way to an increasing demand for use of wideband amplifiers. It should be recognized that distributed amplifiers have been critical *building blocks* in many such systems because of their performance characteristics, which are clearly *wideband*. However, the low efficiency and low output power of distributed amplifiers have made them unsuitable for high-power applications.

Broadband mixers have helped solve some of these problems, because mixers have always played a vital role in the design of efficient communication systems. In general, one can say that the input impedance of an amplifier can be decreased with shunt feedback and increased with series feedback. Further, the output impedance of an amplifier will increase with current feedback and decrease with voltage feedback. When series-feedback is applied, it is also called a *transadmittance amplifier*. An amplifier is called a *current amplifier* when shunt-series feedback is utilized. Advances in modern-day integrated-circuit design have enabled engineers to fabricate, and integrate miniaturized inductor coils and transformers into amplifier circuit boards. Although these coils do not possess excellent characteristics, they have helped the designers to successfully achieve amplifier bandwidth enhancement. Negative feedback has provided engineers with a method for accomplishing increased bandwidth. Further, the nonlinearities and distortion introduced by the amplifier circuit elements can be reduced by proper use of negative feedback. However, negative feedback suffers from a major disadvantage. The increased bandwidth is accomplished with a sacrifice in gain. Further, complexity itself may pose some problems for the circuit designers. There is also a tendency for the amplifier to oscillate.

WIDEBAND SLOT AND PRINTED ANTENNAS

1. INTRODUCTION

Wideband antenna elements are essential for providing wideband scanning array antennas in industry and military applications. Such applications require several features such as wide scan, security, high-speed commu-

nication, and high reliability, and, in many cases, a compact size is required for space-limited mobile antenna systems. Because element size is a critical parameter in determining the scan angle in antenna array configurations, small size is desirable for the antenna arrays supporting wideband applications.

In many civilian and military applications, antenna size, weight, cost, performance, and ease of installation are constraints leading to the selection of low-profile antennas such as microstrip printed and slot antennas. Microstrip antennas were originally proposed in early 1953; however, it was not until the 1970s that further development was achieved in this field, due primarily to the advancement in substrate technology. By exploiting the low-profile, lightweight, conformal configuration, compatibility with integrated circuits and low fabrication cost of these printed circuit board (PCB)-type structures, antenna designers have developed many diversified printed and slot microstrip antenna applications. However, because of the inherent narrow bandwidth characteristics of this class of antennas, an enormous amount of research more recently has been devoted to broadbanding techniques for microstrip printed and slot antennas. Some of these techniques include the use of thicker substrates, odd or optimized shapes of the patch or the slot, aperture coupling, parasitic directors and/or reflectors, and stacks of more than one layer of substrate material, each supporting one or more antenna elements. Microstrip technology utilizing these techniques has enabled many designers to meet the demands of today's communication devices. However, with increasing demands for high-performance dual-band, triband, and wideband and ultraband antennas capable of providing adjustable beamwidth and direction of the mainlobe of the radiation pattern, more sophisticated designs are required.

As a result of these needs, the authors have originated several innovative designs to specifically address these requirements as reported in Refs. 1–5, where new designs of triangle slot antennas with tuning stubs, bowtie slot antennas with tapered tuning stubs, and microstrip-fed printed bowtie antennas for wideband phased-array systems are analyzed and presented. This article provides the detailed performance of one class of the more recently developed printed and slot Lotus antenna elements that support many applications in the X band.

For this, two novel antenna designs will be presented in this article: the coplanar waveguide (CPW)-fed slot Lotus antenna for ultra wideband applications and the microstrip-fed Lotus printed antenna for wideband phased-array systems. The two designs are obtained from smooth and idealized transitions from the feedlines to the antennas, which result in wide bandwidths and low return loss levels.

In addition to regular antenna design for wideband applications, this article also presents multiple band-reconfigurable printed and slot antennas. The multiple-band technology is more redundant to interference and requires lower peak power consumption. Wideband antennas, based on multiple-band technology, normally utilize bandlimited pulses through which information is transmitted with time-spaced pulses at different center frequencies. Thus, the antenna can be constructed from parts that are selected or reconfigured using switches, an

Figure 1. Geometry and parameters of the Lotus slot antenna.

approach that can be employed in most microstrip-based printed and slot antennas. The procedure for designing such reconfigurable antennas will be discussed and experimental verification for several basic antenna structures at X band will also be demonstrated for ideal switching configurations.

The analysis of these antennas will be based on the electromagnetic commercial software packages: momentum of the Agilent advanced design system (ADS), which is a method-of-moments (MoM)-based simulation computer program, and the Ansoft high-frequency structure simulation (HFSS), a finite-element based program. A finite-difference time-domain (FDTD) simulation package developed by the authors is also used in this study. Measurements of the return loss and radiation patterns are presented along with simulation results to further verify the presented designs. The primary objectives of this work is to present how the parameters that affect the characteristics of these new antennas are determined by simulation; to determine the limitations on bandwidth, radiation pattern stability, and antenna scanning capabilities in and array configuration; and to assemble and test a practical prototype antenna in order to validate the simulations and designs achieved.

Figure 3. The effect on S_{11} of changing B_2 . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

2. ULTRAWIDEBAND CPW-FED SLOT LOTUS ANTENNA

In this section, a novel printed slot antenna design fed by coplanar waveguide, called the *Lotus slot antenna*, is introduced. This new antenna is a result of our more recent investigations for designing wideband slot antennas [1,2]. The suggested geometry is shown in Fig. 1, where the antenna consists of two ellipses with horizontal and vertical axes equal to A_1, B_1 and A_2, B_2 for the inner and outer ellipses, respectively. The tapering is truncated at an angle α from the vertical axis of the outer ellipse. The antenna is printed on Rogers RT/Duroid 5880 with $\epsilon_r = 2.2$ and substrate height $h = 1.57$ mm (62 mil).

A parametric study has been performed for this antenna using ADS Momentum. The initial design has A_1, A_2, B_1, B_2 and $\alpha = 9.8, 4.5, 9.8, 4.5$ mm and 0° . Figures 2–4 show that an increase of the radii of the ellipses shifts the resonance frequencies of the antenna to lower frequencies. The parameter B_1 has a significant effect on the resonance frequencies, since by changing B_1 from 9.8 to 17.15 mm, the lower resonance decreases by 2 GHz, while the upper decreases by 5 GHz. This is very important because it allows for shifting the operating band to lower frequencies

Figure 2. The effect on S_{11} of changing B_1 . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 4. The effect on S_{11} of changing A_1 and A_2 . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 5. The effect on S_{11} of changing α . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

without increasing the antenna width. For this study, ultrawide bandwidth is obtained when $B_1 = 12.25$ and 17.15 mm. At the same time, the proper choice of A_1 and A_2 is essential for good return loss levels. From Fig. 5, one notices that the angle α has almost the same effect as B_1 ; whereas an increase of α increases the antenna width. Therefore, to keep the antenna size small α is set equal to zero in the present investigation.

In order to improve the return loss level, two additional parameters, d_1 and d_2 , are introduced and studied. These two parameters change the curvature of the antenna while keeping the slot area almost the same, and as a result a much smoother transition between the feedline and the antenna is obtained. As shown in Fig. 6, introducing d_1 and d_2 improves the return loss level, which results from decreasing the reflection coming from the transition between the narrow CPW slot and the wide Lotus slot.

A design of this antenna with $A_1, A_2, B_1, B_2, d_1, d_2 = 10.1, 4.5, 12.4, 4.25, 0.56, 0.76$ mm and $\alpha = 0^\circ$ is fabricated. The return loss for this design is computed from 5–50 GHz, and, as shown in Fig. 7a, the antenna operates over a large operating band starting from 8 up to >50 GHz. The measurements are compared to the simulation results in Fig. 7c, where good agreement is obtained between the

Figure 6. The effect of changing antenna curvature by d_1 and d_2 . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

two results. The computed radiation patterns using ADS Momentum are shown in Fig. 8 in the E and H planes at 8, 10, and 12 GHz. The radiation pattern is stable in this range, which covers the X band with a cross-polarization level of -6 dB in the H plane and zero in the E plane because of the antenna symmetry. Two elements of this antenna are simulated using ADS Momentum with a separation distance of 2 mm, and the computed coupling is depicted in Fig. 9. The coupling is less than -20 dB over the entire X-band range. The copolarized fields for 1, 8, and 16 elements of the slot Lotus antenna in the H plane are computed using ADS at 10 GHz, and are presented in Fig. 10. The maximum gain increases from 3.69 dB for one element to 12.47 and 15.49 dB for 8- and 16-element arrays, respectively.

3. MICROSTRIP-FED PRINTED LOTUS ANTENNAS

Printed microstrip antennas are widely used in phased-array applications. They are generally economical to produce since they are readily adaptable to hybrid and monolithic integrated circuit (IC) fabrication techniques at RF and microwave frequencies. In addition, they exhibit a very low profile, small size, light weight, low cost, high efficiency, and simple installation.

Among the most widely used printed antennas in phased-array systems are printed dipoles and quasi-Yagi antennas fed by coplanar stripline (CPS), which are usually used to obtain an endfire radiation pattern. In order to feed this antenna, some researchers suggested microstrip-to-CPS transition that includes a 180° phase shifter [6]. The phase shifter consists of a T junction with one side of the microstrip line delayed by a half-wavelength to produce a predominantly odd mode for the CPS. Other researchers feed the dipole with two microstrip lines, where the upper is an extension of the microstrip feedline and the lower is connected to the ground plane directly or through a tapered microstrip [7]. However, the latter method provides omnidirectional patterns and suffers from low bandwidth (BW) (19%). Other researchers used coplanar waveguide (CPW)-to-CPS transitions to feed

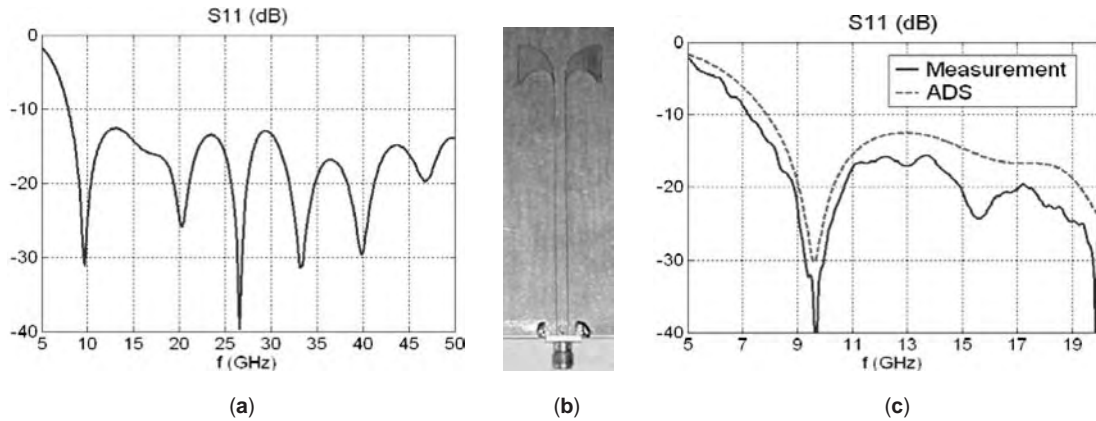

Figure 7. Return loss for the Lotus slot antenna: (a) simulation results up to 50 GHz; (b) printed Lotus prototype; (c) measured versus simulated return loss. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

printed dipole and bowtie antennas [8] that are designed for $100\ \Omega$ characteristic impedance.

An attractive quasi-Yagi antenna design that uses the transition in Ref. 6 is presented in Refs. 9 and 10 exhibiting wide BW (48%) and good radiation characteristics. The antenna consists of a half-wavelength dipole as a driver and an approximately quarter-wavelength rectangular director to increase the gain and improve the front-to-back ratio. While the driver and director are placed on one side of the substrate, the ground plane is placed on the other side and truncated to act as a reflector.

In this section, a novel printed antenna dual to the slot Lotus is designed and presented for additional improvements in terms of bandwidth and return loss level. The new antenna is called the *printed Lotus*, which supports wideband characteristics. The antenna is fed by microstrip line through a modified phase shifter that has a smaller size and better match with the new antenna than the one introduced in Ref. 10.

The proposed antenna element is printed on a Rogers RT/Duroid 6010/6010 LM substrate of a relative dielectric constant of 10.2, a thickness of 25 mil, and a conductor loss ($\tan \delta$) of 0.0023. The use of high-dielectric-constant sub-

strate material reduces radiation losses from the feedline because most of the electromagnetic field is concentrated in the dielectric between the conductive strip and the ground plane. Another benefit in having a high dielectric constant is that the antenna size decreases by the square root of the effective dielectric constant. To minimize conductor loss, the conductor thickness should be greater than 5δ [11], where δ is the skin depth, which is approximately $0.65\ \mu\text{m}$ for copper. The conductor thickness used to fabricate the antenna prototypes in this research is $34\ \mu\text{m}$.

The geometry of the proposed CPS-fed printed Lotus antenna is shown in Fig. 11a. The antenna is defined by two ellipses. The smaller ellipse is located completely in one half of the larger one. The larger ellipse has R_{h1} and R_{v1} as the semi-horizontal and semivertical axes, respectively; the smaller ellipse has R_{h2} and R_{v2} as the semi-horizontal and semivertical axes, respectively, and is rotated by an angle α . The vertical and horizontal distances between point P , shown in Fig. 11a, and the smaller ellipse centerpoint are L_1 and W_1 , respectively. The parameter L_2 defines the vertical dimension of the antenna, while L_3 is the distance between the substrate edge and the antenna in the y direction and L_4 is the length of the CPS.

This study reveals that one of the proper dimensions of the parameters for this antenna R_{h1} , R_{v1} , R_{h2} , R_{v2} , L_1 , W_1 , L_2 , L_3 , and L_4 are equal to 3.4, 3.6, 1.57, 1.06, 3.87, 1.76, 4.2, 5.8 and 4.55 mm, and $\alpha = 41^\circ$, respectively. The CPS dimensional parameters w and s are 0.3 and 0.2 mm, respectively, for an approximate characteristic impedance of 100 Ω . Thus the total width of the antenna is 7 mm, which is 20% less than the quasi-Yagi antenna reported in Refs. 7 and 8. This antenna is simulated using Ansoft HFSS, and the computed return loss is shown in Fig. 11b. On the basis of the simulation results, the antenna operates over a wide frequency range that extends from 7.8 to >20 GHz, except for a small range from 17.7 to 18.7 GHz. This makes the printed Lotus antenna a very good candidate for many applications that require wideband operations.

To feed this design with a microstrip line, improvements for the microstrip-to-CPS transition are required for two reasons: reduction of its horizontal size to be comparable to the small antenna size and improving the matching with the new wideband antenna. The transition presented in the previous section along with five modified transitions, as shown in Fig. 12a as cases 1–6, is used to feed the designed printed Lotus antenna, while the return losses are depicted in Fig. 12b. An average $\lambda_g/2$ difference between phase shifter arms has been reserved for a 10 GHz center frequency. The horizontal dimension is decreased by 28% from 7.5 to 5.4 mm, which, in turn, decreases the coupling between elements in the array environment. The radiation patterns are calculated for these cases, and no significant difference is observed. However, modifying the phase shifter has a very obvious effect on the operating frequency band, return loss level, and BW. The return losses for these different cases are compared in Fig. 12b. The operating band is shifted from (6.6–11.8 GHz) for case 1 to (7.5–13.5 GHz) for cases 3–6. The return loss level decreases uniformly to -15 dB over a very wide range in cases 3, 5, and 6.

Because case 5 shows almost the best BW and return loss level, it will be used in all the following designs. It has a 57% bandwidth relative to -10 dB return loss level and

a 52% BW relative to -15 dB. The dimensions (in millimeters) of the transition section and a comparison between the measured and calculated return loss are shown in Fig. 13. A very good agreement is obtained with a slight increase in the -10 dB BW from 57% to 60% and in the -15 dB BW from 52% to 55.5%. The small discrepancies between measurement and simulation around 10 GHz are due to the imperfect fabrication of the SMA coaxial connector transition. However, one should note that these differences are well below the -15 dB level; thus, the simulations and measurements predict a wideband range of operation for this antenna.

Because of the high dielectric constant, the distance L_3 , shown in Fig. 11a, will have an effect on the radiation pattern in the H plane. As shown in Fig. 14, as L_3 increases from 5.8 to 10 mm, the pattern becomes more concentrated in the y direction, which results in gain enhancement from 5.7 to 7 dB while decreasing the 3 dB beamwidth. At the same time, varying L_3 has a negligible effect on the return loss. Since beamwidth is very important in phased-array applications, L_3 is chosen to be 5.8 mm on the basis of this study.

The radiation patterns at 10 GHz are shown in Fig. 15. The beamwidth is 74° and 143° in the E and H planes, respectively. The maximum gain is around 5.7 dB, and the front-to-back ratio is 17.9 dB. The cross-polarization level is -26 and -29 dB in the E and H planes, respectively, considering only the angles defined by the 3 dB beamwidth. The stability of the radiation pattern is illustrated in Fig. 16, where the copolarized fields in the E and H planes at 8, 10, and 13 GHz, which cover the entire operating band, are compared. The gain is found to vary from 4.2 to 5.7 dB. These characteristics make this antenna a very good candidate for phased-array systems.

A two-element array will be analyzed first in order to reduce the coupling between elements in the x (horizontal) and z (vertical) directions. The most significant source of coupling in the x direction is the surface waves traveling through the substrate from element to element. Introducing slits in the ground plane and gaps in the substrate can

Figure 13. (a) Dimensions (in mm) of the modified phase shifter case 5 and (b) the measured computed return loss for the microstrip-fed printed Lotus through the phase shifter of case 5. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

reduce the effects of the surface waves. Three two-element arrays are designed: the normal case, a case with a gap in the substrate, and a case with both a slit in the ground plane and a gap in the substrate. Figure 17 presents the geometries of these three cases and compares their couplings. The gap improves the coupling from 8.5 to 14 GHz, while using both the slit and gap improves the coupling from 6.5 to 10.5 GHz and from 11.5 to 14 GHz. Since the area from 10.5 to 11.5 GHz is already less than -25 dB, the case with both the slit and gap is considered the best for these design parameters. The effect of the gap and slit on the radiation patterns of two elements is examined. Improvements are noticed in the gain and front-to-back ratio of the resulting radiation pattern. The gain increases from 7.2 dB for the normal case to 7.6 dB when using slit and gap, and the front-to-back ratio also improves from 17.5 to 20.5 dB. The second major source of coupling is the radiation coupling, which cannot be reduced in the x -directed array, whereas this is possible in the z -directed array by adding a metallic sheet in between the antenna elements to prevent the effect of the radiation from the

feedlines and the phase shifters. This is shown in Fig. 18, where the array geometries and the resulting couplings are shown. The metallic sheet improves the coupling in the range of 9.5 to almost 14 GHz; the gain improves from 8.5 to 9.3 dB, and the front-to-back ratio increases from 19.8 to 27.2 dB. However, it decreases the 3 dB beamwidth from 84° to 71° and from 63° to 56° in the E and H planes, respectively. This configuration also affects the radiation patterns for a two-element array in the x direction by increasing the gain from 7.2 to 8.5 dB and the front-to-back ratio from 17.5 to 21 dB. At the same time, it decreases the 3 dB beamwidth from 53° to 49° and from 129° to 103° in the E and H planes, respectively, which is considered an acceptable range for a two-element array.

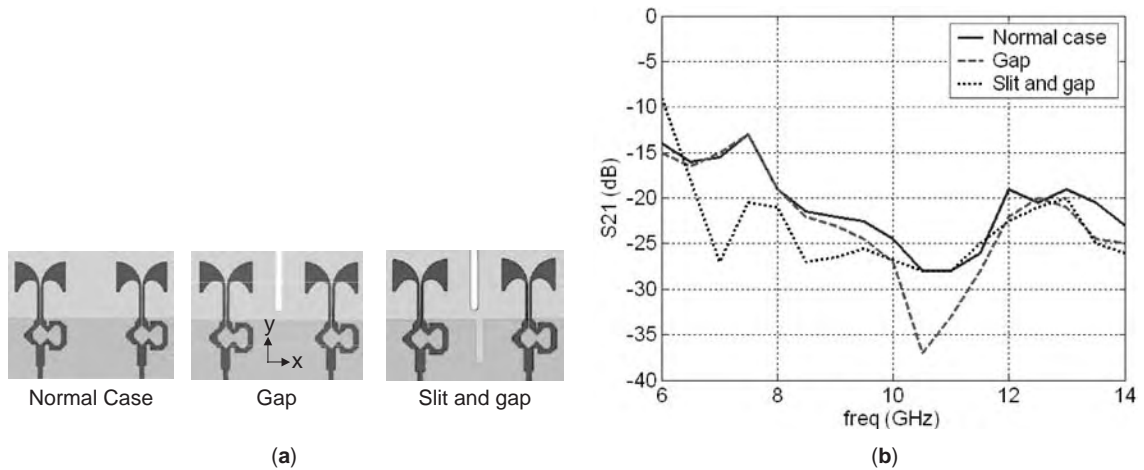

Figure 17. Antenna array configuration in the horizontal direction: (a) geometries; (b) computed coupling. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

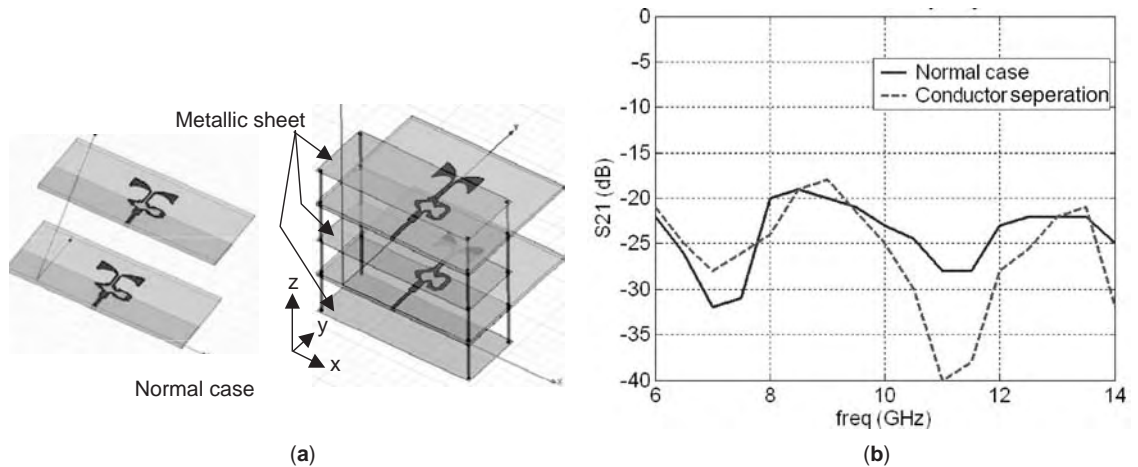

Figure 18. Antenna array configuration in the vertical direction: (a) geometries; (b) computed coupling. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The ideal value of the center-to-center separation distance between elements in array environment (d) is free-space half-wavelength ($\lambda_0/2$) at the center frequency, which is 14.3 mm for an array of these elements. Much higher separation values will cause grating lobes, and much lower separation values will increase the array beamwidth. All the above mentioned two-element arrays are designed for d equal to 14 mm. Thus, the ratio of d/λ_0 for the frequency range 7.5–13.5 GHz ranges from 0.35 to 0.63, which is considered optimum for phased-array systems with the requirements of narrow beamwidth and low grating lobe within this wide range of frequencies.

To examine the maximum scanning angle, the radiation pattern of a 32-element array is analyzed at 10 GHz using the antenna design and visualization (ADV) software package [12] with Dolph–Chebyshev excitation factors calculated for 25 dB sidelobe level. The number 32 is considered for an array of total size less than 45 cm long. For an antenna in the x – y plane, the copolarized field E_ϕ is calculated for steering angles of 0° , 30° , 50° and 70° . Figure 19 shows E_ϕ in the E plane for an array along the x axis, while Fig. 20 shows E_ϕ in the H plane for an array along the z axis. The results in both figures show that the mainbeam of the antenna array starts to deteriorate when the steering angle approaches 70° .

Practical wideband arrays require wideband corporate feed networks to split and deliver the power to the array elements. Two designs are proposed for the microstrip feed network: design 1 and design 2, which are shown in Fig. 21 for a substrate of height = 0.635 mm and $\epsilon_r = 10.2$. In design 1, the power divider consists of two 50- Ω lines of width = 0.6 mm. The matching is obtained by using an impedance transforming line of length S and width D , and tapering the edges by 45° with a length of W , as shown in Fig 21a. In design 2, the power is divided through two 90- Ω branches of thickness = 0.1 mm, two 65- Ω impedance

transformers of thickness = 0.3 mm and length S , and a 50- Ω line of horizontal length L . The matching is obtained by controlling S and L , and tapering the edges 45° with a length of W . The parameters W , S , and L of the two designs are studied using the full-wave analysis of ADS Momentum to improve the return loss and transmission coefficient.

For design 1 with $L = 3$ mm and $S = 1.2$ mm, the effect of W is presented in Fig. 22, where improvement in S11 and S21 is observed as W increases from 0 to 0.9 mm. The effect of L is studied when $W = 0.9$ mm and $S = 1.2$ mm, and the results are presented in Fig. 23, where S is changed from 2.5 to 3.1 mm around the quarter-wavelength at 10 GHz. When increasing S , the null position shifts to lower frequencies. For best return loss at 10 GHz, S is chosen to be 2.75 mm. Finally, the effect of changing D from 0.8 to 1.2 mm is depicted in Fig. 24, with $W = 0.9$ mm and $S = 2.75$ mm. The value of D controls the return loss and transmission levels at the center frequency. The best values out of this analysis are $W = 0.9$ mm (1.5 times the feedline width), $S = 2.75$ mm ($\lambda_g/4$ at 10 GHz), and $D = 1.1$ mm (transformer characteristic resistance = 36 Ω). The average transmission coefficient is -3.2 dB (48%), while the return loss is less than -15 dB from 7 to 13 GHz, and -40 dB at 10 GHz.

For design 2 with $L = 3$ and $S = 1.2$ mm, the effect of W is presented in Fig. 25. As W increases from 0.6 to 0.9 mm, both return loss and transmission improve. Further increase in W results in improvement in the return loss level at the lower frequencies. Next, S is varied from 2.8 to 3.4 mm, where the operating band shifts to lower frequencies as S increases, as shown in Fig. 26. Figure 27 shows the effect of changing L from 0.8 to 1.4 mm, with $W = 0.9$ and $S = 3.2$ mm, where the operating band increases as L increases, but the return loss level at higher frequencies decreases.

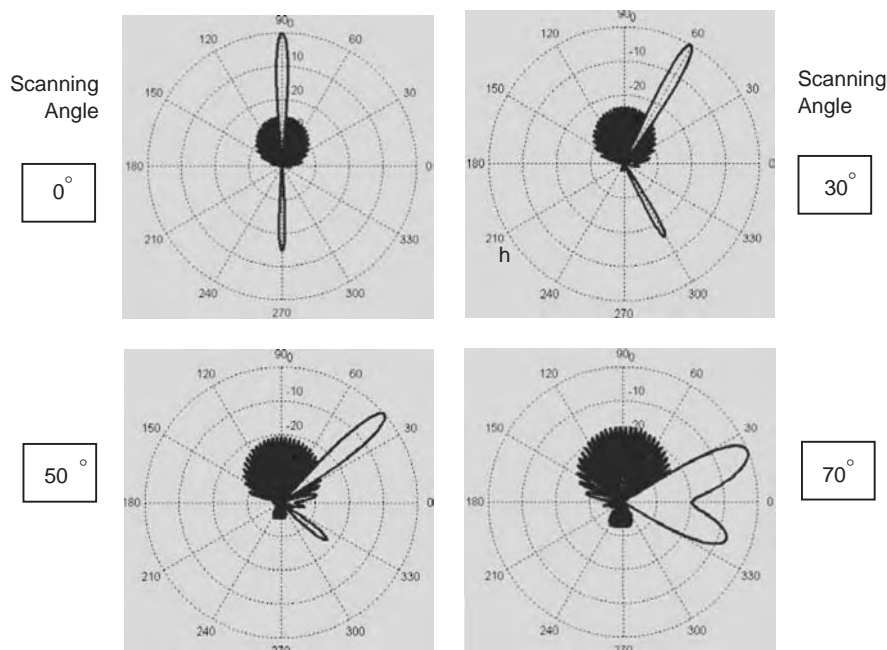

Figure 19. Mainbeam steering using 32-element array of Lotus antenna along the x axis. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

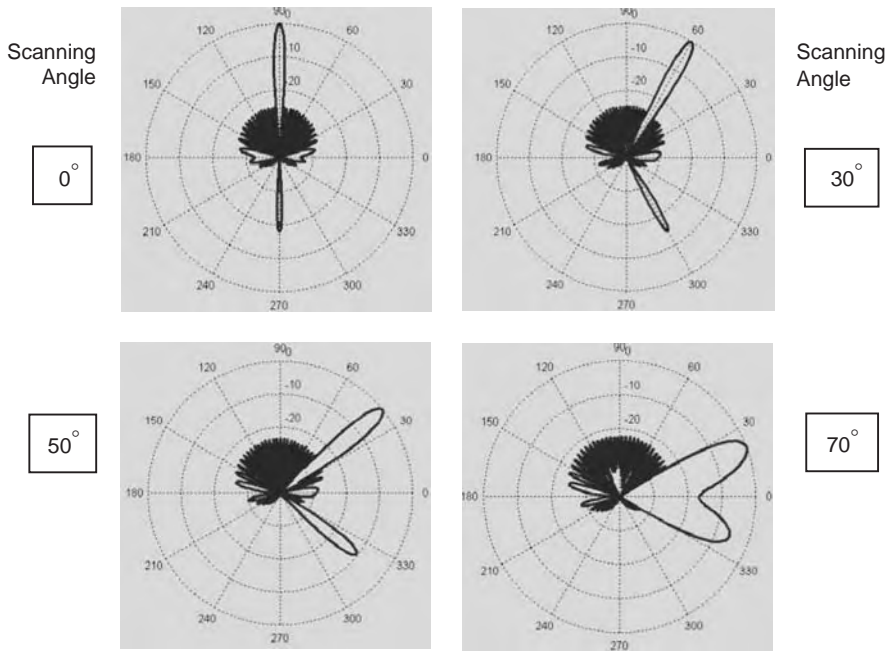

Figure 20. Mainbeam steering 32-element array of Lotus antenna along the z axis. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The case of maximum bandwidth, with $W = 0.9$ mm, $S = 3.2$ mm, and $L = 1.4$ mm, is chosen for further study. To improve the return loss at higher frequencies, S is decreased from 3.2 to 3 mm, as shown in Fig. 28. In the final design $W = 0.9$ mm, $L = 1.4$ mm, and $S = 3$ mm, with an average return loss of -30 dB and a transmission coefficient of -3.16 dB from 8 to 13 GHz. Comparison between the two designs is shown in Fig. 29, where the second design has much wider bandwidth and almost constant transmission. However, accurate fabrication of this final design of the feeding network requires precision machining, due to the small thickness of the microstrip lines. With the available facilities, only the first design is fabricated and used to feed the printed Lotus antenna array.

Two 16-element arrays with one feed for 0° and 50° steering angles are built and measured. The 50° phase shift is obtained by decreasing the length of the feedline gradually, as shown in Fig 30a, and this introduces a progressive time delay that is equivalent to the progressive phase shift that steers the mainbeam 50° . Figures 30b and 30c show the measured return losses and copolarized patterns in the E plane for the two arrays. The bandwidths for the 0° and 50° cases are almost the same, and equal to

about 71%. The sidelobe level for the 50° array is around -12.5 dB with uniform excitation, but this can be significantly decreased by using Dolph–Chebyshev excitations for amplitude tapering.

To conclude this part, the printed Lotus antenna fed by a microstrip line through a modified phase shifter has a wide bandwidth of 55.5% relative to -15 dB and 60% relative to -10 dB. In addition to being very small in size, the antenna exhibits stable far-field radiation characteristics over the entire operating band with relatively high gain, low cross-polarization, very wide beamwidth, and high front-to-back ratio. The antenna arrays investigated have low coupling and high scanning capabilities, while the 16-element array with a feed network yielded 71% impedance bandwidth.

4. RECONFIGURABLE ANTENNAS

Antenna system performance depends on the parameters of the radiating elements, such as the size, shape, and position of each radiating element. Modifying or reconfiguring the parameters of these radiating elements enables

one to use the same antenna for multiple functions at different frequencies or occasions. The conventional method for achieving reconfigurability is to allow reconfigurability between the various predefined conducting or slot regions by using multiple switches to modify the size or shape of the antenna radiating element. Thus, in order to have an additional degree of freedom for enhancing the antenna performance or to tailor its radiation characteristics for a specific application, it is desirable to have dynamic and reliable reconfigurable dimensions. This task can be achieved by using switches, provided these switches and their bias feeding network do not interfere with the antenna performance.

Conventional semiconductor switches are common components in today's microwave systems, and, depending on size and construction, they exhibit parasitic characteristics. The resulting high insertion loss of these switches, ranging from 1 dB to several decibels at millimeter-wave frequencies, is a serious issue for many applications. There is a crucial need for new switch technologies to address the loss issue for next-generation communication and phased-array systems.

The emerging microelectromechanical switch (MEMS) technology has attracted increased interest due to excellent switching characteristics over an extremely wide frequency band. Many RF MEM switching topologies have been reported, and they all show superior characteristics compared with their semiconductor-based counterparts. The low insertion loss, high isolation, and fast switching of MEM switches have been one of the most attractive devices for reconfigurable antennas and for developing wideband phase shifters for antenna arrays. These switches

provide circuits with reduced insertion loss for switching between different linewidths. With the loss reduction in switching components, smaller amplification is required or higher overall gain for the antenna system will be attained. The cost, weight, and heat dissipation problems can also be greatly reduced which improves the entire system efficiency.

A MEMS-switched reconfigurable multiband antenna is one that can be dynamically reconfigured within a few microseconds to serve different applications at drastically different frequency bands. In this article, we do not focus on the development of the MEMS switches themselves [13]. Rather, we use them as ideal control elements that are in an open or closed configuration in a reconfigurable antenna.

The concept of a frequency-reconfigurable rectangular ring slot antenna fed by slotlines or CPW is presented in Ref. 14. A reconfigurable patch antenna is obtained [15] by inserting slits at the nonradiating edges of the patch. A reconfigurable Yagi antenna has been presented [16] to operate at 2.4 and 5.78 GHz for wireless communications.

In this section we present multiple frequency-reconfigurable rectangular microstrip and slot antennas fed by a microstrip line or a coplanar waveguide (CPW) feedline. The reconfiguration for the microstrip antennas is carried out by connecting or disconnecting (switching on or off) appropriate rectangular strips surrounding the patch antenna to model the MEM switches. The shape and number of these strips along with the switching state and position are used to control the operating frequency of the antenna without changing the feeding mechanism. A

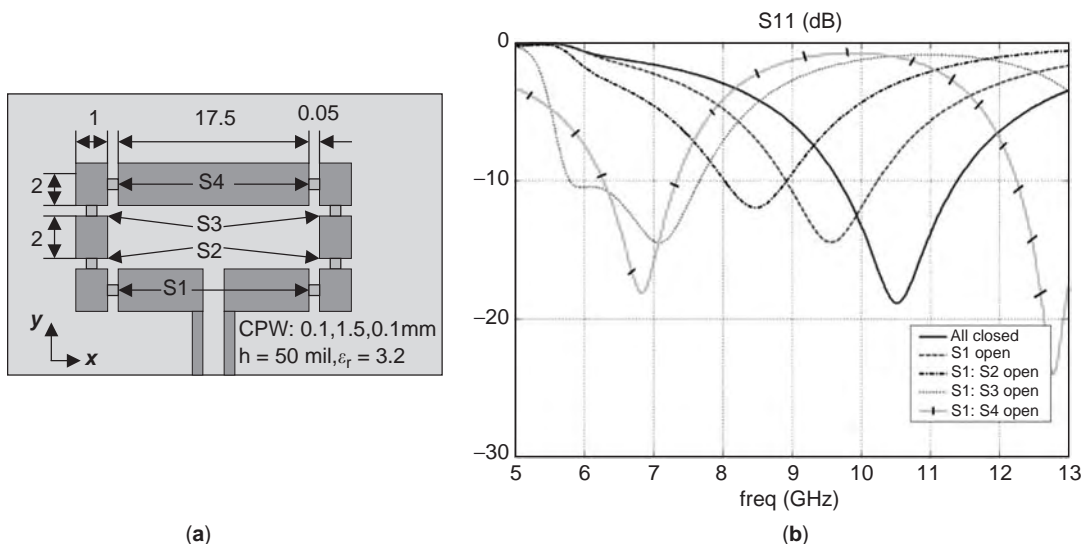

Figure 31. Reconfigurable CPWA (a) geometry and (b) return loss for different states of the switches. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

similar procedure is adapted for slot-type antennas. Full-wave EM simulations using Agilent’s Momentum have been carried out to demonstrate the feasibility of the proposed configurations. The procedure for designing such reconfigurable antennas is discussed, and experimental verification at X band is also conducted for ideal switching configurations. Detailed simulation results are presented for communication systems operating in the C and X frequency bands.

4.1. Reconfigurable Coplanar Patch Slot Antenna

A coplanar patch slot antenna (CPWA) is constructed from a rectangular metallic patch surrounded by a slot that separates the patch from the ground plane. The geometry and dimensions of this antenna along with the four pairs of switches, S_1 – S_4 , that perform the reconfiguration process of the antenna are shown in Fig. 31a, while the mechanism of controlling the return loss by these switches is indicated in the legend of Fig. 31b. Figure 32 shows the

Figure 32. The radiation patterns of the reconfigurable CPWA at the operating frequencies. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

radiation pattern and lists the directivity D and gain G in decibels at the operating frequency f_0 for each configuration. The reconfiguration process here depends on transforming the antenna type from a slot dipole to a CSPA rather than changing the antenna width. When all switches are closed or only S_1 is open, the antenna acts as a slot dipole. The dominant contribution in these two cases comes from the main slot dipole in the presence of neighboring parasitic rectangular slots. The operating frequencies for these two cases are 10.5 and 9.5 GHz with bandwidths of 17% and 14%, respectively. The slot dipole length is around $0.82\lambda_g$, which is the resonance length of the slot dipole [17]. Very low cross-polarization is obtained, as shown in Fig. 32, because no vertical currents exist. When the other switches are opened one after another, the physical length of the slot antenna increases and, consequently, it operates at lower frequencies (8.4, 7.1, and 6.8 GHz), as shown in Fig. 31b. The bandwidth for these three cases is 10%, 23%, and 14%, respectively. Although the maximum bandwidth of the antenna in any of the five states is 23%, the usable bandwidth using the MEM switches extends from 5.7 to 11.4 GHz, which is equivalent to a 67% bandwidth. This is 3 times the maximum bandwidth of each individual case.

The cross-polarization level increases when S_2 and S_3 are opened because the vertical path of the magnetic currents is increased, which contributes to the cross-polarized field component. As shown in Fig. 32, the copolarized fields are almost constant for all cases, providing stable radiation characteristics at different operating frequencies. The maximum gain is found to decrease as the operating frequency increased. As shown in the figure, within the 6.8–10.5 GHz band the gain drops by 1.4 dB for this configuration.

4.2. Reconfigurable Printed Monopole Antenna

The printed monopole antenna presented here is designed for wideband applications. Its operating frequency depends mainly on its vertical length, which should be around $\lambda_g/4$, while the bandwidth depends on its width. Therefore, changing the vertical length would allow for controlling the operating frequency. The geometry and dimensions of this antenna along with four pairs of switches, S_1 – S_4 , that perform the reconfiguration process are shown in Fig. 33a, while Fig. 33b shows the return loss variation for five states of the switches. When the antenna vertical length increases using the switches, the operating band changes from 6–13.5 GHz to 5–11.3 GHz, 4.6–10.3 GHz, 4.2–9.6 GHz, and 3.9–7.1 GHz, with the corresponding bandwidths equal to 77%, 77%, 77%, 78%, and 58%, respectively. Therefore, the usable bandwidth using the MEM switches for this antenna extends from 3.9 to 13.4 GHz, which is equivalent to 110% bandwidth.

The radiation patterns shown in Fig. 34 are calculated for the case when S_1 – S_3 are closed (metal) at different frequencies within the entire operating band. Almost stable copolarized field patterns are obtained, while the highest cross-polarization level is -14 dB at 9 GHz.

4.3. Reconfigurable Slot Dipole Antenna

The geometry and dimensions of the CPW-fed slot dipole antenna with four pairs of switches, S_1 – S_4 , that perform the reconfiguration process are shown in Fig. 35a, while Fig. 35b shows the return loss variation for five states of the switches, and the corresponding radiation pattern, directivity, and gain at the center operating frequency for each case are shown in Fig. 36. The reconfiguration process for this antenna is obtained by changing the antenna

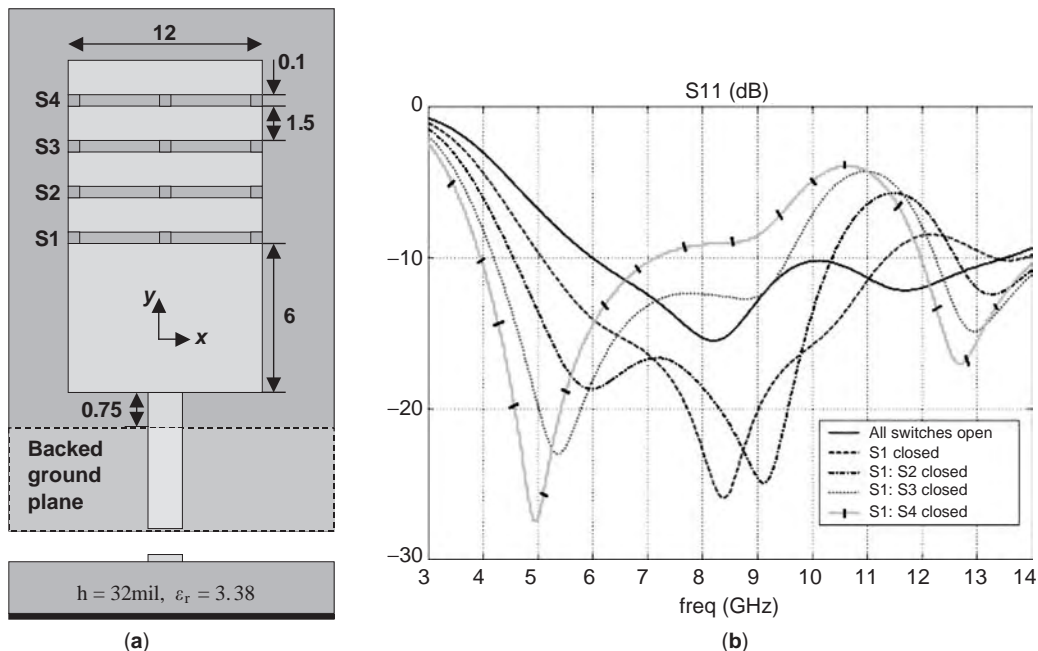

Figure 33. Reconfigurable printed monopole antenna (a) geometry and (b) return loss for different states of the switches. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 34. The radiation patterns of reconfigurable printed monopole antenna with S_1 – S_3 closed. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

width, which is approximately equal to $0.82\lambda_g$ [17]. The original width is 20 mm, and when a pair of switches is opened, the width increases by 2 mm to 28 mm for the case with all switches open. As shown in Fig. 35b, when the antenna width increases using the switches, the center operating frequency decreases from 11 GHz to 9.8, 8.8, 8.0, and 7.3 GHz, and the corresponding bandwidths change from 23% to 22%, 20.5%, 20%, and 20%, respectively.

This design has a stable radiation pattern and very low cross-polarization for all configurations presented, with an almost stable gain of 2.9 dB as shown in Fig. 36. It is also noticeable that the cross-polarization level decreases as the antenna width increases, because the antenna's of the vertical dimension–horizontal dimension (width) ratio decreases as its width increases.

The five configurations of the slot dipole antenna were fabricated, and their return loss and input impedance were measured using the network analyzer HP 8510C. The ground plane is truncated at 3 cm away from the slot antenna edges. A sample picture of one of these antennas

and the measured return loss are shown in Fig. 37. The measured operating frequency decreases from 10.9 to 9.8, 9, 8, and 7.5 GHz, which is very close to the simulation results. However, the bandwidth changes from 35% to 23.5%, 22.5%, 22.5% and 22.4%, which are slightly wider than the bandwidths calculated from the simulation results. A comparison between the simulation results and measurements for the cases with all switches closed, S_1 and S_2 open, and S_1 – S_4 open is shown in Fig. 38, where a very good agreement is observed. Although the maximum bandwidth of any of the five cases of this antenna is 35%, the usable measured bandwidth using the MEM switches extends from 6.6 to 13 GHz, which is equivalent to 65% bandwidth.

5. CONCLUSIONS

This article presents two novel antenna designs and a study of reconfigurable antennas for wideband applications.

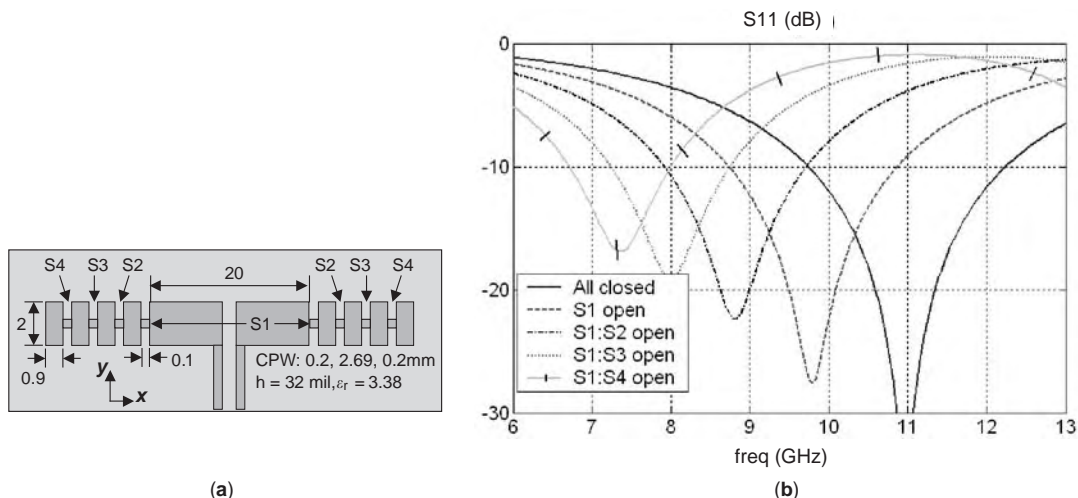

Figure 35. Reconfigurable slot dipole antenna (a) geometry and (b) return loss for different states of the switches. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 36. The radiation patterns of the reconfigurable slot dipole antenna at the operating frequencies. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The presented slot Lotus antenna is a good candidate for ultrawideband applications. The printed Lotus antenna is also an excellent candidate for wideband phased-array systems because of its small size, wide bandwidth, low return loss level over the entire operating band, low coupling between elements, stable radiation patterns over

the entire operating band, and wide scanning capabilities. Finally, antenna reconfiguration using ideal switches shows great promise in controlling the antenna operating band without changing one of the antenna dimensions. This technique permits the antenna to operate at different frequency bands and, consequently, it increases the usable

bandwidth of the antenna to further expand the wideband or multiband operation of printed and slot antennas.

WIRELESS COMMUNICATIONS SYSTEMS

ANA GARCÍA ARMADA

 Madrid, Madrid, Spain

1. INTRODUCTION

The birth of wireless communications systems can be traced back to G. Marconi's experiments to demonstrate the use of radio to contact with ships in the English Channel in 1897. Since then, wireless communications systems have experienced a tremendous evolution, and their use has spread throughout the world.

A brief historical view of the evolution of wireless communications can help us understand the impact of these communications systems in our lives nowadays. After Marconi's experiments, the first practical communication system involving vehicles was deployed by the police of Detroit (USA) at the end of the 1920s. This very first mobile network supported only unidirectional links (from central station to mobile terminals) and was based on amplitude modulation (AM). This unidirectional system was soon improved with bidirectional capability. In 1934 more than 200 police radio systems had been adopted for public safety in the United States, all based in amplitude modulation.

Because of the AM modulation characteristics, vehicle ignition noise was the factor that limited the quality of these early systems. In 1935, E. Armstrong demonstrated frequency modulation (FM) for the first time and, since then, FM became the preferred modulation technique for wireless applications.

After the remarkable improvement in manufacturing and miniaturization achieved during World War II, the number of mobile users experienced an enormous increase, and the main characteristics of wired telephony were introduced in wireless systems. Consequently these early-deployed systems began to saturate the spectrum and the need for more efficient planning of wireless communications systems was identified.

The solution was found during the 1950s and 1960s in AT&T Bell Labs and received the name of *cellular radio-telephony*. The main idea behind the cellular theory, as will be explained in Section 2 of this article, is the reuse of frequencies throughout the area of deployment of a given system. Technology was not ready to implement the cellular concept until the late 1970s.

The first commercial cellular telephone systems were those deployed by the Japanese Nippon Telephone and Telegraph (NTT) Company in 1979, the Nordic Mobile Telephone (NMT) system developed in 1981, and the U.S. Advanced Mobile Phone System (AMPS) implemented in 1983. The European Total Access Cellular System (ETACS) was deployed in 1985 and is virtually identical to AMPS.

These first-generation analog cellular systems were substituted by the second generation of digital cellular systems. In Europe, the different first-generation cellular systems were incompatible with each other because of the different frequency bands and protocols being used. This fact motivated the creation of a special group within CEPT (European Conference of Postal and Telecommunications Administrations) that received the name of GSM (Special Group for Mobile communications). The outcome of the GSM group gave birth to the first pan-European digital cellular system. The GSM standard was first deployed in 1990 using the 900-MHz band and it is gaining worldwide acceptance as the first digital cellular system with modern network features.

The U.S. Digital Cellular (USDC) standard was adopted as a means of increasing by 3 the capacity of AMPS in 1991. In Japan, the Pacific Digital Cellular (PDC) standard or Japanese Digital Cellular (JDC), very similar to the USDC, was adopted.

After the digital revolution in wireless communications, the need of what has been called *personal communication systems* (PCS) has arisen. The idea behind the term *personal communications* is that “anyone [should] be able to communicate anytime and anywhere.” Personal communication systems, also called *personal communication networks* (PCN), are being deployed above 1800 MHz using, among other standards, extended versions of GSM.

Both USDC and GSM are TDMA (time-division multiple-access) systems. A second-generation cellular system based in CDMA (code-division multiple access) was deployed by the U.S. company Qualcomm in 1993 and adopted as an Interim Standard (IS-95).

None of the systems described above has a worldwide projection. The idea of producing an enhanced worldwide standard led the ITU (International Telecommunications Union) to promote the creation of the family of standards named IMT-2000 (International Mobile Telecommunications for the year 2000). This IMT-2000, formerly called FPLMTS (future public land-mobile telephone system), will increase the amount of data that a wireless terminal is able to obtain from the network, giving rise to the possibility of multimedia wireless communications, that is, the third generation of mobile communications. The two main standards of the IMT-2000 family are called WCDMA and CDMA2000 and are being promoted by two international consortia: 3GPP and 3GPP2, 3GPP standing for 3rd-Generation Partnership Project.

The evolution toward 3G has produced some intermediate standards (receiving the name of 2,5G), and wireless local-area networks (WLAN) are receiving great interest as a complement to the existing mobile systems (either 2G, 2,5G, or 3G).

This means that although the history of wireless communications has been driven primarily by the evolution of mobile telephone systems, many different wireless standards are converging in the 3G scenario. A classification of wireless communications systems can give the reader some insight into the similarities and differences of these existing and future systems.

1.1. Classification of Wireless Communications Systems

Wireless communications systems can be classified according to different criteria. One of the preferred rules relies on whether the system is intended for public or private use:

Private mobile radio (PMR) systems are intended for private access and usually they are not connected to the Public Switched Telephone Network (PSTN). They are generally dedicated to management of vehicle fleets and dispatching tasks. They can serve different areas ranging from small local areas to nationwide.

Public mobile telecommunications (PMT) systems are intended to serve great areas, normally nation wide or larger. They are connected to the PSTN and offer similar services as those provided by wired PSTN terminals.

Most of the wireless communications systems used today can be considered to belong to either of these two categories. A comprehensive description is provided in Sections 2 and 4.

1.2. Evolution of the Demand For Wireless Products

The wireless systems industry has grown by orders of magnitude, mainly because of circuit fabrication improvements, large-scale circuit integration, and miniaturization, making small, portable, cheap wireless equipment a reality.

Figure 1. Mobile telephony subscribers and associated job creation in Europe. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

In the European Union (EU), the cellular mobile market is growing at an annual rate of 55%. Figure 1 [1] shows the evolution of subscribers of cellular products and the jobs, created in association with the mobile telephone market. This figure shows that more than 200 million EU citizens were “mobile” in year 2000, and some projections [2] indicate that 80% of the EU population by 2020 will have some form of mobile communication terminal.

On this basis, 280 million terminals need to be designed, manufactured, and provided to the customer. Even if this projection is halved, the number of mobile customers will still approach the present number of wired telephone connections within the EU [2].

In the United States, the number of cellular telephone users grew from 25,000 in 1984 to about 16 million in 1994, and, since then, wireless services have been experiencing customer growth rates up to 50% per year. According to the CTIA (Cellular Telecommunications Industry Association) [3], there were over 60 million wireless subscribers in the United States in June 1998 and more than 130 millions in June 2002 (see Fig. 2).

2. BASIC CONCEPTS AND FUNDAMENTALS OF WIRELESS COMMUNICATIONS

Radio, or wireless communication, is the use of radiated electromagnetic waves that permits the transmission and reception of information over a distance without the use of wires. At the transmitting or sending end, the information to be sent (e.g., a voice signal) is imposed on a locally generated radiofrequency (RF) signal called a *carrier*. The process of imposing the information signal on the carrier is called *modulation*. At the receiver, the information signal (e.g., voice) is extracted from the received signal in a process referred to as *demodulation*.

A pure, unmodulated radio carrier conveys no information and occupies only an infinitesimal amount of the spectrum. Modulation of the radio signal inevitably causes a spreading of the radiowave in frequency. Thus a radio signal conveying information occupies a range of frequencies called a *channel*. In general, the more information that is sent per unit of time, the wider the channel must

be. In addition to extracting the information from the radiowave through demodulation, it is also a principal-function of a receiver to accept only the information in the channel selected and reject other information sent simultaneously in other (e.g., adjacent) channels. The measure of the receiver’s ability to reject interfering signals on other channels is referred to as its *selectivity*. Hence, two or more radio systems can use the radio spectrum in the same area at the same time as long as (1) they are separated sufficiently in terms of frequency (i.e., so that their channels do not overlap) and (2) the receivers involved have sufficient selectivity to reject the signals on adjacent channels.

In many, if not most, communication systems, it is desirable to be able to communicate in both directions at the same time. This system characteristic, which is known as *full-duplex operation*, is desirable because it allows (1) one party in a voice conversation to interrupt the other with a question or (2) one device to immediately request a retransmission of a block of information received in error during a data communications session. There are two basic ways of providing for full-duplex operation in a radio system, as will be explained in Section 3. Once the most general principles of wireless communications have been explained, the fundamentals of the different wireless systems and the frequency bands allocated will be described in detail.

2.1. Cellular Systems

In the early mobile radio systems, the design objective was to achieve a large coverage area by using a single, high-powered transmitter. To avoid interference between users, the same carrier frequency could not be reused throughout the system. Hence, the overall system capacity was equal to the total number of channels: only a few thousand subscribers per system.

A cellular mobile communications system uses a large number of low-power wireless transmitters to create *cells*—the basic geographic service area of a wireless communications system. Variable power levels allow cells to be sized according to the subscriber density and demand within a particular region. As mobile users travel from cell

Figure 2. Evolution of wireless subscriber number in United States between June 1985 and June 2002.

to cell, their conversations are handed off between cells in order to maintain seamless service. Cells can be added to accommodate growth, creating new cells in unserved areas or overlaying cells in existing areas.

2.1.1. Frequency Reuse. In mobile systems, users share a pool of available channels (frequencies, timeslots, or codes). Let us assume that channels are associated with carrier frequencies. Since propagation losses are proportional to (a power of) the distance, the same frequency carrier, or channel, can be reused in cells at some distance away. The design process of selecting and allocating channel groups for all the cellular base stations within a system is called *network planning*. By reusing channels in multiple cells, the system can grow without geographical limits. In addition, this approach makes it possible to use small, battery-powered portable handsets with lower RF (radiofrequency) transmit power than the large vehicular mobile units used in earlier systems.

Reuse is critically dependent on the fact that the electromagnetic field attenuation in the cellular bands tends to be more rapid with distance (R) than it is in free space. As explained in more depth in Section 3, measurements have shown repeatedly that typically the field intensity decays like R^{-n} , with $3 < n < 5$ (in free space $n = 2$). If we assume that propagation attenuation does not depend on the azimuth angle, and that cell boundaries are at the

equisignal points, then a planar service area is optimally covered by the classical hexagonal array of cells.

Because the hexagonal geometry has exactly six equidistant neighbors, the size and geometry of a group of cells that collectively can use a complete set of available channels are limited [26]. Figure 3 shows an example in which seven sets of channels are used, one set in each colored cell. This seven-cell unit, also called *cluster*, is then replicated over the service area.

No similarly colored cells are adjacent, and therefore there are no adjacent cells using the same channel. While real systems never resemble these idealized hexagonal tilings of a plane, the seven-way reuse is typical of that achieved in practice. The preceding illustrations assume that the cells are using omnidirectional antennas. The system capacity, measured in users per square kilometer, can be increased by antenna *sectorization*. If each site is equipped with three sets of directional antennas, with their azimuths separated by 120° , the interference is reduced, allowing smaller clusters, which means an increase in capacity.

2.1.2. Cell Splitting. Economic considerations rendered the concept of creating full systems with many small areas impractical. To overcome this difficulty, system operators developed the idea of *cell splitting*. As a service area becomes full of users, this approach is used to split a single

Figure 3. Illustration of the frequency reuse concept. Cells with the same color use the same set of frequencies. In this example, the cluster size K is equal to 7, and the frequency reuse factor is $\frac{1}{7}$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

area into smaller ones. In this way, urban centers can be split into as many areas as necessary in order to provide acceptable service levels in heavy-traffic regions, while larger, less expensive cells can be used to cover remote rural regions (see Fig. 4).

The cell radii shown in Fig. 4 indicate that there are three types of cells in cellular networks: (1) *macrocells*, used mainly to cover large areas (1–10 km) with low traffic (rural areas); (2) the *microcells*, used in areas with high traffic density, such as suburban areas, with the cells 200-m and 200m–1 km in radius; and (3) *picocells*, or “indoor cells”, having radii between 10 and 200 m. Today, picocellular radio systems are used for wireless office communications.

2.1.3. Architecture of a Cellular Network. A cellular network is composed of three broad functional entities: the *mobile station* (MS) (normally a handset), carried by the subscriber; the *base station* (BS) subsystem, which controls the radiolink with the mobile station; and the *network subsystem*, the main part of which is the mobile services switching center (MSC), which performs the switching of calls between the mobile users, and between mobile and fixed network users. The MSC also handles the mobility management operations.

2.1.4. Handover. In a cellular network, the radiolinks and fixed links required are not permanently allocated for the duration of a call. *Handover*, also known as *handoff*, is the switching of an ongoing call to a different channel or cell (see Fig. 5).

A handover is performed in three stages. The MS continuously gathers information on the received signal level of the MS it is connected with, and all other BSs it can detect. This information is averaged to filter out temporary fluctuations in received-signal level. The averaged data are then passed on to the decision algorithm, which decides whether it will request a handover to another station. When it decides to do so, both the old BS and the MS execute handover.

2.2. Cordless Telephone Systems

Early cordless telephones operate solely as extension telephones to a dedicated base station, which is then connected to a dedicate telephone line with a specific telephone number on the Public Switched Telephone Network (PSTN). More recent cordless telephone systems employ the same technology as the digital cellular standards. However, the central difference is that cellular systems were developed for wide-area coverage, whereas the cordless standards are optimized for local coverage, with high densities of users.

The most recent digital cordless standards incorporate encryption, and support high-speed data (with circuit- and packet-switched modes) as well as fax and voice communications. The cordless standards provide higher speech

Figure 4. Cell splitting is the process of subdividing a congested cell into smaller cells, each with its own (low-powered) base station.

Figure 5. Handover, also known as *handoff*, is a process to switch an ongoing call from one cell to the adjacent cell as the mobile user approaches the cell boundary.

quality than do the mobile cellular standards (GSM, DCS 1800) and comparable with that of fixed networks. Even though digital cordless systems are more suited to stationary environments than vehicles, they also provide a limited degree of mobility in a local area.

Digital cordless systems are able to handle up to 100,000 users/km² in an office environment. They include dynamic channel selection/allocation (DCS/DCA) algorithms, which ensure that the best of the available radio channels are always used. This capability ensures that digital cordless systems can coexist with other systems in the same frequency band while providing high-quality, robust, and secure communications.

2.3. Trunking Systems

Radio trunking is a two-way communications technology where a number of users share a common pool of timeslots or frequencies that are dynamically allocated by the system as and when required. As it applies to radio, trunking is the automatic sharing of channels in a multiple-repeater system. Trunking concepts are based on the presumption that individual subscribers use the system only a small percentage of the time and that a large number of users do not use the system at the same time. Typical users of trunking systems are private corporations with large fleets (ambulances, buses), government departments (fire brigades, police) or utilities (electric power lines, oil pipelines, railways). Unlike other wireless systems, trunking systems can allow “direct mode” communications, that is, direct operation between mobile terminals without use of network infrastructure.

2.4. Differences between Cellular and Trunking Systems

One way of looking at the wireless communications systems is to chart the degree of customization required by users against traffic density. In such a model, the cordless technology is positioned as the technology that offers the

highest density and lowest degree of customization. Next to it are cellular systems, with medium traffic density, while the digital trunking technology is positioned to address low to medium traffic density with a higher degree of customization.

2.4.1. Large Cell Sizes. The different approach in these technologies is also reflected in the spectrum allocation and the cell sizes. At one end, in a dense urban environment, there are digital cordless systems, with cell sizes measured in hundreds of meters and operating at frequencies up to 2 GHz. Cellular systems, which address medium to high user densities with cells sizes measured in kilometers, operate at frequencies of 900 or 1800 MHz. In contrast, trunking systems address urban and suburban, low to medium user densities, with cell sizes of tens of kilometers and operating frequencies in the lower hundreds of megahertz.

2.4.2. Traffic Profile. Another important factor is the traffic profile. In cellular systems, call setup time is typically several seconds, in contrast to the fast push-to-talk operation of 300 ms for trunking systems. Also, while cellular calls are point-to-point (individual calls), the large percentage of trunking calls are group calls operating in an all-informed “open-channel mode.” The average duration of calls is also different: 2 min in cellular networks compared with 20 s for a trunking call.

2.4.3. Decentralized Architecture. The architecture of trunking systems is optimized for the predominance of local traffic. The need for fast call setup demands that the call switching and management be devolved to the lowest possible point in the network. This requires a decentralized, distributed system architecture, comprising distributed databases and loosely coupled autonomous parts. This, in turn, leads to an inherent reliability and fault tolerance with softer failure profiles.

2.5. Paging Systems

A radio paging system is a one-way wireless messaging system that allows continuous accessibility to someone away from the wired communications network. In its most basic form, the person “on the move” carries a palm-sized device (the pager) that has an identification number. The calling party inputs this number, usually through the public telephone network, to the paging system, which then signals the pager to alert the called party.

The paging system makes efficient use of the radio spectrum, enabling it to provide inexpensive functions satisfying customers’ demands. This has contributed to the steady expansion of the paging industry. The introduction of complementary products (e.g., pocket-sized cellular phones, cordless telephones, and multifunctional “communicators”) will inevitably spur the paging industry to provide more value-added services in the future. There will be more varied applications of paging such as sending e-mail, voicemail, faxes (facsimiles), or other useful information to a pager, which will also take on more attractive, innovative forms.

Paging systems vary widely in their complexity and coverage area. While simple paging systems may cover a limited range such as 2–5 km, or may always be confined to within individual buildings, wide-area paging systems can provide worldwide coverage. Although paging receivers are simple and inexpensive, the transmission system is quite sophisticated. Wide-area paging systems consist of a network of many base-station transmitters, and large radio towers that simultaneously broadcast a page from each base station (this is called *simulcasting*).

2.6. Wireless Local-Area Networks

A wireless local-area network (WLAN) is a flexible data communication system implemented as an extension to, or as an alternative for, a wired LAN. WLANs combine data connectivity with user mobility, and, through simplified configuration, enable movable LANs. With wireless LANs, users can access shared information without looking for a place to plug in, and network managers can set up or augment networks without installing or moving wires. Wireless LANs offer the following productivity, convenience, and cost advantages over traditional wired networks:

- *Mobility*—wireless LAN systems can provide LAN users with access to real-time information anywhere in their organization.
- *Installation speed and simplicity*—installing a wireless system can be fast and easy and can eliminate the need to pull cable through walls and ceilings.
- *Installation flexibility*—wireless technology allows the network to go where wire cannot go.
- *Reduced cost of ownership*—while the initial investment required for wireless LAN hardware can be higher than the cost of wired LAN hardware, overall installation expenses and lifecycle costs can be significantly lower.
- *Scalability*—wireless LAN systems can be configured in a variety of topologies to meet the needs of specific applications and installations.

2.6.1. WLAN configurations. The simplest WLAN configuration is an independent LAN that connects a set of PCs with wireless adapters. Any time two or more wireless adapters are within range of each other, they can set up an independent network. These on-demand networks typically require no administration or preconfiguration.

Access points can extend the range of ad hoc LANs by acting as a repeater, effectively doubling the distance between wireless PCs.

In infrastructure WLANs, multiple access points link the WLAN to the wired network and allow users to efficiently share network resources. The access points not only provide communication with the wired network but also mediate wireless network traffic in the immediate neighborhood. Multiple access points can provide wireless coverage for an entire building or campus.

2.7. Wireless Personal Area Networks

A wireless personal area network (WPAN) is a personal-area network — a network for interconnecting devices centered around an individual person — in which the connections are wireless. Because most PANs are wireless, these terms are virtually synonymous. Typically, a wireless WPAN uses some technology that permits communication within about 10 m — in other words, a very short range. One such technology is Bluetooth, which was used as the basis for a new standard, IEEE 802.15.

A WPAN could serve to interconnect all the ordinary computing and communicating devices that many people carry with them today — or it could serve a more specialized purpose such as allowing the surgeon and other team members to communicate during an operation.

A key concept in WPAN technology is known as “plugging in”. In the ideal scenario, when any two WPAN-equipped devices come into close proximity (within several meters of each other) or within a few kilometers of a central server, they can communicate as if connected by a cable. Another important feature is the ability of each device to lock out other devices selectively, preventing needless interference or unauthorized access to information.

The technology for WPANs is in its infancy and is undergoing rapid development. Proposed operating frequencies are around 2.4 GHz in digital modes. The objective is to facilitate seamless operation among home or business devices and systems. Every device in a WPAN will be able to plug into any other device in the same WPAN, provided they are within physical range of one another. In addition, WPANs worldwide will be interconnected

2.8. Frequency Bands Allocated for the Different Wireless Services

In response to rapid growth in the wireless personal communication services, regulatory authorities have steadily increased the amount of spectrum available through successive reallocations of the resource in the higher frequency ranges. Moving higher in frequency to avoid congestion has advantages and disadvantages. Generally speaking, the radiofrequency (RF) devices employed within the system get more costly at higher frequencies, and, in terms of propagation effects, the higher frequencies are subject to more blocking or shadowing by buildings or hills. However, the antennas involved are physically smaller, which is an important attribute for systems that seek to serve small portable units carried on one’s person. At some risk of overgeneralizing, it can be said that (1) the lower-frequency bands are best for economically covering wide areas (suburban and rural areas) where frequency reuse is not as important and (2) the higher-frequency bands are best for covering urban areas where high levels of frequency reuse are desired.

3. TECHNOLOGY

This section of the article addresses basic technical issues related to the transmission in wireless communications systems. The ideas presented herein will allow the reader

to understand the rationale behind the choices made for the standards described in Section 4 of this article.

3.1. A Brief Review of the Propagation Characteristics in Radio Bands

The use of radio propagation exhibits inherent advantages over “line” (copper, coaxial, optic fiber, waveguide) transmission. Some of these advantages are lower cost, faster deployment, and the capability to roam. However, the radio channel is less robust than line channels. Radio propagation is not a stationary phenomenon, but the propagation parameter depends on many factors that engineers cannot control, such as meteorology, or any moving object in the surroundings. This channel instability makes the radio transmission a much more difficult problem than line transmission and determines the design of the equipment.

Physical phenomena that affect both attenuation and delay are free-space propagation, shadowing, and reflections. Moreover, because of the multiple reflections, the path for the signal to travel from the transmitter to the receiver is not unique, but several propagation paths can occur simultaneously producing the phenomenon termed ‘*multipath*.’ This phenomenon affects both fixed and mobile radiolinks; however, channel variability is not an issue for fixed links. Propagation conditions in fixed links vary slowly or do not vary at all.

The radio channel affects amplitude attenuation, angular shift, time delay, and Doppler frequency shift of each propagation path between transmitter and receiver. In mobile links, these three parameters are time-varying and differ for each path. The sum of all these paths results in the following effects: variable signal attenuation, variable signal time delay, temporal spread, and Doppler frequency spread. In mobile communications, because of the many factors involved in the radio propagation and their unpredictable dynamics, these propagation parameters are modeled as random processes. Statistics for amplitude attenuation, time spread and Doppler spread are briefly summarized next.

The variable attenuation suffered by the received signal is usually referred to as “fading.” Fading can be modeled as the sum of three components: large-scale path loss, medium-scale (slowly-varying) fading, and small-scale (rapidly varying) fading.

The total fading is computed as the product (sum in logarithmic scale) of the three abovementioned factors. The large-scale path-loss model accounts for the average attenuation value for a geographic area ranging several hundreds of wavelengths in size. Large-scale loss is modeled as a constant and accounts for free-space attenuation, diffraction, refraction, and reflection. When the line between transmitter and receiver is not obstructed by any object [line of sight (LoS)], the large-scale loss is reduced to the free-space loss, and it can be modeled according to the following equation

$$L_{\text{free space}} = K \left(\frac{d}{\lambda} \right)^2 \quad (1)$$

where K is a constant and λ is the signal wavelength. This attenuation is known as ‘*free-space attenuation*’.

When the propagation environment does not correspond to the free-space scenario, large-scale loss can be modeled as

$$L_{\text{large - scale}} = K \left(\frac{d}{\lambda} \right)^\gamma \quad (2)$$

where γ is an empirical parameter that varies from 1.8 to 6 depending on the environment (outdoor or indoor, flat or mountainous, desert or forest, etc.).

The shadowing caused by natural or manmade objects close to the receiver is the physical effect responsible for slowly varying fading. Although this fading factor has slow dynamics, the shadowing causes the deepest variations of the received-signal level. The medium scale follows a lognormal distribution, where the received power, expressed in logarithmic units (dB), follows a normal (Gaussian) distribution. When designing the link equipment, this fading model has to be considered in one or both of the following ways: (1) the transmitted power has to be increased to compensate for this variable attenuation, typically with a signaling feedback from the receiver known as “closed-loop power control”, or (2) a scrambler must be included after the channel coder in such a way that it can be guaranteed that after descrambling at the receiver two consecutive bits do not simultaneously suffer a deep fading. Thus, the channel decoder is able to correct the errors caused by the deep fade. To guarantee the efficiency of the scrambler, its timelength has to be longer than the fading coherence time. This parameter is studied below.

The multipath is the phenomenon responsible for the fast varying fading. When two paths arriving either with close delays have the same phase, the resulting signal is stronger than those of either path.

However, when both paths arrive with a 180° phase difference, the resulting signal is smaller than the strongest path, or the signal can even vanish. The rapidly varying component follows a Rice or Rayleigh distribution, depending on the existence of LoS. When there is no LoS conditions, the probability distribution function for the received amplitude due to multipath follows a Rayleigh model. When there are LoS conditions, the amplitude pdf follows a Rice distribution.

Rapidly varying fading reduces the quality of the link, or in other words, increases the bit error rate (BER). The techniques usually employed to overcome this quality degradation are forward error-correcting codes, fast transmitted power control, or the usage of space or frequency diversity. Diversity utilizes the fact that the two signals with different carrier frequencies or antenna locations are unlikely to suffer a deep fading simultaneously. Then, proper combination of both frequencies, or antenna locations, can provide effective protection against the fast fading.

As mentioned before, knowledge of the temporal correlation of the fading is as important as the knowledge of the amplitude distribution for the correct system design. The *average fading* time is defined as the expected time the fading exceeds a given attenuation value. For a Rayleigh fading, the average fading time τ_f may be modeled as [4]

$$\tau_f = \frac{\exp(\rho^2) - 1}{\sqrt{2\pi}\rho f_d} \quad (3)$$

where ρ is the ratio between the fading level and its RMS (root-mean-square) value and f_d is the maximum Doppler frequency shift. f_d is calculated as

$$f_d = \frac{V}{\lambda} = \frac{fV}{C} \quad (4)$$

where V is the mobile speed, λ is the signal wavelength, and f is the carrier frequency.

Besides the variable attenuation, multipath causes several copies of the same signal to arrive at the receiver end with different delays. The time difference between the earliest and last paths is known as *delay spread*. Typical values for the delay spread in indoor environments are 50–250 ns for the 900-MHz band and 10–20 ns for the 2.4-GHz band [5]. Typical values in the 900-MHz band for outdoor environments are 10–25 μ s [6].

If the delay spread is smaller than the inverse of the signal bandwidth, the receiver is not able to resolve the different paths, and the multipath affects only the received amplitude; in this case, multipath causes fading but does not produce distortion on the received signal. This fading is known as *flat fading*. The mechanisms available to compensate for this type of fading are channel coding, scrambling, and space and frequency diversity.

However, if the delay spread is larger than the inverse of the bandwidth — comparable or larger than the symbol rate — the multipath causes intersymbol interference, namely, signal distortion. This fading is known as frequency-selective fading. The usage of equalizers can partially or totally overcome the intersymbol interference caused by the frequency-selective fading.

Because of user and/or environment motion, each path arrives with its own Doppler frequency shift, too, which causes a frequency spread of the received signal. This effect, known as *Doppler spread*, is closely related to the coherence time of the multipath channel and the average fading time. All these quantities describe the temporal correlation of the fading.

3.2. Modulations in Wireless Systems

Digital modulation is a simple concept. The transmitter groups the digital information to be sent into packets of N bits. Each of the $M = 2^N$ possible values of the N -bit packet is mapped into a signal, which is properly amplified and transmitted. At the receiver end, the signal arrives corrupted by noise and interference. An optimum receiver detects which signal, among the M possible ones, was transmitted in such a way that the probability of error is minimized.

Radio transmission requires the spectrum of the M possible signals to be centered around the frequency for which the antenna system is designed, which is modulating the signals with the proper carrier frequency. Summarizing, we could say in a very general way that radio digital modulations can be classified into four basic groups, each correspond to a different modulation scheme. So, we could say that there are ASK, PSK, FSK, and QAM digital modulation types, corresponding to amplitude,

phase, frequency, and amplitude–phase combination modulations, respectively.

Amplitude modulations are not advisable for mobile radiolinks. The wide amplitude variability caused by the radio channel fading would mask the changes of amplitude due to modulation. Although it could be envisaged that an automatic gain control (AGC) system in the receiver might compensate for the channel attenuation, it would unnecessarily complicate the system and would require the continuous transmission of a pilot signal to estimate the exact value of the channel attenuation. The same argument as that advanced for amplitude modulation can be applied for amplitude–phase combination, QAM, modulations. Thus, phase or frequency modulation, where amplitude does not carry information, is advisable for mobile communications.

According to the M -PSK (M -level phase shift keying) modulation scheme, pulses containing a sine wave with a constant frequency are transmitted. Each possible transmitted symbol shifts the phase of the sine wave by a different amount. To uniformly spread the phase of the M symbols, the phase shifted is a multiple of $2\pi/M$ radians. Thus the received signal, $s_i(t)$, when the i th symbol is transmitted, follows the expression

$$s_i(t) = \sqrt{\frac{2E}{T}} p(t) \cos\left(2\pi f_c t + i \frac{2\pi}{M}\right) \quad i = 0, \dots, M-1 \quad (5)$$

where E is the average received energy per symbol, T is the symbol timelength, f_c is the carrier frequency, and $p(t)$ corresponds to the pulse conformation. The symbol length T is related to the bit duration T_b as $T = T_b \log_2 M$. Therefore, the symbol rate R is

$$R = \frac{R_b}{\log_2 M} \quad (6)$$

The quality of any digital transmission is measured by the bit error rate (BER). The exact calculation of the BER of an optimum M -PSK receiver cannot be analytically calculated for an arbitrary value of M ; however, the exact expressions for BPSK ($M = 2$) and QPSK ($M = 4$) (binary and quadrature PSK) are

$$\text{BER}_{\text{BPSK}} = \frac{1}{2} \text{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \quad (7)$$

$$\text{BER}_{\text{QPSK}} = \text{erfc}\left(\sqrt{\frac{E}{2N_0}}\right) \left[1 - \frac{1}{4} \text{erfc}\left(\sqrt{\frac{E}{2N_0}}\right)\right] = \text{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \left[1 - \frac{1}{4} \text{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right)\right] \quad (8)$$

where N_0 is the white Gaussian noise spectral power density, E_b is the average received energy per bit, and

$$\text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} dt \quad (9)$$

Average received energy per symbol E , average received energy per bit E_b , and the average received power P are related by

$$E = E_b \log_2 M = PT = PT_b \log_2 M \quad (10)$$

The bandwidth required for the transmission of a M -PSK signal depends on the pulse $p(t)$ shaping. The minimum M -PSK bandwidth is

$$B_{M\text{-PSK}} = \frac{R_b}{\log_2 M} \quad (11)$$

where again R_b is the bit transmission rate. Equation (5) can be rewritten as

$$\begin{aligned} s_i(t) = & \sqrt{\frac{2E}{T}} p(t) \sin\left(i \frac{2\pi}{M}\right) \sin(2\pi f_c t) \\ & - \sqrt{\frac{2E}{T}} p(t) \cos\left(i \frac{2\pi}{M}\right) \cos(2\pi f_c t) \end{aligned} \quad (12)$$

It can be noted in this last equation that both in-phase (cos) and quadrature (sin) components are affected by the same envelope, $p(t)$. Therefore transitions between symbols occur at the same time in both components. When the available bandwidth is small, $p(t)$ is far from a rectangular pulse, and equal (synchronous) shaping for in-phase and quadrature components causes large RF amplitude variation; and amplitude variation represents a handicap for nonlinear power amplifiers, which have better power efficiency.

The straightforward solution for the problem of having amplitude variation in QPSK has been solved by staggering the envelope of the quadrature component by a time delay of $T/2$. This modulation is known as *offset QPSK* (OQPSK). The received signal, $s_i(t)$, when the i th symbol is transmitted follows the expression

$$\begin{aligned} s_i(t) = & \sqrt{\frac{2E}{T}} p(t) \sin\left(i \frac{2\pi}{M}\right) \sin(2\pi f_c t) \\ & - \sqrt{\frac{2E}{T}} p\left(t - \frac{T}{2}\right) \cos\left(i \frac{2\pi}{M}\right) \cos(2\pi f_c t) \end{aligned} \quad (13)$$

Besides lower-frequency spurious emission when it passes through a nonlinear amplifier, OQPSK has the same BER and bandwidth efficiency as does QPSK.

Another solution given to decrease the amplitude range of a QPSK signal under limited bandwidth conditions is the addition of a $\pi/4$ phase to every other transmitted symbol. In this way, the received signal $s_i(t)$ is

$$s_i(t) = \sqrt{\frac{2E}{T}} p(t) \cos\left(2\pi f_c t + i \frac{2\pi}{M} + \begin{cases} 0 \\ \pi/4 \end{cases}\right) \quad i = 0, \dots, 3 \quad (14)$$

where a 0 and $\pi/4$ phase are alternatively added to the carrier.

The second type of modulation with constant amplitude is FSK. According to the FSK modulation scheme, pulses containing a sine wave with a different frequency are transmitted. Each possible transmitted symbol shifts the carrier frequency by a different amount. Frequency modulation has the drawback of larger bandwidth. To overcome this problem to the maximum extent possible, frequency modulation with minimum frequency deviation has been proposed. This modulation is known as *minimum shift keying* (MSK), which is defined by the binary case, $M=2$. In this case, the received signal, $s_i(t)$, when the i th symbol is transmitted follows the expression

$$s_i(t) = \sqrt{\frac{2E}{T}} p(t) \cos\left(2\pi f_c t \pm \frac{\pi}{2T} t + \theta\right) \quad (15)$$

where the \pm signs mean a $\Delta f = 1/(4T)$ positive frequency shift when transmitting a “1” and the same negative frequency shift for the “0” transmission. The phase θ stands for a phase term that is added to each symbol in order to guarantee a continuous phase. For this reason MSK modulation is also known as CPFSK (continuous-phase FSK).

In the GMSK modulation, the “G” stands for Gaussian, and it refers to the fact that the MSK modulation is filtered with a Gaussian frequency response before its transmission. The Gaussian frequency response

$$H(f) = \exp\left(-\frac{\ln(2)}{2} \left(\frac{f}{B}\right)^2\right) \quad (16)$$

limits the 3dB-bandwidth of the transmitted signal to B . In order to increase the bandwidth efficiency, B is adjusted to satisfy $BT_b < 1$. The usual values for B are such that $0.2 \leq BT_b \leq 0.5$.

The exact value of the BER for an optimum GMSK receiver is very complex; however, an BER upper bound accurate enough for any practical propose is given by

$$\text{BER}_{\text{GMSK}} = \frac{1}{2} \text{erfc}\left(\sqrt{0.68 \frac{E}{N_0}}\right) \quad (17)$$

A common objective of all the digital modulations described above is to maximize the spectrum efficiency, which means that they try to minimize the occupied bandwidth for a given transmission bit rate. We introduce next a set of modulation techniques that try just the opposite, to maximize the bandwidth. These modulations are classified under the generic term *spread-spectrum techniques*.

Although it might seem that the usage of such spread-spectrum modulations is an unnecessary waste of spectrum, it can be proved that is not the case as spread-spectrum techniques allow a more efficient usage of the spectrum. In spread spectrum, the spectrum of transmitted signals is artificially spread by a code. This code is different for each link in the same geographic area of the radio network. Although we will not discuss this in detail in this article, the receivers can demodulate separately each link attending to its assigned code, so that the remaining signals in the same portion of the spectrum do not interfere.

As is mentioned in the next section, and explained in detail in the article entitled WIRELESS NETWORKS, the possibility of discriminating links from its code allows the multiple-access technique known as code-division multiple access (CDMA).

The spreading codes used in spread-spectrum modulations consist of a sequence of bits with random appearance. To distinguish the code bits from the information bits, the former are called “chips.” Although the spreading code auto- and cross-correlation functions resemble the auto- and cross-correlation of random sequences, they are generated deterministically by shift registers with specific feedback connections. Thus the receiver can generate an exact copy of the code used by the transmitter.

From a practical perspective, there are two kinds of spread-spectrum modulations: direct sequence (DS) and frequency hopping (FH). The former takes the transmitted bits and multiplies (performs exclusive OR) them by the code sequence before modulations. The chip rate of the spreading code has to be faster than the bit rate in order to spread the spectrum. The latter changes the carrier frequency according to a pattern dictated by the spreading code.

Because of practical implementation issues, DS uses BPSK or QPSK modulators, and FH is used in conjunction with bit FSK modulation. The BER in presence of additive white Gaussian noise is not altered from the expression corresponding to BPSK, QPSK, and FSK respectively.

3.3. Multiple Access

As explained in detail in the WIRELESS NETWORKS article multiple-access techniques can be classified into two generic types: scheduling and contention. The former assigns a fixed amount of resources (timeslot, frequency range, or code) to each link, so there is no possible interference among them. The latter allows several links to access the same resources but establish some mechanisms to minimize the probability of collision, with simultaneous usage of the same resources, and to detect the collision if it occurs.

The simplest and most straightforward multiple access method is known as *frequency-division multiple access* (FDMA). With FDMA, the available spectrum is divided into nonoverlapping slots in the frequency dimension or domain. These frequency slots or channels are then put into a pool and assigned to users on either a manual or automated basis for the duration of their particular call. For example, a 150-kHz block of spectrum could be divided into six channels or frequency slots, each 25 kHz wide. Such an arrangement would allow six simultaneous conversations to take place, each with their own carrier within their own frequency slot.

With *time-division multiple access* (TDMA), the available spectrum is divided into nonoverlapping timeslots in the time dimension or domain. These timeslots or channels are then put into a pool and assigned to users for the duration of their particular call. To continue the example given above, in a TDMA system the 150 kHz of spectrum would be divided into recurring groups (frames) of six timeslots, and each timeslot would carry a sequence of bits

representing a portion of one of six simultaneous conversations.

A third access method is known as *code-division multiple access* (CDMA). As explained above, CDMA is both a modulation and an access technique that is based on the spread-spectrum concept. In spread-spectrum systems, multiple conversations (up to some maximum) simultaneously share the available spectrum in both the time and frequency dimensions. Hence, in a CDMA system, the available spectrum is not channelized in frequency or time as in FDMA and TDMA systems, respectively. Instead, the individual conversations are distinguished through coding; that is, at the transmitter, each conversation channel is processed with a unique spreading code that is used to distribute the signal over the available bandwidth. The receiver uses the unique code to accept the energy associated with a particular code. The other signals present are each identified by a different code and simply produce background noise. In this way, many conversations can be carried simultaneously within the same block of spectrum.

3.4. Implementation of Duplex Channels

Duplex services are those that allow users in the network to send and receive information simultaneously. Obviously, the ability of sending and receiving requires the assignment of two links to each user. Although both links serve the same user, they can be viewed as two independent links; therefore a multiple-access technique has to be chosen. There are two options for the duplex implementation: time-division duplex (TDD), and frequency-division duplex (FDD).

Frequency-division duplexing (FDD) is used to assign two different frequency slots per conversation — one for transmitting and one for receiving. By separating the slots sufficiently in frequency (about 5% of the nominal RF), filters (say, in the portable radio) can be used to prevent the transmitted information from interfering with the simultaneously received information.

Time-division duplexing (TDD) uses the fact that it is possible to share a single radio channel in time. TDD is possible only with digital transmission formats and digital modulation, and is very sensitive to timing. For this reason, TDD has only recently been used for indoor or small-area wireless applications where the physical coverage distances (and thus the radio propagation time delay) are much smaller than the many kilometers used in conventional cellular telephone systems.

TDD simplifies the frequency planning when the service is not symmetric, with different bit rates for the “go and return.” On the other hand, TDD is not advisable for long links because of the long propagation time delays. Large propagation delays require large timeguard gaps between reception and transmission to avoid collisions between them, which results in a low spectral efficiency.

3.5. Recently Developed Modulation Techniques

3.5.1. Wideband CDMA. Wideband code-division multiple access (wideband CDMA) [17] has emerged as the mainstream air interface solution for third-generation

networks. In Europe, Japan, Korea, and the United States wideband CDMA systems are currently being standardized.

Wideband CDMA has a bandwidth of 5 MHz or more (multiples of 5 MHz). The nominal bandwidth for all third-generation proposals is 5 MHz. There are several reasons for choosing this bandwidth:

1. Data rates of 144 and 384 Kbps (kilobits per second), the main targets of third-generation systems, are achievable within 5 MHz bandwidth with a reasonable capacity. Even a 2-Mbps peak rate can be provided under limited conditions.
2. Lack of spectrum calls for reasonably small minimum spectrum allocation, especially if the system has to be deployed within the existing frequency bands already occupied by second-generation systems.
3. The 5-MHz bandwidth can resolve (separate) more multipaths than can narrower bandwidths, increasing diversity and thus improving performance. Larger bandwidths of 10, 15, and 20 MHz have been proposed to support higher data rates more effectively.

Several wideband CDMA proposals have been made for third-generation wireless systems. They can be characterized by the following new advanced properties:

- Provision of multirate services
- Packet-switched data
- Complex spreading
- A coherent uplink using a user-dedicated pilot
- Additional pilot channel in the downlink for beamforming
- Seamless interfrequency handover
- Fast power control in the downlink
- Optional multiuser detection

The third-generation air interface standardization for the schemes based on CDMA seems to focus on two main types of wideband CDMA: network asynchronous and synchronous. In network asynchronous schemes the base stations are not synchronized, while in network synchronous schemes the base stations are synchronized to each other within a few microseconds.

3.5.2. Orthogonal Frequency-Division Multiplexing (OFDM). OFDM is a multicarrier modulation [18] that is finding many wireless applications due to its ability to combat impulsive noise and multipath effects and make fuller use of the system available bandwidth. It has been adopted for the European Digital Audio Broadcasting (DAB) [19] and Digital Video Terrestrial Broadcasting (DVB-T) [20] standards and is under study for new wireless LAN generations (HIPERLAN: high-performance radio LAN).

In an OFDM-based system, the spectrum associated with each elemental piece of data is a small portion of the

total bandwidth (B), which is divided into N subchannels. Each of them is modulated with one information symbol, and they are all multiplexed in frequency.

If T represents the OFDM symbol duration, the N subcarriers are separated by $\Delta f = 1/T$, and thus placed in the following frequencies:

$$f_k = f_0 + k/T, \quad k = 0, 1, \dots, N - 1 \quad (18)$$

One of the main advantages OFDM is the possibility of an easy implementation using a fast Fourier transform algorithm (FFT) [21]. Among its weaknesses, sensitivity to phase noise, frequency offsets and nonlinear effects must be mentioned.

3.5.3. Combination of Multicarrier and CDMA Techniques.

Some ways of combining OFDM and CDMA have been suggested in attempts to obtain the advantages of both techniques. Depending on how they are combined, three different schemes have been developed: multicarrier (MC)-CDMA, multicarrier direct sequence (DS)-CDMA, and multi-tone (MT)-CDMA. They constitute different trade offs between transmitter-receiver complexity, spectral efficiency and bit error rate [22].

4. PRACTICAL WIRELESS SYSTEMS AND PRODUCTS

This section is devoted to describing in detail some practical wireless communications. Descriptions follow after an overview of their frequencies of operation:

Digital trunking systems operate the UHF band in the 400-MHz region:

TETRA (Trans European Trunked RAdio) release 1: 390.0125–392.9875 MHz and 420–425 MHz (digital 12.5–25 kHz channels)

Cordless telephone systems:

CT2 cordless phones: 854–870 MHz (this band will be reserved for CT2 until December 31, 2005)

(Pan European) cordless headphones: 863–865 MHz

DECT Digital European Cordless Telephones: 1880–1900 MHz

Cellular systems operate a band near 800/900 MHz, and, most recently, a band near 1.8/1.9 GHz:

Cellphones—GSM (Global System for Mobile communication; (124 × TDMA 200-kHz channels): 915–960 MHz, uplink (split – 45 MHz: 870–915 MHz, downlink)

ETACS/TACS: 917.0125–949.9875 MHz (25-kHz channels, 12.5-kHz offsets) to be phased out by 2005

EGSM—Extended GSM: 925.2–935 MHz

European Railways GSM system: 921–925 MHz

In-flight digital phones (air–ground): 1800.30–1804.969 MHz (164 × 30.303-kHz channels; ground at –130 MHz)

PCN mobile phones: 1805–1876.5 MHz (split – 95 MHz: 1710–1781.5 MHz)

Future UMTS (IMT-2000, third-generation mobile): 1900–2025 MHz (with 2110–2200) (– 190 MHz)

Wireless LAN: Three media can be used for transmission over wireless LANs. Infrared, radiofrequency and microwave.

Radiofrequency: industrial, scientific, and medical (ISM) frequency bands, 902–928 MHz, 2.4–2.4853 GHz, 5.725–5.85 GHz.

4.1. Cellular Systems

The concepts behind cellular systems were discussed in Section 2. This section briefly presents the networks commercially available nowadays and enumerates the services they provide and the main parameters and differences between them.

During the 1970s and 1980s several analog cellular systems were deployed with a successful acceptance among the public, including AMPS, TACS, and NMT. These systems were analog, and their low spectral efficiency severely limited the network capacity. Moreover, the lack of a unified standard prevented the users from roaming through different countries.

At the beginning of the 1980s, initiatives were taken to develop a new cellular standard with the following goals: digital transmission, high spectral efficiency, high network capacity, international roaming, provision of voice communications and low-bit-rate data (fax), small-size terminals, and digital signaling able to provide advanced services, among others.

The European initiative to provide a pan-European second generation was very successful, coming up with the GSM standard. The U.S. initiative produced the IS-54, which provides services similar to those of GSM. In the 1990s the United States also produced the IS-95, the first cellular system to employ spread-spectrum modulation.

4.1.1. GSM. Although GSM is now available in the frequency range of 1800 MHz, known as DCS-1800, the primary GSM band is 935–960 MHz for the downlink (base to mobile) and 890–915 MHz for the uplink (mobile to base). The duplex method is FDD with a constant go-and-return frequency separation of 45 MHz.

The multiple-access technique used by GSM is TDMA plus FDMA. The available spectrum is divided into frequency channels separated 200 kHz. Each of these frequency channels is divided into 8 timeslots of duration 0.577 ms each, which makes frames of length 4.615 ms. Both traffic and signaling channels are mapped into these TDMA/FDMA physical channels according to a established pattern. The transmitted raw (after channel coding) bit rate is 270.83 kbps for each carrier (i.e., eight TDMA channels). The modulation is GMSK with a bandwidth such that $BT_b = 0.3$, where $1/T_b = 270.83$ kbps.

The signaling of the GSM is an ISDN version adapted to the mobility and radio environment. Figure 6 shows GSM network structure.

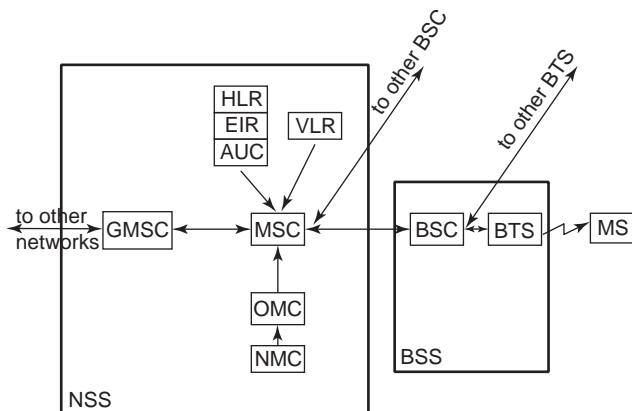

Figure 6. GSM network structure.

The GSM network is divided into three large segments: the mobile station (MS), the base-station subsystem (BSS), and the network switching subsystem (NSS).

BSS consists of the base transceiver station (BTS) and the base-station controller (BSC). BTS performs the physical-layer-related functions, while BSC contains the higher control functions. One BSC may control several (up to 10) BTSs.

The mobile (services) switching center (MSC) routes the calls toward the BSC closer to the MS. MSC gets the location of a particular MS from the home location register (HLR), which is updated so that it always contains the latest location of each mobile in the network. HLR also contains information about the user's profile. When a MS is roaming into a different network, the information in HLR regarding this user is copied to the visitors location register (VLR) of the host network.

The equipment identity register (EIR) and authentication center (AUC) are responsible for the network security and privacy. The operations management center (OMC) and network management center (NMC) handle the resources management and maintenance. Finally, the gateway mobile switching center (GMSC) connects the NSS to other networks.

The carrier services provided by GSM are voice and low-speed data with a maximum bit rate of 9.6 kbps. Voice is digitally coded at 13 K and 6.5 kbps. The former is known as *full-rate* (FR) and the later, as *half-rate* (HR). Although HR provides worse voice quality, it doubles the capacity of the network.

Additional services provided by the GSM network are calling-line identification, call forwarding, call waiting, call holding, multiparty, closed user group, advice of charge, reverse charging, user-to-user signaling, and barring outgoing and ingoing calls.

4.1.2. GPRS and EDGE. The General Packet Radio Service (GPRS) is a standard for data transmission across the GSM network. GPRS is part of the new services provided in phase 2+ of GSM. It supplements the GSM (phase 1) Circuit Switched Data Service by adding new functionalities in the core network that allow a packet-switched data transmission. Apart from the packet switching, GPRS has following novel features respect to GSM:

- *Bit Rate Transmission.* Theoretical maximum speeds of up to 171.2 kilobits per second (kbps) are achievable with GPRS using all eight timeslots at the same time. This is about 10 times faster than the maximum speed provided by circuit-switched GSM networks.
- *Immediacy.* GPRS facilitates instant connections whereby information can be sent or received immediately as the need arises. No dialup modem connection is necessary. This is why GPRS users are sometimes referred to be as being “always connected.” Immediacy is one of the advantages of GPRS when compared to circuit-switched GSM.
- *New Applications.* GPRS facilitates several new applications not previously available over GSM networks because of the limitations in speed of circuit-switched data (9.6 kbps) and message length of the short message service (160 characters).

EDGE (Enhanced Data for GSM Evolution), has been standardized within the European Telecommunications Standards Institute (ETSI) as the final evolution of data communications within the GSM standard. It uses a different modulation scheme to enable data throughput speeds of up to 384 kbps using existing GSM infrastructure.

Third-generation wireless systems will provide high-speed wireless access to wideband multimedia services where spectrum and licenses are made available. Today's GSM operators have two (nonexclusive) options for evolving their networks to third-generation wideband multimedia services: (1) use EDGE in the existing radio spectrum and in small amounts of a new spectrum or (2) use wideband CDMA in a new 2-GHz spectrum or in large amounts of an existing spectrum.

4.1.3. IS-95. In 1993 the Telecommunication Industry Association (TIA) produced the standard for the first CDMA cellular system under the nomenclature of IS-95. The usage of spread-spectrum techniques forecast a larger system capacity.

IS-95 uses a voice codec with variable bit rate. The IS-95 vocoder generates a bitstream at a 9600 bps rate, but it detects the silence periods and reduces the bit rate down to 1200 bps. Usage of a variable transmission rate further increases the network capacity.

Although they follow different spreading schemes, both downlink and uplink channels are spread by a pseudo-noise code of 1.2288 Mchip/s (megachips per second), such that the channel bandwidth is 1.25 MHz. IS-95 uses FDD duplexing with 45 MHz separation between the go-and-return. Frequency allocation is 869–894 MHz for the downlink and 824–849 for the uplink.

In addition to voice service, IS-95 also provides data transmission service at 9.6, 14.4, and 28.8 kbps.

4.1.4. IMT-2000. The goal of third-generation mobile systems is to provide users with worldwide coverage via handsets that have the capability to seamlessly roam between multiple networks (fixed and mobile, cordless and cellular) across regions that currently use different

technologies. Because their objective to provide larger capacity to accommodate multimedia transmission and better quality of service (QoS), third-generation (3G) mobile systems are one step beyond the digital cellular and cordless systems that are now in service. At the global level regarding 3G mobile systems, in ITU (International Telecommunications Union) there has been an initiative, IMT-2000, intended to settle the framework of the future telecommunication infrastructure. IMT-2000 will provide wireless access to the global telecommunications infrastructure through both satellite and terrestrial systems. It is being developed on the basis of the “family of systems” concept designed to be able to connect different radio transmission modules to the same core network equipment.

Different standards development organizations (SDOs)—ARIB (Japan), CWTS (China), TTA (USA), TTC (Korea), TTC (Japan), T1 (USA), and ETSI (Europe)—are participating in the development of this new “family of standards” including the creation of consortia and partnerships. There are two main active 3G partnership projects: 3GPP and 3GPP2. 3GPP is supported by the SDOs that were involved in specification of GSM systems and its evolution, while 3GPP2 comprises the SDOs involved in the ANSI/TIA/EIA-41 network evolution. 3GPP is working toward the definition of IMT-DS and IMT-TC air interfaces, which are better known as the UMTS (Universal Mobile Telecommunication System) on its FDD and TDD modes, respectively. 3GPP2 works toward the definition of an IMT-MC interface, which is better known as CDMA2000.

4.1.5. UMTS. UMTS defines a network architecture somewhat similar to GSM, as can be seen in Fig. 7, where three main functional entities, user equipment (UE), the UMTS terrestrial radio access network (UTRAN), and the core network are defined. The interfaces defined between the UE and the UTRAN is the Radio Interface (Uu) and the interface between the Core Network and the UTRAN, which is called Iu.

In order to simplify the migration from GSM to UMTS (see Fig. 8), the core network proposed for the first phase of UMTS deployment coincides with the GSM 2+ (GPRS) core network. Both the radio network subsystem (RNS) and UE are redefined by UMTS. For terrestrial applications, these two new subsystems, related to the radio interface, are defined by the UTRAN standard.

Functionalities of USIM, ME, Node-B, and RNC in UTRAN are equivalent to the functionalities performed by subscriber identity module (SIM), MT, BTS, and BSC in GSM. However, the specifications for these systems are modified in order to accommodate the higher capacity and better QoS. Maximum and minimum bandwidth of UMTS services are summarized in Table 1. As one of the main novelties of UMTS, the use of spread-spectrum modulation and CDMA can be highlighted to increase the overall network capacity (see Section 3).

4.1.6. CDMA2000. The CDMA2000 is the standard defined by 3GPP2 that includes air interface definition, minimum performance requirements, and definition of

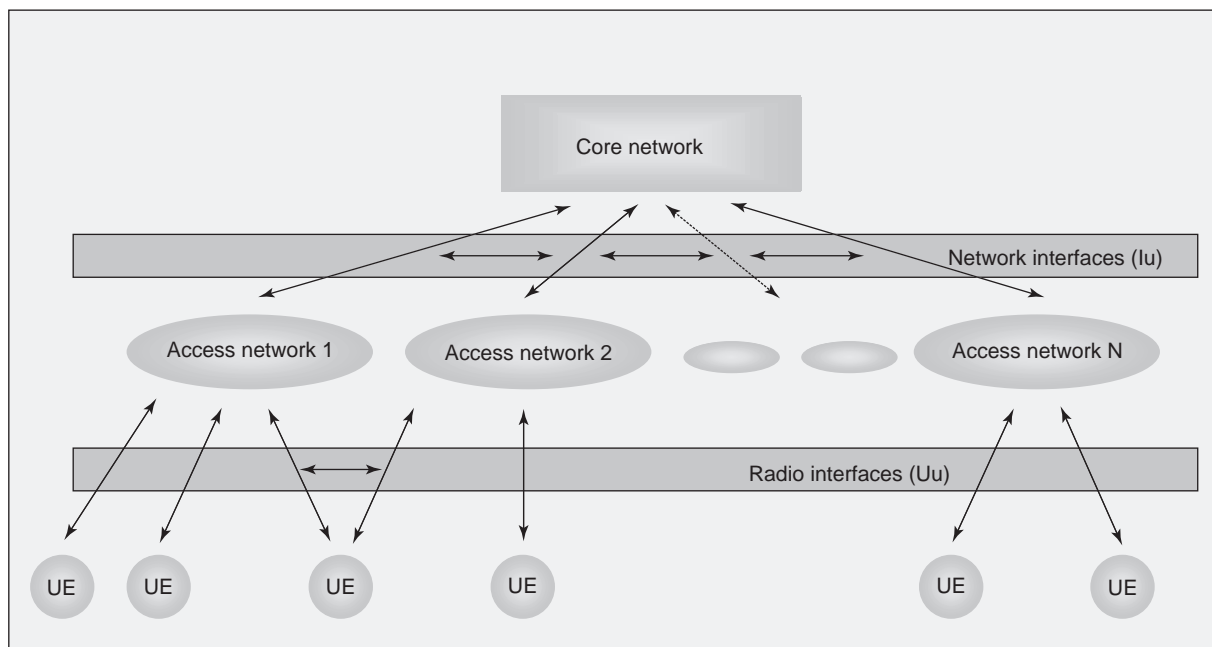

Figure 7. Functional entities in UMTS network architecture.

supported services. It meets all the requirements for the next-generation evolution of the current TIA/EIA-95-B (IS-95) standard and to be part of the “family of systems” concept designed by ITU to be able to connect different radio transmission modules to the same core network equipment. The CDMA2000 standard matches the ITU requirements for the IMT-2000 CDMA Multi-Carrier Mode (MC-CDMA).

The cdma2000 radio interface is a wideband, spread-spectrum interface that uses CDMA technology. It satisfies the ITU requirements for the indoor office, indoor-to-outdoor pedestrian, and vehicular environments. The key

design characteristics include a W-CDMA radio interface offering significant advances to increase performance and capacity, data rates ranging from 1.2 kbps to >2 Mbps, and support a wide range of RF channel bandwidths, advanced medium control access (MAC), turbo codes for higher transmission rates and increased capacity, and support for forward radio interface transmit diversity.

4.2. Cordless Systems

In contrast to cellular radio, cordless systems offer primarily an access technology rather than fully specified

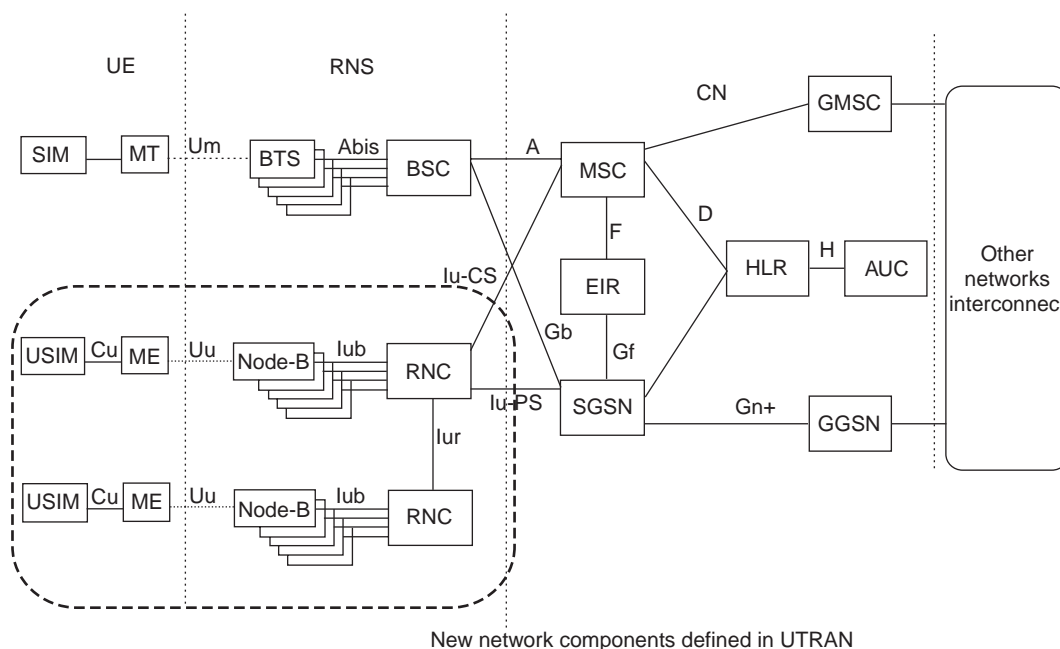

Figure 8. Comparison between GSM and UMTS architectures.

Table 1. Carrier Services Provided by UMTS^a

	FDD		TDD	
	Uplink Bit Rate	Downlink Bit Rate	Uplink Bit Rate	Downlink Bit Rate
Maximum	960	960	3840	3840
Minimum	15	7.5	240	240

^aIn kilobits per second (kbps).

networks. Cordless terminals generally transmit at lower power than cellular, using microcells with a range of a few hundreds of meters. In high-density environments, smaller cells are used to provide traffic densities higher than those obtained by cellular standards.

4.2.1. Services, Features, and Standards. Voice was the only service provided by early analog cordless systems. However, cordless technology has evolved and the cordless data market has become increasingly important as palm-top computers have emerged. DECT standard was specified to provide both voice and data services.

The potential of cordless access to permit user roaming between business and domestic applications was one of the key drivers of digital cordless standards. Also, the opportunity to offer public cordless access, generically known as *Telepoint*, was recognized. Thus, modern cordless telecommunications standards provide the following applications:

1. *Domestic Application.* The earliest application of cordless communication systems was the residential cordless telephone with a very simple base station giving service to the home environment and allowing the use of the telephone in such a small area. The domestic market was dominated by analog products because of the higher relative price of digital products.
2. *Business Application.* The potential business application of cordless telecommunications was one of the early drivers for development of the technology. Although early products focused on Telepoint, WPABX has shown significant progress. Wireless access in the PABX environment enables the user to obtain the wide range of PABX features while roaming across a business area. In new offices, the expense and delay of deploying a PABX can be avoided without the need of wiring up. ISDN as well as voice capabilities supported by the wired PABX can also be supported by WPABX. Also, mobility management functions must be incorporated so as to authenticate and locate users and route incoming calls.
3. *Telepoint.* *Telepoint*, also called *public access*, is a short-range radio system that enables a user with a portable handset to gain access to teleservices via a public fixed network like PSTN. CT2 was the first available Telepoint standard. DECT has also been specified to support public access. Although it is a European concept, the initial success of Telepoint has been in Asia, where early systems, combined with paging, have taken off in spite of the absence of the complementary domestic and business products. In contrast, early Telepoint experiences in Europe

failed to attract a significant number of users, probably because of the lack of standards and products at that time. New experiences were launched in 1992 using CT2 (“Rabbit” launched by Hutchison Telecom in UK, “Bibop” launched by France Telecom, “Birdie” launched by DBP Telekom in Germany, “Greenpoint” launched by PTT Netherlands, “Pointer” launched by Telecom Finland), which started showing greater success but ended up with unsatisfactory results (Rabbit and Birdie were phased out in 1993; Bibop continues with a number of users well below the self-sustaining level). Telepoint trials have also been carried out in Canada and the United States, under experimental FCC licenses. However, the implantation of low-cost personal communication services (PCS) has been a serious threat to the success of Telepoint.

4. *Wireless Access.* Although the applications mentioned in paragraphs 1–3 (above) led to the development of cordless standards and products, a fourth application has emerged with a new potential market for cordless telecommunications: the wireless local loop (WLL). Telecommunication services that used to be provided by wire from an exchange to the user’s premises are alternatively using cost-effective wireless standards. This use has been encouraged by the liberalization of telecommunications monopolies in Europe, leading to a number of potential service providers that do not own the wired infrastructure. Wireless local loops may be provided by different wireless technologies; cordless standards are one possible choice because of their low cost.

The main cordless standards, providing some of the applications listed above are as follows:

- CT0 (Europe) and CT1 (Europe): first-generation analog systems.
- CT2 (Europe): digital cordless FDMA standard using time-division duplex (TDD)
- PACS (USA), PHS (Japan) and DECT (Europe): the latest digital cordless telecommunication systems

Since DECT corresponds to the latest stage in the evolution of cordless systems, it will be explained in greater depth in the following section.

4.2.2. Digital European Cordless Telecommunications (DECT) Standard. DECT is based on a microcellular radio-communication system that provides low-power radio (cordless) access between portable parts (PPs) and fixed parts (FPs) at ranges up to a few hundred meters. The basic technical characteristics are as follows:

- Frequency band: 1880–1900 MHz
- Number of carriers: 10
- Carrier spacing: 1728 MHz
- Peak transmit power: 250 mW
- Carrier multiplex: TDMA; 24 slots per frame
- Framelength: 10 ms
- Basic duplexing: TDD using 2 slots on same RF carrier

- Gross bit rate: 1152 kbps
- Net channel rates: 32 kbit/s B-field (traffic) per slot; 6.4 kbps A-field (control/signaling) per slot

A connection is provided by transmitting bursts of data in the defined timeslots. These may be used to provide simplex or duplex communications. Duplex operation uses a pair of evenly spaced slots: one for transmission and one for reception. The simplest duplex service uses a single pair of timeslots to provide a 32 kbps digital information channel capable of carrying coded speech or other low-rate digital data. Higher data rates are achieved by using more timeslots in the TDMA structure, and a lower data rate may be achieved by using half-slot data bursts.

DECT is able to support a number of alternative system configurations ranging from single-cell equipment (e.g., domestic FPs) to large multiple-cell installations (e.g., large business WPABXs). Direct communication between portable parts (PPs) is also supported.

The protocols are designed to support uncoordinated system installation, even where the systems coexist in the same physical location. Efficient sharing of the radio spectrum (of the physical channels) is achieved using a careful mechanism of dynamic channel selection.

In addition, the DECT protocols provide two internal mechanisms to support rapid handover of calls in progress (both intracell and intercell handover are supported). These handover mechanisms allow a high quality of service to be maintained where the mobility of the PP requires transparent re-connection to another FP or where a new physical channel is required in response to disturbances in the radio environment. Detailed information about DECT standard may be found in Refs. 7–11. The latest introductions to the standard have dealt with interworking with GSM [12] and UMTS [13] and addition of a new packet service named DPRS (DECT Packet Radio Service) [14].

4.3. Trunking Systems

When we refer to a *trunked system*, or, equivalently a *private mobile radio* (PMR) system, we refer to a system where all the users share a pool with all the available channels. If a user wants to make a call, the system allocates one of the idle channels.

4.3.1. Features. The most important features of PMR systems are related to the special nature of their users.

1. PMR users, such as the emergency services, police, and firefighters handle incidents where calls are typically very short and speed of communication is vital. In contrast to cellular systems, where it takes several seconds to establish a call, the access to the PMR network takes tenths of a second.
2. PMR services allow group and broadcast calls.
3. PMR codecs are designed to provide good-quality speech in noisy environments.
4. New digital PMR systems can provide a user, on a dynamic basis, “bandwidth on demand.”

5. One powerful operational mode of PMR systems (not provided by cellular systems) is the so-called direct mode (DMO), the ability for radio handsets to communicate directly with each other without using the network infrastructure.

4.3.2. Standards. For completeness, we will summarize some of the digital technologies available.

The first one is the TETRA (Trans-European Trunked Radio). It is a radio open standard based on TDMA defined by ETSI (European Telecommunications Standards Institute). The TETRA standard contains high functionality for emergency services and is also very well suited for commercial trunked radio users.

There are other systems, all of which are proprietary and directed at users and markets similar to those for TETRA. The major ones are iDEN and ASTRO from Motorola, Aegis and PRISM from Ericsson, and Tetrapol from Matra. However, the majority of users have by now seen the benefits of standardization and are moving away from these proprietary systems.

In response, the manufacturers with their proprietary specifications have been increasingly attempting to have them adopted as a “standard” by national or international standardization bodies. The most active has been Matra, who developed a digital system called MatraCom, MC9600, a 12.5/10-kHz FDMA system initially sold to French Gendarmerie as Rubis and later its derivatives to other customers under various other names such as Acropolis, Pegas, and Nexus.

In order to promote these proprietary technologies as generic, Matra created the name Tetrapol and formed the so-called Tetrapol Forum. Also, as an active ETSI member, Matra has twice tried to have its technology selected by ETSI for the TETRA standard. Having failed on both occasions, the company has, this time as the Tetrapol Forum, declared its intent to have the Tetrapol specification considered for adoption as an ETSI deliverable under a so-called PAS (publicly available standard) procedures.

4.3.3. TETRA: The European Standard for Digital PMR.

TETRA (Trans-European Trunked Radio) is a radio open standard based on TDMA. In contrast to GSM, where manufacturers and operators have determined the specifications, the users, especially emergency service users, have contributed strongly in the creation of the standard. As a result, the TETRA standard contains high functionality for emergency services and is also very well suited for commercial trunked radio users. It is summarized as follows:

1. Technology
 - a. Physical-layer radio
 - i. Modulation: $\pi/4$ DQPSK
 - ii. Transmission rate: 36 kbps
 - iii. Duplex spacing: 10 MHz (45 MHz in 900-MHz band)
 - iv. RF carrier spacing: 25 kHz
 - b. Frequency bands. TETRA has been designed to work in the frequency range from VHF (150 MHz)

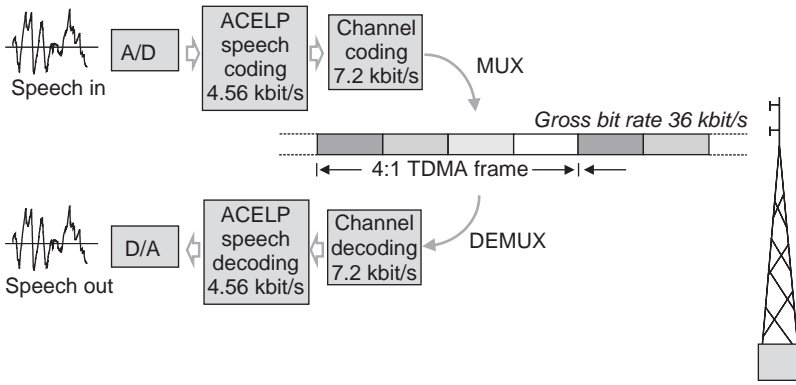

Figure 9. Speech coding and multiplexing in TETRA. Digitized speech is coded, using an ACELP coder, protected, by introducing redundancy, and inserted in a TDMA frame. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

to UHF (900 MHz). In particular, standardization bodies have released bands in the frequency range 380–400 MHz for public safety users.

- c. **Speech coding.** The TETRA codec was designed to provide good-quality speech in harsh environments and voice quality superior to that of GSM in the poor-signal conditions. In TETRA systems speech is digitized and coded using an ACELP (algebraic code-excited linear prediction) speech coder. In order to protect the transmitted information, a channel coder introduces additional redundancy. The resulting bit rate is 7.2 kbps. TETRA has the capability of using four TDMA slots, which allows managing four voice communications on the same carrier (see Fig. 9).
- d. **Data transmission.** TETRA can provide a user, on a dynamic basis, with up to four TDMA slots in a single communication channel, effectively “bandwidth on demand.” This applies to packet-mode and circuit-mode data, with data rates of ≤ 28 kbps.
- e. **TDMA frame structure.** The TETRA frame structure has four slots per TDMA frame. This is further organized as 18 TDMA frames per multiframe, where one frame per multiframe is always used for control signaling. Besides, there is a hyperframe imposed above the multiframe structure. This is for long repeat frame purposes such as encryption synchronization. Each timeslot has 510 (modulating) bits duration and has the basic structure shown in Fig. 10.

- f. **Spectrum efficiency.** TETRA is one the most frequency-efficient standard for mobile communication, equivalent to 6.25 kHz per channel, voice or data. This means that TETRA is currently 4 times more spectrum efficient than GSM, and twice as efficient when the half-rate codec is implemented. Regarding other PMR systems, TETRA can accommodate up to 4 times more users.
2. **Features.** In addition to the features of other public cellular systems, TETRA offers a series of additional services. The most important ones are.
 - a. **Group call and group communication**—a number of users share the same channel. This enables many users to cooperate on a specific task or to monitor the activities of other members of the group.
 - b. **Fast call setup**—TETRA makes it possible to set up calls in less than 0.3 s.
 - c. **Direct mode**—allows terminals to communicate directly with each other independently of the radio infrastructure, or in areas with no coverage.
 - d. **Mobile terminal used as repeater**—a mobile terminal can be used as a repeater and in this way extend the coverage of the TETRA network.
 - e. **Encryption**—TETRA offers a very high degree of encryption of both voice, data, signaling, and user identity. TETRA defines two methods of encryption: air interface encryption and an optional end-to-end encryption for the most critical applications.
 - f. **Broadcast**—transmission of messages to all users of the network.

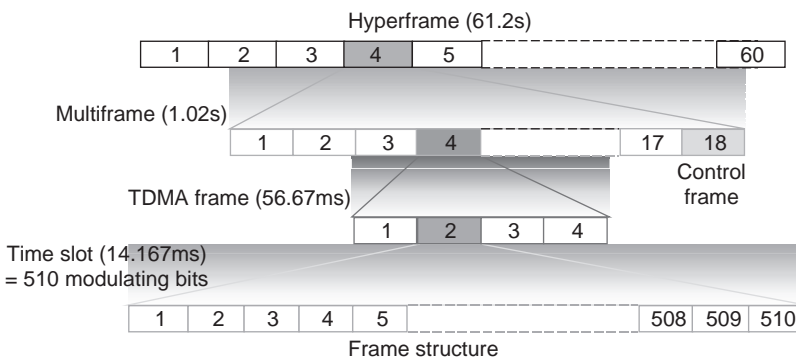

Figure 10. Hierarchical structure of frames in TETRA. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

- g. Priority—possibility of priority in up to eight levels; also, calls with high priority can “overrule” calls with low priority if no idle channels are available.
3. Typical of TETRA users
- a. Public safety and public security (police, fire, ambulance, customs, etc.)
 - b. Transport (airlines, ports, taxis, buses, railways, etc.)
 - c. Utilities (gas, electricity, water, oil, etc.)
 - d. Industry (manufacturing, plant, distribution, etc.)
 - e. Nonemergency authorities (government, public health, environment protection, etc.)

4.4. Paging Systems

A radio paging system is a wireless messaging system that allows continuous accessibility to someone away from the wired communications network. In its most basic form, the person on the move carries a palm-sized device (the pager) that has an identification number. The calling party inputs this number, usually through the public telephone network, to the paging system, which then signals the pager to alert the called party.

Pager types and existing standards are described in this section.

4.4.1. Pager Types. Several types of pagers are commercially available:

- *Tone-only*—pager alerts user; user takes predetermined action, such as calling a predetermined phone number.
- *Numeric pager display*—pager alerts user and displays numeric message; user calls phone number displayed.
- *Alphanumeric and ideographic display*—pager alerts user and displays text message; user can then take necessary action.
- *Tone and voice*—pager alerts user, then delivers short (10–20 s) voice message; user can then take necessary action.
- *Stored voice*—pager silently alerts and stores voice message for recall at user’s convenience.

4.4.2. Standards. Different manufacturers have developed an array of techniques to forward the required information to remote pagers. These techniques, known as *encoding formats*, define the techniques employed to represent the information-carrying data elements of the protocol as well as how to interpret the overall data content.

In many cases, encoding formats send additional data, known as *error detection and correction codes*, that are capable of detecting and recovering incorrectly received data. With error correction, pager receipt reliability is improved dramatically. Both analog and digital transmission techniques are used to transfer information to pagers.

Most paging formats are manufacturer-specific and often proprietary. A few paging protocols have been devel-

oped and put into the public domain so that many different manufacturers may produce compatible pagers. Among these public domain protocols are POCSAG, Swedish Format (MBS), the Radio Data System (RDS) format, and the European Radio Message System (ERMES) format. All of these formats were developed in Europe.

European Radio Message Standard (ERMES) Format.

The European Radio Message Standard (ERMES) is a standard that was developed by a subcommittee of the European Telecommunications Standards Institute (ETSI).

The ERMES digital encoding format supports tone-only, numeric, and alphanumeric paging in addition to data transfer capabilities. The format operates at 6250 bps. ERMES pagers operate on multiple frequencies, scanning for the best frequency for optimum reception.

The paging format uses a modulation mechanism known as “four-level pulse amplitude modulated FM.” In this mechanism, two binary bits of information are transmitted simultaneously through the transmission of one of four signaling frequencies. One set of frequencies is interpreted as the two binary bits “00,” another as “01,” another as “10,” and the final frequency as “11.” Therefore, with frequency transitions at the rate of 3125 per second, 6250 bits of information may be transferred. Under the ERMES protocol, every hour is broken up into 60 cycles, each one minute in duration (cycles 0–59). Each cycle is divided into five equal subsequences of 12 seconds each (subsequences 0–5). Finally, each 12-s period is divided into 16 separate batches (batches A–P). A batch contains separation partitions of information known as the *synchronization partition*, *system information partition*, *the address partition* and the *message partition*.

Within each batch, the address partition contains the first 18 bits (the initial address) of the unique pager number, a 35-bit address known as the *radio identity code* (RIC), ordered in descending order. This technique allows a pager to quickly determine whether its unique address is not part of this batch so that it may return to battery-saving mode. All pagers whose addresses are larger than the initial address can return immediately to battery-saver mode. Messages are transmitted directly after the address partition. The large (35-bit) address field accommodates a global address scheme that can support hundreds of millions of pagers.

4.5. Wireless Local-Area Networks (WLANS)

Wireless local-area networks (WLANS) constitute an evolution of the small-area data communication networks used to interconnect computers and peripherals, in which wired transmission is replaced by radiocommunications. They find their primary use inside buildings or in outdoors locations like the university campus.

The main features and the most commonly used standards are briefly described.

4.5.1. Services, Features, and Standards. The existing service scenarios for WLAN are mainly private local networks in workplaces, campuses, or public areas such as

airports. Universal access points in homes and nomadic access in public places can be provided by either WLAN or cordless standards and are experiencing an increasing interest. The WLAN market currently aims at five categories of applications: healthcare, factory floors, banking, educational institutions, and domestic applications.

Some examples of WLAN standards are

- IEEE 802.11: part of the IEEE 802 family of LAN standards, initially using either infrared (IR), direct-sequence spread spectrum (DSSS), or frequency-hopping spread spectrum (FHSS). Recent extensions looking for higher bit rates have included new modulation techniques (CCK—complementary code keying—in IEEE 802.11b and OFDM—orthogonal frequency-division multiplexing—in 802.11a).
- HIPERLAN: a family of standards prepared by ETSI (European Telecommunications Standards Institute) whose first outcome was HIPERLAN 1 (using GMSK modulation) with little success; the second outcome was HIPERLAN 2, using the same modulation as IEEE 802.11a.
- HomeRF: an WLAN standard specifically designed by the industry for in-home applications with special emphasis on voice services (using a modified version of DECT) and connection of the home computer to the Internet.

Table 2 summarizes the main characteristics of these standards. IEEE 802.11, the most commonly used WLAN standard nowadays, is described more deeply in the following section.

4.5.2. IEEE 802.11 Standard. The IEEE 802.11 standard for WLAN [15] has established itself as a mature standard presenting a well-defined technology that is being adopted by the manufacturers and accepted by users.

The earlier versions of IEEE 802.11 (1997) specified data rates of ≤ 2 Mbps using spread-spectrum technology (direct sequence or frequency hopping) in the 2.4-GHz band. IEEE 802.11b provides data rates of ≤ 11 Mbps in the same band, while IEEE 802.11a, an extension to the 5 GHz band, increases the data rate up to 54 Mbps. Alternatively, the version of 1997 allows infrared technology to be used at 850–950 nm.

Multiple access is based in CSMA/CA (carrier sense multiple access with collision avoidance), a contention-based scheme suitable for asynchronous applications. The

standard also supports a contention-free prioritized point coordination function (PCF) mechanism for time-bounded isochronous applications.

Two network topologies are considered: infrastructure-based and ad hoc.

4.6. Wireless Personal Area Networks (WPANs)

The term *wireless personal area networks* (WPAN) refers to a technology using short-range radiolinks, intended to replace the cable(s) connecting portable and/or fixed electronic devices. Its key features are robustness, low complexity, low power, and low cost, which make it especially suited to mobile handheld devices. The WPAN technology can also offer wireless access to LANs, PSTN, the mobile phone network, and the Internet for a host of home appliances and portable handheld interfaces.

The objective of the WPAN technology is to provide a uniform structure for a wide range of devices to communicate with each other, anywhere in the world, with minimal user effort. This feature introduces the “unconscious connectivity” paradigm, where WPAN devices can connect to those in the proximity almost without any user command or interaction.

4.6.1. Technical Challenges. The above mentioned requirements involve great technical complexity in terms not only of the functionalities to be provided but also of the power and size requirements. In this way, the WPAN technology must face the following technical challenges:

- The system has to use an unlicensed band for universal acceptance and usage. Thus, the industrial—scientific—medical (ISM) band is usually selected for this technology. The challenge here is to make the system robust to interference from other sources in this band, which include not only ISM band communication systems but also microwave ovens.
- Preferably, each transmitter itself should use the minimum power required so as not to increase the noise for other users.
- The transceivers should be able to adapt to a rapidly changing environment, as the devices will usually be mobile. The well-known problems in wireless systems such as multipath fading must be handled.
- The connection establishment and routing protocols must also operate in an environment where the number, location, and variety of WPAN devices will change dynamically with fair amount of rapidity.

Table 2. Characteristics of WLAN Products

	IEEE 802.11b	IEEE 802.11a	Hiperlan 2	HomeRF
Range (m)	30	50	50	50
Modulation	DSSS + CCK	OFDM	OFDM	FHSS
Main scenario	Office	Office	Office	Home
Power	100 mW	1 W	1 W	100 mW
Voice services	No	No	No	Yes
Minimum data rate (Mbps)	1	6	6	0.8
Maximum data rate (Mbps)	11	54	54	1.6

- The size of the implementation should be small for easy integration into handheld and mobile devices.
- The power consumption should not be more than a small fraction of the host device into which the WPAN capability is to be introduced.
- The technology should be adaptable to devices of varying computing power and memory resources. This will ensure that an increasing number of devices can interoperate.
- Automatic and unconscious connection establishment must be provided. The number and identity of devices in proximity will change quite frequently, and it will be very inconvenient to establish connections manually each time. Also, the number of devices will be too large for most users to be able to remember or search the device address of the device that they need to connect to.
- Synchronization of clocks among the communicating units will have to be achieved. As each unit will have its own free-running clock with its own drift, carrying out successful communication, especially CDMA, is a challenge in itself.
- Security considerations have to be satisfied. The WPAN devices will be part of people's personal usage and will contain and communicate their personal information, sensitive business information, or other data that must be protected from being spoofed or mutilated. The encryption facility must thus be provided among other security features.

4.6.2. Bluetooth. Bluetooth wireless technology is a specification designed to enable wireless communication between small, mobile devices. The inspiration behind this technology was the concept of eliminating the need for proprietary cables, which are currently required to enable device connectivity.

While Bluetooth wireless technology has many features unique to its own specification, it has borrowed heavily from several existing wireless standards, including Motorola's Piano, IrDA, IEEE 802.11, and Digital Enhanced Cordless Telecommunications (DECT). Motorola's Piano was developed with the concept of forming ad hoc "personal area networks." This concept was adopted by the Bluetooth SIG to expand the capabilities of the original Bluetooth concept beyond simple cable replacement. The voice data transmission capabilities of Bluetooth are derived from the DECT specification. The object exchange capabilities (the ability to share business card, contact information, messages, etc.) are derived from the IrDA specifications. Bluetooth also inherits the use of the 2.4-GHz ISM band, frequency-hopping spread spectrum (FHSS), authentication, privacy, power management, and LAN capabilities provided by the IEEE 802.11 specification.

There are four major components in any Bluetooth wireless technology system: a radio unit, a baseband unit, a software stack, and application software. The *radio unit* is the actual radio transceiver that enables the wireless link between Bluetooth devices. The *baseband unit* is hardware, consisting of flash memory and a CPU,

which interfaces with the radio unit and the host device electronics at the hardware level. The baseband hardware provides all required functionality to establish and maintain a Bluetooth wireless connection between devices. The *software stack* is essentially driver software or firmware that enables the application-level software to interface with the baseband unit. The *application software* implements the user interface and overall functionality of the Bluetooth device.

4.6.2.1. Bluetooth Radio. Bluetooth Radio uses the unrestricted 2.45-GHz ISM band, which is available globally with slight constraints in some locations relating to bandwidth and power output. Using a frequency hop transceiver with hops occurring at 1600 s^{-1} interference and fading effects are minimized since each packet is transmitted in a different hop frequency.

A time-division duplex scheme is used for full-duplex transmission. Within the range of 10 cm–10 m, a gross data rate of 1 Mbps can be achieved to service mobile and business users. The range can be extended beyond 100 m by increasing the transmit power. Second-generation plans are to increase the data rate to 2 Mbps.

Bluetooth can support an asynchronous data channel, up to three simultaneous synchronous voice channels, or a channel that simultaneously supports asynchronous data and synchronous voice. Each voice channel supports a 64 kbps synchronous (voice) link. The asynchronous channel can support an asymmetric link of 721 kbps maximum in either direction while permitting 57.6 kbps in the return direction, or a 432.6 kbps symmetric link allowing for easy integration of TCP/IP for networking.

Collections of devices connected via Bluetooth technology in an ad hoc fashion are called a *piconet* (Fig. 11a). Each unit can simultaneously communicate with up to seven other units per piconet (Fig. 11b). Although all devices are peer units, one acts as the "master" and the others as "slaves" for the duration of the connection to the piconet. The master unit provides the hopping sequence to synchronize all the devices in the piconet. A scatternet (Fig. 11c) is a collection of piconets that operate independently and are not synchronized. This allows a large group of devices to network with each other by means of smaller subnets. Since each piconet has the capacity of 1 Mbps between devices, scatternets allow the total throughput

Figure 11. Bluetooth scatternet and piconet concepts.

accumulated over all piconets to increase as more piconets are added. Testing has proved that the overall speed reduction of a scatternet consisting of 10 piconets is less than 10% due to collisions. This results in the potential total network throughput of approximately 9Mbps.

5. ADVANCED TECHNOLOGIES AND SYSTEMS

Wireless communications are in continuous evolution [16]. We aim to introduce here some of the technologies and systems that today are yet to be fully developed and will constitute the wireless products of the next decades.

5.1. Advanced Wireless Technologies

Some of the advanced technologies being developed for wireless communications are briefly described as follows.

5.1.1. Multiuser Detection (MUD) and Blind Detection.

The continued expansion of the mobile cellular industry is translated to a need for increasing density of users within any given area without any corresponding increase in the frequency allocation. This heightens the probability of users and/or services interfering with one another, implying a need for new schemes to provide sophisticated interference cancellation approaches for a more efficient utilization of spectrum and space, at any time. Techniques known as *multiuser detection* (also as *joint detection*, *interference cancellation*, or *source separation*) consider multiple-access interference (MAI) not as a simple interference to be suppressed but as a composite signal that can be processed and separated.

The optimum MUD algorithm [23], based in a maximum-likelihood (ML) criterion, has a complexity growing exponentially with the number of users. That is the reason why many different suboptimal schemes are being developed.

Some of these algorithms do not need the introduction of reference sequences as an aid in the detection process, in what is known as *blind detection* [24]. The avoidance of overheads implies a more efficient use of the system capacity.

5.1.2. Smart Antennas. “Smart” antennas (or adaptive antennas) combine multiple antenna elements with a signal-processing capability in order to optimize the radiation and/or reception pattern automatically in response to the signal environment. This ability to adapt to a changing interference environment can dramatically increase the performance characteristics and capacity of a wireless system.

An overview of Smart Antenna applications can be found in Ref. 27.

5.1.3. Space-time Transmission Diversity (STTD). The concept of space-time transmission diversity (STTD) comes from the extrapolation of receivers’ antenna diversity widely used in 2G. The idea of receiver antenna diversity is to place two (several in general) antennas in different locations and select the output of the one with better signal-to-noise-plus-interference ratio (SINR).

Placing two antennas in reception defines two different radio channels, understanding as a channel the radiowave propagation between transmitter antenna and each of the receiving antennas. If the two receiving antennas are sufficiently separated, and for this purpose 10 times the wavelength is enough, the statistics of the two channels are independent. Therefore, the probability of having a deep fading on both channels simultaneously is the square of the probability of having a deep fading on one of them. In consequence the link quality is roughly speaking improved in 3 dB.

The extrapolation of the diversity concept to transmitting antennas is known as *spacetime transmit diversity* (STTD), which works as follows. Two (or several) transmitting antennas placed at relative distant location transmit simultaneously the same information but coded by different coding schemes. The coding schemes should be orthogonal; that is, the coded bit sequences transmitted by each antenna should be orthogonal to each other. In this way, the signal received from each antenna can be demodulated independently, and they can be used as two different copies of the same signal for the diversity purposes.

3G mobile systems may implement STTD techniques. The September 2000 release of 3GPP states that implementation of STTD will be optional for Node-B, but UE shall have the functionalities to support. There are multiple coding schemes for STTD; however, 3GPP adopted a reduced complexity algorithm proposed by Alamouti, which uses only two transmitting antennas [28].

5.2. Future Systems

The deployment of third-generation cellular systems with the provision of multimedia services over wireless networks represents the trends in wireless communications for the near future. Besides, satellite-based mobile services are expected to follow terrestrial systems toward a global 3G.

Now, a step further, the fourth generation, is already being investigated, mainly with two approaches in mind: software-defined radio (SDR) and integration of the multiple existing networks providing different but complementary services.

5.2.1. Mobile Satellite Systems. Because of the global coverage of satellites, mobile satellite services (MSS) systems will fill the gaps in areas where cellular terrestrial systems are physically or economically impractical to be implemented. Satellite systems may be classified according to the orbital altitude of the satellites being used: geostationary satellites (GEO), at an altitude of approximately 36000 km; low-Earth orbit satellites (LEO), at altitudes on the order of 1000 km; medium-Earth-orbit satellites (MEO), at intermediate altitudes between LEO and GEO; and highly elliptical orbit satellites (HEOS), with elliptical orbits of widely varying altitudes.

MSS systems have been implemented and are being designed with any of these types of satellites. One advantage of using GEOs is that global coverage (excluded polar latitudes) can be achieved with only three satellites. LEOs minimize the required transmitted power and propagation

Figure 12. The multiple-system view of the European Commission. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

delay, but LEO systems have produced disappointing results in the deployment experiences of the last years (Iridium, Globalstar, etc.).

An alternative that is being tested in several trials are HAPS systems (high-altitude platform stations). They consist of stratospheric communication platforms that can be deployed in populated areas in order to complement the traffic capabilities of terrestrial systems.

Further details about future satellite systems may be found in Ref. 25.

5.2.2. Software-Defined Radio (SDR). Since the publication of J. Mitola's article in 1994 [29], many efforts have been carried out in order to achieve the so-called software-defined radio (or simply *software radio*). SDR are communication transceivers in which the tendency is toward programming as many functionalities as possible in software, using analog-to-digital and digital-to-analog converters, as close as possible to the antenna. One of the first experiments in the field of SDRs is the U.S. military software radio called "Speakeasy" [30]. After that, several projects have been carried out both in the United States and Europe, where SDRs were intended as a solution to the problem of different 3G standards defined in different parts of the world, contrary to the first idea of a universal unique 3G system.

Today SDRs are seen as the way toward the integration of many different systems, each achieving a different performance level in one of the various scenarios that constitute the target of the fourth generation of wireless communications.

System Integration: Toward Multisystem Multiservice Networks. At present we are witnessing a very wide span of wireless products, many of which have been described in this article, that aim to satisfying the needs of certain users in certain environments. Figure 12 shows as an example the vision of the European Commission with respect to this plethora of wireless communication standards and systems [1].

The current trend toward 4G is not just to invent some new systems, but mainly to take advantage of the capabilities of the many existing standards, making them work

together in a synergic way, so as to fulfill the communication demands of everybody. As mentioned above, one possible way to make different systems work together is through reconfigurable radios (SDRs).

The example of complementary use of wireless systems that is obtaining the greatest attention these days is the combination of cellular and WLAN systems. In this way, both systems satisfy the user's needs, the first achieving a wide coverage but with lower data rates, and the latter filling the data rate gap in small and crowded areas (hot-spots) such as meeting rooms, shopping malls, or airports.

A novel but promising application of the WLAN is what is being called "neighbor-area network" (NAN). This type of network is based on the idea of allowing users from a neighborhood to connect to an access point connected to WAN, typically an ADSL (asymmetric digital subscriber line) connection. In this way, users from that area can connect to the Internet sharing the cost of the WAN connection, so they can access to higher QoS at the same price. With an ordinary base station, wireless networking is possible within a range of about 75 m. But simply replacing the standard access point antenna by a simple rooftop antenna causes the range to increase considerably - certainly to 500 m, and maybe more.

As another example of the synergies that are being encouraged, we may mention the case of TETRA: ETSI Project TETRA release 1 was virtually completed during 2000. A new 3-year work program for TETRA release 2 was approved by the ETSI Board in September 2000. The main objectives of the new release are to enhance TETRA in order to provide packet data at much higher speeds, standardize additional speech codec(s), enable intercommunication between TETRA and other 3G networks without transcoding, and adopt new standards to provide improved interworking and roaming between TETRA and public mobile networks such as GSM, GPRS, and UMTS.

1. INTRODUCTION

The Yagi-Uda antenna, commonly used for broadcast television reception, is one of the most prevalent and recognizable antennas in existence. It has several desirable characteristics, including low cost and simple assembly, low weight, and radiation qualities adequate for many applications. While its popularity has waned in the United States in the past few decades because of the widespread availability of cable and dish-based satellite television services, it remains a familiar accompaniment on roofs throughout the world. Currently, with the introduction of high-definition broadcast television in the United States, the Yagi-Uda antenna is undergoing somewhat of a resurgence in popularity in many areas. It is true, however, that the Yagi-Uda is one of the most commonly found antennas in the world.

The Yagi-Uda was first described in English in 1926 [1] by Professor H. Yagi and (then) Instructor S. Uda at Tohoku University in Sendai city. More commonly referred to is Yagi's English language publication [2] of 1928, which was reprinted in 1997 [3]. The impact of this paper was significant. Included in Ref. 2 were the published comments of J. H. Dellinger, chief of the Radio Division of the Bureau of Standards: "I have never listened to a paper that I felt so sure was destined to be a classic." At this point in radio history, engineers had just begun to develop directional communications systems. The Yagi-Uda provided a practical higher-gain antenna.

The antenna has had a fascinating history, which is detailed by Gentai Sato [4]. According to Sato, although invented in Japan, it was largely forgotten until the Japanese military discovered its application to British radar in 1942. In addition to its common application in radars and television antennas, it is popular with ham radio aficionados.

This article is divided into three sections. In Section 2 the antenna is introduced and key concepts about its operation are discussed. In Section 3 some practical information on designing wire Yagi-Uda antennas is described along with a common graphical technique for determining the dimensions of the elements. In Section 4 a number of newer antennas that utilize the underlying concepts of the wire Yagi-Uda Antenna are described. These antennas are typically intended for higher-frequency applications.

2. THEORY OF OPERATION

A diagram of the typical Yagi-Uda antenna is shown in Fig. 1. It consists of a *driven* element, a single *reflector*, and a number of *director* elements (in this case, five directors are shown). The meaning of these terminologies will be detailed shortly. The configuration forms a directive, endfire array with the main beam focused in the y direction. Design variables are N (total number of elements), l_n (length of n th element), s_n (spacing between n th and $n + 1$ element), and a (radius of the element). Only the antenna elements are shown in the figure; a supporting boom for the elements is also required and may have some effect on the radiation qualities.

The Yagi-Uda's driven element is the only element in the array where the signal is directly fed or collected by transmission lines. The other array elements are parasitic elements that have no direct feeding, thus simplifying the construction of antenna array. Unlike ordinary antenna arrays where the amplitude and phase can be independently defined, the Yagi-Uda utilizes near-field mutual coupling between antenna elements. Although the feeding mechanism of the Yagi-Uda array has significant difference from the ordinary linear antenna array, the elements also line up in a straight line. Thus the majority of linear antenna array theory can be utilized to understand the nature of this antenna array.

From fundamental antenna theory, the far-field radiation pattern of an isotropic point source is proportional to, $I_0 e^{-j\beta r} / 4\pi r$, where I_0 is the current of the point source antenna, β is the free-space propagation constant, and r is the distance from source to the observation point. Now we consider the linear array consisting of isotropic radiators lined up in a straight line along the z axis with elements spaced an equal distance d as in Fig. 2. The contribution from each element forms a far-field radiation pattern as

$$\text{AF} \frac{e^{-j\beta r}}{4\pi r} \quad (1)$$

where AF stands for array factor, expressed in

$$\begin{aligned} \text{AF} = & I_1 + I_2 e^{j\beta d \cos \theta} + I_3 e^{j2\beta d \cos \theta} \\ & + \dots + I_{n+1} e^{jn\beta d \cos \theta} \end{aligned} \quad (2)$$

When a realistic antenna element, such as half-wavelength dipole antenna for typical Yagi-Uda array, is used rather than an isotropic source antenna, the final radiation pattern is obtained from the multiplication of the antenna array factor with the radiation pattern of the single element.

As a preparation for understanding the radiation pattern of Yagi-Uda array, we first consider a two-element array, as in Fig. 3. The array factor for two-element array is

$$\text{AF} = I_1 + I_2 e^{j\beta d \cos \theta} = |I_1| + |I_2| e^{j(\beta d \cos \theta + \alpha)} \quad (3)$$

Figure 1. Geometry of the Yagi-Uda antenna. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

A phase progression α between currents on elements 1 and 2 is assumed. The normalized amplitude of the array factor is often referred to as the *universal radiation pattern*. When the currents have equal amplitude and phase difference α , the array factor can be simplified as a function of $\psi = \beta d \cos \theta + \alpha$:

$$AF = |I_1| (1 + e^{j\psi}) = 2|I_1| e^{j(\psi/2)} \cos\left(\frac{\psi}{2}\right) \quad (4)$$

Thus the normalized amplitude of array factor (universal radiation pattern) is simply written as a function of ψ as

$$f(\psi) = \left| \cos \frac{\psi}{2} \right| \quad (5)$$

The polar plot is a useful tool for visualizing operation of antenna arrays. We shall now explain the graphical procedure [5] for constructing a polar plot. The polar plot is the far-field radiation pattern constructed in a polar coordinate system by referring to the universal radiation pattern obtained from (3). With this arrangement, one can clearly see how the radiation pattern of the array can be obtained with regards to currents amplitude $|I_1|, |I_2|$, phase progression α , and the element spacing d . A few examples in Fig. 4 will give a good idea of how the plots are constructed. For the equal-amplitude excitation, where the conditions for (5) are

valid, we plot the universal radiation pattern $f(\psi)$ as in Fig. 4a. When $\alpha = 0$ and $d = \lambda/2$, the polar plot has its center at $\alpha = 0$ corresponding to $\psi = 0$ and its radius $\beta d = \pi$. The intensity of the far-field radiation at each θ can be found from the projection of θ to the corresponding universal radiation pattern $f(\psi)$. The resulting broadside radiation pattern is plotted in Fig. 4b with its highest peak at $\theta = \pi/2$ and $\theta = -\pi/2$. When $\alpha = \pi$ and $d = \lambda/2$, the center of the polar plot is shifted to $\alpha = \pi$, corresponding to $\psi = \pi$ with the same radius $\beta d = \pi$. The resulting endfire radiation pattern is plotted in Fig. 4c with the highest peak at $\theta = 0$ and $\theta = \pi$. When $\alpha = \pi/2$ and $d = \lambda/4$, the radiation pattern is still endfire but unidirectional with its highest peak at $\theta = \pi$ as plotted in Fig. 4d. From those plots, it is clear that in order for us to have a unidirectional endfire radiation pattern $d \leq \lambda/4$ must be satisfied. As in this example, although the universal radiation pattern is common to all three polar plots, it is possible to shift and scale the polar plot to obtain radiation patterns with different peak directions and shapes. The region in ψ where the radiation pattern is found is called the *visible region*.

The Yagi-Uda array can be discussed in the same manner as we have done for the ordinary endfire array, with the exception that the phase and the amplitude of the current and element spacing are no longer independent. The relationship between induced current on the parasitic element to the excited current on the driven element of the two-element Yagi-Uda array can be found using the

Figure 2. Antenna array made with ideal isotropic antenna source.

Figure 3. Two-element antenna array: (a) ordinary linear array; (b) Yagi-Uda array. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 4. The universal radiation pattern and polar plots for equal amplitude two-element linear array: (a) universal radiation pattern; (b) polar plot for $\alpha=0$, $d=\lambda/2$; (c) polar plot for $\alpha=\pi$, $d=\lambda/2$; (d) polar plot for $\alpha=\pi/2$, $d=\lambda/4$.

concept of the two-port impedance network. Figure 3b shows the two-element Yagi-Uda array using half-wavelength dipoles as antenna elements. The impedance network can be defined as

$$V_1 = I_1 Z_{11} + I_2 Z_{12} \tag{6}$$

$$0 = I_1 Z_{21} + I_2 Z_{22} \tag{7}$$

The voltage at the parasitic element is zero since the middle of the dipole is short-circuited. Using (7), the current on element 1 (driven) and element 2 (parasitic)

can be related as

$$\frac{I_2}{I_1} = -\frac{Z_{12}}{Z_{22}} \tag{8}$$

In summary, the antenna array factor is the same as the ordinary linear array as in (3), although the phase and the amplitude of the currents on the Yagi-Uda array are no longer independent, but rather related to each other with both self- and mutual-impedances of the antenna elements as defined in (8). These facts state that Yagi-Uda antenna's array factor depends on the antenna's self- and mutual-impedances. Thus, the array factor needs to be specifically defined with the actual antenna element rather than isotropic point source. We will continue our discussion of Yagi-Uda array using half-wavelength dipole antenna. This is the most convenient and most popular antenna element for the Yagi-Uda array.

Closed-form expressions for the self- and mutual-impedances of a dipole array are not known, but it is true that impedances are subject to the antenna element spacing and length relative to the wavelength of interest. Although there are a number of analytical studies on characteristics of dipole and Yagi-Uda antennas with various approximations on the currents distribution to solve integral equations [6,7], a more versatile and accurate technique is available from the numerical electromagnetic technique based on the moment method. In this discussion, the numerical code known as *Numerical Electromagnetic Code* (NEC) [8] based on the method moment is utilized to analyze the full-wave characteristics of the Yagi-Uda array with wire dipole antennas. NEC is based on the moment method solution of the rigorous electric field integral equation (EFIE) constructed around the current induced on the wire dipoles with piecewise linear segmentation of the current distribution.

One important advantage of Yagi-Uda is that it can shape the unidirectional beam and thus achieve high directivity. Using the discussion based on polar plot and numerical simulation, we shall see how the dipole length and spacing affects the radiation pattern of the two-element Yagi-Uda antenna. As we discussed earlier, the element spacing d defines the radius of the polar plot while the phase progression α defines the center location of the polar plot. While this holds true for the Yagi-Uda array, the phase progression α is no longer independent from the spacing d . In order for us to control the phase progression independently from the element spacing, we may vary the length of the parasitic element. Uda [9] discussed the effect of varying parasitic element length with ample test results and analytical equations in his two-element array experiments. When the length of parasitic dipole antenna is longer than the resonance, the dipole is inductive (its reactance is positive), and the induced current lags behind the impinged electric field contributing to reflecting radiation backward. On the other hand, when the length of dipole is shorter than the resonance, the dipole is capacitive and the induced current leads the impinged electric field contributing to directing radiation forward.

Since our purpose is to have an antenna array of high directivity, as we have seen in the polar plot of Fig. 4, we

must avoid element spacing anything greater than a half-wavelength. For the first example, we choose dipole radius $a = 0.005\lambda$, a driven element length $l_1 = 0.463\lambda$, parasitic element length $l_2 = 0.496\lambda$, and element spacing $d = 0.2\lambda$. With the current amplitude $|I_1|, |I_2|$ and phase α obtained from numerical solution, we can calculate the universal array factor $|f(\psi)|$ of (3) and obtain the polar plots shown in Fig. 5. The computed phase progression is $\sim 200^\circ$ or 1.11π while the element spacing is $d = 0.2\lambda$, so that the polar plot has $\beta d = 0.4\pi$ radius and is located at 1.11π , contributing to the radiation pattern with the highest peak at $\theta = \pi$ direction and the small peak at the opposite direction. The radiation pattern constructed from element currents corresponds to the H -plane radiation patterns of the dipole Yagi-Uda. The numerically computed radiation patterns come very close to the radiation patterns constructed from the currents and array factor equation. The Yagi-Uda E -plane radiation pattern plotted in Fig. 5c can be obtained by multiplying the single element dipole's E -plane radiation pattern with the array factor polar plot (H -plane radiation pattern) of Fig. 5b. Note that since the current amplitude of the parasitic element is smaller than the one of the driven element, we do not have a null in H -plane radiation pattern even though we cross $\psi = \pi$ in the visible region of polar plot. Since the radiation peak is found in the direction opposite that of the parasitic element, the parasitic element acts as a reflector in this case. On the other hand, the radiation pattern with opposite peak direction can be obtained with shorter parasitic element as in Fig. 6 with parameters $a = 0.005\lambda$, $l_1 = 0.463\lambda$, $l_2 = 0.44\lambda$, and $d = 0.15\lambda$. The computed phase progression on parasitic element is 131° , or 0.73π , bringing the center of polar plot to the left of $\psi = \pi$ in uni-

Figure 5. The two-element Yagi-Uda antenna with a driven element and a reflector element, with parameters $l_1 = 0.463\lambda$, $l_2 = 0.496\lambda$, $a = 0.005\lambda$, $d = 0.2\lambda$: (a) array configuration; (b) universal radiation pattern and corresponding polar plot of H -plane radiation pattern with radiation peak at $\theta = \pi$; (c) computed E -plane radiation pattern. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 6. The two-element Yagi-Uda antenna with a driven element and a director element, with parameters $l_1 = 0.463\lambda$, $l_2 = 0.44\lambda$, $a = 0.005\lambda$, $d = 0.15\lambda$: (a) array configuration; (b) universal radiation pattern and corresponding polar plot of H -plane radiation pattern with radiation peak at $\theta = 0$; (c) computed E -plane radiation pattern. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

versal radiation pattern and a consequent radiation pattern with the highest peak at $\theta = 0$ and the smaller peak at $\theta = \pi$. Since the highest peak is in line with the direction of the parasitic element, the shorter parasitic element in this case acts as a director element.

As the array size increases, the Yagi-Uda antenna array can be discussed and understood as a surface-wave antenna. Provided an array has equal spacing d , the induced current on the element number m can be expressed as

$$I_m = e^{-j\beta_g m d} I_0 \zeta(x) \tag{9}$$

where $\zeta(x)$ describes the amplitude distribution along the x axis and β_g is the propagation constant of the array structure. Analytical studies on Poynting vector along the axis of array by Mailloux [10] reveals that in order for propagation along the axis to exist, and induce current on all the parasitic elements, the propagation along the axis has to be slower than the free-space propagation. The slow wave exists for $k_0 < \beta_g < \pi/d$. The Yagi-Uda is often referred to as a surface-wave antenna, due to the slow-wave excitation along the axis of the array as in surface-wave antennas. Ehrenspeck and Poehler [11] shows in their experimental study that the propagation constant of the Yagi-Uda is indeed slow and for the long Yagi antenna, the propagation constant approaches the Hansen-Woodyard [12] criteria of $\beta_g = \beta + \pi/h$. In their study, the terminal phase difference between driven element and the last director element of the Yagi array is measured near 60° for short array, comes close to 120° for h between 4λ and 8λ then gradually approaches to Hansen-Woodyard criteria of 180° for h is equal to 20λ . Using the condition for 100% efficiency of surface-wave excitation suggested by Zucker [13] as a lower bound,

the final Yagi propagation constant of any array length should remain inside:

$$\beta + \frac{\pi}{3h} < \beta_g < \beta + \frac{\pi}{h} \tag{10}$$

Further discussions regarding surface-wave antenna or traveling-wave antenna treatment of Yagi-Uda antenna are available in the literature [12–15].

Another important Yagi-Uda characteristic is its input impedance. From Eqs. (6) and (8) the input impedance is obtained as follows:

$$Z_{IN} = \frac{V_1}{I_1} = Z_{11} - \frac{Z_{12}^2}{Z_{22}} \tag{11}$$

The second term of this equation shows the strong dependence of the input impedance on the mutual coupling of two elements. A useful practice for matching the input impedance to the feeding transmission line is to slightly adjust the driven element's length so that an imaginary part of the total input impedance is canceled out to zero, enabling us to use a simple impedance transformer such as folded dipole feeding. Although self-impedance of a half-wavelength dipole antenna is about 70Ω, the final input impedance of the Yagi-Uda antenna is in general less than 50Ω. Elliott provides a more discussion on input impedance matching of two-element and three-elements Yagi-Uda antennas using closed-form expressions and tables for thin wire dipole's self-impedance and mutual impedance [16].

3. DESIGN OF THE YAGI-UDA ANTENNA

In this section, a design procedure for the dipole-based Yagi-Uda antenna is discussed. Because of the large number of optimization variables, the Yagi-Uda antenna is typically designed using design curves or tabulated data such as that presented in *Yagi Antenna Design* by Peter Viezbicke [17], in a technical note published by the National Bureau of Standards. The design data are intended to support designs in the HF, VHF, and UHF frequency

bands. Note that the design procedure provides an optimized design to obtain a desired gain at a specific frequency. It does not provide sufficient information on input impedance matching of antenna. This must be considered separately, either experimentally or through additional simulations.

The antennas in the study were constructed from aluminum rods. Mechanical support was provided by a Plexiglas rod perpendicular to and bisecting the Yagi-Uda elements. Effect of the Plexiglas support was studied in detail and is captured in the developed design guidelines. Note that the original reference specifically states that the supporting boom is constructed from *nonconducting Plexiglas*. A number of modern texts erroneously refer to the boom as being fabricated from metal.

Presented with the data is a design method for a specific gain in terms of the antennas physical geometry (element lengths, diameter, and spacing; reflector geometry and supporting boom). The design technique allows specific gains of 7.1, 9.2, 10.2, 12.25, 13.4, and 14.2 dB to be realized. Note that all gains given are relative to that of a λ/2 dipole located the same height above ground; isotropic gain can be obtained by adding 2.16 dB to these values. Note also that the design technique gives a specific array length (0.4, 0.8, 1.2, 2.2, 3.2, and 4.2λ), and are valid for a limited element thickness.

Graphical data supporting the design of the Yagi-Uda antenna are shown in Figs. 7 and 8 and Table 1. Figure 7 is the most important plot, and shows design curves as a function of 2a/λ₀. Figure 7 may be used to determine antenna performance provided that 0.001 ≤ 2a/λ₀ ≤ 0.04. Figure 8 shows compensation data of length of parasitic elements for the various diameters of Plexiglas boom on which the test antenna is mounted. This is used to obtain optimized values for the final design. In addition, Table 1 shows optimized lengths of parasitic elements of six different lengths and gains for the specific case of 2a/λ₀ = 0.0085. Each column represents an antenna design of a different gain.

The design is performed in the following manner. First, frequency and desired gain must be known. Note that gain is limited to one of six specific values, as shown in Table 1. Element and boom diameter should also be

Figure 7. Yagi antenna design data showing relationship between element diameter and element length for different antennas, after Viezbickie [17].

known. Referring to Table 1, choosing the column with the desired gain will provide the length of the antenna (in wavelengths), number of elements, and nonoptimized element length, as well as specifying the design curve for optimizing the element lengths. The element lengths are then plotted onto the correct design curve in Fig. 7 by drawing a horizontal line from the y axis. Then, a vertical line is drawn from the x axis at the desired element diameter and crosses the desired design curves for reflector and director. The director length without boom compensation is given by the value in the intersection of the director line. The highest-order director is assigned this point on the director design curve, and the other elements are translated along this curve, maintaining the same distance between each other as before they were compensated. This will determine the length of all elements without boom compensation, which is read from Fig. 8. The

length indicated for the corresponding boom diameter extends the length of each element. At this point the design is complete, and can be either fabricated or used as a starting point for further optimization. Figure 9 shows the computed H -plane and E -plane radiation patterns of a 17-element Yagi-Uda antenna constructed using parameters for 3.2 λ length array in Table 1. The front : back ratio for this example is approximately 20 dB, and sidelobes are more than 10 dB down from the mainlobe, illustrating how the Yagi-Uda could obtain high directive beam with relatively small antenna size. The normalized currents at the center segment of each of the 17 elements are also plotted in Fig. 10. The energy coupled into parasitic elements becomes smaller as it progresses further away from the driven element but stays at a certain level to the end of array indicating the slow-wave successfully propagates through the array structure as discussed in previous section.

Figure 8. Graph showing effect of supporting boom on element length, after Viezbickie [17].

Figure 9. Radiation patterns for the 17-element Yagi-Uda array. Parasitic elements length and spacing of 3.2λ array in Table 1 are used. The dashed line indicates *H*-plane and solid line, *E*-plane radiation patterns.

While performing further optimizations into the design, either experimentally or through computer simulations, a few general trends have been observed and are well established in the literature [17,18]. First, for a given length of array, reflector spacing and size control the front-to-back ratio and can impact the impedance, but have small impact on the forward gain. The size of the driven element does not affect radiation pattern significantly but rather is chosen to control the input impedance (and is typically resonant). Finally, the director size and spacing have considerable impact on forward gain, front-to-back ratio, and input impedance. The directors must therefore be optimized carefully to obtain maximum performance. Optimization using perturbation techniques [19] and a search algorithm such as the genetic algorithm [20] have also been studied and reported.

Figure 10. Normalized current amplitude at the center segment of a 17-element Yagi-Uda antenna. The array has equal element spacing 0.2λ .

The antenna will also need to be input-matched to the desired reference impedance. The Yagi-Uda is often fed using a twin-lead transmission line with a characteristic impedance of $300\ \Omega$. As stated in the previous section, the input impedance of the Yagi-Uda antenna is somewhat less than that of a half-wave dipole operating at its first resonance ($\sim 70\ \Omega$ for the dipole). For matching to a twin-lead transmission line, the same basic techniques that are used to match the half-wave dipole can be used with the Yagi-Uda antenna. One technique commonly used with dipoles is to use a folded dipole, which increases the driving impedance by a factor of 4. A larger number of folds can be used to achieve even higher impedance transformation. Additionally, stub tuners can be used to provide impedance matching.

The Yagi-Uda can also be stacked, either vertically or horizontally, to increase the gain; design information on this is also included in Ref. 17.

4. MODERN DEVELOPMENTS FOR THE YAGI-UDA ANTENNA

The traditional Yagi-Uda antenna is typically built of metal tubing and typically operates in the megahertz range to a few gigahertz. Many modern applications operate at much higher frequencies that are not compatible with this simple type of fabrication. In the decades since the Yagi-Uda antenna was originally introduced, the fundamental underlying concept has been applied to develop Yagi-Uda-type antennas using radiating elements other than the wire dipole. These antennas utilize the same traveling-wave concept to achieve an endfire radiation pattern, but often bear little visual resemblance to the antenna, which fostered their existence. In this section, a number of these are briefly introduced and discussed.

One practical planar version utilizes a coaxial fed patch antenna with parasitic microstrip patch antennas used as reflector and directors [21]. The structure of the antenna is shown in Fig. 11. The basic configuration of a patch antenna element includes a rectangular (or square in this case) metallic patch on one side of a dielectric substrate that is backed by a metallic ground plane. Feeding of the basic patch antenna can be done in a variety of manners, including edge fed microstrip, aperture coupling or by using a coaxial probe. Huang and Densmore [21] used coaxial probes to feed a square patch at two separate points, resulting in the formation of a circularly polarized beam. The patch antenna by itself has a broadside-directed radiation pattern (referring to the side view in Fig. 11, this would correspond to a mainbeam in the vertical direction). When combined with the reflector and two director parasitic patches, the mainbeam is tilted toward the endfire direction, but does not achieve true endfire operation as in the traditional Yagi-Uda antenna. Huang and Densmore [21] report a maximum directivity of 15 dBi.

According to Huang and Densmore [21], a number of other phenomena were observed with this antenna:

1. A conventional microstrip patch antenna achieves circular radiation by using orthogonal feed points

Figure 11. Microstrip Yagi array configuration, after Huang and Densmore [21].

excited 90° out of phase. For the microstrip Yagi antenna, a phase difference of 110° was required to achieve good circular polarization in the mainbeam direction.

2. The coupling at the two probes was reported to be affected by the parasitic patches. This results in optimal feeding points differing from those for the conventional patch antenna with circular polarization.
3. The addition of the parasitic patches had an impedance match bandwidth enhancement effect. Huang and Densmore [21] reported a 7.5% bandwidth on a 0.64-cm-thick substrate.

One attribute of the microstrip patch antenna is the ease with which multiple elements can be combined to form an array. This is also true of the microstrip Yagi antennas. Huang and Densmore [21], placed four microstrip Yagi antennas side by side to form a larger two-dimensional array. The composite array shown in Fig. 12 has

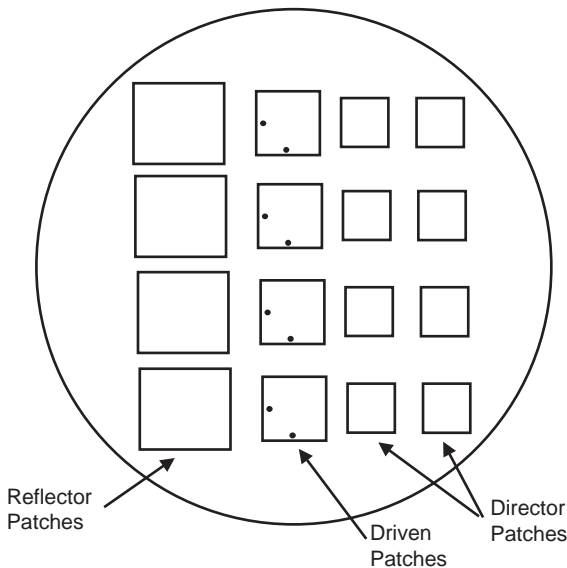

Figure 12. Two-dimensional microstrip Yagi array configuration, after Huang and Densmore [21].

a total of 16 patch antennas (including directors and reflectors), but only four elements are directly driven. To form a similar radiation pattern without using the Yagi-Uda concept, all 16 elements would have to be individually excited by a comparatively more complicated feed network. Other researchers have also used the microstrip Yagi antennas in a two-dimensional array. Figure 13 shows a six-sector Yagi-Uda array with a common parasitic element reported by Honma et al. [22], who use six microstrip Yagi antennas arrayed in a circular pattern intersecting at 60° of each other. The six antennas share a common director enabling a compact design. By switching between elements, the beam is steered in fixed directions. This results in a beamsteering array with a simple feeding structure.

A second class of planar antennas based on the Yagi-Uda concept includes the Yagi slot array. The radiation properties of a wire dipole antenna and an antenna formed from a slot in a metallic structure can be fundamentally related to each other by exchanging their electric and magnetic fields and multiplying by a proportionality constant. This strategy is based on an electromagnetic principle known as *duality*. Additionally, their impedances are directly related by Babinet's principle [23]. The development

Figure 13. Configuration of six-sector patch Yagi-Uda antenna with a common parasitic elements, after Honma et al. [22].

Figure 14. Geometry of Yagi-Uda array constructed from slot elements.

of a slot Yagi-Uda antenna array is therefore a natural extension of the wire Yagi-Uda array, one of the most common applications of the dipole antenna.

The basic geometry of a slot Yagi-Uda antenna is shown in Fig. 14. It can be fed by a variety of techniques, including coplanar waveguide (CPW), microstrip, coaxial probe or rectangular waveguide. The slot antenna ground plane is placed on a dielectric substrate if it is fed using CPW or microstrip. Note that the dielectric substrate is *not* essential if fed by other techniques. As with the microstrip Yagi antenna, the broadside-directed radiation pattern of the slot antenna results in a radiation pattern tilted between broadside and endfire. Additionally, radiation will be emitted into both the top and bottom hemispheres unless a technique is used to prevent this. Since it can be fed with CPW, this type of Yagi-Uda antenna could be potentially used well in to the millimeter range. In practice, high-frequency use may be limited because of the high probability of exciting surface waves in the conductor-backed dielectric substrate.

Although this type of Yagi-Uda antenna has been reported as early as 1963 [24], it appears to have found only limited application. One particularly interesting twist to this story is its application as an efficient TM_0 surface-wave exciter. Constructing the antenna on a relatively thick, high-permittivity substrate enhances the efficient excitation of surface waves. Consequently, the antenna emits almost zero radiation into the air. The majority of the energy is transmitted in the forward direction into the conductor-backed dielectric slab in the TM_0 surface wave. This type of Yagi-Uda surface wave launch can be fed by either CPW or microstrip, and has been demonstrated to be an efficient element for use in dielectric slab power combiners [25].

The planar Yagi-Uda-type antennas discussed in the last few paragraphs do not have a true endfire radiation pattern like that of the original dipole Yagi-Uda antenna. More recently, a planar antenna referred to as a “quasi-Yagi” antenna has been reported that does have this characteristic [26]. This printed dipole array is realized on a high-permittivity substrate with a microstrip feed, as shown in Fig. 15. Unlike the traditional Yagi-Uda antenna, this planar version uses the truncated microstrip ground plane as the reflecting element. This eliminates the necessity of a reflecting dipole element. The result is

Figure 15. Geometry of the quasi-Yagi antenna, after Kaneda et al. [26].

very compact, with a length and width less than half those a free-space wavelength. The planar nature and microstrip feeding allow simple integration of active circuitry and electronics, thus making this antenna a candidate for dense active arrays and in applications requiring a high level of integration.

The antenna itself has proved capable of being scaled to a wide range of frequencies while maintaining good radiation qualities. An X-band version has been studied in detail. The antenna is constructed on a single substrate (0.635-mm-thick Duroid with a $\epsilon_r = 10.2$ for the X-band version) with metallization on both sides. Referring to Fig. 15, the top metallization consists of a microstrip feed, a broadband microstrip-to-coplanar stripline (CPS) balun,

Figure 16. FDTD simulation and measured input return loss of the broadband quasi-Yagi antenna, after Kaneda et al. [26].

Figure 17. Measured E - and H -plane co- and cross-polarization radiation patterns for the (a) low-gain and (b) high-gain versions of the quasi-Yagi antenna. Note that the end direction in (a) is at 0° and is at 270° in (b) due to measurement setup after Kaneda et al. [26].

and two dipole elements (the driven element and the director). The metallization on the backside consists of a truncated ground plane, which acts as the reflector for the antenna. In addition to aiding the endfire radiation pattern, the director is also used for impedance matching.

As with the wire dipole Yagi-Uda antenna, proper design requires optimization of driver, director, and reflector parameters. By performing a parameter study, it was found that the quasi-Yagi could be either optimized for broadband (40–50% for $VSWR < 2$) characteristics with moderate gain (~ 4 dB), or narrow bandwidth (10–20% for $VSWR < 2$) with higher gains (~ 6.5 dB). Detailed dimensions for both of these cases can be found in Ref. 26. The simulated-measured input match for the broadband design is shown in Fig. 16. Note that the matched bandwidth covers the entire X-band. Radiation patterns for the low-gain (broadband) and high-gain (narrowband) versions of the quasi-Yagi antenna are shown in Figs. 17a and 17b, respectively. Note that the phase reference for the two polar plots varies by 90° between the two; the radiation pattern is in the same direction for the two, however. The gain in Fig. 17b is noticeably higher.

5. CONCLUSION

The Yagi-Uda antenna is one of these most recognizable and pervasive antennas in existence. In its classic form it features a remarkable feature set, including low profile, low weight, inexpensive manufacturing, and good radiation characteristics. The physics of its operation were detailed in Section 2. It was found that the antenna relies on a traveling-wave effect and operation relies on phasing of

each element. In Section 3 a classic graphical technique for obtaining specific optimized Yagi-Uda designs is outlined. In Section 4 three planar versions of the Yagi-Uda antenna are described, including the microstrip Yagi antenna constructed from patch antennas, the slot Yagi antenna, and a planar, printed dipole-based version referred to as the “quasi-Yagi” antenna.
